Preface

In the absence of science, opinion prevails.

Readers familiar with the third edition of *A Guide to Treatments that Work* will notice a number of changes in this edition. First, two chapters have been added to the beginning of the book. Chapter 1, written by the editors, examines in detail two perplexing issues raised by critics of *DSM-5*: (1) the unrealized potential to date of neuroscience biomarkers that would yield more accurate and reliable diagnoses and (2) the continuing burden of overdiagnosis for clinicians and patients alike. Both issues have obvious relevance to treatment. Chapter 2, written by R. Dale Walker, M.D., professor of psychiatry at the Oregon Health & Science University (OHSU), director of OHSU's One Sky Center, and a member of the Cherokee Tribe of Oklahoma, and Douglas A. Bigelow, a long-time colleague of Walker's at OHSU, contrast Native American and Western ways of identifying effective treatments for mental and physical disorders, concluding that "evidence-informed culture-based" interventions sometimes constitute best practices in Native communities.

Two new chapters detailing pharmacological treatments for pediatric bipolar disorder (Chapter 9) and pediatric depressive disorder (Chapter 12), written by Martin, Goldberg, Biernacki, and Rynn of the Department of Psychiatry at Columbia University, have also been added. Both reflect substantial recent advances in diagnosis and pharmacological treatment of these troublesome childhood disorders. A new chapter order reflecting a comparable reordering of chapters in *DSM-5* and ICD-11 has also been implemented. In addition, virtually every treatment review chapter in this edition provides for informed discussion and critical assessment of changes in *DSM-5* from *DSM-IV*.

The goals and standards by which chapter authors evaluated research on treatments remain the same in the fourth edition as they were in the first, second, and third. Like its predecessors, this edition of *Treatments that Work* offers detailed evaluative reviews of current research on treatments for disorders for which evidence-based interventions have been developed. They have been written in most instances by psychiatrists and clinical psychologists who were major contributors to that literature. Many of the chapter authors in this edition also wrote for the first three editions.

The standards by which authors were asked to evaluate the methodological rigor of the treatment research they reviewed have not changed either. Summarized here, as they were in the three previous editions, they are designed to enable authors and readers to assess treatment outcome research in light of the methodological adequacy of the research. Those standards, identical to those that guided chapter authors in the first three editions of this book, are as follows:

> The purpose of these chapters is to present the most rigorous, scientifically based evidence for the efficacy and effectiveness of treatments that is available. At the same time it is clear that for some disorders there are treatments widely

recognized by experienced clinicians to be useful that may not have been subjected to rigorous investigation for a variety of reasons. Our aim is to be clear with readers what treatments are felt by a large number of experts to be valuable but have never been properly scientifically examined, and what treatments are known to be of little value.

To do this, it is useful to establish some criteria for evaluating the validity of articles in the literature that are reviewed in writing the chapters. We would like you to keep in mind the following classification when you are reviewing the literature and writing your chapter:

Type 1 Studies: These are the most rigorous and involve a randomized, prospective, controlled clinical trial. Such studies also must involve comparison groups with random assignment, blinded assessments, clear presentation of exclusion and inclusion criteria, state-of-the-art diagnostic methods, adequate sample size to offer statistical power, and clearly described, appropriate statistical methods.

Type 2 Studies: These are clinical trials in which an intervention is made, but some aspects of the Type 1 study requirement are missing. For example, a trial in which a double-blind cannot be maintained; a trial in which two treatments are compared but the assignment is not randomized; and a trial in which there is a clear but not fatal flaw such as a period of observation that is felt to be too short to make fully valid judgments on treatment efficacy. Such studies clearly do not merit the same consideration as type 1 studies but often make important contributions and generally should not be ignored.

Type 3 Studies: These are clearly methodologically limited. Generally, type 3 studies are open treatment studies aiming at obtaining pilot data. They are highly subject to observer bias and can usually do little more than indicate if a treatment is worth pursuing with a more rigorous design. Also included in this category are case-control studies in which patients are identified and then information about treatment is obtained from them retrospectively. Such studies can, of course, provide a great deal of naturalistic information but are prone to all the problems of uncontrolled data collection and retrospective recall error.

Type 4 Studies: Reviews with secondary data analysis can be useful, especially if the data-analytic techniques are sophisticated. Modern methods of meta-analysis attempt to account for the fact that, for example, negative studies tend to be reported at a substantially lower rate than positive outcome studies.

Type 5 Studies: Reviews without secondary data analysis are helpful to give an impression of the literature but are clearly subject to the writer's opinion and sometimes are highly biased.

Type 6 Studies: This encompasses a variety of reports that have marginal value, such as case studies, essays, and opinion papers.

The editors are pleased to acknowledge the essential contributions of the chapter authors to this volume. We take satisfaction from the fact that more than three quarters of the chapters in this book were written by colleagues who contributed as well to most or all of the previous editions of *Treatments that Work*. We are grateful to all our chapter authors, especially those who have been with us since the first edition.

We would also like to thank the three Oxford University Press editors who worked most closely with us to update this edition. Joan Bossert, Vice President and Editorial Director of Oxford University Press (US), a good friend and superb editor, has worked with us since 1996, when we began to plan the first edition. Sarah Harrington, Psychology Editor at Oxford, has also played an important role in this edition, first by convincing us that we ought to do it, and then by helping us think through some important decisions as we went along. Finally, we would like to acknowledge the efforts of Andrea Zekus, who organized and oversaw the production of the volume to ensure that it met the high standards of earlier editions.

Peter E. Nathan, Ph.D.

Summary of Treatments That Work

Syndrome	*Treatments*	*Standards of Proof*	*References*
Agoraphobia (moderate to severe)	**Psychosocial Treatments** • The clinical efficacy of *situational in vivo exposure* for patients with moderate to severe agoraphobia has been established.	• A substantial number of excellent studies, largely type 1	Chapter 14, pp. 409–462 (Barlow, Conklin, & Bentley)
Anorexia Nervosa	**Psychosocial Treatments** • Anorexia nervosa remains extremely challenging to treat. • Initial studies suggest that *cognitive-behavioral therapy (CBT)* may be associated with improved outcome in both the acute and maintenance phases of treatment. • Adapting *CBT* and *Specialist Supportive Clinical Management* for severe and enduring anorexia nervosa can result in better engagement in treatment and significant clinical improvement. **Psychopharmacological Treatments** • The impact of atypical antipsychotic medication, most often *olanzapine*, on weight gain and eating disorder psychopathology in anorexia nervosa has recently been assessed. Results have generally been mixed, inconsistent, and small. • The effectiveness of *fluoxetine* following weight restoration in anorexia nervosa has also been studied; it did not have an impact on time to relapse, weight gain or loss, or core eating disorder pathology above and beyond CBT, and there was no evidence it was superior to placebo.	• A number of randomized controlled trials (RCTs): More methodologically rigorous studies are needed	Chapter 20, pp. 641–658 (Pike, Gianini, Loeb, & Le Grange)

Syndrome	*Treatments*	*Standards of Proof*	*References*
Attention-Deficit/ Hyperactivity Disorder (ADHD)	**Combined Treatments** • Combined behavioral and medication treatments appear to reduce the needed dose or intensity of each intervention.	• A significant number of well-designed studies, primarily type 1	Chapter 3, pp. 55–84 (Pfiffner & Maack)
	Psychopharmacological Treatments • *Psychostimulants* are highly effective in reducing core symptoms of ADHD in children and adults.	• A very large number of RCTs, primarily type 1	Chapter 4, pp. 85-140 (Kass, Posner, & Greenhill)
	Psychosocial Treatments • Of the nonpharmacological treatment approaches for ADHD in children, behavioral interventions have the largest evidence base. • These interventions include *behavioral parent training (BPT)*, *behavioral classroom management (BCM)*, *child skills training (CST)*, *behavioral multicomponent interventions (BMI)*, and *multimodal treatment (MT)*, which combines behavioral interventions and medication.	• A substantial number of RCTs for most of these behavioral treatments, primarily type 1	Chapter 3, pp. 55–84 (Pfiffner & Maack)
Binge Eating Disorder	**Psychosocial Treatments** • *CBT* and *interpersonal therapy (IPT)* have been shown to be the most efficacious in reducing symptoms and improving psychological outcomes. However, these treatments have generally been unsuccessful in producing significant, maintainable weight loss.	• A number of RCTs (type 1 and type 2)	Chapter 20, pp. 641–658 (Pike, Gianini, Loeb, & Le Grange)
	Psychopharmacological Treatments • Three drugs are currently approved by the U.S. Food & Drug Administration (FDA) for treating obesity: *orlistat*, *lorcaserin*, and *phentermine-topiramate*. Of these, only orlistat (a lipase inhibitor) has been studied as a treatment for obese individuals with binge eating disorder, although topiramate (without phentermine) has also been examined. Weight loss associated with these drugs has generally not been maintained.	• A number of type 1 and type 2 RCTs	Chapter 20, pp. 641–658 (Pike, Gianini, Loeb, & Le Grange)

Syndrome	*Treatments*	*Standards of Proof*	*References*
	• In these studies, either tricyclic antidepressants (*imipramine*) or selective serotonin reuptake inhibitors (SSRIs; *fluoxetine*, *fluvoxamine*, *sertraline*, *citalopram*) were used for short-term treatment either in conjunction with psychotherapy or alone. Overall, binge remission rates were significantly higher at the end of treatment in the active medication treatments compared with placebo (40.50% vs. 22.22%). However, these periods of treatment were relatively short and the study with the longest duration did not find a significant difference between fluoxetine and placebo groups.	• A 2008 meta-analysis of seven studies	
Bipolar Disorder in Adults	**Psychopharmacological Treatments**		
	• The pharmacological management of bipolar disorder involves the treatment of acute manic, hypomanic, mixed, and depressive episodes, as well as the prevention of further episodes.		Chapter 8, pp. 237–272 (Keck & McElroy)
	• *Lithium*, *divalproex*, *carbamazepine*, *haloperidol*, *risperidone*, *olanzapine*, *quetiapine*, *ziprasidone*, *aripiprazole*, and *asenapine* have demonstrated efficacy in the treatment of acute mania.	• Many type 1 & type 2 RCTs	
	• Although pharmacological treatment of acute bipolar depression remains understudied, *lithium*, *olanzapine*, *olanzapine-fluoxetine*, *quetiapine*, *lurasidone*, *tricyclic antidepressants*, *monoamine oxidase inhibitors (MAOIs)*, and *fluoxetine* have shown efficacy. • *Lithium*, *lamotrigine*, *olanzapine*, *aripiprazole*, *quetiapine*, and *resperidone* have shown efficacy in relapse prevention.	• A large number of RCTs	

Syndrome	*Treatments*	*Standards of Proof*	*References*
	Combined Treatments		
	• Although pharmacological interventions remain the primary treatment for bipolar disorder, adjunctive psychosocial interventions can increase adherence to medication regimens, decrease hospitalizations and relapses, decrease severity of symptoms, improve quality of life, and enhance mechanisms for coping with stress.	• Four type 1 & 2 studies	Chapter 10, pp. 307–326 (Muralidharan, Miklowitz, & Craighead)
	• *Group psychoeducation* leads to lower rates of recurrence and greater adherence to medication among remitted bipolar patients at both short- and long-term follow-up.	• Three type 1 studies	
	• *Family-based intervention* has been effectively combined with pharmacotherapy to reduce recurrences and hospitalization rates in adult patients.	• Three type 1 studies	
	• *Family psychoeducation and skills training* may be effective adjuncts to pharmacotherapy for bipolar spectrum children and adolescents and youths at high risk for bipolar disorder.		
Bipolar Disorder in Children and Adolescents	**Pharmacological Treatments**		
	• Practice guidelines recommend pharmacotherapy with mood stabilizers or second generation antipsychotics as the first-line treatment for pediatric bipolar disorder. Currently, *lithium*, *risperidone*, *aripiprazole*, *quetiapine*, and *olanzapine* are approved by the FDA for treating bipolar disorder in children and adolescents.	• A number of type 1 and type 2 RCTs	Chapter 9 , pp. 273–306 (Goldberg, Martin, Biernacki, & Rynn)
	Psychosocial Treatments		
	• A growing body of literature also suggests the efficacy of psychosocial interventions with *family psychoeducation* and *skills building* as adjunct treatments to pharmacotherapy.		

Syndrome	*Treatments*	*Standards of Proof*	*References*
Borderline Personality Disorder	**Psychosocial Treatments:**		
	• A meta-analysis found statistically significant effects indicating a beneficial effect of *dialectical behavior therapy (DBT)* over treatment as usual for improvements in anger (two RCTs), parasuicidality (three RCTs), and mental health (two RCTs). All of these effects were moderate to large in size.	• A substantial meta-analysis and a number of RCTs	Chapter 27, pp. 851–870 (Crits-Christoph & Barber)
	• Versions of *psychodynamic therapy* have also shown positive outcomes comparable to DBT.	• Two type 1 RCTs	
	Psychopharmacological Treatments		
	• In borderline personality disorder, evidence of moderate effectiveness is strongest for second-generation antipsychotics and mood stabilizers. However, medications have limited effectiveness and are still viewed as adjunctive to other forms of treatment, particularly psychotherapy.	• A number of RCTs	Chapter 28, pp. 871–906 (Perez-Rodriguez & Siever)
Bulimia Nervosa	**Psychosocial Treatments**		
	• There is strong cumulative support for *CBT* as the treatment of choice for bulimia nervosa. • The utility of *IPT* and *pharmacotherapy* as appropriate alternative treatments in the treatment of bulimia nervosa has also been suggested.	• Many well-designed type 1 and type 2 studies	Chapter 20, pp. 641–658 (Pike, Gianini, Loeb, & Le Grange)
	Psychopharmacological Treatments		
	• *Fluoxetine* is FDA approved for the treatment of bulimia nervosa.	• A substantial number of RCTs	
Conduct Disorder and Oppositional Defiant Disorder	**Psychosocial Treatments**		
	• Several psychosocial interventions have shown strong evidence of efficacy with children and adolescents with conduct disorder. They include *parent management training*, *multisystemic therapy*, *multidimensional treatment foster care model*, *cognitively based treatments*, *functional family therapy*, *brief strategic family therapy*, and *the Good Behavior game*.	• A number of well-designed RCTs, largely type 1, for each intervention	Chapter 5, pp. 141–174 (Kazdin)

Syndrome	*Treatments*	*Standards of Proof*	*References*
	Psychopharmacological Treatments		
	• Psychopharmacological management with FDA-approved agents (*stimulants*, *second-generation antipsychotics*, and *mood stabilizers*) decreases the defiant and aggressive behavior characteristic of disruptive behavior disorders, including conduct disorder and oppositional defiant disorder.	• A number of RCTs, type 1 and type 2	Chapter 4, pp. 85–140 (Kass, Posner, & Greenhill)
Depressive Disorder in Children and Adolescents	**Pharmacological Treatments**		
	• In moderate to severe cases of pediatric depression, medication treatment is recommended, with or without CBT. Currently, *fluoxetine* and *escitalopram* are the only antidepressants approved by the FDA for acute pediatric depression.	• A substantial number of type 1 and type 2 RCTS	Chapter 12 , pp. 355–380 (Biernacki, Martin, Goldberg, & Rynn)
	Psychosocial Treatments		
	• Practice guidelines recommend psychosocial interventions for mild or brief cases of pediatric depression.	• A number of RCTs	
	• Among psychosocial interventions, *CBT* and *IPT for adolescents* (IPT-A) have the largest evidence base for treatment of depressed youth.		
	Combination Treatments		
	• Combination treatment with *CBT* and *antidepressant medication* is superior to treatment with either modality alone.	• A number of RCTs	
Erectile Dysfunction	**Psychopharmacological Treatments**		
	• Investigations have demonstrated the efficacy of *phosphodiesterase type 5 inhibitors* for the treatment of erectile problems of mixed etiologies.	• Well-controlled double-blind multisite (type 1) interventions	Chapter 22, pp. 699–730 (Segraves)
Gambling Disorder	**Psychosocial Treatments**		
	• Specific behavioral (e.g., *CBT*) treatments significantly reduce the symptoms of gambling disorder in the short term compared to waitlist or placebo.	• Several controlled outcome studies (type 1 & type 2)	Chapter 25, pp. 801–826 (Grant, Odlaug, & Potenza)
	• Limited long-term effects of manual-based CBT have also been observed.	• Several small studies	

Syndrome	*Treatments*	*Standards of Proof*	*References*
	Psychopharmacological Treatments • Specific pharmacological (e.g., *naltrexone*, *nalmefene*, *lithium*) treatments significantly reduce the symptoms of gambling disorder in the short term compared to waitlist or placebo. • The long-term benefits of psychopharmacological treatment have not been adequately tested.	• Several controlled outcome studies (type 1 & type 2)	Chapter 25, pp. 801–826 (Grant, Odlaug, & Potenza)
	Combined Treatments • The potential benefit of combining behavioral and drug treatments for gambling disorder remains understudied.		
Generalized Anxiety Disorder	**Psychopharmacological Treatments** • The pharmacological treatments of choice for generalized anxiety disorder are *buspirone* and *antidepressants*, including *SSRIs* and *venlafaxine*.	• A large number of type 1 and type 2 RCTs	Chapter 15, pp. 436–506 (Kimmel, Roy-Byrne, & Cowley)
	Psychosocial Treatments • Recent studies suggest that *CBT* approaches are most successful for generalized anxiety disorder. Specifically, newer variants of CBT that target intolerance of uncertainty or metacognitive beliefs about worry show promising levels of efficacy and superiority to alternative treatments.	• A number of recent well-designed RCTS	Chapter 14, pp. 409–462 (Barlow, Conklin, & Bentley)
Hypersomnolence Disorder and Narcolepsy	**Combined Treatments** • The mainstay of treatment is *pharmacological*, although *adjunctive behavioral therapy* plays a role in adapting to the situation.		Chapter 21, pp. 659–698 (Burman, Buysse, & Reynolds)
	Psychopharmacological Treatments • Treatment is similar for both hypersomnolence and narcolepsy. Treatment aims at symptom control to allow patients to live full personal and professional lives.		Chapter 21, pp. 659–698 (Burman, Buysse, & Reynolds)
	• Medications include *stimulants* (including *amphetamines* and related drugs) and *modafinil* and *armodafinil*. • First-line treatment for cataplexy consists of *antidepressants* (*venlafazine*, *desmethylvenlafaxine*, *duloxetine*, *fluoxetine*).	• A substantial number of well-designed RCTs	

Syndrome	*Treatments*	*Standards of Proof*	*References*
Insomnia	**Psychosocial Treatments** • *Multicomponent CBT for insomnia (CBT-I), stimulus control therapy, and sleep restriction therapy* appear to be most efficacious in reducing sleep latency and improving sleep consolidation by changing behaviors, habits, and cognitions that interfere with sleep. • Behavioral approaches are comparable to medications in efficacy and have been found to be more durable.	• A number of type 1 and type 2 studies	Chapter 21, pp. 659–698 (Burman, Buysse, & Reynolds)
	Psychopharmacological Treatments • The *benzodiazepine receptor agonists* have the best-established scientific basis for use in insomnia. • The melatonin agonist *ramelteon (Rozerem)* is also FDA approved for the treatment of insomnia.	• Many RCTs, both type 1 and type 2	Chapter 21, pp. 659–698 (Burman, Buysse, & Reynolds)
Combination Treatment for Major Depressive and Anxiety Disorders	• There is little evidence that combined psychosocial and medication therapy is superior to either alone in the treatment of mood and anxiety disorders. • Exceptions are adolescents with major depression and those with five or more recurrent moderate to severe episodes as well as augmentation of CBT or IPT in partial responders and nonresponders.		Chapter 16, pp. 507–544 (Aaronson, Katzman, & Moster)
Major Neurocognitive Disorders	**Psychopharmacological Treatments** • The treatment of major neurocognitive disorders, including Alzheimer's disease, is currently symptomatic; the goal is to temporarily improve symptoms or slow the progression of cognitive, psychiatric, and behavioral symptoms.		Chapter 26, pp. 827–850 (Nie & Sultzer)
	• While *cholinesterase inhibitors* and *memantine* are standard treatments for Alzheimer's disease at this time, the literature demonstrates only modest benefit, and critics cite the variability in methodological quality of the trials.	• A very large number of type 1 and type 2 studies	

Syndrome	*Treatments*	*Standards of Proof*	*References*
Obsessive-Compulsive Disorder (OCD)	**Combined Treatments** • There is overwhelming evidence of the most rigorous type supporting the efficacy *of serotonin reuptake inhibitors (SRIs)* in the treatment of OCD. • Along with SRIs, *behavior therapy* must be considered a viable first-line therapy. • The best available data suggest that *behavior therapy*, and perhaps *cognitive therapy*, are at least as effective as medication in some instances and may be superior with respect to risks, costs, and enduring benefits.	• Many type 1 RCTs	Chapter 17, pp. 545–570 (Dougherty, Rauch, & Jenike)
Panic Disorder (with or without Agoraphobia)	**Psychosocial Treatments** • The efficacy of *CBT* for persons with panic disorder with or without agoraphobia has been established. These treatments include some combination of *cognitive elements*, *exposure to interoceptive sensations similar to physiological panic sensations*, *in vivo exposure*, and *breathing retraining*.	• A substantial number of type 1 studies	Chapter 14, pp. 409–462 (Barlow, Conklin, & Bentley)
	• Successful dissemination of *CBT* for panic disorder has recently been established in effectiveness trials.	• Several large effectiveness trials (type 1)	
	Psychopharmacological Treatments • *SSRIs* are now considered the first-line pharmacological treatment for panic disorder, based on their low rate of side effects, lack of dietary restrictions, and absence of tolerance.	• A large number of type 1 and type 2 clinical trials	Chapter 15, pp. 436–506 (Kimmel, Roy-Byrne, & Cowley)
Posttraumatic Stress Disorder (PTSD)	**Psychosocial Treatments** • PTSD treatments work better than treatment as usual; average effect sizes are in the moderate to high range. • A variety of treatments have been established as effective, with no one treatment having superiority. Both present-focused and past-focused models work (neither consistently outperforms the other). • Consistent, significant differences between active treatments have not been reported.	• RCTs with treatment as usual, minimal attention, and waitlist controls	Chapter 18, pp. 571–592 (Najavits & Anderson)

Syndrome	*Treatments*	*Standards of Proof*	*References*
	Psychopharmacological Treatments • Although psychotherapy is considered the first line of treatment for PTSD, advances have been made in the pharmacological treatment of this disorder as well. • Antidepressants are still the first-line pharmacological treatment for PTSD. The SSRIs (e.g., *fluoxetine*, *sertraline*, and *paroxetine*) are efficacious in reducing PTSD-specific symptoms and improving global outcome. Other individual agents found to be efficacious include the tricyclic antidepressant *imipramine* and the MAOI *phenelzine*.	• A large number of RCTs, both type 1 and type 2	Chapter 19, pp. 593–640 (Golier, Michaelides, Genovesi, Chapman, & Yehuda)
Premature Ejaculation	**Psychopharmacological Treatments** • *Serotonergic antidepressants* delay ejaculation in men with premature ejaculation.	• A number of well-designed RCTs (type 1)	Chapter 22, pp. 699–730 (Segraves)
	Psychosocial Treatments • There is suggestive evidence for the efficacy of CBT in the treatment of sexual dysfunction in both sexes, although the number and methodological rigor of such studies are limited and the effect sizes tend to be smaller than those of studies of pharmacological therapies.	• A limited number of type 1 and type 2 RCTs	Chapter 22, pp. 699–730 (Segraves)
Schizophrenia Spectrum Disorders	**Psychopharmacological Treatments** • The first antipsychotic drug, *chlorpromazine*, was introduced in 1954, followed by several similar drugs. With the later introduction *of clozapine*, *risperidone*, *olanzapine*, *quetiapine*, *ziprasidone*, *aripiprazole*, and more recently *paliperidone*, *iloperidone*, *asenapine*, and *lurasidone*, antipsychotic drugs are often classified as first generation or typical (chlorpromazine-like) versus second generation or atypical (clozapine-like). • Both of these broad classes of medications have been demonstrated to safely improve psychotic symptoms in the acute phase of the illness and to reduce the risk of relapse in the maintenance phase of treatment.	• Many type 1 and type 2 controlled studies	Chapter 6, pp. 175–216. (Abbas & Lieberman)

Syndrome	*Treatments*	*Standards of Proof*	*References*
	• Because of the limited efficacy of antipsychotic medication in resolving the full range of schizophrenic psychopathology, adjunctive treatments are often used to reduce morbidity. Drugs such as *benzodiazepines*, *lithium*, *carbamazepine*, *valproic acid*, *antidepressants*, *glutamate agonists*, and *dopamine agonists* have been used alone and in combination with antipsychotic drugs to improve treatment response.	• Many type 1 and type 2 controlled studies	
	Psychosocial Treatments		
	• Cognitive remediation (CR) and social cognitive training (SCT) have been increasingly studied as behavioral interventions to improve disorder-linked cognitive and social cognitive deficits in schizophrenia. They appear to hold considerable promise for improving disorder outcome.	• Over 80 controlled studies and seven meta-analyses of CR and 20 controlled studies and one meta-analysis on SCT have been conducted to date.	Chapter 7, pp. 217–236 (Kurtz)
Sexual Dysfunction in Women after Oophorectomy	**Psychopharmacological Treatments**		
	• *Transdermal testosterone* restores sexual function in women after oophorectomy.	• A number of well-designed RCTs (type 1)	Chapter 22, pp. 699–730 (Segraves)
Social Anxiety Disorder	**Psychopharmacological Treatments**		
	• *SSRIs* and *venlafaxine* are attractive first-line treatments for social anxiety disorder.	• A substantial number of type 1 RCTs	Chapter 15, pp. 463–506 (Kimmel, Roy-Byrne, & Cowley)
	Psychosocial Treatments		
	• The most common treatment approaches for social anxiety disorder include *social skills training*, *relaxation techniques*, *exposure-based methods*, and *multicomponent cognitive-behavioral treatments*; the latter, along with exposure-based procedures, attain the highest level of treatment efficacy.	• Many type 1 RCTs	Chapter 14, pp. 409–462 (Barlow, Conklin, & Bentley)
Specific Phobias	**Psychosocial Treatments**		
	• The treatment of choice for specific phobias is *exposure-based procedures*, particularly *in vivo exposure*.	• A large number of type 1 studies	Chapter 14, pp. 409–462 (Barlow, Conklin, & Bentley)

Syndrome	*Treatments*	*Standards of Proof*	*References*
Substance Use Disorders	**Combined Treatments**		
	• The treatment of substance use disorders with medications is well established, although most experts agree that to be successful pharmacological interventions must be combined with psychosocial therapies.	• A number of well-designed RCTs	Chapter 24, pp. 763–800 (McKay, Kranzler, Kampman, Ashare, & Schnoll)
	Psychopharmacological Treatments		
	• The treatment of alcohol use disorder can now be enhanced by three approved medications based on different mechanisms of action: *disulfiram*, *naltrexone*, and *acamprosate*. A long-acting version of naltrexone is approved by the FDA.	• A large number of type 1 and type 2 RCTs for each substance	Chapter 24, pp. 763–800 (McKay, Kranzler, Kampman, Ashare, & Schnoll)
	• The use of nicotine replacement therapy to induce and maintain smoking cessation significantly increases abstinence rates, as have non-nicotine treatments such as *bupropion* and *varenicline*.	• A large number of type 1 and type 2 controlled trials	
	• *Methadone maintenance* treatment has consistently shown efficacy in the treatment of opioid use disorders; the partial opioid agonist *buprenorphine* has substantially expanded the options for treating this disorder.	• A substantial number of type 1 controlled trials	
	Psychosocial Treatments		
	• The most effective psychosocial treatments for substance use disorders include *cognitive-behavioral interventions*, *motivational interviewing and motivational enhancement*, *contingency management*, *community reinforcement*, *behavioral couples and family therapies*, and *12-step facilitation approaches*.	• A substantial number of type 1 and type 2 trials for each mode of intervention	Chapter 23, pp. 731–762 (Blonigen, Finney, Wilbourne, & Moos)
	• *Brief interventions* are quite effective in the treatment of substance use disorders, especially in those with mild and moderate disorders.	• A very large number of clinical trials	
Trichotillomania	**Psychosocial Treatments**		
	• *CBT* is effective for trichotillomania.	• "Several studies"	Chapter 25, pp. 801–826 (Grant, Odlaug, & Potenza)
	Psychopharmacological Treatments		
	• Two studies (both type 1) in adults (N-*acetylcysteine*, *olanzapine*) for this disorder have shown promise.	• Two type 1 studies	

Syndrome	*Treatments*	*Standards of Proof*	*References*
Unipolar Depression (Major Depressive Disorder [MDD])	**Combined Treatments** • The data for outcomes of psychosocial and pharmacological interventions for major depressive episodes suggest that the two treatment modes are equally efficacious. Meta-analyses lend support for the superior effectiveness of combined psychosocial and pharmacological treatments with chronic depression.	• Many well-designed RCTs	Chapter 13, pp. 381–408 (Craighead, Johnson, Carey, & Dunlop)
	Psychopharmacological Treatments • The treatment of unipolar depression with *antidepressant medication* is well established. • *Tricyclic antidepressants*, the first to be studied extensively, were consistently and significantly more efficacious than placebo. • Tricyclics have now been replaced as the first-line treatment of depression by *SSRIs (fluoxetine, sertraline, paroxetine, citalopram, escitalopram)*, as well as by *serotonin norepinephrine reuptake inhibitors (SNRIs: venlafaxine, duloxetine, desvenlafaxine, levomilnacipran)*. • Other compounds, including *bupropion, vortioxetine, vilazodone*, and *mirtazapine*, have also proven efficacious. • *MAOIs* have generally been reserved for treatment-refractory patients. • Combination and augmentation therapy practices are gaining in popularity for patients who are partial responders and nonresponders to monotherapy.	• Scores of RCTs involving hundreds of thousands of patients	Chapter 11, pp. 327–354 (Prendes-Alvarez, Schatzberg & Nemeroff)
	Psychosocial Treatments • Behavior therapy (BT), CBT, and IPT have each been shown to be effective psychosocial interventions for patients meeting criteria for major depressive disorder.	• Each has been shown to be efficacious by at least two type 1 or type 2 RCTs, as well as numerous meta-analytic reports of the literature.	Chapter 13, pp. 381–408 (Craighead, Johnson, Carey, & Dunlop)

A GUIDE TO TREATMENTS THAT WORK

1

Challenges to Implementing Evidence-Based Treatments

Jack M. Gorman
Peter E. Nathan

The Diagnostic and Statistical Manual of Mental Disorders (5th ed.; *DSM-5*; American Psychiatric Association, 2013) was published in May 2013, six months before this chapter was written, and has been the target of intense criticism through most of the years of its development. This chapter undertakes a detailed examination of two of the most significant issues raised by critics of *DSM-5*. Neither is new, and both are highly relevant to a number of issues addressed in this book. The first matter recognizes the continued absence of viable biomarkers of specific diagnoses. Despite intense efforts by neuroscientists to identify such markers, and strong interest in them by the authors of successive editions of the *DSM*, including *DSM-5*, biomarkers are not a feature of the 2013 nomenclature. We will argue that the problem rests at least as much with the *DSM* system as it does with progress made by neuroscientists. The second question concerns what many critics view as the inordinate influence of the pharmaceutical industry—Big Pharma—on the highly troubling problem of overdiagnosis that began with *DSM-III* (American Psychiatric Association, 1980). These two issues, clearly related to each other and both likely to grow markedly in importance over time, deserve recognition and discussion here.

DSM-5 AND ITS DETRACTORS

Three books critical of *DSM-5* (Burns, 2013; Frances, 2013; Greenberg, 2013) appeared coincident with its publication in May 2013. Many articles, op-ed pieces, and letters to the editor, written by an array of prominent figures in psychiatry and the other mental health professions, also appeared in recent years in prominent print media, including the *New York Times*, *Washington Post*, and *Psychiatric Times*; most were highly critical of both the *DSM-5* process and its emerging content. Numerous critical talks were delivered at public and professional meetings, and a seemingly endless array of concerns about the direction and content of *DSM-5* have been expressed in diverse social media.

Has the volume of criticism of *DSM-5* been greater than that leveled at its predecessors? Almost certainly so, in part because the scope and reach of commentaries facilitated by social media are so much greater than was possible before, and in part because the attack on *DSM-5*, which began very early, before the Work Groups and Task Force were fully constituted, was led by Allen Frances, a highly credible critic because of his lead role in the development of *DSM-IV* (American Psychiatric Association, 1994) and his status as a prominent psychiatric scientist and administrator.

Most criticisms of *DSM-5* are not new; they were also voiced in reaction to earlier versions of the nomenclature. To this end, even though the first two editions of the nomenclature—*DSM-I* (American

Psychiatric Association, 1952) and *DSM-II* (American Psychiatric Association, 1968)—were lauded as the nation's first national psychiatric taxonomies, they were criticized because many of their diagnostic formulations seemed unduly influenced by psychoanalytic theory; because of the almost total absence of empirical data in support of the diagnostic syndromes; and because most of those syndromes were described so briefly and sketchily that they typically generated diagnoses on which clinicians could not agree.

Substantial changes in the diagnostic system introduced in *DSM-III* (1980) and largely maintained in *DSM-IV* (1994) and *DSM-5* (2013) markedly increased diagnostic reliability. A number of diagnoses in the latter nomenclatures were based on empirical data from specifically commissioned field trials. Nonetheless, these instruments too were strongly criticized—for effecting an almost threefold increase in the number of diagnoses, especially for children and adolescents; for introducing a number of new diagnoses largely unsupported by empirical research; and for attempting to "medicalize" diagnosis by highlighting the efficacy of psychopharmacological treatments and the promise of emerging neuroscience findings that many critics felt were unwarranted (Langenbucher & Nathan, 2006; Oltmanns & Castonguay, 2013; Widiger & Edmundson, 2011).

The duration and intensity of attacks on *DSM-5* represent one major difference between the reception accorded that instrument and its predecessors. The other differences stem from the force of criticisms largely directed toward the two matters on which this chapter focuses. Both matters were briefly raised by critics of *DSM-III*, elaborated on by critics of *DSM-IV*, and elevated further to crescendos of concern in *DSM-5*. Both issues seem likely to continue to affect diagnosis and treatment, as well as the future of the *DSM*.

THE PROMISE OF BIOMARKERS, AS YET UNFULFILLED

In the years before the third edition of *DSM* appeared in 1980, hope was expressed that efforts to correlate early findings on brain structure and function with psychiatric disorders would yield linkages with selected *DSM* categories of mental illness. Despite these hopes, expressed by leaders of American psychiatry and psychology as well as many of those involved in *DSM-III* and *DSM-IV* development efforts, breakthroughs sufficient to justify their inclusion in these nomenclatures did not occur. Nonetheless, especially given impressive gains in analytic methods and technical procedures and exciting new findings in neuroscience, it was anticipated that increasingly sophisticated and productive studies of neural transmission, molecular neuroscience, systems neuroscience, genetics, and epidemiology, in accelerating trajectory, would finally anchor selected mental disorder diagnoses to firm neuroscience bases. The leaders of the *DSM-5* development process were outspoken in their anticipation of nothing less at the commencement of the *DSM-5* development process. One of the most important reasons for the intensity of the quest was the belief that such work would finally enable development of rationally designed and, hence, more effective treatments.

Despite these expectations, however, biomarkers and data from neuroscience research are not a prominent feature of *DSM-5*. Allen Frances, one of the most persistent of those recognizing the failure of continuing efforts to relate findings from contemporary neuroscience and neurobiological research to specific DSM-5 diagnoses, presents it this way: "The excessive DSM-5 ambition to effect a paradigm shift in psychiatric diagnosis [included] the unrealistic goal of transforming psychiatric diagnosis by somehow basing it on the exciting findings of neuroscience. This would be wonderful were it possible, but the effort failed for the obvious reason that it is still a bridge too far" (2013, p. 171). Other prominent psychiatrists, including Thomas Insel, director of the National Institute of Mental Health (NIMH); Steven Hyman, a former NIMH director; and Eric Kandel, a psychiatric neuroscientist and Nobel laureate, have also questioned continued reliance on behavioral diagnosis in favor of diagnosis based on neurobiologic markers and have expressed great disappointment at the inability of researchers to date to replace the behavioral diagnosis paradigm that continues to characterize the DSM with a neuroscience-based diagnostic system that would be more rational and more closely tied to treatment options. Opinion is mixed, however, on the issue: Is there already enough neurobiologic evidence to reconfigure components of the diagnostic nomenclature, or is such an effort entirely premature and must it await substantial further developments?

Although progress to date in developing reliable, neuroscience-based correlates of specific psychiatric

disorders has not met the goal of validating specific *DSM-5* categories of illness, a closer look at the research, in our view, yields substantial promise. Indeed, to appreciate how much progress has been made it is often necessary to set aside *DSM* categories, which often mask what has been accomplished in the laboratory.

As briefly noted above, critics of *DSM-III* (American Psychiatric Association, 1987), *DSM-IV*, *DSM-IV-TR* (American Psychiatric Association, 2000), and *DSM-5* argued that all of these nomenclatures constituted covert attempts to "medicalize" psychiatry by their emphases on inherited aspects of mental disorders and pharmacological therapies. In fact, neuroscience has been just as likely to validate experiential causes and psychosocial treatments for psychiatric disorders. Whereas *DSM-I* and *DSM-II* were disparaged because of their reliance on psychoanalytic terms and theory, the latter-day *DSM*s were thought to want to eliminate theory of all kinds in order to reflect the "new psychiatry" of neurotransmitters, the familial recurrence of psychiatric illness, and psychopharmacology. Many of the critics of *DSM-5*, however, insist that there is in fact no proven neuroscientific basis to most if not all psychiatric disorders and that the effort to relate the "bench to the bedside" is based on wishful thinking. The attempt to give psychiatric diagnosis a physical/medical basis is seen as benefitting the pharmaceutical industry and psychiatry to the detriment of psychotherapy and the nonmedical mental health professions. Indeed, as we noted previously and detail below, the other major concern raised by critics of *DSM-5* is that "Big Pharma" has exerted undue influence on our understanding of which psychopharmacological treatments are efficacious.

Regardless of whether one supported or opposed the introduction of *DSM-5*, it is widely believed that to date neuroscience has offered few insights that would establish the validity of individual *DSM* categories. For example, there is not yet a discrete biology for such common conditions as 296.3 (major depressive episode), 295.90 (schizophrenia), or 309.81 (posttraumatic stress disorder). Most of the changes from *DSM-IV* to *DSM-5* are based on epidemiological evidence. Hence, critics have sounded a discouraging alarm that decades of extensive neuroscientific research have been largely fruitless in developing a biological basis for the categorization of mental disorders. Soul searching for some has turned to despair.

Indeed, most of the initial attempts to explain mental disorders on the basis of biomarkers *have* turned out to be inadequate. In the years following the introduction of medications to treat psychiatric disorders, psychopathology was attributed to abnormalities in the neurotransmitter systems targeted by each kind of medication. Thus, because the antipsychotic drugs blocked dopamine effects in the brain, schizophrenia was ascribed to an excess of central nervous system dopamine. The new tricyclic and monoamine oxidase inhibitor antidepressant drugs increased the concentrations of the neurotransmitters serotonin and norepinephrine, and so depression was labeled a serotonin/norepinephrine deficiency disease. These ideas held remarkable traction for more than 20 years, but by 1980 they were already proving to be deficient in explaining what really is wrong in the brains of people with schizophrenia or depression. No one was able to show that there actually is too much dopamine in the brains of people with schizophrenia or too little serotonin in the brains of people with depression. Similarly, the discovery that psychiatric illnesses run in families, based on family, twin, and adoption studies, created the assumption that ultimately all mental disorders would turn out to be caused by genetic mutations. Because such mutations have proven just as elusive for mental disorders as they have for most other chronic illnesses (e.g., diabetes, congestive heart failure, obesity, and kidney failure), it has increasingly seemed to many that the search for a genetic basis for mental illness might also be futile.

Yet this pessimism may be misplaced, for there are indeed strong signs that some definite conclusions about the biology of mental disorders can be made on the basis of preclinical and clinical research. The problem for the current diagnostic system is that these conclusions do not map well onto specific *DSM-5* categories. Thomas Insel, NIMH director, has stressed this point in the creation of the Research Domain Criteria (RDoC) (Cuthbert & Insel, 2013). Rather, a review of progress in the neuroscience of mental disorders suggests that biological findings adhere to specific types of psychopathology that cut across these categories. In other words, the disappointingly low validity of *DSM-5* categories of illness may reflect the fact that biological findings appear to account for symptoms of illness that cut across those categories. Although a great deal of this work involves animal models of psychopathology, much of it is substantiated by clinical findings using the

increasingly sophisticated tools of neuroimaging. In a few instances, this work has led to insights into the development of new therapeutic interventions. It is extremely important to bear in mind, however, that neuroscience and psychopharmacology are not coextensive disciplines. Modern neuroscience, much of which is conducted by nonpsychiatrists, has been as likely to link psychopathology to adverse life experiences and stress as to genetic mutations, and the treatments it validates include a variety of psychosocial interventions, not just drugs.

In this section of the chapter, we will briefly consider data from four examples of this development, recognizing that the list is hardly exhaustive and that even with these four there are still ample reasons for caution before making final pronouncements about the biological foundation of psychopathology. This kind of thinking may be synchronous with what will occur in developing the NIMH RDoC. We also review here solid neuroscientific evidence for a pathway—adverse early childhood experience—that increases the risk for almost all forms of psychopathology and therefore should inform the development of new interventions. In brief, this review encompasses the following:

1. Anxiety disorders and depression share disruption in the normal restraint of the medial prefrontal cortex (mPFC) over the activity of the amygdala, leading to a fearful state and inability to make rational assessments of threat. Interventions that restore the normal balance between mPFC and amygdala are therapeutic for fear-based disorders.
2. Obsessive and compulsive behaviors involve disruption of the sensitivity of pathways from the orbitofrontal cortex (OFC) to the ventral striatum. This applies to such behaviors included as parts of the diagnostic criteria for a wide variety of disorders, including obsessive-compulsive disorder, autism, and addiction.
3. Psychosis, regardless of whether it occurs in an individual with schizophrenia, bipolar disorder, major depression, or amphetamine abuse, is linked to excess dopamine neurotransmission and stimulation of the dopamine type 2 (D_2) receptor in the ventral striatum. Medications that reduce positive psychotic symptoms (hallucinations, delusions, and thought disorder) all inhibit dopamine binding to the D_2 receptor.
4. Addiction to most substances, including alcohol, cocaine, heroin, nicotine, and amphetamines, is accompanied by desensitization of the dopaminergic pathway from the ventral tegmental area (VTA) in the brain stem to the nucleus accumbens (NA) in the limbic cortex.
5. Adverse early life experience disrupts multiple aspects of brain biology, including the epigenetic control of gene expression, and predisposes an individual to most psychiatric illnesses, including schizophrenia, bipolar disorder, and major depression. Treatments that aim at creating more adaptive understanding and response to stimuli reminiscent of these adverse experiences may be critical in ameliorating a diversity of mental disorders.

DISORDERS OF AMYGDALA ACTIVITY AND ITS REGULATION

Seminal preclinical work from the laboratories of scientists such as Joseph LeDoux, Gregory Quirk, and Michael Davis demonstrated over the past three decades that the amygdala, an almond-shaped collection of neurons in the limbic cortex, is at the hub of a network that mediates conditioned (Pavlovian) fear (Ciocchi et al., 2010; Davis, 1992; LeDoux, 2000; Milad & Quirk, 2002; Quirk, Garcia, & González-Lima, 2006; Rodrigues, Schafe, & LeDoux, 2004; Tye et al., 2011). In the classic experiment, a laboratory rodent is conditioned to respond with a freezing response to a tone as it normally does to a mild electric shock. The tone stimulus is relayed from the auditory thalamus to the central nucleus of the amygdala (CNA) and then to the lateral nucleus of the amygdala (LA). From there, information is sent to various effector regions that produce the characteristic fear responses of freezing: increased heart rate, ventilation, and blood pressure and increased production of glucocorticoids. Each step along this relay of fear information is mediated by gene activation and de novo protein synthesis. Particularly crucial for the fear response are glutamatergic neurons in the amygdala (Harvey & Shahid, 2012). Acquisition of conditioned fear can be inhibited by ablation of the amygdala, blocking gene expression or protein synthesis, or antagonism of glutamate neurotransmission. Stress causes dendritic growth in the amygdala, thereby increasing the number of synaptic connections

capable of mediating the fear response (Pillai et al., 2012). In other areas of the brain, such as prefrontal cortex, stress decreases dendritic arbor expansion (Gorman & Docherty, 2010). Within the amygdala itself, the ratio of neuronal propagation from the lateral nucleus to the central nucleus determines trait anxiety levels in rodents (Avrabos et al., 2013).

It has also been shown that extinction of the conditioned fear response requires intact pathways from the mPFC to the amygdala (Berkowitz, Coplan, Reddy, & Gorman, 2006; Quirk et al., 2006). Extinction also requires a well-characterized series of molecular events (Mamiya et al., 2009; Nader, Schafe, & LeDoux, 2000) and creates a memory that does not erase the conditioned fear memory but coexists with it (Bouton, 2002; Milad, Rauch, Pitman, & Quirk., 2006). Thus, the fear response is readily reactivated and must be reconsolidated to remain in permanent memory. Protein synthesis inhibitors can block reconsolidation of a reactivated fear memory and erase it (Hupbach, Gomez, Hardt, & Nadel, 2007; Milekic & Alberini, 2002). In humans, the beta-adrenergic receptor antagonist propranolol also blocks reconsolidation of fear (Kindt, Soeter, & Vervliet, 2009).

As this work was published, clinical scientists immediately wondered whether the molecular biology of conditioned fear bears any relationship to pathologic fear states in humans, such as panic attacks and phobias. A large body of brain imaging studies has now confirmed that, just as in laboratory animals, the connection between the amygdala and mPFC is inversely correlated with anxiety (Kim & Whalen, 2009; Kim et al., 2011; Phelps, Delgado, Nearing, & LeDoux, 2004). That is, the stronger the functional connection between the mPFC and the amygdala, the lower the level of anxiety in the individual. Furthermore, many brain imaging studies have shown that patients with anxiety disorders and with depression, both unipolar and bipolar, manifest exaggerated amygdala responses and/or volume (Davey, Allen, Harrison, & Yücel, 2011; Holmes et al., 2012; Kuo, Kaloupek, & Woodward, 2012; Lipka, Miltner, & Straube, 2011; Nitschke et al., 2009; Perlman et al., 2012; Tao et al., 2012; Versace et al., 2010). A postmortem study showed abnormal amygdala anatomy in suicide victims (Gos et al., 2010). Abnormal amygdala responses have even been seen in young children with depression (Gaffrey et al., 2011; Gaffrey, Barch, Singer, Shenoy, & Luy, 2013). Reduced mPFC responses and functional connectivity between the prefrontal cortex and the amygdala are also well reported in mood and anxiety disorders (Burghy et al., 2012; de Carvalho et al., 2010; Erk et al., 2010; Etkin, Prater, Schatzberg, Menon, & Greicius, 2009; Garakani et al., 2007; Kim et al., 2011; Kong et al., 2013; Milad et al., 2006, 2009; Moses-Kolko et al., 2010; Williams et al., 2006).

Disruptions in amgydala/mPFC function in anxiety and depression have led to insights into treatment of these conditions. Antidepressant medications that are effective in treating mood and anxiety disorders normalize amygdala responses (Faria et al., 2012; Ruhé, Booij, Verlman, Michel, & Schene, 2012; Sheline et al., 2001; Victor, Furey, Fromm, Öhman, & Drevets, 2010). Antidepressants also reduce fear responses in fear-conditioned rats (Burghardt, Sullivan, McEwen, Gorman, & LeDoux, 2004). However, just as they do in humans with panic disorder, antidepressants appear to interfere with extinction of conditioned fear (Barlow et al., 2000; Burghardt, Sigurdsson, Gorman, McEwen, & LeDoux, 2013). Reasoning that behavior therapy of phobias is analogous to extinction of conditioned fear, clinical studies have shown that glutamate analogues such as D-cycloserine enhance the therapeutic effect in patients just as they promote extinction in laboratory animals (Bouton, Vurbic, & Woods, 2008; Hoffman et al., 2006; Ressler et al., 2004). Dissociation between the anterior cingulate, a brain region closely associated with the mPFC, and the amygdala predicted treatment response to the experimental antidepressant agent ketamine (Salvadore et al., 2010). These findings may even apply to some aspects of psychoanalytic psychotherapy (Gorman & Roose, 2011).

The key here is that abnormalities in amygdala responses are common across a broad range of mood and anxiety disorders (Ressler & Mayberg, 2007). As Etkin and Schatzberg (2011) noted, "These data support the existence of a common abnormality in anxiety and depression in the ventral cingulate and the amygdala, which may be related to a shared genetic etiology." That anxiety disorders and depression share a common biology is no surprise given the high degree of comorbidity between them (Kessler, Ruscio, Shear, & Wittchen, 2010).

Focusing on the amygdala and its connection to the mPFC is, of course, a simplification of a highly complex neural network that involves many other brain regions, including the dorsolateral PFC, the

anterior cingulate cortex, the bed nucleus of the stria terminalis, the insula, and the hippocampus. As LeDoux (2014) and Berkowitz and colleagues (2006) have noted, unlike laboratory rodents, humans employ a whole set of higher-order cognitive functions that interact with the automatic functions embedded in the amygdala and its connections. As a result, LeDoux pointed out (2014), the expression of conditioned fear in a rodent and the experience of conscious fear in humans are not coterminous. Yet the basic premise holds true even when the complexity of neural function is considered: the fear pathways and molecules that are involved in fear and its extinction in laboratory animals are also involved in fear responses in humans and are disrupted across a broad range of mood and anxiety disorders. Although there are clearly differences in symptomatic presentation among patients with the various *DSM-5* types of anxiety and mood disorders, research suggests that they share at least one common biological underpinning.

DISORDERS OF THE CONNECTION BETWEEN THE ORBITOFRONTAL CORTEX AND THE VENTRAL STRIATUM

While progress in understanding brain circuits underlying anxiety and depression followed the pathway from preclinical to clinical brain imaging studies, the elucidation of a specific brain network underlying compulsive and obsessive symptoms ran in the opposite direction. In this case, the abnormal circuit activity runs from a region in the frontal cortex, the orbitofrontal cortex (OFC), to the ventral striatum. As Rauch and Carlezon (2013) noted, "Decades of functional brain imaging data indicate that in [obsessive-compulsive disorder], the nodes of this network exhibit hyperactivity at rest that is exacerbated during a symptom induction and attenuated by successful treatment."

For many years since the publication of the *DSM-III* in 1980 first laid out the modern categories of psychiatric diagnosis, many experts expressed the belief that obsessive-compulsive disorder (OCD) was incorrectly placed among the anxiety disorders (Stein et al., 2010). Indeed, in *DSM-5*, OCD is no longer included in the anxiety disorders but is instead in its own category with several other conditions that involve repetitive behaviors. Almost from the beginning of the application of modern brain imaging technologies to mental disorders, investigators studied patients with OCD. More than 15 years ago Saxena, Brody, Schwartz, and Baxter (1998) were able to assemble a literature search of brain imaging studies involving patients with OCD and reported a general finding of hyperactivity in pathways from the OFC to the striatum. Since then several studies and excellent reviews have appeared, all pointing to the same abnormally regulated brain network (Chamberlain et al., 2008; Milad & Rauch, 2012; Saxena & Rauch, 2000; Whiteside, Port, & Abramowitz, 2004).

Once again, dysfunction in this circuit is not limited to a single *DSM* category of illness but appears to occur in many situations in which there is a failure to regulate behavior or thoughts, such as eating disorders, tics and Tourette syndrome, and substance abuse (Marsh, Maia, & Peterson, 2009a; Marsh et al., 2009b). Thus, the brain region–specific abnormalities adhere to a set of abnormal symptoms and behaviors that cut across multiple categories of illness.

Only much more recently, however, have elegant animal studies elucidated the nature of the abnormalities in this circuit. Mice with a deletion of the SAP90/PSD95-associated protein 3 (SAPAP3) gene, which is highly expressed in the striatum, were shown to exhibit marked compulsive grooming behaviors (Welch et al., 2007). Further study of these mice revealed abnormalities in corticostriatal synapses (Yang & Lu, 2011). Most recently, two elegant studies have provided important corroboration of the clinical imaging findings. Ahmari and colleagues (2013) used the technique of optogenetics, which enables direct stimulation of light-sensitive neurons in a specific brain pathway, to stimulate glutamatergic neurons in the projections from the OFC to the ventromedial striatum in mouse brain. Repeated stimulation of these neurons led to compulsive grooming behavior. Burguière, Monteiro, Feng, and Graybiel (2013) obtained direct electrophysiologic recordings from the OFC and striatum in the *Sapap3* mutant mice. They found that the excessive grooming behavior in these mice was directly related to a failure to inhibit neurons in the striatum. Next they showed that optogenetic stimulation of the mouse OFC restored normal inhibition to the striatal neurons and blocked excessive grooming. Thus, the Ahmari and the Burguière studies documented that compulsive behavior in the mouse is under the direct control of the OFC–striatal pathway, the same pathway that has been shown to

be dysfunctional in humans who display abnormal repetitive thoughts and behaviors.

Once again we must acknowledge that we have simplified the anatomy involved in these circuits. Human imaging studies in patients with OCD and other compulsive behavior–related disorders reveal the involvement of other brain regions, including the thalamus and the anterior cingulate. Furthermore, to the degree that the competitive behaviors in these disorders are responses to fear, the mPFC and amygdala are apparently invoked as well. Nevertheless, we once again have strong evidence that specific abnormalities in specific brain circuits are involved in a type of symptomatic presentation. This, we hope, will translate into treatments that attempt to restore OFC control over glutamate neurons in the ventral striatum. For example, knowledge of the neurocircuitry involved in OCD has led to studies of deep brain stimulation in patients whose conditions are refractory to medication and psychotherapeutic interventions. These studies, in which electrodes are implanted directly into structures within these pathways, have been reported to be successful in small pilot trials (Rauch et al., 2006).

Positive Symptoms of Psychosis and Enhanced Dopamine Transmission in the Striatum

The discovery in the 1950s and 1960s that newly developed medications capable of relieving psychotic symptoms in patients with schizophrenia all had the property of blocking the ability of dopamine to bind to its receptor sites in the central nervous system led to the "dopamine hypothesis" of schizophrenia (Eyles, Felder, & Meyer, 2012; Lau, Wang, Hsu, & Liu, 2013; Madras, 2013). According to this hypothesis, the "cause" of schizophrenia is an excess amount of dopamine in the brain. Just as was the case for the "serotonergic" and "noradrenergic" hypotheses of mood and anxiety disorders, this idea is based on the logic that if a drug works in patients with an illness (proposition A) and the drug targets a specific neurotransmitter system (proposition B), then the illness must be the result of an abnormality in that neurotransmitter system (conclusion C).

Patients with schizophrenia are indeed more behaviorally sensitive to the effects of dopamine agonists such as amphetamine than healthy controls (Seeman, 2013). Nevertheless, it eventually became apparent that the antipsychotic drugs that block the D_2 receptor are effective in treating only one aspect of schizophrenia, the so-called positive psychotic symptoms (hallucinations, delusions, thought disorder), and do not ameliorate the protean negative, cognitive, or affective symptoms of the disorder. Moreover, cognitive symptoms seem to predate positive symptoms in patients with schizophrenia and to be more closely related to long-term function. Thus, schizophrenia is increasingly referred to as a cognitive disorder (Kahn & Keefe, 2013) and the dopaminergic hypothesis disparaged. Propositions A and B may both be true to some extent, but they are not sufficient to reach conclusion C.

There is no question that inferring causality from the mechanism of action of a drug in the central nervous system is a perilous undertaking. The dopaminergic hypothesis now seems naïve. But it is also the case that abundant research has confirmed that excessive dopaminergic activity in the striatum is a reliable accompaniment of a specific and well-characterized set of symptoms. The problem is that these symptoms do not restrict themselves to a single *DSM-5* condition and therefore do not explain any single class of disorder. Rather, "hyperdopaminergic" neurotransmission is almost certainly present in the striatum of patients experiencing positive psychotic symptoms, regardless of whether the patient has been diagnosed with schizophrenia, bipolar mania, or amphetamine-induced psychosis. An extensive series of studies in the past 30 years have shown that when a patient hears voices and develops paranoid delusions, it is very likely that the dopamine pathways in the mesolimbic pathway that culminate in the striatum are hyperactive and that any medication that blocks the D_2 receptor will alleviate those symptoms.

To be sure, the animal models derived from the dopaminergic hypothesis of schizophrenia were never entirely satisfying, largely because it is nearly impossible to grasp what positive psychotic symptoms, let alone the full syndrome of schizophrenia, would entail in a rodent. Most of these models involved administering dopamine agonists such as apomorphine and amphetamine to rats and measuring subsequently elevated levels of locomotor hyperactivity and stereotypy (Geyer & Moghaddam, 2002; Jones, Watson, & Fone, 2011). Not surprisingly, these responses could be blocked by antipsychotic drugs that restrict access of dopamine agonists to the D_2 receptor. Perhaps more encouraging was the finding that dopamine agonists produced the

same abnormalities in the prepulse inhibition (PPI) test in rodents as are seen both in unmedicated patients with schizophrenia and in healthy controls given amphetamine and that these abnormalities in the sensory gating paradigm could also be blocked by antipsychotic medications, including the second-generation antipsychotics (Braff, 2010; Powell, Zhou, & Geyer, 2009).

It is at the level of functional imaging studies in patients with schizophrenia, some using remarkably clever methods to measure in vivo dopamine activity, that the association between hyperdopaminergic function and psychotic symptoms has been clearly elucidated. Studies using positron emission tomography (PET) and single photon emission computed tomography (SPECT) demonstrate excess release of dopamine by neurons in the ventral striatum and consequent alterations in D_2 receptor number and function in both medicated and unmedicated patients with schizophrenia (Brunelin, Fecteau, & Suaud-Chagny, 2013; Laruelle, 1998; Laruelle & Abi-Dargham, 1999; McGowan, Lawrence, Sales, Quested, & Grasby, 2004). In a series of studies using a novel approach, Abi-Dargham, Laruelle, and colleagues administered the dopamine-depleting agent alpha-methyl-para-tyrosine (AMPT) to healthy controls and antipsychotic drug–naïve patients with schizophrenia, thus enabling them to create a true baseline state (Abi-Dargham, van de Giessen, Slifstein, Kegeles, & Laruelle, 2009). Using SPECT imaging of D_2 receptors they once again showed increased dopamine release in the patients compared to the controls. These findings relate most closely to untreated patients with positive psychotic symptoms and predict favorable response to antipsychotic medications (Miyake, 2011).

In terms of antipsychotic effects, imaging studies have shown that there is a tight correlation between medication efficacy and D_2 receptor binding and that approximately 65% of available D_2 receptors must be blocked for a drug to have antipsychotic effects (Kapur, Zipursky, Jones, Remington, & Houle, 2000; Tauscher & Kapur, 2001; Yilmaz et al., 2012). At 80% D_2 receptor occupancy, however, extrapyramidal symptoms emerge as a significant clinical limitation of antipsychotic drugs (Kapur, 1998; Stone, Davis, Leucht, & Pilowsky, 2009). Thus, because second-generation antipsychotic drugs are more likely to remain within this narrow therapeutic window than first-generation ones, they are less likely to cause extrapyramidal symptoms at therapeutic doses (Howes et al., 2009; Kapur & Mamo, 2003). Understanding the role of dopamine and the D_2 receptor in the genesis of positive psychotic symptoms has therefore led to important insights into the mechanism of action of antipsychotic drugs and created a pathway for developing better treatments.

Unfortunately, far fewer brain imaging studies evaluating dopamine neurotransmission in patients with bipolar disorder than with schizophrenia have been published. Performing brain imaging studies on patients in an acute manic state is plainly a Herculean task. Nevertheless, available studies suggest excessive mesolimbic dopamine activity (Anand et al., 2000, 2011; Cousins, Butts, & Young, 2009). Of note, Pearlson and colleagues (1995) used PET scanning to show that elevated D_2 receptor numbers were more closely associated with psychotic than mood symptoms in bipolar patients. The same conclusion was reached by Gonul, Coburn, and Kula (2009) in their review of imaging studies involving bipolar patients.

We have then a solid and well-replicated set of findings linking a specific disturbance in a neurotransmitter (dopamine) in a specific brain region (ventral striatum) to a specific set of psychiatric symptoms (positive psychotic symptoms). Furthermore, these findings explain the mechanism of action of a therapeutic intervention (antipsychotic drugs). There is no question that this represents only the tip of the iceberg in terms of what is wrong with patients with schizophrenia, bipolar disorder, and addiction to psychostimulant drugs. Nevertheless, it represents a coherent and important story that belies the notion that translational neuroscience research has ubiquitously failed to reveal fundamental aspects of psychopathology.

Substance Abuse Causes Sensitization of the Ventral Tegmental Area–Nucleus Accumbens Dopamine Pathway

Nora Volkow, the director of the National Institute on Drug Abuse, recently pointed out that "all drugs of abuse increase dopamine, which is crucial for their effect" (Levin, 2013). In so stating, Volkow referred to her own work as well as a multitude of others showing that drugs of abuse cause the same biological changes in laboratory animals and humans. What may be most remarkable about these findings is that they apply to almost all abused substances—alcohol, nicotine,

stimulants, and opiates—even though each has its own chemistry and receptor targets in the brain.

Volkow has been at the forefront of research using brain imaging to show the central role played by the brain's so-called reward pathway in all forms of drug addiction. This circuit, also called the mesolimbic pathway, comprises dopaminergic neurons that originate in the VTA of the midbrain and project to striatal areas, most prominently the NA. Many forms of rewarding experiences stimulate activity via the VTA–NA pathway, and rats will press levers to obtain stimulation of this pathway. Similarly, alcohol, cocaine, heroin, and nicotine—almost all addictive substances—activate the VTA–NA dopamine neurons, producing a pleasurable feeling at first (Gardner, 2011; Hou, Tian, & Zhang, 2012; Ross & Peselow, 2009; Volkow, Wang, Fowler, Tomasi, & Telang, 2011). Although heroin, for example, is an opioid and therefore targets the brain's opiate receptors, it causes a powerful release of dopamine from nerve terminals in the VTA–NA pathway (Hou et al., 2012). Animal studies and brain imaging studies in humans converge to show that dopamine levels are indeed increased in the VTA–NA circuit after addictive drug ingestion (Feltenstein & See, 2008). For a variety of reasons, only some of which are currently clear (e.g., exposure to high levels of stress, family history of substance abuse), a percentage of individuals become obsessed with these substances and dependent on their effects on the dopamine pathway. These individuals, both animal and human, begin taking the substance repeatedly.

Animal and clinical studies have both shown that repeated administration of addictive substances induces a reduction in availability of dopamine and its receptors in the VTA–NA pathway (Gardner et al., 2011; Maldonado, 2003; Weiss, Markou, Lorang, & Koob, 1992). In monkeys addicted to cocaine, the lower the number of available D_2 receptors, the greater the rates of cocaine self-administration (Nader et al., 2006). PET studies have shown that reduction in dopamine function is also the case in human addicts (Martinez et al., 2012; Volkow, Fowler, Wang, Swanson, & Telang, 2007). Alcoholics, for example, show reduced dopamine response when given the dopamine agonist methylphenidate as compared to control subjects during PET scanning (Volkow et al., 2013). The VTA–NA circuit is weaker the longer a person has been addicted to cocaine (Gu et al., 2010). This makes it imperative that the addict either take greater amounts of the abused substance more frequently to obtain consistent effects or succumb to the highly dysphoric symptoms of withdrawal.

The molecular mechanisms by which addictive substances produce alterations in neuronal responsiveness in the VTA–NA pathway are rapidly becoming clear. Eric Nestler, among others, has shown that repeated administration of most addictive substances leads to predictable changes in gene expression, mediated in part by epigenetic effects. Within the NA, the genes encoding several proteins, including sirtuins (Ferguson et al., 2013), transcription factors like ΔFosB, and growth factors like brain-derived neurotrophic factor (BDNF), are activated by drug administration (Bilinski et al., 2012; Kelz et al., 1999; McCarthy, Brown, & Bhide, 2012; McGinty, Whitfield, & Berglind, 2010; Nestler, 2012; Nestler, Barrot, & Self, 2001; Schmidt et al., 2012). These changes in gene expression are mediated by drug-induced epigenetic alterations in the acetylation and methylation of histones and DNA (see below for further explanation) (Maze & Russo, 2010; Nestler, 2013).

As is the case with the other three examples of neurobiological progress in understanding mental illness discussed so far, the VTA–NA dopamine story for drug addiction has complexities and limitations. This pathway is, of course, highly interconnected with many other brain networks and is influenced by a host of other neurotransmitters besides dopamine. And despite the fact that the biology of drug addiction's effects on dopamine in the mesolimbic pathway is quite extensively confirmed, it has not yielded clinical interventions yet. Nevertheless the findings are quite remarkable for their consistency across multiple substances and multiple species. Substances whose primary molecular targets in the brain are highly divergent are involved: nicotine, which targets the acetylcholine receptor; heroin and narcotic analgesics such as oxycodone, which target the endorphin system; cocaine and methylphenidate, which target the dopamine transporter protein; and alcohol, which targets multiple brain systems, especially GABA and benzodiazepine receptors. All of these have in common acute stimulation and chronic downregulation of the dopamine "reward" pathway, whether these phenomena are looked at with magnetic resonance imaging (MRI) and PET scans in humans or microdialysis and electrophysiologic recording in laboratory animals. The underlying genetic and epigenetic

changes that underpin addiction, craving, and withdrawal are elegantly understood. Clearly, understanding the biology of drug addiction has been, and will likely continue to be, one of the triumphs of translational research from basic to clinical science in our understanding of mental illness. Furthermore, this understanding will help guide the development of both psychotherapeutic and somatic interventions. It will be critical to understand, for example, which of the many psychosocial interventions now employed to treat addiction affect the VTA–NA pathway and whether positive response is correlated with changes in activity. This kind of work can now be easily done with available neuroimaging techniques. Direct stimulation of the VTA–NA pathway with deep brain stimulation is also being explored as a treatment option (Arulpragasam et al., 2013).

Adverse Early Life Experiences Increase Risk for Most Mental Disorders

The four examples discussed thus far in this section highlight instances in which preclinical research and clinical research are synchronous in identifying discrete abnormalities in brain function that are consistently associated with specific psychiatric symptoms and/or behaviors. They do not tell us, however, why some individuals have these abnormalities and others do not. For most of the latter half of the twentieth century the prevailing belief among scientists was that the reasons for these differences among people rested in variations in the genome.

When medications for psychiatric illnesses were introduced in the late 1950s, the dominant school of thought about psychopathology was psychoanalysis. Although Freud occasionally mentioned "constitutive" factors to explain the genesis of mental illness, psychoanalysis relies mainly on the effects of early life events, primarily interactions with parents, as the determinants of later behavioral and emotional abnormalities. But then psychopharmacologists, flushed with the success of new antidepressants and antipsychotics in clinical practice, pointed out that the newly employed medications worked regardless of an individual patient's life experiences and therefore downplayed the significance of adverse life events in the pathogenesis of mental disturbances. Cognitive-behavioral therapy also deals mainly with current symptoms rather than historical events and therefore supports the idea that early life adversity is not a major factor, at least in the successful treatment of a psychiatric illness. These ideas quickly attracted the attention of mental health advocacy groups, who had long been burdened with nonsensical labels like the "schizophrenogenic mother." When *DSM-III* revolutionized the system of psychiatric diagnosis in 1980, it included only one disorder with clear ties to life events: posttraumatic stress disorder (PTSD). In this case alone was it acknowledged that extreme traumatic events could be the proximate cause of a psychiatric syndrome.

An enormous amount of research has thus been conducted attempting to locate the genetic basis of mental disorders. There is absolutely no doubt that many disorders are indeed heavily influenced by inherited factors. Family, twin, and adoption studies clearly show that as much as 50% to 60% of the variance in whether one gets a psychiatric illness is attributable to heritable factors. Because these conditions are not inherited according to the principles of simple Mendelian genetics (i.e., mutations in discrete dominant and recessive genes), the search for the complex, multigenetic causes of mental illness has been difficult. So far, we have many promising leads for mutations in genes that predispose to specific psychiatric illnesses. There is little doubt that as genetic techniques continue to advance, more and more specific genetic signatures for psychiatric illness will be found. However, current evidence suggests that there is considerable overlap among *DSM* categories of illness in abnormal genetic markers (Cross-Disorder Group of the Psychiatric Genomics Consortium, 2013). Once again, it is likely that our current notion of such categories will be eroded and rearranged as more information is forthcoming for genetic research.

At the same time, however, there has been a remarkable revival in more recent years of investigation into experiential causes of mental disorders. This work has led to clear preclinical and clinical evidence that early life adversity, working through well-defined biological mechanisms, predisposes an individual to later development of a mental disorder. Much of the recent work linking early life adversity to psychopathology involves the long-term effects of child abuse, which has been shown to increase the risk of a range of disorders, including conduct disorder, antisocial personality disorder, anxiety disorders, substance use disorder, and depression (Heim & Nemeroff, 2001; Kessler, Davis, & Kendler, 1997; McLaughlin et al.,

2010; Withers, Tarasoff, & Stewart, 2013; Young, Abelson, Curtis, & Nesse, 1997). Childhood maltreatment is associated with long-lived structural and functional abnormalities in brain regions such as the amygdala and anterior cingulate (Dannlowski et al., 2012; McCrory, De Brito, & Viding, 2012). But dramatic and obvious forms of early life trauma may not be required for there to be stress-related effects on the brain. Studies have even reported that urban dwelling and urban upbringing, both linked to adverse mental health outcomes, are linked to changes in activity of the amygdala and anterior cingulate cortex (Lederbogen et al., 2011; McKenzie, Murray, & Booth, 2013).

Perhaps even more striking are the mounting data that childhood adversity also predisposes to psychotic illnesses (Kelleher et al., 2013; Stilo & Murray, 2010; Varese et al., 2012). Murray and colleagues have shown that childhood immigrant status is a significant risk factor for developing schizophrenia and that this effect cannot be accounted for by familial or genetic factors alone (McDonald & Murray, 2000). Importantly, valid and reliable methods for assessing childhood adversity have been developed for research into schizophrenia and other disorders (Brown, Craig, Harris, Handley, & Harvey, 2007). Thus, a condition that has in recent years been thought to be purely caused by abnormal genes and physical prenatal insults (e.g., infection and malnutrition of pregnant women) now seems clearly to have early life stress as a component of its etiology.

The work demonstrating that early life adversity is an important risk factor for developing mental disorders is reflected in an abundance of preclinical studies in which adverse rearing produces permanent changes in gene expression, brain structure and function, and behavior into adulthood (Rinaman, Banihashemi, & Koehnle, 2011). Michael Meaney, Paul Plotsky, and many others have shown that adverse early rearing experiences in mice and other rodents lead both to long-lived fearful behaviors and discrete biological changes, including pronounced and permanent effects on the regulation of glucocorticoids and other stress hormones (Caldji et al., 1998; Caldji, Diorio, & Meaney, 2000; Liu et al., 1997). Neonatal isolation stress even increases self-administration of cocaine in adult rats (Kosten, Miserendino, & Kehoe, 2000). In a series of experiments with the bonnet macaque nonhuman primate, Rosenbaum, Coplan, and colleagues found that a type of adverse rearing experience during infancy called variable foraging demand results in fearfulness and elevated levels of the stress hormone corticotropin-releasing hormone in the cerebrospinal fluid of adult animals (Coplan et al., 1996). Just as early life stress predisposes rats to a life of anxiety-like behavior, so does enriched early life experience reduce such behaviors (Baldini et al., 2013; Francis, Diorio, Plotsky, & Meaney, 2002).

An exciting line of investigation has shown that early life adversity produces longstanding changes in the epigenetic regulation of gene expression. Maternal care affects the expression of genes encoding proteins such as corticotropin-releasing factor and oxytocin that regulate emotion and behavior in adult offspring (Meaney, 2001). These changes in gene expression occur because of alterations in levels of DNA methylation and acetylation, which generally suppress and enhance gene expression, respectively (Weaver et al., 2004). Nestler's group subjected mice to both social defeat stress and social isolation, both of which lead to depressive-like behaviors. They showed that both maneuvers increase methylation of histones, the proteins that are packaged with DNA in the cell nucleus, in the NA, thus repressing the expression of several genes (Wilkinson et al., 2009). This effect of stress on methylation is reversed by treatment with the antidepressant imipramine. Earlier, the group had shown that imipramine reverses histone methylation and downregulation of gene expression by increasing histone acetylation of promoter regions of genes, like those encoding the transcription factor BDNF (Tsankova et al., 2006). Findings like these raise the possibility that inhibitors of histone deacetylase (HDAC), which increase gene expression by enhancing acetylation, may be useful antidepressant medications (Covington et al., 2009). Changes in methylation of histones and therefore gene expression produced by early life stress in laboratory animals are persistent and associated with behavioral changes throughout the life of laboratory animals (Murgatroyd et al., 2009). In the monkeys raised under the variable foraging demand condition mentioned above, animals with greater DNA methylation of the gene encoding the serotonin reuptake protein (5-HTT), the molecular target of many antidepressant medications, were most at risk for later behavioral abnormalities (Kinnally et al., 2011). Similarly, surrogate-peer–reared rhesus monkeys demonstrate differential DNA methylation in prefrontal cortex and peripheral cells into adulthood compared with maternal-reared animals

(Provençal et al., 2012). Stress produces enduring changes in DNA methylation in humans as well as rodents (Ursini et al., 2011). Differences in histone acetylation have been reported in young patients with schizophrenia compared to age-matched controls (Tang, Dean, & Thomas, 2011).

Thus there is now abundant evidence that early life experience operates through a set of well-defined changes in brain structure, function, and gene expression to determine emotions and behaviors throughout life. Evidence for this is found in both preclinical and clinical studies that identify the same brain circuits as affected by early life adversity. The story continues in the laboratory, where the mechanism for these effects—epigenetic control of gene expression—is beginning to unfold. In the laboratory, both altering experience and administering medications can reverse many of these changes, even in adult animals many years remote from the original early life adversity. This raises the expectation that psychotherapy and medications will similarly be shown to work through disordered neural circuits and abnormally expressed genes to ameliorate psychiatric disorders that have been caused, at least in part, by exposure to traumatic life events.

Implications

We conclude that scientists and clinicians should take heart in the amazing amount of progress that has been made since 1980, when *DSM-III* was published, in understanding the neurobiological basis of mental illness. These findings will likely result in wholesale revisions of our diagnostic nomenclature. We cannot yet point to an array of new treatments directly based on recent advances in basic and clinical neuroscience, but progress is being made. For one thing, it is important to know whether nonmedication interventions produce observable changes in human brains and whether these changes are correlated with symptomatic response. We have cited some examples of this being the case with respect to psychotherapy for mood and anxiety disorders. More such information will help define which interventions are most effective for which specific set of symptoms and for which individual patients and will inevitably lead to refinements of current treatment approaches and the development of new ones. On the somatic side, although it is too early to tell whether it will prove clinically useful, the convergence of basic and clinical research has brought about the exciting new trials of the anti-glutamatergic anesthetic ketamine as a rapid-onset treatment for depression. Directly stimulating specific malfunctioning brain circuits with deep brain stimulation is another example in which biology is guiding the development of therapy. It is therefore critically important that research follow the concordance of laboratory and clinical evidence in making diagnostic categories rather than the current practice of trying to make the science fit into our preexisting categories of illness. This approach should go a long way in sharpening our ability to develop therapeutic interventions that target specific clusters of symptoms and offer our patients meaningful relief.

BIG PHARMA: DIAGNOSIS AND TREATMENT

The subtitle of Allen Frances's *Saving Normal* ("An Insider's Revolt against Out-of-Control Psychiatric Diagnosis, *DSM-5*, Big Pharma, and the Medicalization of Ordinary Life") targets his principal *DSM-5* targets. The material in the preceding section of this chapter questions the pessimism with which Frances and others in psychiatry view the potential of neuroscience research to yield important diagnostic payoffs. By contrast, the insistent criticisms of the role of the pharmaceutical industry in skewing diagnostic and treatment practices in psychiatry, as examined here, seems appropriately placed.

Here is a quote from Frances (2013) in what he scathingly calls "Big Pharma":

> Big Pharma is really big and incredibly successful. Worldwide sales exceed $700 billion each year. . . and the profit margin, at a whopping 17 percent, is among the highest of any industry. Why so big and so successful? The companies justify their high prices and enormous returns by touting their research effort to advance medical science and improve patient care. This is mostly fluff. Pharma spends twice as much money ($60 billion) on promotion as on research. (p. 90)

The coin of the realm for demonstrating clinical efficacy of any new treatment, whether for a mental disorder or a medical illness, is the double-blind, randomized, controlled trial, also known as the RCT. Among other touted virtues, this methodology is

believed to be foolproof against investigator bias. If the scientists conducting a trial do not know whether a research subject is being administered the investigational intervention or a placebo, then biased assessment of outcome should be rendered impossible.

Much, of course, has been written about the ways in which the RCT can fall short of this lofty expectation. It is said to be harder to conduct a blinded trial when psychotherapy is the active intervention than when it is a medication because of the difficulty designing credible placebo psychotherapies. Double blinds in medication trials, however, are sometimes easily broken when an active medication has recognizable adverse side effects not shared by the supposedly matched placebo. Also, only a small subset of patients with any diagnosis actually turn out to meet the inclusion criteria for most RCTs, making generalizability suspect.

None of these potential shortcomings of RCTs arouse the level of fervor, however, that the issue of pharmaceutical company funding generates. Because there is generally no commercial source of funding for studies of psychosocial interventions, they are believed to be less prone to biased assessment. While that is unlikely to be entirely the case—partisans of one type of psychotherapy over another may have a financial stake in a study's outcome and may even decide to withhold publication of a negative finding that does not support their favored intervention—it is clearly the case that studies of medication interventions are far more susceptible to financial pressures and biases.

It is now well documented that drug trials funded by pharmaceutical companies are more likely to report positive findings than those funded by other sources such as federal or nonprofit organization grants (Bekelman, Li, & Gross, 2003; Kelly Jr. et al., 2006; Lundh, Sismondo, Lexchin, Busuioc, & Bero, 2012; Perlis et al., 2005). Part of this problem stems from the unwillingness of drug companies to publish papers reporting negative results of trials involving their proprietary products. Such publication bias can have a profound effect on the impression we have of whether a drug actually makes a clinically meaningful difference (Koesters, Guaiana, Cipriani, Becker, & Barbui, 2013). Mandated registries of clinical trials that make negative results publicly available are designed to ameliorate this problem (Turner, 2013), but it is not yet clear whether they successfully address publication bias and balance the picture. We do not know whether scientists, clinicians, journal editors, or the public actually consult these registries when making decisions about the relative validity of results promulgated by the pharmaceutical industry.

There are many ways besides publication bias that industry funding can distort our understanding of a drug's true risks and benefits. For example, a recent study found that antidepressant drugs under investigation made by a study sponsor were given at higher doses than comparison drugs and that higher dosing was associated with better outcomes (Sinyor et al., 2012). Thus, at the earliest stages of study design, the funding source can bias study outcomes even when the design appears to be a perfectly respectable RCT.

It is also claimed that industry distorts the recommendations and decisions made by committees and organizations charged with producing practice guidelines and diagnostic systems. Cosgrove, Bursztajn, Krimsky, Anaya, and Walker (2009) reported that 95% of the members of three American Psychiatric Association Clinical Practice Guideline committees had financial ties to drug companies that make medications recommended in the guidelines. One criticism of *DSM-IV* was that a high percentage of panel members had relationships with the pharmaceutical industry (Cosgrove, Krimsky, Vijayaraghavan, & Schneider, 2006). This led to a disclosure policy of such relationships for *DSM-5* panel members. Nevertheless, Cosgrove and Krimsky (2012) found that there was no reduction in financial conflicts of interest between *DSM-IV* and *DSM-5*. How these potential conflicts of interest actually affect clinical care is unclear, especially considering that psychiatric diagnosis appears not to be the guiding factor in most decisions about what treatment to employ: A recent study found that a majority of people who take psychotropic medications had not received a specific psychiatric diagnosis (Wiechers, Leslie, & Rosenheck, 2013). Ties between industry and members of guideline and expert panels are not limited to psychiatry and appear to be ubiquitous throughout medicine (Moynihan et al., 2013).

Implications

There is currently a significant diminution in development efforts of psychotropic medications among major pharmaceutical companies. This stems from several factors, including the fact that many of the

"second-generation" antidepressants and antipsychotics are now off patent, making it difficult for drug companies to get newer, more expensive medications onto pharmacy formularies. An equally important factor is the low success rate of psychotropic medication development programs: Psychiatric drugs take longer to develop and have higher rates of failure than almost all other classes of medication (Sanders, 2013). Several large, prominent pharmaceutical companies have recently announced they are abandoning psychiatric drug development, further threatening hope that drugs for mental illness with substantially better efficacy and a reduced adverse side effect burden will be discovered. We are faced with the dilemma, then, of wanting to place more regulations on the conduct of clinical trials of psychotropic medications to reduce industry-related bias while at the same time wishing to spur development of breakthrough medications with novel mechanisms of action. As we grapple in this book with adjudicating which treatments for mental disorders are most effective, it is important to temper this latter wish with a sober recognition that currently available pharmaceutical industry–funded clinical trials of psychotropic drugs and expert recommendations about them are prone to significant conflicts of interest and subject to a variety of types of bias.

Evidence-Informed, Culture-Based Interventions and Best Practices in American Indian and Alaska Native Communities

R. Dale Walker
Douglas A. Bigelow

In this chapter, we provide information and advice to audiences at the practice, program management, and governance levels concerned with "evidence-based programs and practices" (EBP) in Native communities. While blending all sources of best practices to yield continuously improving best practices is our primary purpose, we emphasize a defense of culture-based knowledge and practice because the systematic attempt to impose an EBP mandate on providers of behavioral health services in Native communities has not been an incentive to incorporate scientifically tested information about interventions. The approach we recommend, on the other hand, respects and accommodates culture-based knowledge, ways of knowing, and practice in Native communities, while facilitating the uptake of science-based knowledge. We describe several entrées to collaboration with Native communities: understanding and appreciating Native culture, knowledge, and healing practices; a logic model, used to frame our descriptions of evidence-informed culture-based interventions in a science-friendly fashion; the concept of "culture-as-treatment" and "cultural renaissance;" and some researchable theories of action underlying traditional healing strategy and techniques. We identify a means, compatible with local culture and context, of accelerating evidence-informed culture-based interventions: kernels. In a larger sense, our approach has relevance to any special population, whether indigenous, inner city, impoverished, homeless, or elderly.

INTRODUCTION

The One Sky Center (R. Dale Walker, MD, director) has sought out and promoted best practices in mental health, suicide, substance abuse, violence, and other behavioral health prevention and treatment practices and programs. Our population of interest is "aboriginal," "indigenous," "first nations" people worldwide, with a focus on Native (North) Americans, especially American Indians and Alaska Natives (AI/AN).[1] The Center has partnered with a number of other AI/AN academic, technical assistance, and governmental groups in projects ranging from local initiatives to broad multisite multiprogram initiatives. We have worked with individuals including horse whisperers, medicine persons, Indian health professionals, and politicians.

In this chapter, we share some of what we have learned about collaborative work striving toward best practice in AI/AN communities.[2] We have tried to

meet the very different needs for information and advice of several audiences: professionally trained clinicians who wish to practice EBP[3] in AI/AN communities; program leaders in AI/AN communities who wish to introduce EBP into their services; regulators, funders, and policymakers who wish to advance EBP in AI/AN communities; and social and behavioral scientists studying what works and how. The common, overarching purpose is continuously improving best practices for the purpose of better behavioral health and quality of life in Native Communities.

Throughout we have raised the profile of culture in the blend of sources of best practices.[4] While blending all sources of best practices is our primary purpose, we emphasize a defense of culture-based knowledge and practice for an important reason. There has been a systematic attempt to impose an EBP mandate on providers of AI/AN behavioral health services. This imposition is not an incentive to incorporate scientifically tested information about interventions (which we advocate) but rather a requirement that tribal programs be replications of programs drawn from an official list of model programs,[5] implemented with the assistance of the program developer, and subjected to fidelity testing to prove the protocols are implemented as originally designed and tested (which we oppose). In general, this mandate runs into a serious threat to external validity and challenges us to better understand science and its application.

The special problems for AI/AN communities with the EBP mandate are that model programs are especially difficult to generalize to Indian communities from the unique sites in which they were developed and evaluated. Developer training and fidelity testing are alien processes, and the loss of familiar and accepted practices can be traumatic for the tribe. Even if a model program were chosen, the personnel, training, and testing capacity to implement are rarely available. Finally, the very mandate, per se, is in conflict with principles of sovereignty and consultation.[6] However well intentioned, the EBP mandate is actually oppressive, disempowering, and a bad fit for AI/AN communities: a recipe for exacerbating, not ameliorating, health disparities. The approach we recommend, on the other hand, respects and accommodates culture-based knowledge, ways of knowing, and practice in AI/AN communities, while facilitating the uptake of science-based knowledge (Walker & Bigelow, 2011). We name this blend *evidence-informed culture-based interventions* and *tribal best practices*.

In merging epistemologically differing bodies of knowledge, it is helpful to identify underlying commonality. Different cultures use different ways of implementing healing, but there are fundamental commonalities. Behavioral treatments or ways of healing—psychiatric, psychological, social, and traditional—include changing expectancies, persuasion, motivation, education, personal narrative construction, storytelling, using placebo (mind–body) effects, diet, exercise, training/practice, and drugs. These largely face-to-face interventions rely upon healer characteristics and performance that are culture-specific, phenotypically, but, more fundamentally, generate trust, belief, hope, and expectation, which are essential to the effectiveness of such face-to-face interventions. Some contextual or environmental healing interventions depend upon vision, organization, and leadership. From this set of common treatment/healing fundamentals, we venture into our examination of behavioral health services in AI/AN communities.

The first place to look for science-based behavioral health programming applicable to an AI/AN target population are the EBP model program lists that have searchable databases with "American Indian/Alaska Natives" as a search criterion (e.g., Coalition for Evidence Based Policy, 2012; Community Preventative Services Task Force, 2013; National Indian Health Board, 2009; Office of Juvenile Justice and Delinquency Prevention, n.d.; One Sky Center, n.d.; Substance Abuse and Mental Health Services Administration [SAMHSA], n.d.c; University of Colorado, Institute of Behavioral Science, Center for the Study and Prevention of Violence, 2013). For example, the SAMHSA National Registry of Evidence-based Programs and Practices (NREPP) lists 323 interventions, 107 of which are identified as including 50% or more AI/AN subjects in the evaluation(s), and, of those, 83 are classified as having been evaluated using an "experimental" study design (SAMHSA, 2013).[7] These model programs are presumed by many to be synonymous with "scientific-evidence–based" interventions.

A few of those model programs have been tested in AI/AN communities (Chaffin, Bard, BigFoot, & Maher, 2012; Harper & Hornbuckle, n.d.); a few have been adapted for AI/AN communities (BigFoot & Braden, 2007; BigFoot & Funderburk, n.d.; BigFoot & Schmidt, 2010; Dionne, Davis, Sheeber, & Madrigal, 2009); and a few cross-walks between EBP and

culture-based interventions have been described. Many culture-based AI/AN behavioral health prevention and treatment practices and programs have been described (e.g., Echo-Hawk, 2011), but few would be categorized as EBP, and even fewer at a type 1 level of evidence (Yellow Horse & Yellow Horse Brave Heart, 2005).

Indeed, notably few scientific studies of practices and programs in Indian Country are reported in the literature or collected on lists of EBPs (Bartgis & Bigfoot, 2010; Del Grosso, Kleinman, Esposito, Martin, & Paulsell, 2012; Gone & Alcantara, 2007; Gone & Calf Looking, 2011). Among the culture-based interventions in AI/AN communities that have been listed, few have been developed, evaluated, and recognized as EBPs. One that has is Project Venture (Native Indian Youth Leadership Program, 2008; SAMHSA, n.d.e). Like Gone and Alcantara (2007) and Whitbeck, Walls, and Welch (2012), we believe that "Western" prevention and treatment scientists are largely unaware of the prevention and treatment work going on in AI/AN communities, and we urge a paradigm shift from adapting Western prevention and treatment science EBPs to creating cultural "best practices" from within AI/AN communities, incorporating relevant scientifically tested knowledge, and proceeding to evaluate the results. That paradigm shift is facilitated by understanding the differing epistemologies of Western, scientific, and traditional Native American approaches to healing.

Developing and disseminating evidence-informed culture-based interventions in AI/AN communities (as in all societies) involves shared cultural assumptions and values. As in all communities, practices and programs that work effectively are tailored to unique local contexts. AI/AN community contexts include tribal and class diversity, sovereignty, historical and continuing grievances, communication patterns, and economic marginalization. While context and culture, per se, are important to effectiveness, North American Natives are also the indigenous people of North American and, unlike other numerically minority peoples, AI/AN tribes have unique status and rights; this further increases the importance of local context and culture. The law requires respect and accommodation. The purpose of this chapter is to provide some guidance on the nature, role, and importance of culture and local context to those pursuing improvement in AI/AN services at the practice, program management, and governance levels.

Three major sources of evidence for knowledge informing behavioral health services are science, practice, and culture. *Epistemology* is the branch of philosophy that examines "ways of knowing" and, especially, how "evidence" works to yield both the content and certainty of a body of knowledge. Within that body of knowledge are "best practices"—that is, what a well-educated and experienced member of the culture would regard as the preferable way of doing things. A full-scale discussion of these epistemologies would be helpful but is beyond the scope of this chapter. The summary presented below is vital for those seeking to establish practices that are supportable in an indigenous world (as we have discovered, bridging the three worlds in our work). In our professional training and public education program, our mantra is *Science + Practice + Indigenous Culture = Best Practices.*

SCIENCE-BASED KNOWLEDGE

It is important for us to see science-based evidence, knowledge, and practice in a multicultural perspective. In particular, while valuing science we must avoid scientism, a belief that science is the only true way to acquire knowledge about reality and the nature of things; near-deification of the "scientific method;" flaunting the trappings of science; and preoccupation with "demarcation" between science and other ways of knowing. Science is, indeed, a powerful way of knowing, and the dependable scientific knowledge base has grown enormously. However, scientific information is far from perfectly true or dependable on its own terms (Ioannidis, 2005), and it is also constantly churning (Arbesman, 2012). The philosophy of science (including a dedicated association and journal) addresses epistemological and other issues in what we think of as the culture of science.

Science-based knowledge has driven technological advances, including agriculture capable of feeding a population plus generating surplus food capable of supporting specialists; manufacturing of tools and equipment; and healing materials and procedures, all resulting in Western prosperity and power (Diamond, 1999). Because of the tremendous success of basic natural science and science-based technology in botany/agriculture, physics/manufacturing, microbiology/surgery, and medicine, there has been a mistaken presumption of similar power in the area of

behavioral and social practice. But, especially in the social sciences, scientists and philosophers of science have adopted causal complexity, social influences, and pragmatism as the operative framework for scientific knowledge and practice, which places some philosophic limits on science-based knowledge in the social and behavioral health realms.

Contextual mediator and moderator variables (Baron & Kenny, 1986) change outcomes—for example, rural/remote versus urban setting contexts. There are other limitations on classical science in behavioral health. The appropriate scientific method depends on the characteristics of the research topic; randomized controlled trials are rarely appropriate for nondrug behavioral health studies. Human subject issues raised by the Belmont Report, the Helsinki Accord, the Code of Federal Regulations, and so forth constrain research designs; for example, a no-treatment control is prohibited while best extant treatment is required as the control; randomized assignment is difficult; and randomized selection is nearly impossible. Internal validity depends on sensitive research design, control, and measurement of all theoretically important variables (Lipsey, 1990). Further, the "unknown unknowns" among independent, mediator, and moderator factors can attenuate internal validity. Local and cultural context constrains external validity (generalizability). Where local context and culture are very strong factors (washing out the controlled variables), we have, de facto, evidence-informed community- and culture-based best practices.[8]

Behavioral medicine is greatly concerned with body–mind continuity and the meaning of illness and intervention. Management of placebo effects by bedside manner, reassurances, and similar practices are instrumental to outcomes. Not very amenable to control are

- *Choice*, a powerful factor in making an intervention work, which limits the scientific utility of random assignment
- *Self-healing belief*, guided by *expert healers*, which limits the scientific utility of blinding and double-blinding
- Guided development of *unique interpersonal relationships*, a key to health and thriving, which limits the scientific utility of controlling treatment conditions
- *Complex webs of interrelated and reciprocal factors* not reducible to simple, linear causal models, which limits the opportunity to isolate "active ingredients"

We mention some of the philosophic and logistic limitations on science-based knowledge in social and behavioral health science in order to leave room for the legitimate contributions of practice and, especially, culture-based knowledge. But scientifically developed information remains critical to quality improvement. Descriptions of interventions that are amenable to scientific study (i.e., specific, operationalized, and logically arrayed) are a concrete scientific advance over nonspecific, metaphorical description more typical of traditional knowledge. This entrée leads to other advances, especially evaluation of effectiveness by research methods that work in the local and cultural context.[9]

PRACTICE-BASED KNOWLEDGE

The utility of practice-based knowledge and evidence is acknowledged in the U.S. federal initiative *Service to Science*, as well as in the SAMHSA publication on multiple streams of evidence (Center for Substance Abuse Treatment, 2006), the Institute of Medicine report on the learning community (Institute of Medicine, 2005), and professional association publications (e.g., American Psychological Association, 2005).

Although practice-based evidence does perpetuate some ineffective or harmful traditions despite contrary scientific evidence, there is, nevertheless, rigor in its generation. Beliefs, principles, and theories acquired in training lead to in situ trial and error, which leads to methodical observation, which leads to professional opinion (American Psychiatric Association, 2011; Rust & Cooper, 2007). An intriguing recent example is the theory and treatment of phantom limb pain using mirrors and the hypothetical mirror neuron (Ramachandran & Hirstein, 1998). Practice experience is transformed into practice-based evidence by a rigorously structured process. Experts are assembled in conferences, work groups, Institute of Medicine roundtables, and similar venues. Published research evidence is presented to such expert assemblies. Practice experiences of participants and their colleagues are compiled and presented. The quality and meaning of data are debated by the expert assembly. Conclusions are drawn from evidence and a formal consensus process produces a document of guidelines or other

recommendations or standards for practice. The consensus (i.e., practice-based knowledge) is then disseminated in a structured manner. Practice guidelines are promulgated by professional associations. Program standards are adopted and applied by accreditation and standards organizations. Resource materials are distributed.

Practice-based evidence underlies the main body of knowledge available to, and applied by, all professional health workers, including Indian health workers working in AI/AN communities (Gray, Carter, Carter, LaFromboise, & Bigfoot, 2012). Advanced and continuing education and mentoring (Walker, n.d.) are the principal means of informing practice in AI/AN communities with both science- and practice-based knowledge and skills. Increasing the behavioral health workforce with practitioners who are educated, trained, and mentored in practice-based knowledge is by far the largest and most powerful entrée of evidence-based best practices into AI/AN communities' behavioral health services.

INDIGENOUS CULTURAL KNOWLEDGE, EVIDENCE, AND PRACTICE

We must have some knowledge of, and appreciation for, culture-based knowledge, evidence, and practice if we are to effectively participate in behavioral health services and to ameliorate disproportionate levels of behavioral health problems in AI/AN communities. Culture-based knowledge and evidence facilitates the derivation of new and improved culture-based interventions. Systematically documented, culture-based knowledge and interventions can lead to the design and application of culturally appropriate tests of efficacy/effectiveness, as well as a growing body of operationalized, sharable culture-based knowledge. Newly proposed culture-based interventions can be validated using evaluations consistent with AI/AN communities' assumptions, values, and epistemology (Cauldwell et al., 2005; Simonds & Christopher, 2013). Cross-walks among practice-, science-, and culture-based practices and programs can be identified. Culture-based interventions and the associated body of knowledge can be more efficiently and effectively disseminated throughout AI/AN communities to improve programs. Finally, the recognition and application of culture-based knowledge is an act of empowerment; this further strengthens AI/AN communities in their efforts to improve the quality of life of American Indians. Conscientious attention to culture-based interventions helps offset "historical trauma" and the inevitable culture, societal, infrastructure, and environmental wrecking that has accompanied conquest.

Culture-based knowledge deals with all the circumstances, survival challenges, and means of thriving and prospering that indigenous peoples have experienced over the millennia (Diamond, 2012) and the challenges they now face as a conquered, stigmatized, and oppressed minority population. Culture-based knowledge includes an extensive, practical knowledge of natural resources, such as agricultural, technical, and ecological uses; cultigens; medicines; and uses of flora and fauna. Culture-based knowledge of family and social milieu has been similarly critical to survival of the species. A body of spiritual beliefs has been developed by every culture to assist in coping with existence. Finally, culture-based practices have been developed over the millennia using trial and error to improve healing, health, and thriving. All human societies have developed and depended on traditional cultural knowledge for survival and thriving for tens of thousands of years before the Scientific Revolution—culture-based knowledge is effective to an appreciable degree, prima facie. While science-based knowledge and practice has hugely advanced healing, traditional culture-based knowledge and practice remain uniquely relevant and useful.

"Indigenous" refers to the first people to inhabit an area; it also means a prestate level of political organization—that is, chiefdoms, tribes, bands, clans, and family (Diamond, 2012; World Health Organization, 2013). Native North Americans lived mainly in chiefdoms. Indigenous culture-based knowledge and practice is characteristically tied to particulars—for example, the actual land on which indigenous people have been living; the web of relationships within a specific social context; and local linguistic expression, content, and meaning. Although the knowledge deals with particulars within a specific context, it also provides a connection through particulars to creation, all of nature, and the cosmos. It is a way of "grounding" a people's experience of existence. Equipped with this culture-based knowledge, individual traditional people have a sense

of relationship, a resource for taking responsibility for their own lives, and models of competent and correct behavior. These grounding anchors are central to behavioral health.

A traditional culture provides health definitions, beliefs about causes and treatments, historically proven (or, at least, accepted) health practices, and cultural assumptions and values not only underlying healing but also giving health itself a place among other concerns. The culture contains concepts of the causes of disease/disorder/injury, including spirits, gods, offenses, moral hazard, and random distribution. It has a concept of its own power/powerlessness, usually shaped by its experiences of conquest, catastrophe, plague, and so forth. Each culture has practices that exploit the power of the mind (e.g., the placebo effect) and social relationships and interaction (e.g., support groups, ritual, and ceremony) to affect health. Each culture has knowledge of substances (e.g., herbs), and the power of asylum and rest to affect health. Altogether, culture-based knowledge provides a substantial basis for effective healing, even in the context of today's science-based medicine.

NATIVE AMERICAN TARGET POPULATION

To understand culture-based knowledge and practice, we should know something about the target population. "Native North American" can be defined as people living north of Mexico since before the European invasion beginning in 1492. The size of the population at that time is undetermined and highly controversial, but subsequent mortality due to introduced infectious disease was of epidemic proportions, which remains salient today. There are now about 1.4 million Aboriginal Canadians (First Nations, Metis, Inuit, and others) (4.3% of the Canadian population) (Statistics Canada, 2011) and about 600 bands and reserves. About half the Canadian Aboriginal population lives on reserves. There are about 5.2 million American Indians and Alaska Natives (1.7% of the U.S. population), about half in combination with other races (Norris, Vines, & Hoeffel, 2012), close to 600 federally recognized tribes, and about 300 reservations. In addition, there are some state-recognized tribes, as well as tribes seeking recognition. There are approximately 300 spoken (or formerly spoken) indigenous languages north of Mexico, 269 of which are grouped into about 30 families.

The Native American group (like other aboriginal populations around the world) includes cultural subgroups that are very important for healing knowledge and practice. Traditional people who speak the tribal language and hold traditional beliefs are characteristically older, rural, and remote (although some younger, urban, and middle-class people are enthusiastically participating in a renaissance of traditional cultures). Reaching older, rural, and remote traditional people requires profound sensitivity to and understanding of culture-based knowledge and practice. Reaching younger people often requires a basic understanding of and manifest respect for culture-based knowledge and practice. Professionally grounded and trained people are serving reservation and urban Indian peoples and contribute a practice-based and bicultural perspective. They provide cultural guidance to Western professionals, when the latter are receptive. There are also established urban peoples who maintain a tribal identity as well as those who maintain a primarily Western identity. Some persons of Native American ancestry do not have a strong cultural identity, but most Native Americans have a healthy respect and affection for their cultural "roots," with or without cultural participation, contact, or knowledge.

Epidemiology and Etiology in AI/AN Communities

There is a large literature on behavioral health problems and their causes in AI/AN communities (e.g., American Psychiatric Association Office of Minority and National Affairs, 2010; Brodeur, 2001; Hendrix, n.d.; James, Schwartz, & Berndt, 2009; Jones, 2006; U.S. National Library of Medicine, 2013; University of Maryland, 2003).

An overview is presented in *Healthy People 2010* (U.S. Surgeon General, U.S. Department of Health and Human Services, 2000, and U.S. Department of Health and Human Services., 2001), which reports health-related data from the National Vital Statistics System, Centers for Disease Control and Prevention, and National Center for Health Statistics. In these documents, age-standardized rates of AI/AN suicide and homicide (all ages) are compared with total population rates. Death from all causes among older AI/AN youth (i.e., young

adults) is about 50% higher. Suicide rates are slightly higher, while homicide rates are, again, about 50% higher. Nonfatal physical assault is related to the prevalence of homicide and is about three times higher than the rate of the total AI/AN and non-AI/AN population. At the same time, unintentional deaths in total and deaths due to motor vehicle crashes, residential fires, and drowning are nearly double the total population rate.

Death due to cirrhosis of the liver (usually caused by excess alcohol consumption) is about two and a half times the total population rate, while alcohol- and drug-related crashes are triple. Adolescent alcohol use, accidents, and assaults seem to be the outstanding pattern; ameliorating these is a long-term goal of behavioral health treatment and prevention in AI/AN communities.

A follow-up report from the Centers for Disease Control shows progress toward reducing these target problems circa 2007 (Garcia, Kepple, & Hallquist, n.d.). Generally, there was some movement toward some health goals, but the disparities continue unchanged.

While epidemiologic data (especially statistics generated in the course of delivering public services) suffer from a number of errors[10] that affect comparisons between a subgroup and the total population, these epidemiological data still reflect a substantial opportunity[11] for improving the quality of life through behavioral health interventions.

Social Factors in American Indian/Alaska Native Communities

Epidemiology and etiology include the role of social factors in health status (Fig. 2.1). Social factors are a very large factor in health status (Geiger, 2006; Marmour, 2004; U.S. Surgeon General, 2012), particularly in AI/AN communities (Mikkonen & Raphael, 2010).

To improve health status, we must treat social factors rather than just the individual in clinical isolation. A substantial proportion of health disparities disadvantaging Native American peoples are attributable to the social factors of damaged cultures, environmental degradation, trauma of conquest and subsequent oppression, economic marginalization, and current low socioeconomic status.

Treating social factors includes dealing with the patient's circumstances but also directly acting upon the community and the culture. Thus, "culture *is* prevention and treatment" has action implications.

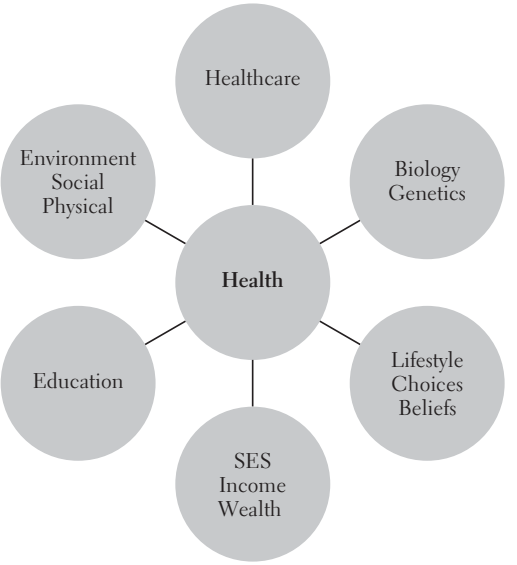

FIGURE 2.1 Major Determinants of Health Status

A LOGIC MODEL FOR CULTURE-BASED INTERVENTIONS

Participation in AI/AN communities to help ameliorate behavioral health problems and disparities is an art. One of the modes of entry into AI/AN communities for the One Sky Center has been helping tribes to construct logic models for federally funded projects. We successfully used Figure 2.2 in three national, multisite, multiprogram projects. We use this model here to frame a survey of some AI/AN communities' behavioral health service strategies. This survey provides a programmatic context for the reader.

The logic model guides description of a project by specifying what kind of descriptive content should be used and how it should be organized. It identifies key functional relationships to be explained (e.g., logical relationship among causes of the problem, interventions, and outcomes). Logic models are vital for grant writing, as well as planning, project management, and program evaluation. When a group of people builds a logic model together, the logic model also catalyzes the group process by providing a structure for bringing together diverse facts and perspectives.

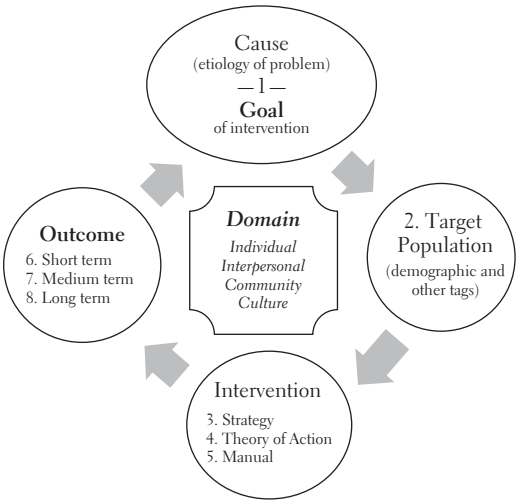

FIGURE 2.2 Logic Model for Behavioral Health Interventions

Logic models, too, are powerful communication devices, helping to bridge the gap between culture-based and evidence-based interventions. A culture-based intervention may initially be described as intervening in "a good way" according to an Elder's knowledge of tradition (An elder for the tribe, 2008), together with his or her wisdom and experience. While paying respectful attention is culturally appropriate and productive, translation into a scientific framework can also be feasible and useful. While premises of the culture-based intervention may include references to the spiritual, we can also find expression in analogous natural facts and principles. Behind traditional ways of doing things, there are often concrete facts and reasoned inferences. Beliefs, rituals, and artifacts can be treated both reverentially and as subjective phenomena described objectively. This bridgework is helpful for collaboration.

The logic model introduces a conceptual approach and a knowledge base more familiar to a science-oriented community. Logical description is an important mode of reasoning in a science-oriented community. Using a logic model facilitates theoretical and logical scrutiny, which strengthens credibility. The logic model lends itself to research design and measurement, which renders the intervention more amenable to independent evaluation and replication. That, too, strengthens the credibility of the intervention.

The logic model also has local utility, especially when drawn in a cultural format such as a medicine wheel or hoop. It stimulates a critical, rigorous review of an intervention by the culture-based intervention participants, which is helpful even when underlying belief in the intervention rests on tradition. Reconsidering presumptions about cause leads us to look for additional information and to redesign the approach accordingly.

Manualizing the intervention may lead to better scaling of the effort and allocation of resources. A manual also makes it easier to train and manage project personnel. In addition, mapping the chain of short/medium/long-term outcomes may lead to a more realistic focus. Altogether, the rationale for a logic model for a culture-based intervention includes its utility for the assessment, planning, and management of an intervention.

One Sky Center helped to develop a form to capture content for a program logic model, including definitions and examples, that was adopted by the Oregon Tribal Best Practices panel (Oregon Addictions and Mental Health Services, n.d.). This document is an example of both substantive and procedural collaboration with Native communities.

CULTURE-BASED PROGRAMMATIC STRATEGIES

Next we describe some culture-based programmatic strategies (item 3 in Fig. 2.2) that are in use in AI/AN communities today. Here we group programmatic strategies by domains of the target population (item 2, Fig. 2.2). These are strategies focused on individuals, families, public health, and culture itself. An illustrative overview, rather than an exhaustive research review, is our purpose here. We start with the individual domain.

Treatment of Individuals

The Matrix Model program (Matrix Institute on Addictions, n.d.; Obert et al., 2000; Rawson et al., 1995) incorporates a number of interventions into a comprehensive, intensive outpatient treatment program that has been successfully used in AI/AN communities. The Matrix Model is listed on NREPP (SAMHSA, n.d.a) as an EBP based on three experimental studies at a type 2 level.

Motivational Interviewing (SAMHSA, n.d.b) is a cultural adaptation of the established protocol (Miller & Rollnick, 2002), which is itself a further development of the Stages of Change model (Prochaska, Norcross, & DiClemente, 1994). Readiness to change and interventions that facilitate such readiness have long been known to be critical to the improvement of health. Motivational interviewing is listed on NREPP as an EBP based on six experimental studies at a type 1 level. Manual downloads for Motivational Interviewing/Enhancement in AI/AN communities are available at the One Sky Center site (Tomlin, Walker, Grover, Arquette, & Stewart, n.d.) and elsewhere (Venner, Feldstein, & Tafoya, 2006).

Intervention Focused on the Family

Some causes of mental illness, suicide, violence, and substance abuse lie within families. Families are also the victims of mental illness, suicide, violence, and substance abuse. Parenting is extremely important to the healthy functioning and development of a child (Kumpfer, 1999). Culture provides guidance and parents provide models together with close monitoring and discipline. When either is lacking or distorted, unhealthy behavior patterns may be transmitted and unhealthy behavior may be instigated. For example, parental neglect and abuse is a risk factor for a child's mental illness, suicide, violence, and substance abuse. Even average parenting skills may be insufficient to protect the child against toxic environments outside the family—for example, bullying at school or peer norms of risky behavior. Challenging child behavior can also overwhelm a parent's capacity to respond in a positive, constructive manner. Parent skill training can put the parents back in charge and help reduce the risk for mental illness, suicide, violence, and substance abuse and can improve health and thriving (Besaw, Kalt, Wilson, & Zemler, 2004; Kumpfer & Tait, 2002; National Indian Child Welfare Association [NICWA], n.d.).

The model program, Multi-Systemic Family Therapy, based on social-ecological and social learning systems theories, is one of the best-known parental skills interventions used in AI/AN communities (Littell, Campbell, Green, & Toews, 2005; Multisystemic therapy: Treatment model, n.d.). The original goal of Multi-Systemic Family Therapy was to improve the behavior of offending youth. However, the intervention deals with the broad spectrum of unhealthy behaviors, including those increasing the risk of mental illness, suicide, violence, and substance abuse. Interventions typically aim to improve caregiver discipline practices, enhance family affective relations, decrease youth association with deviant peers, increase youth association with prosocial peers, improve youth school or vocational performance, engage youth in prosocial recreational outlets, and develop an indigenous support network of extended family, neighbors, and friends to help caregivers achieve and maintain such changes. Specific treatment techniques used to facilitate these gains are integrated from those therapies that have the most empirical support, including cognitive-behavioral, behavioral, and the pragmatic family therapies. Other therapies falling into this model are Multi-Family Psychoeducational Psychotherapy (MF-PEP) level 4 based on four experimental studies, Multidimensional Treatment Foster Care (MTFC) level 2 based on three experimental studies, Multisystemic Therapy (MST) for Juvenile Offenders level 4 based on six experimental studies, Multisystemic Therapy for Youth With Problem Sexual Behaviors (MST-PSB) level 4 based on two experimental studies, and Multisystemic Therapy With Psychiatric Supports (MST-Psychiatric) level 4 based on two experimental studies (SAMHSA, n.d.c).

The American Indian Strengthening Families Program is an evidence-based family skills training program housed at the University of Utah and listed as a model program by SAMHSA under NREPP (Kumpfer, 1999; SAMHSA, n.d.d). Skills are taught in child, parent, and family sessions.

Home visiting programs are concerned with parenting. Early Childhood Home Visitation mitigates maltreatment, abuse, and neglect in order to prevent the development of illness, suicide, violence, and substance abuse later on. A thoroughgoing survey and evaluation provides an illuminating overview of programming and research in one area of behavioral health services in Native communities (Del Grosso, Kleinman, Esposito, Martin, & Paulsell, 2012). These authors were able to discover 19 programs and evaluated the quality of evidence as low ($n = 13$), medium ($n = 4$), or high ($n = 2$). They were unable to establish the effectiveness of these programs based on that evidence but did identify some lessons about EBP in tribal communities: the importance of tribal leader and community input into the adaptation of EBP, the

importance of cultural sensitivity and competence of staff, and the importance of building programs on cultural strengths and customs of the community.

Public Health Intervention Strategies

Continuing with the logic model, public health strategies bridge between strategies focused on the individual/interpersonal domains, on the one hand, and strategies focused on the community/cultural domains, on the other. Public health strategies are more influenced by the disease model of Western medicine than are the community/cultural domains, which we return to in the next section. The public health strategies focus on changing the immediate external causes, mediators, and moderators of mental illness, suicide, violence, and substance abuse in AI/AN communities. Public health strategies embrace and incorporate culture-based practices such as Gathering of Native Americans (Neumann, n.d.), adaptations such as "block parties" (Walker, Bigelow, LePak, & Singer, 2011, p. 328), as well as culture-based practices like powwow.

Risk Factor Reduction

A central public health approach is reducing exposure to risks. This can be achieved by removing the risk (e.g., closing down drug houses), by shielding the people at risk from the source of risk (e.g., establishing, monitoring, and enforcing rules), and by warning the people at risk about the risk (e.g., public education).

Many risk-reduction interventions for behavioral health problems are based on the theory that individuals make decisions based on information. Preventing unhealthy diet and lifestyle, substance abuse, risky sexual behavior, dangerous driving, suicidal impulse, bullying, violence, and so forth includes providing information on the consequences of risky behavior and methods of dealing with that risk.

One means of reducing exposure to risks is public education (also known as social marketing). Such campaigns use media, posters, lectures, and promotional events to raise awareness of risk, encourage risk avoidance in the general public, and mobilize the community's front-line institutions (schools, churches, workplaces, law enforcement, justice, and corrections) to eliminate risks. This public education approach is well known in its use to promote better diet and exercise and to discourage tobacco and excessive alcohol use. Participation of the Native community itself in developing and implementing the campaign is an important outcome.

Protective/Resiliency Factor Enhancement

Another central public health approach is strengthening resiliency and establishing protective factors in the community. The enhancement of protective/resiliency factors is one of the most frequently used approaches to mental illness, suicide, violence, and substance abuse prevention. Elders pass on culture via modeling, stories, advice, values, rules/guidelines for living, and a personal connection with the past. Hall and Raudenbush (2005) developed a protocol for this intervention called "Wisdom Teachings: Lessons Learned from Gathering of Elders." One Sky Center seized the opportunity to facilitate publication, distribution, and promotion of this document, which is an example of productive collaboration with Native communities.

The National Football League Players Association and Johns Hopkins Center for American Indian Health hold an annual Native Vision Sports and Life Skills Camp. AI/AN youth are taught sports by the professionals and engage in festivities. The messages to youth are stories of personal hardship, courage, and victory. Native leaders participate to encourage citizenship, respect for elders, and Indian pride. The Career and Life Skills Curriculum of the Native American Achievement Program at Arizona State University encourages achievement of academic goals, determination of career goals, attainment of leadership skills, and development of personal life skills. The outcome is persistence and graduation (Hammond, 2003), which has long-term health outcomes.

Techniques for resisting peer influence and asserting healthy self-interest are taught by NREPP-listed programs such as Promoting Alternative Thinking Strategies, I Can Problem Solve, Al's Pals, Improving Social Awareness-Social Problem Solving, Peer Coping Skills Training, Social-Moral Reasoning Development Program, and Viewpoints.

Natural experiment and case study methods have provided scientific evidence to prove the safety and effectiveness of a number of culture-based interventions, resulting in NREPP recognition for some,

including Project Venture (Carter, Straits, & Hall, 2007), a service learning program. Instructions for obtaining the program replication guide are available at the Project Venture site (Native Indian Youth Leadership Program, 2008). The service learning theory of action upon which Project Venture is based is that giving to the community (i.e., service) develops moral character, constructive habits, and a lasting emotional attachment to the community. In addition to the bonding aspects of service learning, these projects provide activity, challenge, and skill development.

The Zuni/American Indian Life Skills Development Curriculum is a school-based, culturally tailored, suicide prevention curriculum (LaFromboise, 1995; SAMHSA, n.d.f). It is listed as a model program based on two quasiexperimental studies with a quality of evidence that would be rated at level 2 or 3. This EBP teaches communication, problem solving, management of stress and depression, anger regulation, and goal-setting skills. It also increases knowledge of suicide. Methods are informing, demonstrating skill, and feedback on student performance. Outcomes are reduced suicide probability and hopelessness and increased problem-solving and suicide intervention skills. A manual is available (LaFramboise, 1996).

The Journeys of the Circle project, Canoe Journey, a Metaphor for Life's Journey program (Marlatt, Larimer, Hawkins, & et al, 2003), is a particularly good example of how scientific and traditional, culture-based approaches were combined to create an EBP (Marlatt, Larimer, Hawkins, et al., 2003). This program was developed over three years as part of the Journeys of the Circle Project, with the scientific and practice partner being the Addictive Behaviors Research Center of the University of Washington (Alan Marlatt, principal investigator) and the culture partner being the Seattle Indian Health Board (SIHB), a nonprofit organization serving the health needs of the Native community in King County, Washington, for more than 30 years (Ralph Forquera, director).

The program addressed culturally specific risk factors identified in the research literature: ethnic dislocation, acculturation stress, alienation from the larger culture, and unstructured time on reservations, during which drinking is also a response to boredom. The intervention strategy was to reestablish the canoe tradition; strengthen native identity; involve members of the community, canoe clubs, and canoe families; and build in the feature that all canoes are drug- and alcohol-free.

A comprehensive life skills curriculum was developed to help youth make choices that motivate positive actions while avoiding the hazards of alcohol, tobacco, and other drugs. It used a combination of life skills, activity, and community involvement. The eight-week skills course taught communication, decision making, goals setting, and other skills through the following eight sessions: The Medicine Wheel/Canoe Journey as a Metaphor; Who Am I? Beginning at the Center; Community Help and Support: Help on the Journey; The Quest: Goal Setting; Overcoming Obstacles: Solving Problems; Effective Communication: Listening to Others and Moods and Coping with Negative Emotions; and Strengthening our Body and Spirit.

A sample population (n = 50) was recruited from Seattle public school enrollments and outpatient service contacts at SIHB. The majority of participants were Native adolescents living in an urban setting. Assessment measures were the Comprehensive Adolescent Severity Index, past month substance use (tobacco, alcohol, marijuana, any drugs excluding tobacco), Rutgers Alcohol Problem Index, alcohol-related consequences, Situational Confidence Questionnaire, and confidence to resist the urge to drink heavily.

The research was of a one-group pre–post design. Results were trends toward reduced alcohol, marijuana, and other drug use and increased confidence to resist the urge to drink in multiple contexts. Participants reported a significant decrease in alcohol-related consequences at follow-up. The Canoe Journey evaluation may be classified as type 2.

A manual is available (La Marr & Marlatt, 2007). The Canoe Journey has now become a major event in the Pacific Northwest and Canada. One Sky Center again funded development of a Native community's local Canoe Journey manual for schoolchildren—another example of collaboration.

Intervention Strategies Focused on Community Competency

Community structure and functioning are sources of health and thriving of individuals (and families); in contrast, structural defects and dysfunction in

communities contribute powerfully to mental illness, suicide, violence, and substance abuse. Communities have, to varying degrees, the leadership, organization, and capacity (i.e., the community competence) to improve the quality of life for members, to provide opportunities, and to rise to challenges.

Unique opportunities also exist in indigenous communities for community mobilization. Resources for this mobilization include traditional values and principles supportive of healthy living and cultural content that can be applied to community mobilization.

Prochaska and DiClemente's (Prochaska, Norcross, & DiClemente, 1994) individual change model is the basis for quite a few community mobilization protocols, including the Tri-ethnic Center for Prevention at Colorado State University (2011). The Community Readiness Model is theory- and evidence-based, manualized, and supported with an extensive training program, together with quantified, normed community assessment.

The Community Readiness Model applies Prochaska and DiClemente's model of personal readiness for change to the community. The model not only assesses readiness for prevention interventions but also participates in mobilizing and moving an AI/AN community forward along the readiness path, instituting prevention as it progresses. The manual is downloadable. The One Sky Center developed a format for the next step after readiness, collecting community-wide data for a community to tackle a suicide epidemic (One Sky Center, 2005).

Gathering of Native Americans (GONA)[12] (Kauffman & Associates, 1999; Neumann, n.d.) is a four-day gathering for Native Americans who want to become change agents, community developers, and leaders. The GONA is based on several ideas: Community healing is necessary for prevention; healthy traditions in the Native American community are key to effective prevention; the holistic approach to wellness is a traditional part of Native American belief systems; every community member is of value in empowering the community; and the GONA is a safe place for communities to share, heal, and plan for action.

GONA takes participants through four stages of development—belonging, mastery, interdependence, and generosity. The cultural ideas communicated are healthy traditions and community healing, holistic approach, historical trauma, people's contribution to leadership and healing within a community, support and empowerment for people, rituals and teachings, feelings and healings into action, and use of a safe place. The outcomes are enhanced motivation for community action and understanding of the opportunities.

White Bison has published a seven-step approach to community development (White Bison Inc., n.d.a) and provides training for coalition building (Using Clan Knowledge) (White Bison Inc., 2004) specific to AI/AN communities. The method includes community readiness assessment, GONA training, and an adapted Community Anti-Drug Coalitions of America approach to coalition building and operations. White Bison Inc. is an organizational base for the Wellbriety movement, which includes a number of culturally based programs, projects, teachings, and materials aimed at improving AI/AN health (White Bison Inc., n.d.b). These include the Sacred Hoop Journey; Coalition Building through Clan Knowledge; Families, Mothers, Fathers, Sons, and Daughters of Tradition; Fire-starters; Warrior Down; The Healing Forest; and The Medicine Wheel and the Twelve Steps. Printed, video, and in-person training are available for these interventions.

Participation and collaboration by Western-trained health professionals include technical assistance using science-based knowledge and skills for gathering, evaluating, and implementing those techniques.

Intervention Strategies Focused on Culture

Cultures, like communities, can be made less risky, healthier, and better able to cope with threats to health and thriving. As an object of an intervention itself, culture is rediscovered and reinvigorated. Traditional strengths are preserved while evolving toward meeting current conditions. Rediscovery and reinvigoration of AI/AN culture is central to many AI/AN agendas, including nation rebuilding (Harvard Project on American Indian Economic Development, 2007; Honoring Nations Board of Governors, 2014). This is frequently a primary objective of AI/AN communities and the people who lead and serve them, so it must be a major principle of a culture-based strategy for AI/AN communities.

Rediscovering and reestablishing language, arts, ceremonies and identity is part of preserving the strengths of cultures that have been damaged by conquest and other adversities. Reestablishment

of institutions and self-government (sovereignty) (Harvard University, 2010) are among the strategies designed to strengthen such cultures.

At the same time, envisioning the future and identifying current opportunities for improving health, social, and economic status are essential to the health and thriving of AI/AN communities. One very well-developed strategy for revitalizing an indigenous culture is the Access to Determinants of Health developed by Four Worlds Institute (n.d). This protocol is logically stated, methodologically thorough, and well documented.

The health and thriving of individuals (and families and communities) is supported and directed by a culture, but culture itself requires participation and nurturance from its people, as well as contributions to its constructive evolution. Badly damaged cultures are a major contributor to youth suicide, violence, substance abuse, and pathologies of all kinds. Maintenance of healthy culture, treatment of sick culture, and rehabilitation of badly damaged culture require civic leadership as well as popular participation. Important aspects of civic leadership include both "how to do it" (methods) and the "vision."

Culture *Is* Treatment and Prevention

The belief that "culture *is* treatment" has been advanced by professionals, government leaders, and AI/AN activists (Brady, 1995; Gone & Calf Looking, 2011; SAMHSA, n.d.g; White Bison Inc., n.d.d). Cultural teachings, practices, and social conventions yield balance of mind, body, spirit, and emotions. Living in a good way, as guided by cultural leaders and written in the heart, will bring behavioral health. Traditional cultural beliefs and practices constitute a principal form of treatment and prevention, per se. "Culture *is* prevention" means an awareness of (and participation in) the values, traditions, ceremonies, and sense of community, per se, that improves health and thriving while preventing mental illness, suicide, violence, and substance abuse (White Bison Inc., 2014).

Culture as an intervention shares the stage with Western-style risk-reduction and protective interventions for mental illness, suicide, violence, and substance abuse. As an intervention, culture (consisting of stories, ceremonies, knowledge, skills, values, and so forth) is used to strengthen individuals, families, and communities. As an intervention, culture provides constructive, time-filling activity as well as social services and productivity. As an intervention, cultural activities provide social contact and a vehicle for the communication of caring. A common culture-based intervention is reinstituting a traditional mentoring relationship between elders and youth.

There are many culture-based interventions, each to be found in different forms at different times and cultural locations. These are described in a great many documents, many of which are not part of any professional literature. Documentation and artifacts are being collected in university and government archives. We will mention several interventions that have some application in the prevention and treatment of mental illness, suicide, violence, and substance abuse as part of the global goals of culture-based interventions. General descriptions are provided, but there are tribal and community variations within each intervention.

Flute playing is used, like meditation, in self-discovery and self-healing. Dancing, fasting, drumming, making of relations, medicine wheel, naming, pipe, powwow, potlatch, giveaways, honoring, rites of passage, ritual art, masks, sand painting, shaking tent, singing, and smudging ceremonies are culture-based interventions to promote health and thriving, bring good fortune, and heal. These interventions produce trances and visions, focus and entrain the mind, and connect to the spirit world. They establish and strengthen interpersonal relationships; create or transform identity; provide instruction on values, morals, principles, and behavioral protocols; and relieve feelings of loss, guilt, and fear. They apply to mental illness, suicide, violence, and substance abuse in individual, interpersonal, and community domains. Recognition, respect, and referral are the collaborative entrées.

CULTURE-BASED TREATMENT TECHNIQUES AND TECHNOLOGIES

In this section, we describe culture-based intervention in its own terms, but with reference to Western analogues. We draw from literature on aboriginal peoples worldwide but focus on Native Americans, especially American Indians. This background is helpful for partnering and bridging between culture-based interventions and EBP.

Until 1,500 (ancient civilizations' medicine), 500 (beginnings of Western medicine), or even just over 100 years ago (beginnings of modern Western medicine), all humans relied entirely on culture-based, traditional healing to cope with disorders, diseases, and injury, as well as behavioral problems. Some still do. With 100 billion neurons, 100 trillion synapses, and a lot of observation, trial, and error over long periods of time, prescientific humans did a pretty good job of developing knowledge and practice to maintain their health status. There were some iatrogenic healing practices, but that is also true of modern medicine. Traditional healing could not ameliorate every illness, injury, or disorder, but neither can the best, modern, science-based medicine and surgery, let alone modern behavioral health services.

Worldwide, culture-based knowledge and interventions have some notable characteristics. They rest heavily on ideas about the spiritual world, its entities, and their connection with the "real" or waking world. They seek harmony as a primary condition leading to health. They use meditation, mindfulness, and other psychological techniques to access the powerful mind–body connection. They use magic (e.g., the illusion that a foreign object is being removed from the patient's body by a medicine person using a suction pipe). They also use herbal and similar remedies, many of which are found in refined forms in pharmacies today (e.g., willow bark/aspirin).

It is important to bore down below programmatic strategies for the fundamental cultural perspective on healing. One website gives a concise description of some healing practices (Dancing to Eagle Spirit Society, 2008b). Some of the features of American Indian traditional healing include a healer in costume, sucking out pathology with tube and hands, and then disposing of the pathology by burial; display and use of medicine bundles; communication with spirits via trances; performing curing songs, dances, drumming, spells, and feasts; conducting purification ceremonies; administering herbs (topical, fumigant, emetics); representing health-related forces by sand painting; playing of musical instruments to entrain mental process (e.g., eliciting theta waves); use of costume, fetishes, charms, animal and vegetable substances; propitiation of spirits; and involvement of family and community ("social support"). Healers develop competency through dreams, inheritance, apprenticeship, and the usual trial and error.

Notable characteristics of culture-based healing in AI/AN communities include storytelling, myths, sacred symbols and artifacts, ceremonies and rituals, shamans, medicine people, and traditional healers. Healers' recommendations to patients include lifestyle changes, offerings to spirits, diet, improved knowledge of language and culture, meditation, and engaging in certain treatments. The outcome of the diagnostic process is focus, expectations, commitment, and mobilization of effort.

This body of knowledge and practice is very complex and takes a great deal of training, practice, and experience. No unqualified person should aspire to deliver these services; . Serious Adverse Events are a real risk. It would also be seen by the target population as presumptuous, which undercuts the critically important trust of the community (Aldred, 2000). However, when practicing in AI/AN communities today, it is important to appreciate traditional healing and to be ready and able to collaborate with indigenous healers, as demonstrated by the Nuka system of care in south-central Alaska (Gottlieb, 2013).

American Indian Traditional Medicine

American Indian healing practices include (to put them in Western terms) teaching and learning, counseling and persuasion, shaping expectancies, social learning, use of placebos, mythology and storytelling to provide guidance, training in self-regulation, herbals, and food and fun. We can see some parallels and underlying commonality between Western and Native American approaches in the following details.

Culture-specific elements of mental health, suicide, violence, and substance abuse prevention (e.g., White Bison, Sons/Daughters of tradition [White Bison Inc., n.d.c]) aim to make members of the indigenous culture feel valued, included, empowered, and responsible—these are an offset to historical marginalization and oppression. Culture-specific elements tailor interventions by means of culturally appropriate language (e.g., passages of text, speech in indigenous words—which are powerful whether understood or not), terminology with special meaning (e.g., "all my relations"), traditional graphic elements (e.g., use of circles more often than lines, use of symbolic feathers), significant items of traditional dress (e.g., ornamentation), concept-laden symbols (e.g., medicine wheel), ceremonial music (e.g., drumming),

culturally specific forms of common social process (e.g., diplomatic protocols for expressing honoring and respectfulness), social institutions (e.g., powwow), references to social structure (e.g., importance of lineage, clan), ideas of spirituality and universal relatedness, and so forth.

Culture-specific aspects of mental health, suicide, violence, and substance abuse prevention respond to the culturally unique meanings of those disorders, identify and address the culturally unique risk and protective factors for those disorders, and identify and use or accommodate culturally unique interventions.

Adaptation of EBP interventions includes dealing with causes of mental health, suicide, violence, and substance abuse unique to the circumstances of many AI/AN communities, and taking advantage of treatment modes that are believed in by members of those communities. Adaptation is not a simple process (Castro, Barrera Jr, & Holleran Steiker, 2010). The EBP takes on unique traditional elements (BigFoot & Braden, 2007; BigFoot & Funderburk, n.d.; BigFoot & Schmidt, 2010). Healing from loss, recovering from trauma (directly experienced or historical), healing from sexual abuse, and transforming normalized co-dependent thinking processes are required for many members of AI/AN communities with behavioral health issues. The twelve-step process of Alcoholics Anonymous is a well-known protocol that is similar to a number of interventions for the target population of addicted persons (e.g., "The Red Road to Sobriety"; White Bison Inc., 2002). Discovering and rebuilding individuals' cultural identity through flute playing, working with horses (e.g., Native American Horse Program; Oregon Addictions and Mental Health Services, n.d.), traditional meditation, and mentorship by elders are unique opportunities that AI/AN cultures provide for individual treatment of at-risk persons. Others include storytelling, sweat lodge, and talking circle (Oregon Addictions and Mental Health Services, n.d.).

Integrated medicine: AI/AN culture and traditional medicine are also used as a partner with Western medicine and healing (e.g., the Nuka system of care in south-central Alaska; Gottlieb, 2013). It is used to create expectancy and engagement of patient, healer, family, and community. Some of the treatment is provided by traditional medicine people. Controlled research showed that spiritual healing sessions are effective in creating high expectations in both healer and patient (vs. controls) and, subsequently, greater improvement in objectively evaluated medical outcomes (Wirth, 1995).

Definitions: AI/AN healing includes beliefs, practices, botanical medicines, religion, spirituality, and rituals among the several hundred AI tribes and AN villages. AI/AN traditional healing and medicine means "practices shaped by long-standing cultural world-views and values" (Johnston, 2002). Etiological theory includes offending spirits, being victimized by witchcraft/spells, poisons, and living in disharmony. The healer is an intermediary between spirit and living worlds in the context of a living world infiltrated by a powerful spirit world (Moulton, 2001). It is concerned at least as much with prevention as curing. When curing has done all it can, traditional healing provides comfort, support, and reconciliation to the natural course of life, including morbidity and mortality. Religion and spiritual matters are completely intertwined with health. Principal goals are balance in the four realms of spiritual, emotional, mental and physical health; following a cultural path/routine; and sharing in the cycle of life (Hunter, Logan, Goulet, & Barton, 2006). Purification, cleansing, and cognitive change are central themes.

Spirituality of AI/AN people is crucial to their culture-based practices, as to everything in the traditional AI/AN way of life. Traditional belief is that everything has a spirit—celestial bodies, flora, fauna, inanimate objects (like bodies of water), and people. These spirits exist both in a spirit world and in the observable, material, waking world. Knowledge is received from the spiritual world, as are healing influences. A state of harmony with the spirits is sought—good health and thriving depend upon it. Connection to the spirit world is a sophisticated religious practice of healers, especially those known to the Western world as "shamans."

Goals of AI/AN traditional medicine and healing are wholeness, balance, harmony, beauty, meaning, spiritual well-being, restoration of emotional and physical health, and well-being (Cohen, 2003). Traditional healing and medicine confront imbalances, negative thinking, and unhealthy lifestyle. The outcome of such interventions is restoration of well-being and harmony and change of thought, feeling, and behavior. In particular, indigenous medicine has the task of healing emotional pain. If anything, AI/AN healing is more concerned with behavioral health than physical, although that distinction is not made. It focuses on psychological/spiritual healing of

the person (or community) even more than curing a disease.

Exposed to many traumas and much pain, and with little access to Western medicine, even for the illnesses, disorders, and injuries with which Western medicine does best, AI/AN peoples have had to rely on traditional healing and medicine by default. In dealing with disease, the goal may not be a cure. A good transition into the next world is important, even when mortality cannot be prevented.

"Health" means a person has a sense of purpose, follows inner guidance (inscribed by the Creator), walks on a path of beauty, lives in balance and harmony, has good thoughts, is grateful, and is respectful and generous (Cohen, 2003). One concept of illness is fragmentation of the soul, with some parts lost to another dimension or reality or world. This soul illness is very much a part of mental illness, suicide, violence, and substance abuse. The West knows this sort of condition as dissociation or, in other cases, depression with its sequelae (Kramer, 2005). The goal of soul healing is to attract back those lost soul fragments.

Because illness is a matter of morality, balance, and spiritual forces, not all presenting problems are treatable as health problems. Some are nature's retribution (for disrespect or violation of taboos). Some are an expression of self-centeredness, unbalanced living, or feeble constitution. These illnesses (or threat of them) serve a social purpose: protecting the integrity of the culture. Some illnesses are imposed by sorcerers or nonhuman evil entities. Some illnesses involve the intrusion of supernatural objects. Other illnesses initiate transformational passage to a higher level of being or a new role.

Diagnosis rests on experience and acute observation, while the more overt adjuncts to diagnostic procedures include communication with spirits, sacred bundles, pipes, masks, and so forth. Intuition, sensitivity, and spiritual awareness are key assets of traditional diagnosticians. The healer engages the patient by explaining his or her philosophy and plausible causes of illness and acceptance of offerings and gifts. Among the causes a diagnosis may reveal are discord in prominent social relationships (e.g., male/female; Quintero, 1995). Other causes are cruel words, abusive behavior, and violence. Failure to love and care for one's spouse and children, and desertion of them, are taboo violations causing illness in the person, community, and tribe.

Treatment includes teaching, mentoring, and counseling; ritual, ceremony, prayer, and songs; laying on of hands; smudging; community ceremonies (e.g., chanting, singing, dancing, and sweat lodge); and botanicals. Traditional practitioners use the most powerful intervention known to any healing practice: skillful and effective use of the well-known, powerful, but sometimes misunderstood "placebo" (mind–body) effect (Bonvillain, 1997).

Prayer helps to focus the mind on harmony and balance among all things, free of anger, fear, and strife. Music invokes ideas and its rhythm entrains the mind. Smudging affects consciousness, feeling, and sensitivity through the ritual, possibly potentiated by the aerosols. (The sense of smell remains the most evocative of our senses.) Oral and topical application of botanicals also involves rituals, an active ingredient in addition to the activity of the substance per se. Massage is used in a fashion more like acupuncture than sports medicine—it helps to visualize the disorder and the healing process.

Counseling may be potentiated by sacred venues like ceremonial lodges and associated sacred rituals. Ceremony affirms cultural values and identity and involves communicating with spirits, placating them, and gaining release from their perceived controlling influence. A sweat lodge ceremony can overcome avoidance and denial and get the patient back in touch with primal wisdom (i.e., doing what he or she already knows is right).

Mehl-Madrona (1999) identified eight principles of traditional healing: healing takes time and time is healing; healing takes place within the context of a relationship; achieving an energy of activation is necessary; systems are isomorphic (biological, psychological, cosmic); self-discovering in peace and quiet (avoidance of distraction); awareness of emotions; bed rest; and ceremony. Following are some examples of traditional treatments.

Medicine Wheel: The Medicine Wheel, also known as the Sacred Hoop (Laframboise & Sherbina, 2008; Montour, 2000) is a framework and symbol of healing as well as a grounding in the life cycle, range of personal characteristics, seasonal cycle, and geographic location. The four cardinal points (east, south, west, north, and sometimes up/down) are occupied by spirits. This is the design of the medicine wheel that is depicted and used throughout AI/AN communities (Cohen, 1998). Many ideas about existence, including the cycle of life, and many structures

and activities, including healing ones, are physically oriented to this design. This template is particularly useful in describing behavioral health programs in AI/AN communities.

Wiping of Tears: The Wiping Away of Tears is a traditional ceremony to purge survivors of resultant destructive emotions and thoughts. Sacred objects and materials are used and songs are sung. It includes forgiving those who caused pain and loss of life. Tears may be symbolically washed from the faces of victims and grieving mourners. The ceremony ends a period of mourning, leaving victims with reduced pain and allowing them to move on.

Sweat Lodge: A sweat lodge ceremony (Laframboise, 2008b; Windwalker, n.d.) is a widely used and flexible ceremony that involves steam generated by hot rocks in a dark enclosure. Water, sometimes including herbs, is applied to the hot rock by a medicine person who also leads the ceremony. The ceremony includes the medicine person, subject, relations, and guardians. The sweat lodge has spatial orientation (four directions, spirit world) and is constructed to hold in heat and be dark. There is an important etiquette. The ceremony is a tangible and decisive commitment to accomplishing something and requires fortitude. The outcome is physical and mental experiences (purification, renewal, and fresh start) and affirmation of an individual's sense of personal and cultural identity.

Talking Circle: The talking circle (Bureau of Indian Affairs, n.d.; Running Wolf & Rickard, 2003; Umbriet, 2003) is a group activity that enables orderly expression, unburdening, and consolation. The circle is a symbol of connectivity and completeness. The outcome is emotional and social healing. (Western group therapy and support groups operate in a similar way for similar purposes.)

Vision Quest: The vision quest (Bentley, n.d.) begins with a premise that individuals are put on the earth for a reason, but that reason is often unclear. Chandler and Lalonde (2008) have demonstrated the causal relationship between personal vision and suicide. The vision quest is a very serious, arduous journey into the spirit world to learn what that purpose is. It involves extensive preparation and guidance from a medicine man. Symbolic objects are made or gathered, prayers are said and a mindset is created, a ceremony is held, and the supplicant is taken to a certain spot where he remains for a given period of time, during which he prays and has visions. Then he is brought back to share the vision with the medicine man and to integrate the experience into his life. An important anthropological text, *Black Elk Speaks*, illustrates the acquisition of a vision and the lifelong process of spelling out its implications (Neihardt, 2008).

Many more traditional healing practices are listed by Echo-Hawk (2011) and Dancing to Eagle Spirit Society (2008b).

Theories of Action

We infer theories of action (item 6 in Fig. 2.2) underlying strategies. Following are some theories underlying the range of culture-based interventions. Some of these might be described as techniques, but they also get to the theories underlying culture-based techniques. Identifying, spelling out, and testing these theories is on the science agenda for culture-based knowledge.

Storytelling

There are two aspects of storytelling to understand: the content of the stories and the psychology of the *telling*. The content of stories relates personal experience to myths, provides moral instruction, transmits ethical values, and provides an education on the relationship to land and traditions. Many stories are now posted on the Internet (Native Daughters, n.d.). They need little or no interpretation. Dreams, too, are fragmentary stories. They are easily thought of as communications from the spirit world that can be decoded by wise elders, shamans, and psychoanalysts. Stories have characters, predicaments, and attempted extrication—a virtual reality for the critical themes of life. Stories facilitate practice in social skills and allow the freedom to experience scenarios without the full consequences. The content of stories is often cultural myths that contain shared beliefs and values. Thus, the content of stories and dream-stories provides a therapeutic tool for healers.

Telling stories involves powerfully healing and instructive psychology. The human mind has a drive to find meaning; it cannot accept uncertainty, randomness, and coincidence. Stories provide explanations for fragmentary and ambiguous information. This drive appears so powerful that certain neurological injuries compel the individual to invent implausible

stories to explain inconsistencies, to which the victim adheres tenaciously (Ramachandran, 2011; Sacks, 2012). People tell or hear stories 24/7, not passively but eagerly and actively (Gottschall, 2012; Simmons, 2001). A storyteller has ready access to the mind, and a skillful storyteller takes over the audience's mind with just a few words. Stories can move and change us; they have significant power over us. Stories activate sympathetic physical responses. When stories are told by grandmothers, medicine persons, and significant others (as opposed to simply reading them), they carry additional impact related to the storyteller and the setting (e.g., family living room, community lodge). Ritual, musical, and other adjuncts further add to their impact. Both the content and the telling of AI/AN stories are important for treatment purposes (e.g., Native American Story Telling; Oregon Addictions and Mental Health Services, n.d.).

Native American Myth

Like every society, including modern European and North American ones (Campbell & Moyers, 1988), Native Americans believe the natural world is paralleled by and interlaced with a supernatural one. There are differences in the exact nature and powers of the saints, deities, and spirits; the ways they are depicted and the protocols for addressing them; and the forms in which all of these concepts and practices are assembled into a "religion" with officers, edifices, and rituals. But all human societies have developed (or, as they may prefer to put it, have had revealed to them) spiritual concepts and practices to help explain and cope with existence.

Survival for hunter-gatherers and small-scale agricultural communities until very recently was more precarious than we can imagine. With a few exceptions, life was short, dangerous, brutal, and riddled with illness and starvation (Diamond, 2012). These societies had to develop an empirically based body of knowledge and skills in each major area of life (e.g., hunting, fishing, vegetable and fruit gathering, agriculture, war, and health maintenance). Where dependable, sufficient natural resources and peace prevailed, tribes were quite successful.

Native American spirit knowledge is conveyed in myth and legend by storytellers (elders), singing and drumming, and carvings and paintings. The nature of this body of knowledge and practice varies among tribes and over time, but there are fundamental themes.

One fundamental theme that bears directly on behavioral health is the way Native Americans see and value a bond with nature, animals, and the land. Among special relationships are animal protectors. The condition of these bonds and, in particular, harmony is central to health. Actual physical disruption of the relationships (ecological degradation, ceremonial lapse) is distressing and pathogenic. Health interventions are focused on improving these relationships for both individuals and communities.

Native American myths also include origin, creation, and creator tales. These are key assumptions in individual identity and all forms of group activity. Many motivational interventions use these concepts to drive behavioral healing. Meetings normally begin and end with appeals (prayers) built on these concepts as a means of orienting participants and encouraging dedicated effort. Even when secular professionals are leading meetings, it is proper protocol to request elders or other traditional individuals to speak the prayers, during which they sometimes convey keynotes for the meeting.

Myths are part of everyday life, explaining, inspiring awe, and identifying action implications, for example (American Folklore, 2013; Native Languages.org, n.d.; StoneE Producktions, 1996). A coyote crossing the road requires an appropriate response, as delineated in some tribal myths. Food is set aside for ancestor spirits, as stipulated in others. Every natural phenomenon has its spirit and is regarded accordingly in daily activity. Spiritual and supernatural stories about natural entities—geologic features, plants, animals—explain and remind people of their meaning and utility (where later Western society puts such entities into phylogenetic classification systems). These myths are often used in healing to explain what has happened to the patient and what to do about it. Myths cross-walk to Western diagnoses and therapy to some degree.

Myths explain the presence of resources such as food and the befalling of adversity such as bad weather, disease, and failure to prevail. Many myths identify taboos and their enforcement by supernatural powers. Spirits can be offended, alienated, and angered. The myths also indicate what remedial actions may be taken. Propitiation, obedience, and offerings are important instrumental behavior. Taboo violation is important in explaining behavioral health

problems and gives patients something to do about their remediation. Remedial action may be quite similar to many Western therapeutic recommendations.

Soul Flight, Retrieval

A number of cultures around the world have a notion that parts of the body, especially the soul, disappear, which underlies morbidity. Among Native American tribes there is a soul theory that includes the idea of soul flight. This is important for the explanation and treatment of mental illness. The patient may have been invaded by a bad spirit that carries off the soul, or the soul may have left as a result of conflict and trauma. The treatment is administered by a shaman who, as a result of a special relationship to the spirit world, finds and rescues the soul by means of a journey (Ingerman, 1991; Torres, 2002).

"Souls" are the source of life and vitality, emotions, feelings, and sentiments. Souls leave the body as a means of surviving intolerable experiences of accident, violence, abandonment, dishonor, and so forth. The patient experiences something like exacerbated major depression with deep apathy and/or severe anxiety. Even more common is a sense of incompleteness, disconnection, and dissociation. Consequences also include physical illness, addiction, and debilitation. The presenting signs and symptoms are well known to Westerners, but Native American etiology and treatments differ somewhat.

The shaman uses rattles, magic objects, soul catchers, and medicine bags to facilitate the session (analogous to medical paraphernalia). The patient is surrounded by family and community supporters (at the treatment event, not ancillary to it). Drumming affects the shaman's brain wave patterns, leading to a trance. The shaman passes into the spirit world and, with the assistance of a guardian animal and other helping spirits, tracks down the soul in a dreamlike world in which time, space, and other waking-world parameters do not apply. Strong intention (commitment) on the part of the patient and the shaman is required. In the course of the journey, the shaman develops an explanation for the soul loss. The shaman catches or persuades the soul to return to the waking world. The shaman reinstates the soul in the patient's physical body by blowing it into the heart and brain. Then the shaman recounts the journey, providing the patient with insight. The patient goes forward, integrating the contribution into his or her life.

A Western professional versed in phenomenology is able to accept this view of reality and the effectiveness of the practice and identify cross-walks and possible opportunities for collaborative treatment. With both patient and healer convinced of efficacy, soul rescue is similar to the role of Western "talk therapy," except that the shaman with his store of cultural knowledge (which the patient shares) is driving the insight. As in Western therapies, the work is not over when the session ends.

Shamans, Medicine People, Healers

The healing practice of the shamanic tradition is based on their special relationship with the spirit world, as well as charisma, dramatic talents, and insight skills. The premise is that compliance with rules and respect for spirits of nature and ancestors bring wellness and good fortune. Causes of illness include disobedience; lack of respect; projection of a foreign object into the victim's body by hostile spirits or sorcerers; and the victim's soul having been stolen, lured away, or left the body. Shamanic treatment includes extraction of foreign bodies, tracking and rescuing the soul, and calling upon the healing power of nature spirits. To apply this treatment, shamans make contact with spirit world during trance.

In addition to shamans, there are other kinds of healers in AI/AN communities, including medicine people, diviners, and herbalists. They contribute to healing by leading ceremonies, rites, songs, and dream interpretation. Some of the ceremonies include sun dance, vision quest, rites of purification (sweat lodge), funeral rites, and puberty rites. They employ physical tools such as costume, pipes, dream catchers (Laframboise, 2008a), and medicine bundles (Dancing to Eagle Spirit Society, 2008).

Over tens of thousands of years, a great deal of cognition has been applied to creating and evaluating cultural instrumentalities (e.g., the spirit and dream world; description and classification of the natural world with demons, monsters, guardians, heroes, and personages for animals and natural phenomena), to explaining significant objects and events through myth, and to enabling people to cope with existence through propitiation, remediation, healing, seeking guidance, protection, requesting supplies of natural

resources, as well as requesting relief of deprivation and duress.

Placebo: Relationship; Ceremony/Ritual; Meaning

While medicine and surgery are less developed in traditional healing, we are beginning to understand the very powerful placebo effect underlying some healing, techniques that effectively elicit the placebo effect for healing purposes, specific methods of placebo action, and the extent and limitations of its usefulness (Beecher, 1955; Kaptchuk, 1998; Kaptchuk, Petrovic, Wager, & Benedetti, 2013; Moerman, 2002). Placebo research yields complex facts, principles, and theory: Placebos are neither as miraculous as some enthusiasts believe nor as inefficacious as some critics assert. The placebo effect refers to use of the mind–body connection to produce health-related effects. The important "continuous subjective" outcomes are clearest (Harvard Medical School, 2012). The curious case of phantom limbs and the amelioration of associated pain cast some light on the underlying neurology of some placebo effects (Chan et al., 2007; Ramachandran, 2011; Ramachandran & Hirstein, 1998). Similarly, we are also beginning to understand the role of "harmony," "personal continuity" (Chandler & Lalonde, 2008), social status or social factors (Marmour, 2004), and relationships in health and healing. These factors are very culture-bound (at the phenotypic level), and clearly they all have some significant part to play in etiology and healing.

Herbals

In *Native American Medicinal Plants*, anthropologist Daniel E. Moerman (2002) describes the medicinal use of more than 2,700 plants by 218 Native American tribes, including 82 categories of medicinal uses, including analgesics, contraceptives, gastrointestinal aids, hypotensive medicines, sedatives, and toothache remedies. Some of these herbal treatments have been reviewed by the Mayo Clinic (2010) and the National Geographic Society (Johnson, Foster, Low Dog, & Kiefer, 2010). Many of the active ingredients are now provided in a refined form in drugstores with greater purity and consistency of dosage. Although herbals are chemical substances, the results of scientific studies of herbals are somewhat like those for placebos. Furthermore, their medicinal action is somewhat conflated with the placebo effect. While the "little white pills" generally come with dry pharmacologic fact sheets, herbals come with a body of aboriginal lore that can explain and potentiate the effect of the herb. Altogether, indigenous peoples had a pretty well-developed pharmacopeia.

Process of Teaching and Learning

Behavioral health prevention and treatment everywhere include guidance and information for living and healing ("counseling"). Learning and guidance in dealing with current conditions are transmitted through traditions, ceremonies, and daily observations. Self-knowledge and capabilities are realized by dealing with challenges and decisions based on learning by experience, observing, listening, and participating in cultural activities. In Western terms, learning includes shaping expectancies (Kirsch, 1999; Rotter, 1954) and social (observational) learning of behavior and consequences (Bandura, 1977).

Theories, philosophies, histories, ceremonies, and stories are ways of knowing about life and living, as are talking circles, participant observations, experiential learning, modeling, meditation, prayers, ceremonies, and storytelling. The cultural life of the community consists of many of these teaching events, some in response to special events, some as life-cycle passages, and some annual ceremonies. Observation and doing, authentic experiences, individualized instruction, and enjoyment inculcate proficiency as a member of the culture. Importantly, children participate even before they understand what is going on.

Members of the community are responsible for acquiring, possessing, and sharing/teaching knowledge, which results in oral and symbolic transmission from generation to generation by modeling, practice, and animation. The knowledge they pass on is embedded in songs, ceremonies, artwork, the language, worldview, and "teachings." Elders have a special responsibility, authority, and respect in regard to this task (Hall & Raudenbush, 2005).

Healing is accomplished by use of teaching and learning to anchor the individual in his or her culture and its resources. Some Western collaborative efforts, including those of One Sky Center, consist of building local cultural assets into evidence-based modules such as home visiting protocols (achieving school

readiness by telling traditional stories combined with learning to read them).

Fun and Food as Treatment

Many administrators and budget analysts cannot abide the thought of expenditures for fun and food as a line item in a program budget. Yet fun and food are powerful therapeutic tools. Both are attractive, which facilitates engagement; both catalyze interpersonal warmth and bonding; and both are positive reinforcements for desired behavior. Many preventive and treatment events in AI/AN communities depend upon fun and food. Feasting is essential to most Native American cultural events. The collaborating Westerner should help justify fun and food with Western behavioral and social theory, use budgeting creatively, and plan on using this potent intervention.

Bottom Line on Culture-Based Interventions

Again, the purpose of this section is to enable behavioral health providers to appreciate and collaborate with indigenous healing in AI/AN communities. Providing behavioral health services that work in AI/AN communities is no simple matter. Non-Indians have to abandon some Western baggage, embrace the assumptions and values of AI/AN communities, and develop an unusually deep understanding of what works and how. We have to see beyond the superficial face of what passes for efficacious in each culture to grasp the underlying "active ingredients." Some indigenous beliefs are fallacious and some practices are ineffective or even harmful, but the same is true for some Western beliefs and practices. "More research is needed," and, in the meantime, an open and flexible mind is imperative. Success in collaborating with Native communities depends on sensitive and thoughtful inclusion of culture-based interventions.

PROGRAMS, PRACTICES, AND KERNELS

Sources such as the NREPP describe complete packages of procedures and contexts, better known as "programs" or "model programs." Programs are packages of practices together with service delivery, and structural components, such as 28-day residential, nurse-family, multisystemic, assertive community therapy, and so forth. Programs have "core components" that are thought to be responsible for program outcomes. Replication of programs with the expectation of equal efficacy, therefore, requires fidelity in implementing those core components. This constitutes good scientific practice, but replication means, in effect, holding culture and local context constant—which is impossible. Measurement precision varies in all scientific work; there is no one scientific method; hypothetical constructs are hypothetical; scientific knowledge is evolving; facts are tentative; and the causal chain model is of limited application while complexity is the rule.

If programs are molar, practices are more molecular—skills, techniques, and strategies such as supportive, confrontational, nondirective, and so forth are based on theory and supported by practice evidence. This distinction helps to clarify the problem with generalizing model programs to diverse cultures and contexts. The primary means of introducing science-informed best practices into community- and culture-based programming is by professional training and mentoring in best practices.

The term "best practices" does in fact refer to practices in many nooks and crannies of health services. "Practices" are defined as routine business or professional activities, such as using a checklist in an operating room (Fixen et al., 2005; see Arriga et al., 2013). "Best" means that, based on scientific, practice, and cultural evidence, some practices are preferable. Continuous quality improvement is the ongoing process of discovering and applying best practices. A program manual will describe a number of best practices (item 5 in Fig. 2.2).

Kernels: Basic Units of Influence in Behavioral Health Services

There is a concept of science-based knowledge that is much more amenable to incorporation into locally and culturally based programming than practices and programs. Evidence-based *kernels* (Embry & Biglan, 2008) are more atomic than molecular practices and much more atomic than molar programs. Kernels are the unheralded active components of existing programs. Kernels, such as the ubiquitous "time out," are fundamental units of behavior-influencing techniques

having both empirical and theoretical bases. The four primary mechanisms of kernels are (1) providing consequences for behavior, (2) establishing antecedent stimuli for behavior, (3) altering people's relational framing about targeted behaviors, and (4) altering physiology that affects behavior. Kernels are specific to age groups. New or modified programs can be created by assembling groups of kernels. Since the kernels are evidence-based, the programs that incorporate them have a reasonable claim to efficacy. This fact provides a useful bridge between culture-based interventions and Western EBP. Instead of trying to adapt EBP, we can (1) innovate culture-based interventions and (2) identify and incorporate synergistic evidence-based kernels. Fifty-two examples of empirically supported kernels are given in Embry and Biglan (2008). This is a concrete contribution to creating evidence-informed programs in AI/AN communities.

Table 2.1 shows some examples of kernels with their empirical support: verbal praise (Leblanc, Ricciardi, & Luiselli, 2005; Lowe & McLaughlin, 1974; Marchant & Young, 2001; Marchant, Young, & West, 2004; Martens, Hiralall, & Bradley, 1997; Matheson & Shriver, 2005; Robinson & Robinson, 2000; Scott, Spender, Doolan, Jacobs, & Aspland, 2001), time out (Fabiano et al., 2004; Kazdin, 1980; Wolf, Risley, Johston, Harris, & Allen, 1967), and Turtle Technique (Heffner, Greco, & Eifert, 2003; Robin, Schneider, & Dolnick, 1976).

The concept of kernels is well supported by scientific evidence but has not been widely discussed or applied to the conceptualization or use of EBP. Kernels provide concrete, evidence-based steps that can be used for the manual (Fig. 2.2, item 5). Introducing these kernels into culture-based intervention is the least conflict-laden means of achieving evidence-informed programs in Native communities.

CONCLUSIONS

Large health disparities in AI/AN communities present an opportunity for behavioral health professionals to contribute greatly to the health of Native Americans. To seize upon this opportunity, it is necessary to understand and appreciate tribal worldview, epistemology, and healing practices. The same is true for working in all indigenous communities and, indeed, there are some general similarities worldwide: The practitioner always needs to understand and appreciate the target population. In fact, there are also some general commonalities (e.g., spirituality, placebo effects) among societies, indigenous and advanced.

TABLE 2.1 Selected Kernels

Kernel: Verbal Praise	
Description	*Behaviors affected*
Person or group receives spoken (or signed) recognition for engagement in target acts, which may be descriptive or simple acknowledgments	Cooperation, social competence, academic engagement/achievement, positive parent–child interactions or marital relations; better sales; reduced disruptive or aggressive behavior; reduced *DSM-IV* symptoms
Kernel: Time Out	
Description	*Behaviors affected*
Using timer, remove from natural reinforcement for 1 min for each year of age	Decreases noncompliance, argumentative behavior, and mood outbursts
Kernel: Turtle Technique	
Description	*Behaviors affected*
Using a turtle metaphor, child holds self, verbal frame, breathes through nose, and engages in subverbal or verbal self-coaching, with peer or adult reinforcement	Reduces arousal and aggression against peers or adults

We conclude that a certain attitude and protocol are essential to working in AI/AN communities. In this chapter, we have helped the reader to appreciate some of the limitations on our science-based body of knowledge and practice and to understand that best practices derive from multiple streams of evidence, including those that are science-, practice-, and culture-based. There is more than one way of knowing, which has an impact on what one refers and defers to during collaborative work. Even for those enlightened professionals already holding this philosophical and diplomatic view, it remains a task of skill and delicacy to put that respectful and encompassing attitude into practice in the field. *Faux pas* will happen, but sincere effort is noticed and appreciated, even when imperfect.

Beyond general respect and appreciation, cultural competence also requires boring down to a certain level of detail. We conclude that spirituality is a fundamental aspect of the Native American worldview. Spirituality means that the seen world is paralleled by and interwoven with an unseen one that influences etiology, outcomes, and practices—what causes things, what are the consequences of things, and what one does about it. There are quasireligious protocols—such as opening and closing prayers—related to the spiritual worldview, but more important is the spirituality precept itself. Illness and healing are seen through that prism. The fact that these precepts are conceptual, rather than positivistic facts or even hypothetical constructs, in no way diminishes their efficacy and importance.

In addition to prayers, the Western professional experiences other practices and protocols in Native communities not normally encountered in mainstream programs. Drumming, chanting, dancing, bundles of sacred objects, smudging, trances, medicine wheel, costumes, masks, honoring ceremonies, and other culture-specific components of traditional healing will become part of the partnering. It takes a little time, but the Western professional with a respectful attitude will become comfortable with these aspects of an effective partnership in AI/AN communities. These practices can be incorporated into treatment by referral to an appropriate provider or venue.

We conclude that a number of theories of action underlie healing practices in AI/AN communities. At this theoretical level there are notable commonalities with Western behavioral health strategies. Storytelling is how elders, healers, and others impart models for good living and problem resolution for individual Native Americans. Myths become a shared conceptual base for the society that can, for example, facilitate such healing practices as soul retrieval. Flight and loss of soul is understood to be the cause of some behavioral health disorders, and soul retrieval through trances and journeys into the spirit world is an important part of remediation. The retrieval service is provided by recognized and respected healers.

"Placebos" are not limited to just inert pills and deception; they are uses of the mind–body connection. The competent management of the placebo effect is a very powerful tool in the hands of Native American healers, who go to great length and sophistication to maximize the effect. Herbals and other substances with useful active ingredients have been identified in the natural environment over the millennia by Native Americans and are still used with beneficial effect.

The entire traditional healing enterprise in AI/AN communities involves teaching and learning processes with responsibilities for one and all, especially elders. Leaders (or funders or regulators) of healing in AI/AN communities need to recognize that fun and food are essential program material.

The high prevalence of behavioral health problems is attributable to social factors, the usual consequences of invasion, conquest, occupation, and oppression that have been visited upon all peoples at one time or another, but notably by advanced, Western nation-states upon indigenous peoples in the last 500 years or so. Despite major improvements in Western attitudes toward indigenous peoples, specific social factors are at work today, including deprivation of environmental resources, low socioeconomic status, dysfunctional political structures and leadership, damaged culture (which would otherwise guide and incentivize good ways of living), and racism. We conclude that effective behavioral health strategies need to encompass public health, community development, nation development, and cultural renaissance.

The merging of traditional with science- and practice-based practices has been helped along by the education, training, and mentoring of Native American professionals as well as by partnering with traditional healers. But capacity is still disproportionately limited in AI/AN communities, and professional work—education, training, mentoring, and

partnering—is aimed at capacity building. And capacity building has to be part of the continuous quality improvement effort.

We have tried logic models and conclude that they provide a helpful tool for bridging culture-, practice-, and science-based approaches to behavioral health services. The model presented in this chapter facilitates communication and exploration of cultural approaches in a format recognized by Western professionals. The logic modeling process also carries benefits recognized by Western professionals—conceptual exploration, development, and evaluation. We have concluded that another Western conceptual tool, kernels, also provides a very useful way of incorporating science-based knowledge into local and culture-based programming. While implementing EBP with fidelity creates a collision of cultures, the incorporation of the smallest units of science-based behavioral influence, the kernel, is synergistic, yielding scientific evidence-informed interventions.

With these attitudes and background information, Western professionals trained in EBP will collaborate successfully in AI/AN communities. Leaders in program improvement and administrative officials will have a better understanding of culture-based proposals and programming. This information also provides scientists with a perspective for studying culture-based interventions.

ACKNOWLEDGMENTS

One Sky Center acknowledges and deeply appreciates the partnership and contribution of knowledge by many tribal communities in the United States and Canada; the collegial partnership of Kauffman & Associates, White Bison, First Nations Behavioral Health Association, Association of American Indian Physicians, and many other organizations all working toward improving behavioral health in American Indian communities; and National Institute of Health agencies that funded some of the work reported here. We also appreciate the patient and helpful guidance provided by the editors of this book in the preparation of this manuscript.

NOTES

1. There are a number of names for our population of interest. We use "American Indian/Alaska Native," which is widely accepted.

2. We use "Native communities" synonymously with the legal term "Indian Country" as a way of recognizing the agency of communities and their members.

3. There are several ways of referring to scientific evidence-based programs. "Evidence-based programs and practices" is drawn from the frequently referenced National Registry of Evidence-Based Programs and Practices.

4. "Best practices" are what a well-educated and experienced member of the culture would regard as the preferable way of doing things.

5. EBP are offered as model programs and include supports for their implementation, including manuals, consultation, fidelity testing, and so forth (usually for sale). Replication of model programs is somewhat like establishing franchises, which involves some local ownership issues (matters of feeling and participation) as well as major, troublesome implementation issues usually attributed to flawed fidelity.

6. Sovereignty, consultation, and federal-government-to-tribal government relations are spelled out in U.S. and Canadian treaties, executive orders, and legal precedent. These legal instruments accord unique status and rights to tribes that are not accorded to minority groups in general, as well as placing limitations on nontribal governments over AI/AN matters and placing obligations on nontribal governments to support tribal resource needs (including health). Many member states of the United Nations have signed the Declaration of the Rights of Indigenous Peoples, encompassing land, identity, culture, language, employment, health, education, and self-determination.

7. NREPP uses a scale of quality of research different from the one used in this book. There are six criteria: reliability of measures, validity of measures, intervention fidelity, missing data and attrition, potential confounding variables, and appropriateness of analysis. NREPP reviewers use a scale of 0.0 to 4.0, with 4.0 being the highest rating given.

Levels on evidence mentioned in this chapter are as used throughout this book

Cite page number in book where "levels" are defined

8. The original, tested model program itself with its unique personnel, subjects, and conditions, is locally and culturally based.

9. Scientific methods are not limited just to "experiments" or "randomized clinical/controlled trials" but, rather, include any available method that increases knowledge and certainty of knowledge.

10. Misclassification of ethnicity and misclassification of cause of morbidity or mortality are significant contaminants of data affecting etiologic interpretations.

11. *Target-tropism* is the phenomenon of behavior automatically orienting to the identified target. It is

better to identify opportunities for improvement rather than problems wherever possible.

12. There are two Gathering of Native Americans (GONA) programs. One is a powwow supported by a dedicated organization. The GONA referred to here is a training program recently supported by the Native American Center for Excellence operated by Kauffman & Associates, Inc., and funded by SAMHSA. Printed material can be difficult to find as it has been moved about from site to site.

Nonpharmacologic Treatments for Childhood Attention-Deficit/ Hyperactivity Disorder and Their Combination with Medication

Linda J. Pfiffner
Lauren M. Haack

The high prevalence, serious functional impairments, and chronic nature of attention-deficit/ hyperactivity disorder (ADHD) have fueled the development of treatments for the disorder for more than five decades. Behavioral interventions have been the most well-researched, consistently applied, and effective of the nonpharmacologic treatments for ADHD. This chapter begins with an update on the latest research related to the phenomenology and associated impairments of ADHD, followed by a summary of the latest research on behavioral interventions, applying rigorous typology standards for clinical trials. We consider multiple outcome domains and cross-setting treatment effects in view of the far-reaching impact of the disorder. We also review the latest research on incremental effects of combined behavioral and medication treatments, given the limited capacity of either treatment to normalize functioning or substantially alter long-term outcomes. The current limited effects of other nonpharmacologic treatments, including cognitive training and neurofeedback, are also discussed. While evidence supporting behavioral interventions continues to mount, important areas for future research include the need to better tailor treatments to nonresponders and partial responders, improve accessibility to broader populations, and foster treatment innovations to improve long-term outcomes.

DESCRIPTION OF ADHD

ADHD is one of the most common and well-researched childhood disorders. Over the past thirty years, the disorder's name and diagnostic criteria have undergone a number of changes in parallel with the refinement of the conceptualization of the disorder. In the most recent revision of the *Diagnostic and Statistical Manual for Mental Disorders* (5th ed., *DSM-5*; American Psychiatric Association [APA], 2013), the symptoms of ADHD have remained the same as in the *Diagnostic and Statistical Manual for Mental Disorders* (4th ed., *DSM-IV*; APA, 1994). Specifically, ADHD is characterized by a constellation of inattention and/or hyperactivity/impulsivity symptoms. In addition, because these kinds of problems can be normative during childhood, diagnostic criteria specify that they must occur with sufficient frequency and severity to compromise daily functioning in at least two settings, usually home and school (see *DSM-5* Diagnostic Criteria for Attention-Deficit Hyperactivity Disorder [APA, 2013]). ADHD is classified according to the pattern of elevations in the two symptom groupings. In *DSM-IV*, these were

referred to as subtypes (i.e., predominantly inattentive, predominantly hyperactive, or combined), but in *DSM*-5, these types are now referred to as "presentations." The criteria for presentation are the same as for type and reflect the predominant pattern of symptoms at the time of the evaluation. The change in terms reflects research showing that the types are often unstable during development (Willcutt, 2012), with the implication that current symptom presentation may change over time. Controversy continues over the quantitative versus qualitative distinction between the types/presentations (e.g., Milich et al., 2001). Regardless, studies reveal a number of differences between the two presentations that should be considered in treatment planning, including differences in cognitive/attention-deficit profiles (sluggish cognitive tempo; slow processing speed), gender distribution, comorbid disorders, social impairments, and some aspects of treatment response (Bauermeister et al., 2005; Milich et al., 2001).

Three additional changes have been made to the ADHD diagnostic criteria in *DSM*-5 (APA, 2013). First, the age-of-onset criterion was broadened from "before the age of 7" to "before the age of 12." This decision was based on difficulty specifying exact age of childhood onset retrospectively and data showing similar impairment for youth identified with symptoms before seven and those identified after seven but before the teenage years (Willcutt, 2012). Second, the symptom count threshold was reduced for individuals age seventeen and older, due to data showing continued impairment despite some reductions in symptom presence over development (Tannock, 2013). Third, the *DSM*-5 includes three severity modifiers (mild, moderate, severe) to reflect the number of symptoms and level of impairment. These changes to *DSM*-5 are unlikely to alter the prevalence, correlates, or treatment response of ADHD for most children and adolescents significantly; thus, the ADHD literature based on *DSM-IV* criteria should apply to the *DSM*-5 presentations. We will use the *DSM*-5 terminology throughout this chapter, recognizing, however, that the studies were conducted with youth classified by the *DSM-IV* types.

Prevalence rates for ADHD in children and adolescents range from 5.9% to 7.1% when standardized diagnostic procedures are followed, based on a recent meta-analytic review, with more boys affected than girls (Willcutt, 2012). However, community rates established from a national survey conducted by the Centers for Disease Control and Prevention are higher (according to parent report, 11% of youth four to seventeen years of age have ever been diagnosed with ADHD), and regional and cultural variations in prevalence have been reported, with the highest rates occurring among Caucasians relative to other groups and in the South and Midwest, with rates close to 15% (Visser et al., 2014). Variability in prevalence appears to be mostly explained by differences in diagnostic algorithms and methodology (Willcutt, 2012).

Impairment for youth with ADHD typically occurs across most domains of functioning. Academic problems are pervasive for all ADHD presentations (DuPaul et al., 2004). Students with ADHD consistently exhibit lower rates of on-task behavior during instruction and independent work periods that are likely to underlie a number of adverse academic outcomes (Imeraj et al., 2013). Crucially, classwork and homework completion, test and report card grades, as well as tests of academic achievement are significantly lower among youth with than those without ADHD (Langberg et al., 2011; Power et al., 2006; Schultz et al., 2009). As students with ADHD proceed through schooling, prospective follow-up studies show they are at considerable risk for placement in special education classrooms, grade retention, school failure, early dropout, and juvenile delinquency (Barkley, 2006; Barkley et al., 1990; Fischer et al., 1993), and girls in particular are at increased risk for self-harm and suicide (Hinshaw et al., 2012).

ADHD symptoms also contribute to interpersonal problems with peers, parents, and teachers (Mikami, 2010), problems that can be exacerbated by associated aggression, argumentativeness, disruptiveness, and lack of self-control (Pfiffner et al., 2000). They have less sustained social interaction and are less actively engaged in reciprocal play (Bellanti & Bierman, 2000; Mikami et al., 2007), and their peer interaction styles tend to be overly negative (Mikami, 2010). At least half of those with ADHD are rejected by their peers, and many others, especially those with the inattentive presentation, are neglected or ignored by their peer group; most have few friendships (Pfiffner et al., 2000). ADHD also affects family functioning, which is characterized by parent–child conflict and parental stress (Johnston & Mash, 2001). Parents of children with ADHD demonstrate higher levels of negative and ineffective parenting (e.g., power assertive, punitive, inconsistent) and lower levels of positive or warm parenting relative to parents of comparison children

(Gerdes et al., 2003; Johnston & Mash, 2001). These parenting styles predict poor academic outcomes, peer relations, and social skills and aggressive behavior and have an adverse impact on school success overall (Hinshaw et al., 2000; Kaiser et al., 2011).

Current conceptualizations of ADHD implicate multiple, rather than singular, neuropsychological weaknesses. That is, no specific weakness (e.g., overall executive functions, delay aversion, motivational dysfunction, response variability, processing speed) has been found to be either a necessary or sufficient cause of the disorder (Willcutt & Bidwell, 2011), and recent theoretical models propose that ADHD arises from weaknesses in multiple cognitive domains. While multiple etiologies may result in ADHD, heritability is substantial and genetic and neurologic factors are considered leading causes (Nigg, 2006). However, biologic markers are yet to be reliably identified, and diagnosis continues to be based on clinical history, behavioral observations of parents and teachers, and consideration of comorbid conditions. Parenting and teaching practices are not causal, but social environmental factors can influence severity, extent of impairment, and comorbid problems. The latter include oppositional defiant and conduct disorders (often above 50%), as well as anxiety disorders (25%) and depressive disorders (29% to 45%) (Barkley, 2006; Jarrett & Ollendick, 2008; Spencer, Biederman, & Mick, 2007). Even if full *DSM* criteria are not met for a comorbid disorder, subclinical levels of difficulty are often present.

In recent years, the societal cost of ADHD has become increasingly clear. In a recent review of nineteen studies, Doshi and colleagues (2012) estimated that the national annual incremental costs of ADHD in children range from $38 to $72 billion. For children the largest cost categories are health care ($21 to $44 billion) and education ($15 to $25 billion). These costs, along with the serious and chronic impairment across most domains of daily functioning, underscore the need for effective treatments for this disorder.

CONCEPTUAL UNDERPINNINGS OF BEHAVIORAL INTERVENTIONS

For the past five decades, behavioral interventions have been the most well-researched and consistently implemented nonpharmacologic, psychosocial treatments for ADHD. Based on social learning theory, behavioral approaches for ADHD emphasize the importance of environmental/social contingencies in fostering and maintaining problem behaviors (i.e., "contingency theory" [Patterson, 1982]) and also incorporate modeling and imitation and cognitive factors (e.g., cognitive appraisals and attributions). Situational factors are conceptualized as key determinants of immediate behaviors and impairments regardless of the underlying neurobiologic propensity. Behavioral interventions typically include a "functional behavior analysis," which involves specifying behaviors (positive behaviors to increase or negative behaviors to decrease) and then identifying each behavior's antecedents (variables setting the stage for or preceding the behavior) and consequences (variables maintaining the behavior). Based on this analysis, specific strategies for modifying antecedents and consequences are selected for a behavior intervention plan with the goal of reducing problem behavior and promoting desired behavior. Generally, the behavioral approach to intervention selects target behaviors for treatment that cause impairment in daily living (e.g., academic, social behavior) rather than targeting diagnostic symptoms per se, although it is important to note that these interventions often do have powerful direct and indirect effects on diagnostic symptoms. More recently, the behavioral approach to treatment has been expanded to include child skills training, often imbedded within cognitive-behavioral strategies (Villodas et al., 2013). These interventions are based on a skill-deficit model and posit that directly teaching the skills and strategies will improve performance in daily academic and/or social activities.

Recent studies on responses of youth with ADHD to rewards and punishments underscore the utility of behavioral interventions for this population. These studies suggest that ADHD is associated with neurally based motivational systems that respond poorly to usual contingencies from parents and teachers (i.e., a reduced response to delayed, inconsistent, or weak contingencies) but well to immediate, salient, and consistent contingencies (Pfiffner, 2008; Sonuga-Barke, 2011). Specifically, children with ADHD appear to have a higher threshold for rewards (Haenlein & Caul, 1987) and are less responsive to partial reinforcement (Parry & Douglas, 1983), delayed reinforcement (Sonuga-Barke, 2005), and signs of punishments or loss of rewards (Quay, 1997) than children without ADHD. Such reward-related deficits may relate, at a neural level, to a lack of receptors for dopamine

in key brain tracts (Volkow et al., 2009). Behavioral interventions that stress immediate, predictable, and salient rewards, appropriate consequences, consistent routines, and clearly structured rules and expectations are well suited to address these motivational problems.

OUTCOMES OF NONPHARMACOLOGIC TREATMENT STUDIES

Before describing the current status of evidence, we briefly review the findings of the preceding review, which covered the years 1980 to the mid-2000s (see Hinshaw et al., 2007). In that review, behavioral interventions were divided into two categories: direct contingency management and clinical behavior therapy. Direct contingency management included studies of intensive reward and punishment procedures in specialized treatment facilities or demonstration classroom or summer treatment programs. Clinical behavior therapy procedures involved consultation with parents or teachers, who then implemented the behavior management strategies in their usual environments. Direct contingency management, appraised mostly through single-case experimental designs, showed large effects while the contingencies were administered but little generalization to nontreated settings. Studies of clinical behavior therapy showed significant effects as well, but the strongest outcomes were mostly based on parent and teacher report rather than independent observations, leaving open the possibility of informant bias as an explanatory factor. Behaviorally oriented social skills training showed initial promise, but not consistently so across studies. Hinshaw and colleagues (2007) also reported outcomes from several investigations using a combination of direct contingency management and clinical behavior therapy, but effects on symptom reduction were not as great in comparison to effects of medication. Furthermore, they reported that combined intensive behavioral intervention and medication did not always yield greater effects than medication alone, although they did appear to more consistently yield normalization of behavior patterns and may have had a somewhat broader impact on impairment domains than medication alone. In addition, combination treatments were reported to be especially useful for cases with ADHD and comorbid conditions. The need for improving the impact, scope, and long-term effects of behavioral interventions was stressed since existing psychosocial treatments fell short of clinically sufficient benefit. In addition, greater use of objective measures of outcome was recommended. There was also a call to develop other types of nonpharmacologic interventions, drawing upon underlying mechanisms of the disorder and/or impairments.

A number of important advances in these areas have been made since the last review. In a recent meta-analysis, Fabiano and colleagues (2009b) reported large between-group effect sizes (d = .83) for behavioral interventions when collapsed across outcome measures. The largest effects were seen for parent-rated functional impairment, teacher-rated ADHD symptoms, and academic productivity. Although a different meta-analysis reported smaller effects for behavioral interventions (Sonuga-Barke et al., 2013), the criteria for study inclusion in the latter review were quite restricted (e.g., only those with an ADHD symptom outcome and blinded assessment), and as a result much of the literature supporting behavioral intervention effects on functional impairment, arguably the most clinically important outcomes, was not considered.

For this update, we include randomized controlled trials (RCTs) published since the last review (dates: 2007 through 2013) that meet criteria for either type 1 or 2 using the standards-of-proof framework for this volume. We also include studies of comparisons and combinations of behavioral interventions and medication using single-case experimental designs (e.g., reversal or multiple-baseline). Although the latter studies do not meet criteria specified in the standards-of-proof framework, they do include rigorous control for nontreatment factors and are uniquely informative about multimodal treatment effects.

We have modified the classifications of behavioral treatments used in the previous edition of this chapter to reflect advances in research that conceptualize treatment by setting and agent of change and for closer consistency with other meta-analyses and reviews (e.g., Evans et al., 2013; Fabiano et al., 2009b; Pelham & Fabiano, 2008). We divide interventions according to the focus of the intervention as follows: behavioral parent training (BPT), behavioral classroom management (BCM), child skills training, behavioral multicomponent interventions, and multimodal treatment combining behavioral interventions and medication. In addition, a new category for cognitive and neurofeedback studies has been added, given

the recent publication of controlled outcomes studies for these treatments.

Table 3.1 presents key features of RCTs of behavioral interventions with diagnosed cases of ADHD completed between 2007 and 2013. For each study, we highlight participants, study design and treatment description, outcome domains and raters, main findings, and effect size/clinical significance. Studies of other nonpharmacologic treatments are not included in the table, given the sparse evidence for their efficacy. Following our review of outcome studies within each treatment category, we summarize overall findings and limitations and provide recommendations for future research.

Behavioral Parent Training

BPT has been confirmed as an efficacious treatment based on three separate reviews since 1998 (Evans et al., 2013; Pelham & Fabiano, 2008; Pelham et al., 1998). BPT directly targets negative and ineffective parenting, which is a well-documented correlate of ADHD. In this intervention, a clinician works with parents either individually or in groups to provide psychoeducation about ADHD, to teach parents behavior modification principles and strategies, and to adapt these strategies to individual families' home environments. Most BPT curricula specify a common set of skills over the course of eight to sixteen sessions focused on (1) improving parent–child relationships through increasing quality time together; (2) increasing positive behaviors through the use of effective instructions and rewards such as desirable activities and privileges, specific praise, and other forms of positive reinforcement; and (3) reducing problem behaviors by implementing prudent corrective statements and time-out and response-cost procedures or by employing planned ignoring to curtail attention-seeking behaviors. Parents learn to use strategies taught in sessions to alter both antecedents and consequences of problem behaviors in commonly challenging situations such as morning or evening routine, homework completion, and/or independence in other home-based tasks.

Since the last version of this chapter, six additional RCTs have been added to the scientific evidence base for BPT with diagnosed cases of ADHD. New studies are largely adaptations of existing delivery models that broaden the effects of training by increasing access and/or reaching individuals who appear to be less responsive to parent training, including those from economically or socially disadvantaged backgrounds or those who have their own mental health issues. Chacko and colleagues (2009) adapted BPT for single mothers (Strategies for Enhance Positive Parenting [STEPP]) by adding to standard BPT strategies to improve motivation to engage in the treatment, increasing the length of treatment sessions, addressing practical barriers (e.g., childcare), and incorporating staff modeling of the behavioral strategies. This approach improved attendance, engagement, and satisfaction with treatment relative to traditional BPT. STEPP also resulted in greater improvements in oppositional defiant disorder symptoms, parent–child and family-related impairment, and observations of parenting relative to traditional BPT and outperformed a waitlist control on these measures at posttreatment but not at follow-up.

BPT also has been adapted for fathers by integrating activities appealing to fathers (e.g., sports) into the training curriculum (Chacko et al., 2009; Fabiano et al., 2009a). The intervention, referred to as COACHES, includes group BPT for fathers followed by soccer practice during which fathers coached their children using their new skills and received feedback from counselors. Results show that the COACHES program resulted in similar effects as standard BPT on ADHD-related child outcomes. However, fathers who received COACHES relative to BPT had better attendance, less dropout, better homework compliance, and greater satisfaction with treatment, all indicating greater engagement with the father-focused treatment. In a second study, COACHES resulted in greater improvement on unblinded observations of fathers' use of praise and negative talk and paternal reports of child behavior problems relative to a waitlist control, with evidence of maintenance at follow-up (Fabiano et al., 2012).

Adaptations to BPT have also been developed for depressed mothers by adding cognitive-behavioral strategies to treat the mother's depressive symptoms (Chronis-Tuscano et al., 2013). This is particularly relevant for mothers of children with ADHD, who are more likely to experience depression than are parents of control children (Johnston & Mash, 2001). In comparison to traditional BPT, the enhanced BPT (Integrated Parenting Intervention) resulted in greater improvement at posttreatment on observations of negative parenting and child deviance as well as

TABLE 3.1 Findings From Behavioral Clinical Trials From 2007 to 2013

Behavioral Parent Training (BPT) Clinical Trials

Study	*Participants*	*Study Design and Nonpharmacologic Treatment Description*	*Outcome Domains & Raters**	*Main Findings+*	*Effect Size and Clinical Significance*
Chacko et al., 2009	N = 120 Ages 5-12 Dx: *DSM-IV* ADHD	Type 2 between-subject waitlist control design 1. Enhanced BPT for single mothers (9 weeks: STEPP) 2. Traditional BPT (9 weeks) 3. Waitlist Control	A. ADHD symptoms (P) B. ODD symptoms (P) C. Functional impairment (P) D. Parenting behavior (O) E. Parent stress (P) F. Parent depression	A. 1 = 2 = 3 B–D. 1 & 2 > 3 at post only; 1 > 2 at post only E. 1 > 2 > 3 at post only F. 1 = 2 = 3	Small to large effect sizes for significant contrasts indicating improvement after 1 & 2 A–E. 1 > 2 > 3 for normalization, although the difference was not significant
Chronis-Tuscano et al., 2013	N = 98 Ages 6–12 Dx: *DSM-IV* ADHD	Type 1 between-subject waitlist control design 1. Enhanced BPT for depressed mothers (14 weeks: IPI-A) 2. Traditional BPT (14 weeks)	A. Disruptive behavior disorder symptoms (P) B. Functional impairment (P) C. Parent depression (P) D. Parenting behavior (O*) E. Child behavior (O*)	A. 1 > 2 at FU only B, C. 1 > 2 at post and FU D, E. 1 > 2 at post only	Small to large effect sizes for significant contrasts A & B. 1 > 2 for reliable improvements D. 1 > 2 for normalization
Fabiano, Pelham, et al., 2009	N = 75 Ages 6–12 Dx: *DSM-IV* ADHD	Type 2 between-subject waitlist control design 1. BPT for fathers (8 weeks: COACHES) 2. Traditional BPT (8 weeks)	A. ADHD symptoms (P) B. ODD symptoms (P) C. Functional impairment (P) D. Social functioning (P)	A, B, D. 1 = 2 indicating improvement C.1 > 2 as rated by fathers; 1 = 2 as rated by mothers	N/A
Fabiano et al., 2012	N = 55 Ages 6–12 Dx: *DSM-IV* ADHD	Type 2 between-subject waitlist control design 1. BPT for fathers (8 weeks COACHES) 2. Community control *Note*: 46% of treatment group & 60% of community control using medication; no differences emerged	A. Behavior problems (P) B. Parenting behavior (O)	A. 1 > 2 at post only as rated by fathers; 1 = 2 as rated by mothers B. 1 > 2 at post and FU	A. 1 = 2 for normalization of problem behaviors

McGrath et al., 2011	N: 72 Ages 8–12 Dx: *DSM-IV* ADHD	Type 2 between-subject community control design 1. BPT (12 sessions via telephone: Strongest Families program) 2. Community control	A. ADHD diagnosis (P) B. ADHD symptoms (P)	A & B. 1 > 2 at 240- and 365-day but not at 120-day assessment	N/A
Mikami et al., 2010	N: 62 Ages 6–10 Dx: *DSM-IV* ADHD (42 of 62 ADHD-C; 40 of 62 medicated)	Type 1 between-subject community control design 1. BPT (8 sessions Parent Friendship Coaching) 2. Community control	A. Social impairment (P,T*) B. Social acceptance (T*) C. Parenting skills (O*) E. Parenting behavior (O*)	A. 1 > at post and 1-month FU (P only) B–D. 1 > 2	Small to large effect sizes for significant contrasts
Behavioral Classroom Management (BCM) Clinical Trials					
Fabiano et al., 2010	N = 63 Ages 6–12 Dx: *DSM-IV* ADHD; 15% inattentive type, 85% combined type	Type 1 between-subject community control design 1. BCM (6 weeks Daily Report Card) 2. Community control *Note*: 46% of treatment group & 60% of community control using medication; no differences between groups emerged	A. Academic performance (T; O) B. Academic achievement testing C. ADHD symptoms (T) D. ODD & CD symptoms (T) E. IEP goals F. Classroom behavior (O*) G. Student–teacher relationship (T) H. Functional impairment (T)	A. 1 > 2 for academic productivity and success only B, C. 1 = 2 D–F. 1 > 2 G, H. 1 = 2	Medium effect sizes for significant contrasts A. 1 > 2 for normalization of problem behaviors D. 1 > 2 for normalization of ODD/CD symptoms
Mikami et al., 2013	N: 24 Ages 6.8–9.8 Dx: *DSM-IV* ADHD	Type 2 between-subject repeated measures crossover design 1. Enhanced BCM (4 weeks Enhanced Classroom Contingency System focused on Social Skills: MOSAIC) 2. Traditional BCM (4 weeks Traditional Classroom Contingency System focused on Social Skills: COMET)	A. Peer acceptance (T) B. Social functioning (O*) C. Problem behaviors (T) D. ODD & CD symptoms (T)	A. 1 > 2 B–D. 1 = 2	Large effect sizes for significant contrasts

Study	*Participants*	*Study Design and Nonpharmacologic Treatment Description*	*Outcome Domains & Raters**	*Main Findings+*	*Effect Size and Clinical Significance*
Murray et al., 2008	N = 24 Grades K–5 Dx: *DSM-IV* ADHD *Note*: partial randomization due to school year end and recruitment timing	Type 2 between-subject community control design 1. BCM (4 months Daily Report Card) 2. Community control *Note*: most participants were already receiving ADHD treatment, such as medication, IEP/504s, and individual therapy. No participants in group 2 were receiving a DRC, although some had a classroom behavior plan.	A. Academic performance (T) B. Classroom impairment (T)	A. 1 > 2 for academic skills and total academic performance B. 1 = 2, with both groups indicating improvement	A. Large effect sizes for significant contrasts
Behavioral Child Skills Training (BCS) Clinical Trials					
Abikoff et al., 2013	N = 158 Ages 8–11 Dx: *DSM-IV* ADHD	Type 2 between-subject waitlist control design 1. BCST (20 sessions Organizational Skills Training: OST) 2. BMC (20 sessions Parents and Teachers Helping Kids with Organization: PATHKO) 3. Waitlist control	A. Organizational skills (P,T) B. Academic functioning (T) C. Homework problems (P) D. Family functioning (P) E. School attitude (P,T)	A. 1 > 2 > 3 at post and FU (P), 1 = 2 > 3 at post and FU (T) B–D. 1 = 2 > 3 E. 1 = 2 = 3	Medium to very large effect sizes for significant contrasts; 60% of children in 1 & 2 normalized in organization vs. 3% in 3
Langberg et al., 2012	N: 47 Ages 11–14 Dx: *DSM-IV* ADHD	Type 2 between-subject waitlist control design 1. BCST (16 sessions Organization Skills Training: HOPS) 2. Waitlist control *Note*: Majority of participants receiving ADHD medication and/or academic services/accommodations	A. Organizational skills (P,T) B. Homework problems (P,T) C. ADHD symptoms (P,T) D. School grades	A. 1 > 2 at post and 3 month FU (P only) B. 1 > 2 at post and 3-month FU (P only) C. 1 > 2 at post only (P only) D. 1 > 2	Large to very large effect sizes for significant contrasts

Behavioral Multicomponent (BMC) Clinical Trials

Evans et al., 2011	N = 49 Ages 10–13 Dx: *DSM-IV* ADHD	Type 2 between-subject community control design 1. BMC (6 months Challenging Horizons; incorporates BCST, BPT, & family meetings) 2. Community control	A. ADHD symptoms (P,T) B. Functional impairment (P,T) C. Academic performance (T) D. School grades	A. 1 > 2 for HI symptoms (P) B. 1 > 2 (T) C. 1 > 2 for Language Arts & Social Studies (T) D. 1 = 2	Medium effect sizes for significant contrasts
Kern et al., 2007	N = 135 Ages 3–5 Dx: *DSM-IV* ADHD	Type 2 between-subject design 1. BMC (18 months incorporating BPT and assessment-based intervention in the home and class) 2. BPT (18 months)	A. ADHD symptoms (P,T) B. Social functioning (P,T) C. Academic performance (T) D. Academic achievement testing	A–D. 1 = 2 with both indicating significant improvement	N/A
Meyer & Kelley, 2007	N = 42 Ages 11–14 Dx: *DSM-IV* ADHD combined type	Type 2 between-subjects waitlist control design 1. BPT (Parent Monitoring Group with children present) 2. BCST (Self-Monitoring Group with parents present) 3. Waitlist control	A. Homework problems (P,T) B. Classroom behavior (T)	A. 1 & 2 > 3 at post and FU B. 1 = 2 = 3	N/A
Pfiffner et al., 2007	N: 69 Ages 7–11 Dx: *DSM-IV* ADHD inattentive type	Type 2 between-subject community control design 1. BMC (12 weeks incorporating BPT, BCST, and BCM: Child Life and Attention Skills Program) 2. Community control	A. ADHD-I symptoms (P,T) B. Sluggish cognitive tempo symptoms (P,T) C. Social functioning (P,T) D. Organizational skills (P,T) E. Life skills (C) F. Functional impairment (P,T)	A&F. 1 > 2 at post and FU B–E. 1 > 2 at post indicating maintenance to FU	Medium to large effect sizes for all significant contrasts

+Unless specifically noted, results reflect all measures and raters for each outcome.

ratings of impairment; group differences in maternal depressive symptoms and child disruptive behavior and impairment were also observed at follow-up.

One additional study addressed logistical barriers associated with parent attendance at sessions. McGrath and colleagues (2011) adapted BPT for telephone delivery. In this study, handouts and videos were provided for parents to view at home and twelve forty-minute telephone sessions were conducted to review the content. Results at eight-month and one-year follow-ups showed that the telephone format outperformed a community control in terms of ADHD symptom reduction (no other outcomes were assessed), and families were very satisfied with their telephone coaches.

In addition to these adaptations, BPT has been expanded beyond improving home behavior and parent–child relationships to improving friendship problems in an innovative approach developed by Mikami and colleagues (2010). This approach is supported by research showing that parents may contribute to their children's peer relationship problems by failing to facilitate successful playdates for their children, displaying more criticism during their child's peer interaction, and modeling fewer successful social skills (Mikami, 2010). The Parental Friendship Coaching (PFC) intervention includes eight ninety-minute sessions focused on teaching parents how to teach their children to interact successfully with peers during a playdate. Also covered are behavioral interventions and collaborative problem solving between parents and children before and after playdates. Relative to a community control group, PFC predicted improvements in children's social skills and friendship quality on playdates as reported by parents, and peer acceptance and rejection as reported by teachers unaware of treatment status. PFC also predicted increases in blinded observations of parenting practices, including facilitation of peer interactions and reductions in criticism, which had been taught during the treatment sessions and which mediated the improvements in children's peer relationships. Notably, effects were seen at school even though teachers were unaware of treatment condition and contingencies were not in effect.

Although implemented with an undiagnosed sample, an additional RCT supports BPT. Thompson and colleagues (2009) adapted BPT for preschool children at risk for ADHD by including an increased focus on factors underlying ADHD, including self-regulation and the quality of mother–child interactions. Significant effects of the treatment were found on parent reports of ADHD symptoms and social and behavioral problems compared to a usual community care condition.

Behavioral Classroom Management/Behavioral School Interventions

BCM, like BPT, has been classified as a well-established treatment for ADHD for over fifteen years (Evans et al., 2013; Pelham et al., 1998; Pelham & Fabiano, 2008). As discussed above, early definitive studies of BCM using single-subject experimental methodologies in controlled or specialized classrooms revealed that systematic behavioral contingencies in the form of positive reinforcement (e.g., token economies) and/or prudent negative consequences yield powerful effects on observed behaviors, including on-task behavior and academic productivity while the programs are in effect (Hinshaw et al., 2007). In a recent meta-analysis of sixty studies conducted between 1996 and 2010, school-based interventions, including contingency management as well as academic and self-regulation interventions, were associated with moderate to large improvements in academic and behavioral functioning of students with ADHD (DuPaul et al., 2012). Studies of academic (e.g., peer tutoring, computer-assisted) and self-regulation interventions represent new additions to the evidence base for behavioral interventions since the last review. While promising, these studies are limited to single-subject designs (so are not included in the table); larger sample controlled trials of these intervention approaches are needed.

Since the last review three randomized trials of BCM have been published, all of which are supportive. The first two studies evaluated the efficacy of a Daily Report Card (DRC) for elementary students with ADHD, one in the context of general education (Murray et al., 2008) and one in the context of special education services (Fabiano et al., 2010). The DRC has been used extensively over the years, including as an intervention in several multicomponent studies (Barkley et al., 2000; MTA, 1999; Owens et al., 2005), but had not been systematically evaluated in a large randomized trial. The DRC asks the teacher to rate predetermined specific behaviors targeted for improvement each day; the parent provides rewards at home based on the day's ratings. Murray and

colleagues (2008) used a conjoint behavioral consultation approach to engage parents and teachers in the treatment; Fabiano and colleagues (2010) used separate teacher and parent training meetings. Compared to services as usual, the DRC condition in both studies led to significant improvements in academic skills and productivity (Murray et al., 2008) and teacher ratings of academic productivity, parent and teacher ratings of oppositional defiant disorder and conduct disorder, and blinded observations of classroom behavior (Fabiano et al., 2010).

Mikami and colleagues (2013) compared two methods of managing classroom behavior of elementary school-aged students in an analogue classroom setting. The two treatments both included behavioral contingency management. However, in one of the treatments, MOSAIC, peer inclusion training was added to reduce rejection, social devaluation, and exclusion of children with ADHD. At the end of the two-week program, social behavior problems did not differ between the two groups. However, children (especially boys) with ADHD in the MOSAIC group were less often rejected by their peers and had more reciprocated friendships than those in the standard BCM condition. This study shows that while traditional contingency management improves social behaviors, strategies to increase peer group inclusiveness can provide incremental benefits for peer relationships among youth with ADHD.

Child Skills Training

In contrast to BPT and BCM, which train parents and teachers to deliver the intervention to children, child skills training programs directly train children in skills they then apply themselves. Organizational skills training programs address the substantial difficulties youth with ADHD have in organizing tasks, managing their time, and planning effectively (Langberg et al., 2011, 2008). These skills are particularly important in academic settings since poor organizational skills often translate into problems with classwork and homework completion, test performance, and report card grades, all of which are crucial to academic success (Power et al., 2006; Schultz et al., 2009).

Two programs, one for children (Abikoff et al., 2013) and one for adolescents (Langberg et al., 2012), have recently been evaluated in randomized trials. Both approaches involve training youth in strategies for organizing their belongings (e.g., binders, backpacks, lockers) and tracking assignments using an assignment book. Checklists are used to manage multiple tasks, and incentives are used to reward successful organization. Abikoff and colleagues (2013) compared the Organizational Skills Training intervention delivered directly to children to PATHKO, an intervention that involved training parents and teachers to reinforce children contingently for meeting endpoint target goals and a waitlist control. Organizational Skills Training and PATHKO each involved twenty individual sessions over ten to twelve weeks. Both treatments resulted in robust sustained functional improvements per parent and teacher report of organizational skills as well as family relations relative to the waitlist control group. Organizational Skills Training showed greater effects on a parent-reported measure of organizational skills than PATHKO, but in most ways the two treatments were comparable. Clinically significant effects were notable, with 60% of children in both of the treatment conditions, but only 3% of the control group, no longer meeting inclusion criteria for organizational skills problems,. In contrast to many studies, effects were maintained at follow-up during the subsequent school year.

In a second study, Langberg and colleagues (2012) evaluated the Homework, Organization, and Planning Skills intervention with middle-school students with ADHD. This intervention includes sixteen sessions designed to be implemented by school-based mental health professionals in the school setting. Two parent sessions are also included to encourage parent monitoring and reinforcement of child skills. Children receiving the intervention demonstrated significant improvements relative to a waitlist comparison group on parent ratings of ADHD, organization, planning, and homework completion, although these positive outcomes did not extend to teacher reports. Of note was the fact that school clinicians were able to implement the manualized intervention with fidelity despite no formal ongoing consultation.

Behavioral Multicomponent Interventions

Driven by limited cross-site generalizability of treatment gains, a number of multicomponent behavioral interventions recently have been developed and evaluated. These multicomponent interventions include

a combination of BPT, BCM, and/or child skills training across all age groups from preschool through high school. In addition to directly targeting problems across home and school contexts, these intervention combinations can synergize the effects of the individual components. This may be especially true for child skills training, since it is likely that such skills training will be most beneficial when ongoing monitoring and incentives are provided by parents and/or teachers, since didactic learning alone likely will be insufficient.

The Child Life and Attention Skills (CLAS) program includes home, school, and child skills training components and targets children with the inattentive presentation of ADHD (Pfiffner et al., 2007). The program emphasizes adaptive skills, functional competence, and compensatory strategies; uses cues, prompts, and routines; and involves teachers and parents to provide necessary environmental supports at school and at home. Parents and children attend eight to ten concurrent group meetings and up to five family meetings, and teachers attend up to five consultation meetings with a therapist and each child's family. Children are taught a series of modules focused on independence (homework/study skills, self-care skills, getting chores done, routines, organization, and time tools) and social skills (making friends, handling teasing, assertion, accepting, being a good sport, and problem solving). The parent group acquires strategies to support their children's use of the child skills at home and at school as well as traditional BPT strategies adapted to address impairments of the inattentive presentation. Teacher consultation meetings focus on development and implementation of an individualized daily report card and classroom accommodations specific to the concerns of each child (e.g., additional time or "time challenges" to complete work, preferential seating, reduction in workload, use of assignment book, use of completed work folder). Target behaviors are based on the needs of each child and typically include academic work (e.g., completion of assigned work, completion and return of homework, accuracy of completed work), work behavior/study skills (e.g., following directions, having necessary materials to begin work, getting started on work, staying on task), and social interactions (e.g., entering peer groups, accepting consequences, being a good sport, using assertive behavior). Skills taught in the child group are shared with teachers so that the children's use of these skills can be reinforced (often by including them as targets on the classroom challenge) at school. Parents are taught a set of transferable skills for working with their child's teachers in the future.

The results of an RCT indicate that children who received CLAS had significant improvements in aggregate parent and teacher ratings of ADHD symptoms and severity, as well as social and organizational skills, at posttreatment relative to a community control; these improvements were sustained at three to five months of follow-up (Pfiffner et al., 2007). These results were subsequently replicated and extended in a large-scale, two-site randomized clinical trial of CLAS that revealed significant benefit for the integrated, multicomponent treatment compared to usual care on parent and teacher reports of inattention symptoms and social, organizational, and global impairments; the gains compared to BPT on parent and teacher reports of organizational skills and teacher reports of inattention symptoms and social and global impairment, with evidence of maintenance of treatment effects at five to seven months of follow-up (Pfiffner et al., 2014).

Based on the success of CLAS, Pfiffner and her colleagues extended this program to target all ADHD presentations, with the objective of establishing sustainable implementation in a public school setting (Pfiffner et al., 2011). The adapted intervention, the Collaborative Life Skills program, is designed to be implemented at the child's school by existing school mental health personnel. Findings from a within-subject design reveal broad benefits on attention, academics, organization, social behavior, and classroom engagement (Pfiffner et al., 2013); a randomized trial comparing Collaborative Life Skills to usual school services is under way.

Power and colleagues (2012) expanded the focus of traditional parent training programs by developing the Family-School Success program, a family-mediated educational intervention with BPT and BCM components. Family-School Success includes twelve sessions with six co-occurring parent education and child recreational group sessions, four individualized family therapy sessions, and two family–school consultation sessions including parents and teachers. Standard behavioral parent education strategies were combined with a daily report card, homework interventions, and conjoint behavior consultation. In comparison to a psychoeducation support group, Family-School Success resulted in small to moderate effects on the quality of family–school

relationships, homework performance, and negative/ineffective parenting, even though about 40% of the youth were already taking medication (Power et al., 2012). A version of Family-School Success has been developed for younger elementary students at risk for ADHD, with promising effects on parenting skills and teacher ratings of ADHD and oppositional defiant disorder symptoms and the student–teacher relationship (Mautone et al., 2012).

Multicomponent programs have also been evaluated for preschool and early elementary school. Kern and colleagues (2007) compared a multicomponent, multisetting intervention (including parent education classes and individualized assessment-based intervention in the home and in the preschool or daycare) to parent education alone. Both interventions resulted in comparable and significant improvements in children's behavior and preacademic skills at posttreatment and one year later, although the absence of a no-treatment control group limits understanding of the role of maturation in these changes.

The Incredible Years program (Webster-Stratton et al., 2011) includes BPT, BCM, and child skill training components, which can be implemented separately or combined. This intervention was developed for preschool disruptive behavior problems but was evaluated specifically for four- to six-year olds with ADHD in a recent twenty-week RCT combining only the BPT and child skills training components. Results showed improvements in child inattention, hyperactivity, externalizing behaviors, social competence, and emotion regulation by mother and father reports relative to a waitlist control. Improvement in maternal parenting was also notable per mother self-report and independent observations. Treatment effects were also found at school as seen in teacher-reported externalizing behavior and observations of children's social interactions in the classroom and on tests of social problem solving and feelings literacy.

The First Steps to Success program, also developed for externalizing problems, combines BPT and BCM and was evaluated for children with ADHD in kindergarten through third grades. School personnel implement BPT and BCM in the school, targeting children's externalizing behavior problems. The program consists of thirty days of BCM at school and six home sessions focused on teaching parents BPT strategies. Seeley and colleagues (2009) compared First Steps to a usual care control group and found greater improvement in ADHD behaviors, social skills, and academic problems at school with the First Steps program. However, improvements were not found at home, suggesting that the parent component may not have been sufficient.

Multicomponent treatments also are beginning to emerge at the middle- and high-school level. This is a time when expectations for academic, social, and behavioral independence increase exponentially, and the increased demands are especially challenging for youth with ADHD. Developmental adaptations have been made to programs originally developed for younger youth to better fit the needs of adolescents and to address the changing requirements at school. For example, given their increased cognitive capacity and desire for independence, there is an increased emphasis on teens taking a more active role in their own treatment. Organizational skills interventions are prominently featured in these treatments, given the importance of these skills and notable deficits for ADHD in this area. Meyer and Kelley (2007) evaluated the effectiveness of a one-session training (followed by weekly follow-up phone calls for four weeks) for middle-school youth with ADHD; the training focused on strategies for effective homework completion, monitoring of targeted homework behavior, and general study skills. The effectiveness of self-monitoring versus parent monitoring of homework after the one-session training was compared. Results indicate that both interventions improved parent-rated homework problems and teacher-rated classroom performance, as well as percentage of completed homework, compared to a waitlist control group.

The Challenging Horizons Program (Evans et al., 2011) is a comprehensive school-based treatment program for adolescents with ADHD that combines components for the family and teen and is integrated into the school setting. It incorporates many of the features discussed above. An after-school version has been evaluated in comparison to a community care control condition (Evans et al., 2011). The program consists of three family check-up meetings to motivate and engage families in the treatment. Thereafter, students attend the program for 2.5 hours two days a week, where they receive group interventions for improving social and educational skills. They also receive one-on-one meetings with a counselor to review progress, practice specific skills, and maintain a therapeutic relationship and connection with the program. The counselors work with each student's

parents and teachers to ensure that appropriate problems are being addressed and to facilitate generalization from the after-school program to school and home. Every student uses an assignment notebook for homework, with school and home contingencies for its correct use. Students are also taught note-taking and study skills; they practice these first in the program and then are required to show that they use the skills at school and at home. Outcomes show that students in the Challenging Horizons Program improved relative to those in the control condition on measures of symptoms per parent report and school impairment per teacher report (Evans et al., 2011).

Incremental Effects of Multimodal Combination Treatments

Given the powerful short-term effects of medication and behavioral interventions, yet the limited capacity of either treatment modality to normalize functioning or to substantially alter long-term adverse outcomes, a key question over the years has been whether behavioral interventions can add incremental improvement to medication or vice versa. An underlying assumption has been that the combined treatment might provide optimal effects, since medication and behavioral interventions would each target different domains and medication would allow for sufficient symptom management to allow children to learn adaptive skills taught through behavioral interventions, which they could then apply across time and settings to improve generalization.

The largest study to have evaluated the separate and combined effects of psychosocial and medication treatments continues to be the Multisite Treatment Study for ADHD (MTA), conducted in the 1990s; follow-up of participants has occurred at regular intervals since then. As reviewed in the previous version of the chapter, 579 children aged seven to 9.9 years were randomly assigned to (a) medication management, (b) intensive behavioral treatment (BI, combining BPT, BCM, and an intensive summer treatment program), (c) combined behavioral and medication treatment, or (d) community comparison. The behavioral treatment included thirty-five BPT sessions for parents, both group and individual; therapist-facilitated consultation and coordination with the children's teachers; an eight-week summer treatment program; and paraprofessional aide involvement in the classroom for three months following the summer treatment program. These treatments were faded toward the end of the fourteen-month intervention period.

Of particular relevance to the topic of this chapter, initial published findings revealed that BI produced gains in ADHD symptoms, comorbid symptoms, and school, family, and peer-related impairments similar to community care (most of whom were taking medication); the benefits of BI on ADHD and oppositional defiant disorder symptom reduction were smaller than those from medication; and measures showing gains from BI were based on parent and teacher ratings rather than objective measures. Since then, several secondary studies have shown stronger effects for BI: Composite measures of parent and teacher rating scales show superiority of BI over community care and incremental benefit from combined treatment over medication alone. Most recently, Langberg and colleagues (2010) showed main effects for BI on parent ratings of homework problems; only those who received BI demonstrated sustained improvement (ten months after treatment ended) in homework problems in comparison to routine community care. Unique benefits of BI were also found on an objective measure of observed parenting skill during a clinic-based parent–child interaction (Wells et al., 2006). Outcomes from other objective assessments, including peer sociometric indicators and blinded classroom observations, have failed to show clear benefit from BI.

Since the last review, thirty-six-month and eight-year follow-up data have been published. At thirty-six months, reports of substance abuse were lower for both behavioral treatment groups compared to medication only and the community control (Molina et al., 2007). No group differences have been reported on any other measures of symptoms and impairments at either of these time points.

Two additional randomized trials of medication and BI have been published since the last review. A study by Van Den Hoofdakker and colleagues (2007) evaluated BPT as an adjunct to routine clinical care in the form of family support and medication as needed. They found that BPT enhanced the effectiveness of routine clinical care in reducing behavioral and internalizing problems and in reducing prescriptions for polypharmaceutical treatment. In contrast, Van de Oord and colleagues (2007) failed to find an additive effect of ten-week multimodal behavioral treatment to optimally dosed stimulant treatment on parent and teacher reported ADHD

symptoms and social skills, parenting stress, or child self-report of self-worth and anxiety. These latter findings are in concert with earlier studies that failed to find incremental effects of BI with optimally dosed youth (e.g., Abikoff et al., 2004; Hechtman et al., 2004).

These inconsistencies within and across studies highlight the difficulty of evaluating the comparative and incremental effects of BI and medication. The findings reveal that these treatments may indeed differ in their relative effects on different outcome measures. Also, inconsistent findings may be the result of differences in the relative intensities of BI and medication across studies. Evidence for this comes from studies that have been carried in the context of a summer treatment program that allowed for careful standardization and control of varying intensities or doses of BI and medication. Treatments were evaluated in a classroom setting (Fabiano et al., 2007) and replicated in a social-recreational setting (Pelham et al., 2014). Multiple doses of behavior modification (none or low and high intensity) were crossed with medication (placebo, 0.15, 0.3, 0.6 mg/kg methyphenidate). The intensity of behavior modification was varied according to how various aspects of standard BCM were applied (use of rules, point system, DRC, time-out, social reinforcement, rewards), with the high intensity representing the most consistent and contingent application of these systems and the low intensity representing a less consistent and contingent application that was more similar to a regular classroom or recreational setting; the no behavior modification condition did not implement these systems. Results indicated that incremental effects of combined treatments occurred at the low doses of treatment, with increasing dose of either resulting in more modest improvement. There were no benefits of combined treatments when the dosage of either treatment was high. In addition, low-dose behavior modification combined with a low dose of medication was equivalent to a high dose of medication or high behavior modification used alone. These results clearly demonstrate that questions about relative efficacy and incremental effects need to take into account the dose or intensity of each treatment.

Moderators and Mediators of Treatment Outcome

A number of factors have been found to moderate the impact of BPT, in part due to barriers to treatment engagement and attrition (Lundahl, Risser, & Lovejoy, 2006). Moderators include low income, parent education level, single-parent families, a lack of father involvement, high parent stress, and a lack of parent social support; all predict less favorable outcomes (Chronis et al., 2004; Harwood & Eyberg, 2006; Pelham & Fabiano, 2008). In addition, severe marital discord, parent psychopathology (e.g., depression, ADHD, antisocial behavior), and parental drug abuse or dependence all can reduce the efficacy of parent training (Chronis et al., 2004). Moreover, positive parental expectations before and throughout treatment have been found to predict better treatment engagement in BPT and better child outcomes (Kaiser et al., 2010), and including a child component can reduce premature termination in BPT (Miller & Prinz, 1990), suggesting that including the child in treatment may exert a positive effect on parents' motivation for treatment. Practical aspects, such as program times, locations, activities, and advertised benefits of the treatment, also influence utilization of BPT programs (Cunningham et al., 2008).

Child factors also predict response to parent training. The severity and nature of symptoms and problems are likely the strongest predictors of whether or not (or to what degree) treatment produces desired change. For example, Langberg and colleagues (2010) found that, at the twenty-four-month follow-up in the MTA study, the benefits of the combined intervention on homework problems were strongest for children with moderate parent-rated ADHD symptoms.

Few studies have examined specific mediators and moderators of BCM, but as with BPT, it is likely that implementation factors such as engagement and fidelity are important. For example, although evidence supports the utility of specific interventions, such as DRC, recent studies show that practical considerations such as holding conjoint parent–teacher consultation meetings at the child's school (Murray, Rabiner, Schulte, & Newitt, 2008) and allotting leave time for teachers so that they can attend consultation meetings are important (Owens et al., 2008). The use of existing school infrastructure for engaging teachers and implementing the treatment may result in more sustainable implementation of interventions (Atkins et al., 2008).

Although not evaluated for ADHD per se, a variety of process factors associated with implementation of behavioral treatments also can affect outcome. As with any intervention, the therapist–client relationship influences outcome in behavior therapy

(Webster-Stratton & Herbert, 1993). Therapist warmth, knowledge of social learning principles and disruptive behavior disorders, likeability, and communication skills all are likely to contribute to more positive outcomes. Helpful therapist behaviors include active listening skills to guide and maintain parents' responses to open-ended questions, whereas overly supportive statements early in therapy may reinforce feelings of client helplessness, which might contribute to dropout (Harwood & Eyberg, 2006). Active parental engagement and compliance with treatment, as measured by parental adherence to between-session assignments (e.g., the extent to which they implement the strategies they are taught) and to a lesser extent attendance at sessions, are important predictors of child outcomes (Clarke et al., 2013). Compliance with treatment can be enhanced using motivational strategies (Dishion et al., 2003; Nock & Kazdin, 2005) and specific prompts (e.g., reminder phone calls between sessions that prompt parents to complete homework or to come to the next session).

Finally, studies have evaluated mechanisms underlying effects of treatment and report that improved child outcomes appear to be a function of the degree of change in the areas directly targeted in the treatment. For example, for parent-mediated interventions, changes in parenting predict child outcomes. In the MTA study, the combination treatment, when associated with improved parenting, was prone to yield not just improvement in behavior but also normalization of such behavior (Hinshaw et al., 2000). In a separate study of BPT, improvement in child behavior was mediated by change in observed maternal negative parenting (Chronis-Tuscano et al., 2011). In child-focused intervention, the degree of change would be expected to relate to the extent to which the child used the organizational skills taught. Indeed, Langberg and colleagues (2013) found that adoption of the binder materials organization system predicted parent-rated improvements in organization, planning, and homework problems and demonstrated the benefit of teaching students with ADHD to use a structured binder organization system for organizing and transferring work to and from school.

Cognitive Training/Neurofeedback

In recent years, treatment efforts have been directed to modify neurocognitive deficits, which are thought to underlie many of the core symptoms and impairments of children with ADHD. Computer-based training exercises with extensive practice and feedback have been employed to facilitate development of hypothesized areas of executive function and attention deficiencies. Improvement in these underlying processes has been posited to transfer to improvements in other tasks and activities relying on these processes, such as academic functioning. Several randomized trials have evaluated one such program, Cogmed Working Memory Training (CWMT). CWMT is a computer-mediated program with a gamelike interface that requires children to complete working memory tasks, with the difficulty level of the working memory demands adjusted based on performance after each trial. Children complete these tasks for approximately twenty-five to forty-five minutes daily for four to six weeks. Although trials have generally found improvements on trained working memory tasks (resembling tasks in CWMT) and to a lesser extent on nontrained cognitive tasks (which rely on the same cognitive processes) relative to a waitlist control (Beck et al., 2010), a placebo control (Chacko et al., 2013; Green et al., 2012; Klingberg et al., 2005), or an active treatment comparison (Gray et al., 2012), effects on ADHD symptoms and day-to-day impairments have been minimal. Although several studies reported some improvements in parent ratings of ADHD symptoms (Beck et al., 2010; Klingberg et al., 2005), effects on blinded teacher ratings or academic functioning/achievement have not been found. In the most methodologically rigorous evaluation of CWMT, in which concerns from previous studies of CWMT about the equivalence of the placebo version were addressed, no differences were found on any outcome measure other than improvement on verbal and nonverbal working memory storage (Chacko et al., 2013). Thus, while CWMT can improve certain aspects of working memory, there is no evidence that it can affect any other domains of functioning.

Other cognitive training programs aim to improve selective and sustained attention (Hagan et al., 2008; Kerns et al., 1999; Semrud-Clikeman et al., 1999; Shalev et al., 2007). These attention training programs also use computer-mediated tasks and follow a similar training regimen as that described for CWMT (Hagan et al., 2008; Shalev et al., 2007). Evidence for treatment effects on daily functioning is limited. In a recent meta-analysis of twenty-five

studies of cognitive training, Rapport and colleagues (2013) reported some preliminary evidence for improvement on trained tasks measuring short-term memory (medium effect size) and unblinded raters' assessment of ADHD symptoms (parents) but scant evidence of any transfer to unblinded ratings of symptoms and daily functioning at home or school or on tests of academic functioning.

Neurofeedback has been used to alter brainwave patterns posited to underlie ADHD and has been evaluated as a potential treatment for children with ADHD (Lofthouse et al., 2011; Sherlin et al., 2010). Children with ADHD have been found to have low levels of arousal in frontal areas of the brain as a result of excessive theta (slow) waves and a deficit of beta (fast) waves. Children are taught how to control their brain activity patterns through auditory and visual feedback on changes in the brain's electrical activity measured by scalp electrodes. Through intensive neurofeedback training (approximately thirty to forty hours over two to three months), the goal is to teach children through operant and classical conditioning to increase beta and decrease theta brain wave patterns in frontal areas. Several studies have reported evidence that this treatment can improve beta–theta activity as well as symptoms of ADHD per blinded parent and teacher report (Bakhshayesh et al., 2011; Gevensleben et al., 2009, 2010), but effects on measures of social, academic, and home functioning have not been found. However, methodological concerns persist (lack of adequate blinding of study participants, raters, and neurofeedback raters; no studies with appropriate placebo treatments, such as sham-neurofeedback, that simulate the nonspecific effects of neurofeedback; and failure to track concomitant treatment [Lofthouse et al., 2012]), which limit the conclusions that can be made about overall effectiveness.

Cultural Factors

The behavioral treatments described in this chapter have been developed and tested with predominately English-speaking European American samples; thus, the extent to which these treatments and treatment outcomes generalize to diverse samples is not clear. Very few behavioral clinical trials included adequate numbers from diverse populations to investigate differential treatment outcomes among groups. One exception can be found in secondary analyses from the MTA study by Jones and colleagues (2010), which compared behavioral treatment effects for African American, Latino, and Caucasian children. Results suggested that all three groups responded comparably, providing initial promise regarding the universality of behavioral interventions (Jones et al., 2010). However, the MTA study excluded participants without English proficiency, limiting generalization to this likely less acculturated population, and sample sizes for other ethnic minority groups, such as Asian or American Indian families, were insufficient for separate analyses.

Current guidelines for evidence-based treatment with ethnic minority youth call for the examination of culturally modified treatments (for full reviews, see Huey & Polo, 2008; Miranda et al., 2005). Although several culturally modified treatments for children have been developed with positive results (e.g., PCIT for Mexican Americans by McCabe & Yeh [2009]), no trials investigating culturally modified ADHD treatments have been reported to date. It may be especially important to examine the impact of culture and ethnicity on behavioral treatments, as these interventions focus on modifying the social environment (e.g., parenting practices), which can be highly influenced by culture (Weis & Toolis, 2010). Crucially, despite the fact that ethnic minority children display comparable rates of ADHD, they are far less likely to receive ADHD services and participate in research compared to nonminority youth (Alegría et al., 2007; Eiraldi et al., 2006; Faraone et al., 2003; National Institutes of Health, 2002; Willcutt, 2012). Culturally modified recruitment strategies may be necessary to ensure adequate representation of ethnic minority populations (e.g., Haack et al., 2012, in press; Ojeda et al., 2011). Also, culturally appropriate assessment measures validated with the specific population of interest may be needed (Haack & Gerdes, 2011; Lee & Humphreys, 2011). For example, the ADHD-FX (Haack et al., in press), which was developed specifically for use with Latino families, emphasizes functional impairment related to academic, social, and family functioning, since these constructs are thought to be less culturally biased than ADHD symptomatology (Gerdes et al., 2013; Rothe, 2005).

SUMMARY OF FINDINGS

The evidence base for behavioral interventions has continued to expand in recent years, broadening both

the impact and scope of these interventions, as summarized in the points below.

1. Several type 1 studies, which have the highest level of scientific rigor, show strong, positive effects of BPT, BCM, and behavioral multicomponent interventions. Effects are seen on parent and teacher reports of ADHD symptoms, key areas of impairment including social competence and acceptance, and academic productivity as well as on blinded observations of classroom behaviors and parent–child interactions. Many more type 2 RCTs also show statistically and clinical significant positive effects of BPT, BCM, childhood skills teaching, and multicomponent behavioral interventions on parent and teacher ratings of symptoms, social and academic functioning, and parent–child relationships compared to no treatment and active treatment controls. Together these studies confirm the status of behavioral interventions as well-established treatments for ADHD.
2. Adaptations of BPT have been developed to address barriers and reach new populations. Programs specifically designed for fathers, single mothers, and depressed mothers all report benefits relative to no-treatment controls. Although child outcomes from these adapted models are not always superior to traditional BPT (e.g., Fabiano et al., 2009a), the adapted treatments do appear to increase parent engagement and treatment satisfaction, and gains from these adapted treatments have been maintained in follow-up assessments up to one year later. Telephone-mediated delivery also shows initial efficacy and holds promise for addressing travel barriers.
3. Novel organizational skills training programs for children show positive effects for ameliorating the common and impairing organizational deficits that typically accompany ADHD symptoms. This form of treatment has the potential to improve treatment generalization since youth can apply these skills across settings and there is less reliance on parents and teachers to consistently support the youth's efforts through special contingencies. There is some suggestion that the assumptions of greater generalizability may hold (e.g., Abikoff et al., 2013; Meyer & Kelley, 2007), and at least one study showed normalization of organizational skills in 60% of cases (Abikoff et al., 2013). Studies of academic interventions and self-regulation are also promising but have yet to be evaluated in a large-scale randomized trial.
4. There is greater use of cross-setting and multiple component behavioral treatments that infuse treatment throughout the day to address longstanding concerns about a lack of generalization and maintenance of treatment gains. These studies show superior outcome to no treatment or usual care controls and, more importantly, are showing improved maintenance of treatment gains (often into the next school year) and overall greater cross-setting effects than single-setting treatments (Abikoff et al., 2013; Pfiffner et al., 2014; Webster-Stratton et al., 2011). Recent efforts focused on promoting effective school–home partnerships have yielded benefits for family–teacher relationships as well as student outcomes even among families of medicated children (Power et al., 2012).
5. The previous (2007) review reported that BI, on average, was less effective than medication and that the jury was still out as to whether combination treatments were superior to medication alone. Since then, it has become increasingly clear that comparisons of medication and BI are complex and difficult; there is a need to take into account a number of factors, including the outcome being measured and the dose of the intervention. When this is accomplished, combined multimodal treatments appear to reduce the needed dose or intensity of each intervention. In addition, existing medication treatments appear to have greatest impact on symptom reduction, while behavioral treatments may have greatest impact on some areas of impairment (e.g., parenting, homework success), consistent with the respective targets of these two treatment modalities.
6. There has been an increase in research on treatments for adolescents and preschool children showing that BI, with developmentally appropriate adaptations, can be effective with these age groups.
7. There have been a number of efforts to develop alternative nonpharmacologic treatments,

including cognitive training and neurofeedback. Although existing cognitive training programs have not been found to be efficacious, there is some preliminary evidence to support neurofeedback, but further study is needed before clinical application can be recommended.

3. While some studies have shown evidence of maintenance of gains, the time period assessed is relatively short (months rather than years) (Abikoff et al., 2013, Pfiffner et al., 2007). As a consequence, ongoing or at least periodic treatment, especially during periods of developmental transition, may be necessary.

LIMITATIONS AND QUALIFICATIONS

A number of limitations and qualifications need to be considered.

1. Although several additional type 1 outcome studies of BI have been reported, there are still relatively few of these in comparison to the number of type 1 studies of medication, mostly because there has been limited use of objective or blinded measures. As a result, a good deal of the evidence supporting the use of BI remains based on reports from parents and teachers who were involved with the treatment. Clearly, there is a need for documentation of BI effects using nonbiased measures of outcome, especially outcomes related to real-world indices of successful functioning (e.g., report card grades, academic achievement, sociometric ratings).
2. The size of treatment effects, while large, is usually below full normalization. Often, this is a function of the extent to which parents and teachers can implement the treatment recommendations with fidelity (e.g., Clarke et al., 2013). It is notable that the one study with high rates of normalization (60%) was conducted with a relatively high-functioning population (Abikoff et al., 2013). In addition, treatment effects are less prominent on sociometric measures, although a recent trial shows effects on teacher perceptions of peer acceptance from teachers blinded to the intervention (Mikami et al., 2013). Also, behavioral treatments have had little impact on academic achievement, although they have had very strong positive effects on academic productivity and homework performance. Gains in achievement may require longer-term treatment and/or greater focus on academic skill building.

FUTURE DIRECTIONS

Findings from this review, coupled with those of the previous review, provide strong support for the efficacy of BI for ADHD. The next generation of studies would do well to address the above limitations and discover how we can maximize effects and tailor current clinical approaches to best meet the needs of varied children, families, and circumstances.

1. Larger-scale trials are needed to evaluate mechanisms of change and moderators of effects to better tailor existing interventions and to develop innovative approaches to treat those who may not be responding as well. Successful tailoring of interventions will also require evaluations of optimal dosing, combinations, and sequencing of various behavioral treatment components as well as behavioral and medication treatments for individual children and families. In addition, closer links between advances in basic science delineating the underlying mechanisms of the disorder and clinical science on intervention development may identify more targeted treatments.
2. There is a pressing need to improve the accessibility of empirically supported behavioral treatments to broad, high-risk populations. The vast majority of RCTs included in this review have been conducted in university-based clinic settings with highly trained clinicians. However, these interventions are seldom implemented in other settings, such as schools or community clinics, and are therefore not available to many of those in greatest need. The extent to which these interventions can be directly exported to the community is not known, although recent efforts suggest that with some relatively minor modifications and focused training for providers, this should be possible (Pfiffner et al.,

2013). Issues of cost-effectiveness are critical for successful translation and dissemination into community settings. Interventions need to be feasible and acceptable, as do the training requirements for those who deliver the interventions (e.g., clinicians, teachers). To this end, innovative approaches may include greater use of existing community resources and emerging technologies (e.g., interactive Web-based treatment and training). Also, culturally modified treatment programs may be necessary to encourage participation, engagement, and optimal treatment outcomes across diverse ethnicities and cultures.

3. Greater attention to issues of engagement, adherence, and implementation fidelity on the part of all treatment participants (e.g., teachers, parents, and students) is critical given the association between these factors and treatment outcome (e.g., Clarke et al., 2013; Langberg et al., 2013; Villodas et al., 2013). Targeted treatments to optimize these factors are needed. These efforts also may be facilitated by recent and ongoing technological advances (e.g., use of smartphones for monitoring or implementing behavioral strategies).
4. Long-term outcomes after behavioral interventions have been discontinued have been disappointing (Molina et al., 2007) but are consistent with a chronic disease model of ADHD. Treatment approaches for sustaining effects and addressing new problems that are expected to arise during key developmental transitions (e.g., transition to middle and high school) are needed.
5. Finally, policy research on the ways in which behavioral treatments can best be provided and financed within systems of care (e.g., schools, public and private insurance, community agencies) is sorely needed so that these services become more accessible to all youth and families in need.

Pharmacological Treatments for Attention-Deficit/Hyperactivity Disorder and Disruptive Behavior Disorders

Erica Kass
Jonathan E. Posner
Laurence L. Greenhill

More than 225 placebo-controlled type 1 investigations demonstrate that psychostimulants are highly effective in reducing core symptoms of attention-deficit/hyperactivity disorder (ADHD) in children and adults. In contrast, there are limited type I studies demonstrating that psychopharmacological management with U.S. Food & Drug Administration (FDA)-approved agents for ADHD (stimulants and nonstimulants), atypical antipsychotics, and mood stabilizers decrease the defiant and aggressive behavior characteristic of disruptive behavior disorders, including conduct disorder (CD) and oppositional defiant disorder (ODD). Stimulant treatment evidence has been supplemented by two large multisite randomized controlled trials (RCTs)—the Multimodal Treatment Study of ADHD (MTA Study) and the Preschool ADHD Treatment Study (PATS). RCTs from the past 15 years continue to report several key adverse events associated with stimulants—insomnia, decreased appetite, stomachache, and headache—but have not supported rarer and more serious problems, such as cardiovascular accidents or sudden unexpected death, which were reported in 2006 in the FDA's Adverse Event Report System. Although psychostimulants have been shown to retain their efficacy for as long as 14 months, their long-term academic and social benefits are not as robust. Nonstimulant agents for which there is more limited evidence of efficacy include atomoxetine (ATX), α-agonists, modafinil, and bupropion.

INTRODUCTION

Stimulant medications have become first-line agents for treating ADHD, a major public health problem in the United States. The American Psychiatric Association states in the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*) that 5% of children have ADHD. The percentage of U.S. school-aged children with a parent report of current medication treatment for ADHD increased from 4.8% in 2007 to 6.1% in 2011. Among those children reported as currently having a diagnosis of ADHD, 69% were taking medication. (Visser et al., 2014). Although the use of ADHD medications is generally lower in European countries than in the United States, the same trend with increased number of prescriptions has been documented in the Netherlands, Denmark, and Spain (Hodgkins, Sasane, & Meijer, 2011; Pottegard, Bjerregaard, Glintborg,

Hallas, & Moreno, 2012; Treceno et al., 2012). A population-based study in Denmark revealed that the percentage of children and adolescents with ADHD being treated with one or more ADHD medications (61%) was similar to the percentage being treated in the United States (69%) (Dalsgaard et al., 2013).

Stimulants ameliorate core ADHD symptoms by reducing excessive gross motor activity, decreasing off-task behavior, increasing compliance with adult requests, and decreasing aggression (Greenhill, Halperin, & Abikoff, 1999). Not only are they effective, but they also have a rapid onset of action and a low rate of adverse events, with only 4% of children having to change to another medication in a controlled study of adverse events (Barkley et al., 1990). This rapid and robust response explains, to some degree, why published treatment research on childhood ADHD in the past four decades has focused on stimulants (Vitiello & Jensen, 1995). Academic researchers have relied on either methylphenidate (MPH) or the amphetamines to study response patterns, adverse events, "normalization" during drug treatment, and patient characteristics among nonresponders.

This chapter updates previous reviews of the ADHD medication treatments that work. As with other chapters in this volume, the study classification system based on published evidence will be used to guide the reader, as shown below. This chapter will include (a) a brief historical perspective on ADHD drug treatment studies, using type 5 reviews to highlight conceptual notions driving drug research; (b) an updated description of current psychopharmacological treatments of choice, supported by recently published type 1 RCTs; (c) a perspective on controversies surrounding the safety of ADHD psychopharmacological interventions; and (d) an updated review of current psychopharmacological treatments of choice for children and adolescents with ODD and CD and aggression (sometimes grouped together with ADHD as the "disruptive behavior disorders"). This final section is an addition to the fourth edition of *Treatments That Work*. In a variety of studies done over the past two decades, the prevalence of children diagnosed with ADHD and either ODD or CD has been shown to range from 45% to 85%, averaging about 55% across studies (Barkely, 2006; Pliszka, 2009), making ODD and CD the most common comorbidities associated with ADHD. Notably, children, especially boys, exhibiting both ADHD and aggressive CD appear to be at the highest risk for poor longitudinal outcomes (Mannuzza et al., 1993).

PREVALENCE OF STIMULANT MEDICATION USE IN THE UNITED STATES

Psychostimulant use has increased fivefold since 1989, and this has raised concern at the U.S. Drug Enforcement Administration—which regulates production—about the risk of abuse and diversion. Production of MPH has tripled over a 10-year period, and 90% of U.S.-produced MPH is used in the United States. Increased MPH use could mean increases in ADHD prevalence, a change in the ADHD diagnosis, improved recognition of ADHD by physicians, broadened indications for use, or an increase in drug diversion and prescription for profit or abuse (Goldman et al., 1998). Analysis of managed-care datasets revealed a 2.5-fold increase in prescribing in the 1990–1995 time period, accounted for by longer durations of treatment, inclusion of girls and patients with predominantly inattention subtype, and treatment of high school students (Safer et al., 1996). An epidemiologically based survey in four different communities found that only one eighth of diagnosed ADHD children received adequate stimulant treatment (Jensen et al., 1999b); another survey in rural North Carolina found many school-age children taking stimulants did not meet *DSM-IV* criteria for ADHD (Angold et al., 2000).

According to a study conducted by the National Institute of Health (NIH) and the Agency for Healthcare Research and Quality, the rate of stimulant prescriptions rose slowly but steadily among children under age 19 from 1996 to 2008. Specifically, the rate went from 2.4% in 1996 to 3.5% in 2008. This corresponded to an average growth rate increase of 3.4% per year, substantially less than the growth rate between 1987 and 1996, which averaged about 17% per year. Overall, prescription use among 6-to 12-year-olds was highest, going from 4.2% in 1996 to 5.1% in 2008, but the fastest growth occurred among 13- to 18-year-olds, going from 2.3% in 1996 to 4.9% in 2008. A hypothesis explaining this increase among adolescents may reflect the recent recognition that as children age they do not always grow out of their symptoms (Zuvekas & Vitello, 2012). Prescription use among preschoolers has remained very low at 0.1% from 2004 onward, and this is the only age group with decreased use between 2002 and 2008.

However, more recent U.S. studies of community samples and Centers for Disease Control & Prevention (CDC)-sponsored epidemiologic data

estimate that prevalence rates of ADHD are higher than what is reflected by rates of stimulant prescriptions. Analysis of insurance claims data have documented steady increases in the prevalence of ambulatory visits for ADHD diagnoses between 2001 and 2010 (Garfield et al., 2012; Getahun et al., 2013). The National Comorbidity Survey, a national face-to-face survey of 10,123 children aged 13 to 17 years in the continental United States, suggested that the lifetime prevalence of ADHD among adolescents was 8.7% (Merikangas et al., 2010). The National Health Interview Survey is a large-scale survey of U.S school-aged children (4 to 17 years) that asks parents about clinician-diagnosed illnesses. Parents' reports of a history of ADHD increased from 7.8% in 2003 to 11% in 2011 (approximately 6.4 million children). This represents an increase of 42% in less than a decade. Among those with a history of an ADHD diagnosis, 83% were reported as currently having ADHD (8.8%) (Visser et al., 2014).

Treatment of adults with ADHD has been the fastest area of increase in the use of stimulant medications. Analysis of data from the 1994 to 2009 National Ambulatory Medical Care Survey (number of visits: 372,702) examined the percentage of adult visits (those 18 years and older) in which stimulants were prescribed. Between 1994 and 2009, there was a substantial increase in stimulant prescriptions during adult outpatient visits, especially for younger adults. Namely, the percentage of visits in which stimulants were prescribed increased from 0.11% (1994 to 1997) to 0.70% (2006 to 2009). Among adults aged 18 to 29 years, the corresponding increase in stimulant visits went from 0.17% to 1.83% (Olfson et al., 2013).

DIAGNOSIS OF ADHD

Treatment with stimulants is indicated when there is a diagnosis of ADHD. However, the ADHD diagnosis has been controversial because there are no confirmatory laboratory tests. The diagnosis is further complicated because the criteria have been revised five times over the past thirty years. The most recent criteria appear in the *DSM*-5 (APA, 2013). ADHD covers two symptom domains (inattention and hyperactivity-impulsivity) and is subdivided into predominantly inattentive, predominantly hyperactive-impulsive, and combined subtypes (APA, 2013).

Guidelines for making the ADHD diagnosis in the office practice context have been published by the American Academy of Pediatrics (2011) and the American Academy of Child and Adolescent Psychiatry (AACAP, 2007). Because ADHD is so prevalent, the AACAP recommends that screening for ADHD should be part of any patient's mental health assessment. This can be accomplished by asking questions about inattention, impulsivity, and hyperactivity, and whether such symptoms cause impairment. In addition, prior to interviewing the patient, the clinician may find it helpful to ask parents and teachers to fill out rating scales containing *DSM-5* symptoms of ADHD. Useful rating scales include the Vanderbilt ADHD Diagnostic Parent Scale (VADPRS), the Vanderbilt ADHD Diagnostic Teacher Rating Scale (VADTRS), the Conners' Parent Rating Scale-Revised, the Conners' Teacher Rating Scale-Revised, and the Swanson, Nolan, and Pelham Rating Scale, Version IV (SNAP-IV). A positive screen on a rating scale, however, does not make a definitive diagnosis of ADHD.

The diagnosis of ADHD must be established by history taken from multiple informants, including the child, the parents, and the teacher. The clinician should address each of the five major *DSM-5* criteria, including age of onset (before age twelve), requirement for impairment in a minimum of two settings, six-month duration of symptoms, and a differential diagnosis ruling out other diagnostic conditions that can cause a patient to experience inattention, hyperactivity, or impulsivity. The confirmation depends on specific symptom criteria encompassing the type, duration, severity, and frequency of ADHD problems. A comorbid diagnosis of autism spectrum disorder is no longer exclusionary of an ADHD diagnosis. The patient must experience at least six out of nine ADHD symptoms in either or both inattention and hyperactivity-impulsivity symptom lists, giving positive endorsement only if the symptom occurs often (at least half of the time). The symptoms must start in childhood, prior to age twelve, and have a chronic course.

A physical examination and medical history should be carried out during the diagnostic evaluation. If the medical examination and history are unremarkable, no additional laboratory or neurological testing is required (AACAP, 2007). Similarly, no routine psychological testing is needed for the diagnosis of ADHD, but it should be performed if "the

patient's history suggests low general cognitive ability or low achievement in language or mathematics relative to the patient's intellectual ability," beyond that accounted for by the ADHD symptoms themselves (AACAP, 2007).

The next diagnostic procedure includes an interview of the child or adolescent to determine whether other psychiatric disorders are present that account for the impairment. Whereas it is helpful to interview a preschool or school-age child with the parent present, older children and adolescents should be interviewed alone because they are more likely to discuss symptoms of substance use, suicidal ideation or behavior, or depression with the parent absent. Because ADHD behaviors in youth are often attenuated during the first few visits with a clinician, direct observations of the child's behaviors in the office cannot be used to confirm or deny the diagnosis of ADHD.

Since a majority of children with ADHD also suffer from at least one other Axis I psychiatric disorder (Biederman et al., 1991), the clinician should ask about symptoms of ODD, CD, depression, anxiety disorders, tic disorders, substance use disorders, ASD, and mania. Symptoms of these disorders are captured by parent symptom checklists (e.g., Achenbach Child Behavior Check List) and rating scales (e.g., SNAP-IV). In addition, the clinician should obtain information about the family history and the patient's prenatal history, developmental milestones, and medical history.

HISTORICAL PERSPECTIVE

In 1937, Bradley, looking for a new treatment for headaches, serendipitously observed that disturbed children and adolescents responded to Benzedrine, a racemic form of amphetamine. This treatment had a dramatic calming effect, while simultaneously producing an increase in academic productivity and a "zest for work." Bradley published other type 6 studies reporting the improvement of children during amphetamine treatment (Bradley, 1937; Bradley & Bowen, 1941). The earliest investigations of these drugs suggested that psychostimulants operated by stabilizing cortical circuits, as shown by their ability to increase the seizure threshold (Laufer, Denhoff, & Solomon, 1957). These medications also decreased oppositional behavior in boys with CD attending a residential school (Eisenberg et al., 1961) and reliably reduced the target symptoms of ADHD as measured by parents and teachers (Conners, Eisenberg, & Barcai, 1967). However, these early protocols lacked uniform diagnostic criteria, reliability measures, and multiple observers, so they must be judged type 2 studies. Since then, more carefully designed, placebo-controlled studies have demonstrated that both amphetamine- and MPH-based compounds produce statistically significant and clinically meaningful reductions in ADHD symptoms within one hour of taking an effective dose. Starting in 1977 (Barkley, 1977), a series of type 5 literature reviews summarized these studies. Wilens and Biederman's (1992) MEDLINE search retrieved more than 990 psychostimulant treatment studies published between 1982 and 1991. Further verification appeared in a type 4 meta-analysis (Swanson, 1993) that analyzed the reviews, concluding that the most marked effects of stimulants can be observed on teacher measures of classroom behavior (with effect sizes ranging from 0.63 to 0.85) and that lesser effect sizes (in the range of 0.19 to 0.47) can be identified on measures of intelligence or academic achievement. The effect sizes observed on teacher ratings would satisfy rigorous phase III, premarketing, investigational new drug applications to the FDA.

The psychostimulants MPH and dextroamphetamine (DEX) produced significant reductions in task-irrelevant activity and classroom disturbance (Barkley, 1977; Jacobvitz, Sroufe, Stewart, & Leffert, 1990), with robust responses occurring in 65% to 75% of the 4,777 ADHD subjects treated (Wilens & Biederman, 1992). This review included 4 preschool, 96 school-age, 6 adolescent, and 6 adult controlled studies. More recent type 4 meta-analyses verified these findings and included "A Review of Therapies for Attention Deficit Hyperactivity Disorder" by the Canadian Coordinating Office for Health Technology Assessment (Pelham, Hoffman, Lock, & SUNY CONCERTA Study Group, 2000), "The Treatment of Attention Deficit Hyperactivity Disorder: An Evidence Report," contracted to the McMaster University Evidence-Based Practice Center by the Agency for Health Care Research and Quality (1998), and others (Campbell & Ewing, 1990; Leech, Richardson, Goldschmidt, & Day, 1999).

The large type 5 reviews touch on diverse types of responses to stimulants, including the best methods of determining the optimal stimulant dose to reduce ADHD behaviors (Barkley, 1977, 1982; DuPaul &

Barkley, 1990), the mechanisms of action (Solanto, 1984), whether stimulant response is diagnostically specific (Gittelman, 1980), and the ability of these medications to enhance other therapies (Gittelman, 1987). In addition, dosing methods, paradoxical stimulant effects, and whether stimulants improve academic performance (DuPaul & Barkley, 1990; Jacobvitz et al., 1990) are addressed.

Dosing methods and dose-response issues were considered in the seminal paper by Sprague and Sleator (1977), which reported dissociation of cognitive and behavioral MPH responses in ADHD children. Using weight-adjusted doses, they found that children responded optimally to a memory task at a low dose (0.3 mg/kg) but required higher doses (1.0 mg/kg) to attain optimal behavioral control in the classroom. This paper established the customary weight-adjusted MPH dosing standard that would permeate the ADHD drug-treatment literature until the present and also raised the question whether MPH doses optimized for behavior might not be best for learning.

Reviews of pre-1990 drug studies (Jacobvitz et al., 1990; Wilens & Biederman, 1992) concluded that there was no diagnostically specific positive response to stimulants for ADHD children. No differences in response were found between stimulant-treated ADHD children, stimulant-treated normal children, or clinically referred non-ADHD children (Rapport et al., 1980). Also rejected was the notion that ADHD children show a "paradoxical" slowdown response to stimulants. Rather, the literature shows a decrease in aimless activity, an increase in attention, and an elevation in heart rate and blood pressure in all groups of children, regardless of diagnosis.

These reviews also grappled with the question of whether stimulants, so successful in short-term trials, lead to long-term improvements. ADHD follow-up studies (Barkley, Fischer, Edelbrock, & Smallish, 1990; Mannuzza, Klein, Bessler, Malloy, & LaPadula, 1993; Weiss & Hechtman, 1993) have demonstrated that ADHD core symptoms continue into late adolescence and even into adult life. No stimulant benefit has been shown to persist when children are treated over the years, as indicated in the 2-year posttreatment follow-up reports of the National Institute of Mental Health (NIMH) MTA Study (Jensen, Arnold, Severe, Vitiello, & Hoagwood, 2004). Although ADHD symptom reduction was greatest in the two stimulant-treated groups at the end of the 14-month treatment, both medication- and non–medication-treated groups had equal but limited benefit at 24 and 36 months after randomization. Although evidence for short-term gains in arithmetic performance exists (Pelham, Bender, Caddell, Booth, & Moorer, 1985), other evidence (Charles, Schain, & Guthrie, 1979) points to a lack of differences in long-term academic achievement between treated and untreated ADHD children.

Despite the breadth and depth of the stimulant treatment literature showing robust evidence of an acute powerful "treatment that works," most long-term studies continue to present stiff challenges. Randomization cannot be maintained over years, so that selection biases confound the interpretation of the results from long-term follow-up programs. Observations lasting years lose random assignment, fail to maintain checks on treatment adherence, and experience high attrition rates. Studies continue to use global improvement rather than objective measures of ADHD symptoms to optimize individual medication doses. No mention is made of whether the time of dosing is controlled. The majority of drug studies covered by reviews lasted 6 weeks or less, too brief to generalize to typical medication treatments, which average 3 years. Since no common definition of a categorical treatment responder has been established, it has been difficult to interpret meta-analytic research looking across studies for identical response patterns in children.

LARGE RANDOMIZED CONTROLLED TRIALS OF STIMULANT MEDICATION

Generalizability and statistical power were limited in earlier ADHD treatment studies because they were conducted at one site, often with a clinical population with local characteristics. A new era in ADHD treatment studies was ushered in during the early 1990s, when clinical trial science was applied to the ADHD field. First NIMH, and then the pharmaceutical industry, began to employ multisite clinical trial designs to determine the safety and efficacy of stimulants. This allowed investigators to recruit subjects from several performance sites to obtain the sample size needed to make estimates of the efficacy of the drug. Extending the duration of stimulant drug exposure became a key design goal in these large multisite clinical trials. Up to 1995, only 22 published stimulant

studies lasted longer than three weeks (Schachar & Tannock, 1993). The few long-duration stimulant studies published before the 1990s had been constrained by their retrospective methods, lack of standard outcome measures, restrictive inclusion criteria that rejected patients with comorbid disorders, irregular prescribing patterns (Sherman, 1991), and lack of compliance measures (Richters et al., 1995).

The MTA Study was designed to address most of the shortcomings of the pre-1990 ADHD treatment trials. It established a standard in RCT sample size, diagnostic rigor, quality control, use of standardized measures, parallel design, and randomization that the large pharmaceutical stimulant trials followed beginning in the late 1990s. The MTA Study recruited almost 600 children with ADHD from seven performance sites in the United States and Canada using uniform diagnostic criteria, randomized these subjects to different treatments, and then maintained them for 14 months on those treatments, employing intent-to-treat methods not previously used for this population. The study goal was to compare the relative effectiveness of four randomly assigned 14-month treatments: algorithmic medication management (MedMgt), behavioral treatment (Beh), combination of MedMgt and Beh (Comb), and community comparison group (CC) receiving treatment as usual (Arnold et al., 1997). The study questions included the following: (a) Do Beh and MedMgt treatments result in comparable levels of improvement over time? (b) Do participants assigned to Comb show greater improvement over time than those assigned to either MedMgt or to Beh? and (c) Do participants assigned to any of the three MTA intensive treatments show greater improvement over time than those assigned to treatment as usual in the community (CC)? Assessment points for measured outcomes were evaluated in multiple domains before, during, and at the end of treatment (with Comb and MedMgt subjects on medication at time of assessment).

Children randomized to medication management alone (MedMgt, $N = 144$) or to combined treatment (Comb, $N = 145$) began treatment with a 28-day, double-blind, placebo-controlled titration to identify each child's optimal MPH dose. Due to its 3- to 4-hour duration of action, immediate-release MPH (IR-MPH) and placebo were administered three times daily (Greenhill et al., 1996, 2001a). Medication conditions were switched daily to reduce error variance. Parents and teachers rated ADHD symptoms and impairment daily. During titration, a repeated-measures ANOVA revealed a main effect of MPH/placebo dose with greater effects on teachers' ratings ($F(3) = 100.6$, $N = 223$, $p = .0001$; effect sizes 0.8 to 1.3) than on parents' ratings ($F(3) = 55.61$, $N = 253$, $p = .00001$; effect sizes 0.4 to 0.6). Dose did not interact with between-subjects factors (period, dose order, comorbid diagnosis, site, or treatment group). Drug-related adverse events were reported more often by parents than by teachers, who rated irritability highest on placebo. The distribution of the best MPH starting doses determined during titration (10 to 50 mg/day), response rate (77%), and adverse event profile across six sites and multiple subgroups suggest that MPH titration in office practice should explore MPH's full dosage range in 7- to 10-year-old children over 25 kg in weight. Parent weekend symptom ratings showed daytime drug effects, but not as clearly as weekday after-school ratings. Nonresponders to MPH were older, had less severe symptoms, and were medication naïve.

Data were analyzed through intent-to-treat random-effects regression. All four groups at 14 months (end of the active treatment period) showed sizable reductions in symptoms over time, with significant differences among them in degrees of change. For ADHD symptoms, children in the combined and medication management groups showed significantly greater improvement than those given intensive behavioral treatment or community care. However, combined and medication management treatments did not differ significantly for ADHD symptoms. As measured by teacher-rated social skills, parent–child relations, and reading achievement, combined treatment proved significantly better than other treatments in reducing symptom scores for internalizing symptoms. The MTA Study medication strategies were superior to treatment as usual in the community, despite the fact that two thirds of community-treated subjects received medication during the study period. The combined treatment did not yield significantly greater benefits than medication management for core ADHD symptoms, but it may have provided modest additional advantages for non-ADHD-symptom and positive functioning outcomes.

The MTA is the largest and most methodologically sophisticated randomized multisite pediatric ADHD treatment study to date that includes monomodal and combined treatments. These therapeutic methods had been previously shown effective in

simpler two-arm (active vs. placebo) controlled studies (Pelham, 1989; Pelham & Murphy, 1986). Due to its size, the MTA Study was able to address comparative treatment questions. It concluded that stimulant medication efficacy can be realized across diverse settings and patient groups, is more effective than behavioral modification for core ADHD symptoms and can be maintained during chronic therapy lasting more than a year.

The MTA replicated findings from smaller long-duration stimulant trials—the 102-child New York/Montreal Study (Klein, Abikoff, Hechtman, & Weiss, 2004), the 91-child Toronto study (Schachar, Tannock, Cunningham, & Corkum, 1997), and the 62-child Gillberg (Gillberg et al., 1997) study. Collectively, these smaller multisite studies show a persistence of medication effects over time. Within-subject effect sizes reported 12 to 24 months following the MPH treatment resembled those previously reported in short-duration studies (Elia, Borcherding, Rapoport, & Keysor, 1991; Thurber & Walker, 1983). Domain of greatest improvement differed among studies, with one (Gillberg et al., 1997) showing greater effects at home and another (Schachar et al., 1997) showing greater effects at school. The total mean MPH daily dose reported by the three long-duration studies ranged between 33 and 37.5 mg. The one DEX study that examined the effects of different doses reported a mean dose half of this level, agreeing with the general ratio of DEX to MPH doses. Persistent stimulant drug side effects and assignment to placebo treatment were associated with dropout. Fortunately, the attrition rate from placebo assignment was low, allowing ample time for standard 8-week efficacy trials to be conducted.

Long-term follow-up data from the MTA are not as promising. A 2007 study that followed children who had participated in the MTA Study found that 3 years after the trial began the initial advantages of medication management alone or in combination with behavioral treatment over purely behavioral or routine community care had waned after 14 months of controlled treatment had ended (Jensen et al., 2007a). Additional follow-up studies reporting key outcomes at 6 and 8 years demonstrated that despite overall maintenance of improvement in functioning relative to baseline (pretreatment), the MTA group as a whole was functioning significantly less well than the non-ADHD classmate sample recruited at 24 months (Molina et al., 2009). As the authors suggested, these findings provide evidence that the differential effects of the ADHD treatments, evident when the interventions were delivered, attenuated when the intensity of treatment was relaxed.

CURRENT PSYCHOPHARMACOLOGICAL AGENTS' EFFICACY AND UTILITY

Two groups of stimulants are currently approved by the FDA for ADHD treatment in children. These are available in both brand and generic, and in immediate-release (short-duration) and long-duration formulations: the amphetamines (Adderall, Dexedrine, Vyvanse) and the methylphenidates (Concerta, Metadate ER, Metadate CD, Methylin ER, Ritalin, Ritalin SR, Ritalin LA, Focalin, Daytrana Patch, Quillivant XR). Characteristics of these stimulants can be found in Table 4.1. DEX and MPH are structurally related to the catecholamines (dopamine [DA] and norepinephrine [NE]). The term *psychostimulant* used for these compounds refers to their ability to increase central nervous system activity in some but not all brain regions.

Compared with placebo, psychostimulants have a significantly greater ability to reduce ADHD symptoms, such as overactivity (e.g., fidgetiness and off-task behavior during direct observation), and to eliminate behavior that causes disruptions in the classroom (e.g., constant requests of the teacher during direct observation; Jacobvitz et al., 1990). In experimental settings, stimulants have been shown to improve child behavior during parent–child interactions (Barkley & Cunningham, 1979) and problem-solving activities with peers (Whalen et al., 1989). The behavior of children with ADHD has a tendency to elicit negative, directive, and controlling behavior from parents and peers (Campbell, 1973). When these children are placed on stimulants, their mothers' rate of disapproval, commands, and control diminishes to the extent seen in mothers' of non-ADHD children (Barkley & Cunningham, 1979; Barkley et al., 1984; Humphries, Kinsbourne, & Swanson, 1978). In the laboratory, stimulant-treated ADHD children demonstrate major improvements during experimenter-paced continuous performance tests (Halperin, Matier, Bedi, Sharma, & Newcorn, 1992), paired-associate learning, cued and free

TABLE 4.1 Stimulant Drugs with FDA Indication for ADHD

Medication (Brand Name)	*Available Dose of Preparation*	*Starting Dose/Maximum Dose*	*Indicated Age (Years) for Psychiatric Use*	*Duration of Action (hours)*
Methylphenidate (MPH)				
Short Acting				
Methylphenidate HCl (*Ritalin*)	5-, 10-, 20-mg tabs	2.5 mg b.i.d./30 mg/day	6+	3–5
Methylphenidate HCl Chewable Tabs (*Methylin*)	2.5-, 5-, 10-mg tabs	2.5 mg b.i.d./30 mg/day	6+	3–5
Methylphenidate HCl Solution (*Methylin solution*)	5 mg/5 mL, 10 mg/5 mL	2.5 mg b.i.d./30 mg/day	6+	3–5
Dexmethylphenidate HCl (*Focalin*)	2.5-, 5-, 10-mg tabs	2.5 mg b.i.d./20 mg/day	6+	5–6
Intermediate Acting				
Methylphenidate HCl Extended-Release (*Metadate ER*)†	10-, 20-mg tabs	10 mg AM/60 mg/day	6+	4–8
Methylphenidate HCl Extended-Release (*Methylin ER*)†	10-, 20-mg tabs	10 mg AM/60 mg/day	6+	4–8
Methylphenidate HCl Extended-Release (*Ritalin SR*)†	20-mg tabs	20 mg AM/60 mg/day	6+	4–8
Long Acting				
Methylphenidate HCl Extended-Release (*Ritalin LA*)‡	10-, 20-, 30-, 40-mg caps	10 mg AM/60 mg/day	6+	6–8
Methylphenidate HCl Extended-Release (*Metadate CD*)‡	10-, 20-, 30-, 40-, 50-, 60-mg tabs	10 mg AM/60 mg/day	6+	6–8
Methylphenidate HCl Extended-Release (*Concerta*)†	18-, 27-, 36-, 54-mg tabs	18 mg AM/54 mg/day or 72 mg/day in children 12+	6+	10–12
Dexmethylphenidate beaded (*Focalin XR*)‡*	5-, 10-, 15-, 20-, 25-, 30-, 35-, 40-mg caps	5 mg AM/30 mg/day	6+	8–12
Methylphenidate Extended-Release Solution (*Quillivant XR*)	25 mg/5 mL	20 mg AM/60 mg/day	6+	8–12
Methylphenidate Transdermal Patch (*Daytrana*)	12.5 cm^2 (10 mg), 18.75 cm^2 (15 mg), 25 cm^2 (20 mg), 37.5 cm^2 (30 mg)	10 mg AM/9 hrs. (off 15 hrs)/ 30 mg/day	6+	10–12 *Note*: Apply 2 hrs. before desired effect; drug effects may persist up to 5 hrs after patch removal

Amphetamines				
Short Acting				
Mixed Amphetamine Salts (*Adderall*)	5-, 7.5-, 10-, 12.5-, 15-, 20-, 30-mg tabs	2.5 mg b.i.d./40 mg/day	3+	4–6
Dextroamphetamine Sulfate (*Dexedrine*)	5-, 10-mg tabs	2.5 mg b.i.d./40 mg/day	3+	4–6
Dextroamphetamine Sulfate Liquid (*ProCentra*)	5 mg/5 mL	2.5 mg b.i.d./40 mg/day	3+	4–6
Methamphetamine (*Desoxyn*)	5-mg tabs	5 mg b.i.d./25 mg/day	6+	4–6
Intermediate Acting				
Dextroamphetamine Sulfate (*Dexadrine Spansule*)	5-, 10-, 15-mg caps	5 mg AM/40 mg/day	3+	6–8
Long Acting				
Mixed Amphetamine Salts Long Acting (*Adderall XR*)[‡*]	5-, 10-, 15-, 20-, 25-, 30-mg caps	5 mg AM/30 mg/day or 40mg/day in children 12+	6+	8–10
Lisdexamfetamine (*Vyvanse*)[¥*]	20-, 30-, 40-, 50-, 60-, 70-mg caps	30 mg AM/70 mg/day	6+	Up to 12

Safety—Black box warning: All stimulants have increased risk of abuse

Safety—General warnings and precautions (Non-black box): All stimulants have increased risk of the following

- Serious Cardiovascular Events
- Increase in Blood Pressure
- Psychiatric Adverse Events
- Seizures
- Visual Disturbance
- Tics
- Long-Term Suppression of Growth

[†] Must be swallowed (not crushed or chewed)

[‡] Capsule can be opened and medication sprinkled on applesauce

[¥] Can be dissolved in liquid

[*] FDA approved for treating adult ADHD

recall, auditory and reading comprehension, spelling recall, and arithmetic computation (Pelham & Bender, 1982; Stephens, Pelham, & Skinner, 1984). Some studies show correlations between plasma levels of MPH and performance on a laboratory task (Greenhill, 1995), but plasma levels rarely correlate with clinical response. Likewise, hyperactive conduct-disordered children and preadolescents observed in structured and unstructured school settings show reductions in aggressive behavior when treated with stimulants (Hinshaw, 1991). Stimulants can also reduce the display of covert antisocial behaviors such as stealing and property destruction (Hinshaw, Heller, & McHale, 1992).

Psychostimulants are thought to block the reuptake of dopamine and norepinephrine into the presynaptic neuron in the central nervous system and increase the concentration of these neurotransmitters in the interneuronal space. Changes in a single neurotransmitter that regulate an ADHD child's under- or over-aroused central nervous system have been discounted (Solanto, 1984; Zametkin & Rapoport, 1987). A two-part theory of stimulant action has been postulated (McCracken, 1991) in which stimulants increase DA release, producing enhanced autoreceptor-mediated inhibition of ascending DA neurons, while simultaneously increasing adrenergic-mediated inhibition of the noradrenergic-locus coeruleus via epinephrine activity. This theory awaits confirmation from basic research in animals and imaging studies in humans.

One of the most important findings in the stimulant treatment literature is the high degree of short-term efficacy for behavioral targets, with weaker effects for cognition and learning. Conners (personal communication, 1993) notes that 0.8, 1.0, and 0.9 effect sizes are reported for behavioral improvements in type 4 meta-analytic reviews of stimulant drug actions (Kavale, 1982; Ottenbacher & Cooper, 1983; Thurber & Walker, 1983). These behavioral responses to stimulant treatment, when compared with placebo, resemble the treatment efficacy of antibiotics. Less powerful effects are found in laboratory measures of cognitive changes, in particular on the continuous performance task, for which effect sizes of these medications range between 0.6 and 0.5 for omissions and commissions, respectively, in a within-subject design (Milich, Licht, Murphy, & Pelham, 1989) and 0.6 and 1.8 in a between-subject study (Schechter & Keuezer, 1985).

Psychostimulants have continued to show behavioral efficacy in the type 1 RCTs published over the past 10 years (Table 4.2). These modern-day controlled trials have matured with the field and now use multiple-dose conditions with multiple stimulants (Newcorn et al., 2008), parallel designs (Spencer et al., 1995), and normalization as a common definition of response (Abikoff & Gittelman, 1985; Rapport, Denney, DuPaul, & Gardner, 1994). These studies assess psychostimulant use in special ADHD populations, including adolescents (Klorman et al., 1990), adults (Spencer et al., 1995), children with intellectual disabilities (Horn et al., 1991), and subjects with comorbid anxiety disorders and other internalizing disorders and with tic disorders (Gadow, Sverd, Sprafkin, Nolan, & Ezor, 1995). As shown in Table 4.2, 70% of ADHD subjects respond to stimulants and less than 13% respond to placebo (Greenhill et al., 2001b).

Studies have also attempted to learn more about stimulant nonresponders. Some drug trials (Douglas, Barr, Amin, O'Neill, & Britton, 1988) report a 100% response rate in small samples in which multiple MPH doses are used. Others find that a trial involving two stimulants effectively lowers the nonresponse rate. Elia and colleagues (1991) reduced the 32% nonresponse rate to a single psychostimulant to less than 4% when members of both stimulant classes, DEX and MPH, were titrated sequentially in the same subject. However, the rate of medication nonresponse might be higher if children with comorbidity are included in the sample. Finally, a few studies have used the double-blind or single-blind placebo discontinuation models to determine whether the child continues to respond to stimulants after being treated for 1 year or more. One study found that 80% of ADHD children relapsed when switched single blind from MPH to a placebo after 8 months of treatment (H. Abikoff, personal communication, 1994). Even so, these observations about the "rare nonresponder" do not address the rate of placebo response. Few, if any, of the current RCTs are parallel designs, which can evaluate whether placebo response emerges at some point over the entire drug trial. Few treatment studies prescreen for placebo responders, so the numbers of actual medication responders in any sample of ADHD children might be closer to 55%, not the 75% to 96% often quoted. Furthermore, these estimates apply to group effects and do not inform the clinician about the individual patient.

TABLE 4.2 Controlled Studies Showing Stimulant Efficacy in ADHD Drug Treatments (N = 2,234)

Study (Year)	*N*	*Age Range (Years)*	*Design*	*Drug (dose)*	*Duration*	*Response*	*Comment*
Abikoff & Gittleman (1985)	28	6–12	ADHD vs. normal controls	MPH (41 mg/day) PB	8 weeks	80.9%	ADHD children normalized
Abikoff et al. (2004)	103	7–9	ADHD	MPH (33.7 mg) t.i.d.	2 years	100%; SD 2.7	No advantage to combination treatment
Barkley et al. (1989)	74	6–13	X-over (37 agg & 37 non agg)	MPH (0.3, 0.5) PB	4 weeks	80%	Agg responsive to MPH
Barkley et al. (1991)	40	6–12	X-over (23 ADHD & 17 ADHD-W)	MPH (5, 10, 15 mg b.i.d.) PB b.i.d.	6 weeks	ADHD 95%; ADHD-W 76%	Fewer children with ADHD-W respond, need low dose
Biederman et al. (2007b)	290	6—2	Parallel	LDX (30, 50, or 70 mg/day) PB	4 weeks	Effect size > 1.2 for all dose ranges	Greatest effect size seen in the 70-mg group
Castellanos et al. (1997)	20	6–13	X-over (Pts. with ADHD + Tourette's)	MPH (45 mg bid) DEX (22.5 mg bid)	9 weeks	ADHD + TS	Emergence of tics was dose-related.
Douglas et al. (1988)	19	7–13	X-over	MPH (0.15, 0.3, 0.6) PB	2 weeks	100%	Linear D/R relationships
Douglas et al. (1995)	17	6–11	X-over	MPH (0.3, 0.6, 0.9) PB	4 weeks	Behavior 70%	No cognitive toxicity at high doses, linear D/R curves
DuPaul & Rapport (1993)	56	6–12	X-over 31 ADHD, 25 normal	MPH (20 mg/day) PB bid	6 weeks	Behavior 78%, attention 61%	MPH can normalize classroom beh; 25% of ADHD subjects did not normalize academics
DuPaul et al. (1994)	40	6–12	X-over 12 high anxiety 17 mid anxiety 11 low anxiety	MPH (5, 10, 15 mg/day); PB single dose	6 weeks	High 68% Nortriptyline Mid 70% Nortriptyline Low 82% Nortriptyline	25% of internalizing group deteriorated ADHD meds
Elia et al. (1991)	48	6–12	X-over	MPH (0.5, 0.8, 1.5) DEX (0.25, 0.5, 0.75) PB bid	6 weeks	MPH 79% DEX 86%	Response rate for two stimulants: 96%

(*continued*)

TABLE 4.2 (continued)

Study (Year)	N	Age Range (Years)	Design	Drug (dose)	Duration	Response	Comment
Gadow et al. (1995)	34	6–12	ADHD + tic disorder	MPH (0.1, 0.3, 0.5) PB bid	8 weeks	MPH 100%	No responders to beh; MD's motor tic ratings show 2 min. increases on drug; only shows effects of 8 wks. of txt
Gillberg et al. (1997)	62	6–12	Parallel	MAS (17 mg) PB b.i.d.	60 weeks	70%; 27-40% improve	No dropouts but only 25% PB group at 15-mo assessment
Greenhill et al. (2001)	277	6–12	Parallel	Long-acting MPH (Metadate CD) PB	3 weeks	70%	Mean total dose: 40 mg/day; FDA registration
Greenhill et al (2002)	321	6–12	Parallel	MPH-MR (*Metadate-ER*) (20, 60 mg/day) PB tid	3 weeks	MPH-MR 64%; PB 27%	Mean MPH-MR daily dose = 40.7 mg (1.28 mg/kg per day)
Greenhill et al. Preschool ADHD Treatment Study (PATS) (2006a)	165	3–5.5	X-over	IR-MPH (1.25, 2.5, 5, 7.5 mg t.i.d.); PB t.i.d.	70 weeks	88%	Optimal IR-MPH dose = 14.22 ± 8.1 mg/day (0.7 + 0.4 mg/kg per day); treatment effect sizes < than in school-age children
Greenhill et al. (2006b)	165	6–17	Parallel	d-MPH-ER (*Focalin LA*) (5–30 mg/day) PB qday	7 weeks	d-MPH-ER 67.3%; PB 13.3%	Mean d-MPH-ER daily dose = 24 mg
Klein et al. (1997)	84	12–18	Parallel	MPH (1.0) b.i.d.	5 weeks	MPH 9–78% PB 9–29%	MPH reduced ratings of antisocial beh
Klorman et al. (1990)	48	6–15	X-over	MPH (0.26) PB t.i.d.	6 weeks	MPH 60%	Fewer med benefits in adolescents
McGough et al. (2006)	97	6–17	X-over	MPH transdermal system on 9 hrs/day (12.5, 18.75, 25, 37.5 cm^2); PB	2 weeks	79.8%	MPH transdermal system is well tolerated and significantly more efficacious than PB
MTA Cooperative Group (1999)	579	7–9	Parallel	MPH (<0.8) t.i.d.	4 weeks (14 months)	MPH 77% DEX 10% None 13%	Titration trial for multisite multimodal study; full study data for 288 on 38.7 mg MPH
Musten et al. (1997)	31	4–6	X-over	MPH (0.3, 0.5) PB b.i.d.	3 weeks	MPH > NA	MPH improves attention in preschoolers
Pelham et al. (1990)	22	8–13	X-over	MPH 10 mg b.i.d.; PB b.i.d.; DEX spansule 10 mg; PEM 56.25 qd	24 days	Stim 68%	DEX span, PEM best for beh 27% did best on DEX; 18% on SR; 18% on PEM; 5% on MPH id.

Pelham et al. (1995)	28		X-over	PEM (18.75, 37.5, 75, 112.5 mg); PB qd	7 weeks	PEM 89%; PB 0%	PEM dose ≥ 37.5 mg/d lasts 2–7 hrs; efficacy and time course = MPH
Rapport et al. (1988)	22	6–10	X-over	MPH (5, 10, 15 mg) PB	5 weeks	72%	MPH response same in home and school
Rapport et al. (1994)	76	6–12	X-over	MPH (5, 10, 15, 20 mg) PB	5 weeks	94% behavioral; 53% attention	MPH normalizes beh> academics; higher doses better, linear D/R curve
Schachar et al. (1997)	91	6–12	Parallel	MPH (33.5 mg) PB b.i.d.	52 weeks	0.7 SD effect size	15% side effects: affective, over-focusing led to dropouts
Spencer et al. (1995)	23	18–60	X-over	MPH (1.0 mg/kg/day)	7 weeks	MPH 78% PB 4%	MPH at 1 mg/kg per day produces improvement in adults equivalent to that seen in children
Swanson et al. (1998)	29	7–14	X-over	MAS (5, 10, 15, 20); MPH; PB	7 weeks	100%	Adderall peaks at 3 hrs; MPH at 1.5 hrs
Tannock et al. (1995a)	40	6–12	X-over 17 ADHD-ANX	MPH (0.3, 0.6)	2 weeks	70%	Activity level better in both groups; working memory not improved in anxious kids
Tannock et al. (1995b)	28	6–12	X-over	MPH (0.3, 0.6); PB	2 weeks	70%	Effects on behavior D/R curve linear, but effects on response inhibition U-shaped suggest adjustment dose on objective measures
Taylor et al. (1987)	38	6–10	X-over	MPH (0.2–1.4); PB	6 weeks	58%	Severe ADHD symptom, better response
Whalen et al. (1989)	25	6.3–12	X-over	MPH (0.3,0.5)	5 weeks	48–72%	MPH helps, not normalizes, peer status
Wigal et al. (2004)	132	6–17	Parallel	d-MPH; d,l-MPH; PB b.i.d.	4 weeks	d-MPH 67%; d,l-MPH 49%	Average d-MPH dose (18.25 mg) is as safe and effective as half of the average d,l-MPH dose (32.14 mg)
Wilens et al. (2006)	177	13–18	Parallel	OROS-MPH (18, 36, 72 mg qd); PB	2 weeks	OROS-MPH 52%: PB 31%	OROS-MPH is well tolerated and effective in adolescents at up to 72 mg daily dose
Wolraich et al. (2001)	277	6–12	Parallel	OROS MPH (36 mg); MPH t.i.d.; PB	4 weeks	62%	Concerta rated effective by teachers and parents

Doses listed as mg/kg per dose, and medication is given twice daily unless otherwise stated.

PB, placebo; X-over, crossover design; ANX, anxiety; MPH, methylphenidate; DEX, dextroamphetamine; PEM, pemoline; MAS, mixed amphetamine salts (*Adderall*); mg/kg per day, dosage in mg/kg per day; Agg, aggression; ADHD-W, ADD without hyperactivity; beh, behavior; att, attention; FDA, Food and Drug Administration; D/R curve, dose-response curve.

USE OF PSYCHOSTIMULANTS IN CHILDREN YOUNGER THAN 6 YEARS

The signs and symptoms of ADHD, such as particularly pronounced motor activity, excessive climbing, aggressivity, and destructiveness, may be evident before age three. These signs can disrupt family life and make nursery school attendance difficult. Campbell found that many hyperactive preschoolers did not "grow out of" this behavior but maintained their hyperkinesis in grade school (Campbell et al., 1977). More recently, Lahey and his colleagues conducted an 8-year follow-up study in 118 children, aged 4 to 6 years, who initially met *DSM-IV* criteria for ADHD. The study found that 81% of children with ADHD combined type and 73.9% of those with predominantly hyperactive subtype continued to meet criteria for any ADHD subtype, (Lahey et al., 2005). Follow-up of the NIMH Preschool ADHD Treatment Study (PATS) sample of children ages 3 to 5 some 6 years later confirmed the long-term stability of the ADHD diagnosis beginning in the preschool phase of development (Riddle et al., 2013). Even though these early ADHD symptoms resemble the behaviors among older ADHD patients, the diagnostic manuals give little guidance about how to determine the validity of the ADHD diagnosis in the preschool years. School-age norms gathered on standard teacher global rating forms, such as the Conners Teacher Questionnaire, have not included preschoolers in the past (Conners, personal communication).

Until recently, there were only a handful of small, single-site, published studies addressing stimulant treatment in preschoolers. For the amphetamines, there is only one single-case intensive study suggesting that DEX reduces temper outbursts in a toddler (Speltz et al., 1988). MPH treatment studies have found that the drug ameliorates mother–child interactions (Barkley, 1988) in a linear dose-response fashion, perhaps related to increasing child compliance and decreased symptomatic intensity. No pharmacokinetic studies have been done in this age group to determine whether younger children metabolize psychostimulants differently than older children.

A comprehensive review of preschool stimulant treatment studies (Connor, 2002) identified nine controlled studies ($N = 206$) of stimulants in children under the age of 6 (Barkley, 1988; Barkley et al., 1984; Conners, 1975; Handen et al., 1999; Mayes et al., 1994; Musten et al., 1997; Schleifer et al., 1975). MPH doses ranged from 2.5 to 30 mg/day (0.15 to 1.0 mg/kg per day). Most of the studies showed MPH efficacy at weight-adjusted doses comparable to those reported for older school-age children, producing improvements in structured situations but not in free play (Schleifer et al., 1975). These studies, particularly if they involved preschoolers with developmental delays, suggested that stimulants may produce higher rates of side effects, including tearfulness and irritability, than would be expected in school-age children (Handen et al., 1999). This suggests that preschoolers with ADHD should be started on low MPH doses.

Interpretations of these early data are difficult because of methodologic differences among the nine studies, which used very different inclusion/exclusion criteria, diagnostic definitions, ratings forms, and study designs, thus making a meta-analysis impossible. Unlike the increased rate of stimulant use in adolescents, and the relatively stable use among 6- to 12-year-olds, the rate of stimulant prescriptions written for preschool children declined between 1996 and 2008 (Zuvekas et al., 2012).

To address the lack of methodologically sound data on the safety and efficacy of MPH in preschool ADHD children, the NIMH launched a six-performance-site, randomized, placebo-controlled trial of MPH, the PATS. This study recruited 303 children (3 to 5 years old); 279 of their parents were entered into a 10-week course of behavior modification training. For one third of these children, ADHD symptoms improved so dramatically with behavior therapy alone that they did not progress to the medication phase of the study. Of the children who did not respond to parent training, 183 families agreed to enter the PATS medication protocol. Of these, 165 families were randomized into a double-blind, placebo-controlled, crossover design dose-optimization study that began with a 1-week, open, stepwise safety phase exposing all the preschoolers to the drug before their entry into the double-blind protocol. The children were given medication (placebo, 1.25, 2.5, 5, or 7.5 mg) capsules three times a day, and the dose was switched each week. Blind raters selected the MPH dose for each child that produced the best compromise between lowering ADHD symptoms without creating significant adverse events (Kollins et al., 2006). The mean "best" total daily MPH dose for all the preschoolers as determined by the raters was 14 mg, or 0.75 mg/kg per day, which was lower than the mean dose of

1.0 mg/kg per day MPH reported by the MTA Study (Greenhill et al., 2006a).

On their "best" dose, the 165 preschoolers in the PATS showed a significant decrease in ADHD symptoms compared with their response to placebo. A subset of 114 children was then randomized to a double-blind, parallel-design study, with half randomized to their best MPH dose and the other half to placebo. The teacher reports showed significant continued improvements for those on MPH. However, 11% of PATS subjects discontinued the trial because of MPH-associated adverse events, which is far more than the 2% of subjects who stopped the MTA Study for similar reasons. The preschool group showed a significantly higher rate of irritability, decreased appetite, delay in sleep onset, and proneness to crying in the MPH condition than they did on placebo (Wigal et al., 2006). An open pharmacokinetic pilot study done on a small subset of PATS patients suggested that preschoolers with ADHD show significantly lower MPH clearance than do school-age children even when corrected for weight (Wigal et al., 2006).

USE OF PSYCHOSTIMULANTS IN THE TREATMENT OF ADULTS WITH ADHD

Until recently, the prevalence and severity of ADHD in adults, as well as indications for treatment, were not clear. Contrary to the assumption that children outgrow their childhood problems, ADHD symptoms persist into adulthood. From 2% (Mannuzza et al., 1993) to 27% of patients (Barkley, Fischer, Smallish, & Fletcher, 2002) are estimated to continue having the disorder into the adult life range. Epidemiologic data from the National Comorbidity Study that sampled 3,199 individuals, aged 18 to 44 years, estimated the point prevalence of adult ADHD to be 4.4% (Kessler et al., 2006).

As ADHD problems from childhood onset persist into adolescence, the impairment from the disorder continues. Almost 30% of ADHD adolescents fail a course in school; 46% are suspended; and most have difficulties taking notes, planning assignments, writing, and transitioning from homework to self-motivated study, resulting in academic underachievement. As adults, individuals with childhood histories of ADHD continue to have significant problems in both their professional and personal lives. When left untreated, this population tends to have poorer educational performance, is more likely to be fired from or impulsively quit a job, makes more frequent job changes, and earns less income (Kotsopoulos et al., 2013). In addition, this population endorses having more psychological distress, more marriages, poorer driving skills, and more motor vehicle accidents (Biederman et al., 2006; Merkel et al., 2013; Murphy & Barkley, 1996). In a study of Swedish national registers, Lichtenstein and colleagues (2012) compared the rates of criminality among patients with ADHD both on and off medication. This study found that rates of criminality were lower during periods when this cohort was receiving ADHD medication (reduction of 32% in the criminality rate for men and 41% for women).

If adolescents with ADHD begin to smoke, they have much more difficulty stopping. Substance use disorders are also high in adults who had suffered from ADHD as children, ranging from 18% (Mannuzza et al., 2002) to 43% (Barkley et al., 2002). When adolescents with ADHD begin to drive, they are more likely than their peers to get speeding violations, to have their licenses revoked, and to be involved in motor vehicle accidents with significant damage to themselves and their vehicles (Barkley et al., 1993, 1996). In his Milwaukee follow-up study, Barkley reported that 40% of children with ADHD continue to have impairing ADHD as adults. If they also had childhood comorbid CD, their rates of other disorders in adulthood greatly increase, including depression (27% more than ADHD children without CD) and substance use/abuse disorders (up to 24%), and 21% have personality disorders, particularly antisocial personality disorder (up to 25%) (Fischer et al., 2002).

As adults, patients with childhood histories of ADHD continue to have problems (Barkley et al., 1990; Biederman et al., 1996; Mannuzza et al., 1998; Weiss et al., 1985). Between 66% and 85% were reported to suffer from at least one impairing symptom of ADHD. Although 80% of parents report that their older adolescents show persistence of ADHD symptoms from childhood, including impulsiveness, easy distractibility, inattentiveness, easily bored attitude, and restlessness, other types of impairments are also noted during interviews with the parents. Compared with controls, the index group report fewer years of education completed, a higher incidence of antisocial personality disorder, lower scores on clinician-rated global assessment rating scales,

more complaints of restlessness, as well as sexual and interpersonal problems.

The first stimulant treatment studies of adults with ADHD did not show the high response rates seen in children. Mattes and Boswell (Mattes, Boswell, & Oliver, 1984) reported little benefit from MPH, but others have found more robust effects (Ratey, Greenberg, & Lindem, 1991; Wender, Reimherr, & Wood, 1981). As a result, other drugs have been tested in adults with ADHD symptoms, including fluoxetine (Sabelsky, 1990), nomifensine (Shekim, Masterson, Cantwell, Hanna, & McCracken, 1989), pargyline (Wender, Wood, Reimherr, & Ward, 1994), bupropion (Wender & Reimherr, 1990), the monoamine oxidase (MAO) inhibitor selegiline (Ernst et al., 1995), and the long-acting methamphetamine compound desoxyn gradumets (Wender, 1994). Whereas the nicotinic analogue ABT 418 significantly reduced ADHD symptoms (Pelham et al., 2000), the antinarcoleptic modafinil (Provigil) failed to separate from placebo in multisite controlled trials of three doses (100, 200, and 400 mg; Cephalon press release, July 31, 2000). Wilens and Biederman (1992) pointed out that the initial studies of stimulant-treated adults were inconclusive due to the low stimulant dosages used, the high rate of comorbid disorders in the patients, and/or the lack of a clear childhood ADHD history. A number of these studies used self-report outcome measures, even though adult ADHD patients appear to be unreliable reporters of their own behaviors. When the clinicians served as reporters and weight-adjusted doses of stimulants were used, the adult response rates were just as elevated as those in school-age children.

The efficacy of MPH (Spencer et al., 1995), mixed salts of amphetamine (MAS) (Spencer et al., 2001), and ATX (Michelson et al., 2003; Spencer et al., 1998) in adults has been established by double-blind, placebo-controlled RCTs. MPH's efficacy was shown in a 7-week, double-blind comparison of MPH (1 mg/kg per dose) and placebo carried out in 23 adult ADHD patients; 78% showed improvement on MPH versus 4% who responded to placebo (Spencer et al., 1995). The MPH response was independent of gender, comorbidity, or family history of psychiatric disorders. At the target dose of 1.0 mg/kg side effects included loss of appetite, insomnia, and anxiety. MAS efficacy was also ascertained in a 7-week, randomized, double-blind, placebo-controlled trial for 27 adults meeting *DSM-IV* criteria for ADHD of childhood onset with symptoms persistent into adulthood (Spencer et al., 2001). MAS treatment with a mean b.i.d. dose of 54 mg was associated with a 42% drop in ADHD symptom severity, with improvement seen in the first week. Finally, ATX treatment was associated with a significant improvement in ADHD symptoms as compared to placebo over a 10-week study period (Michelson et al., 2003; Spencer et al., 2001).

Currently, the following medications are FDA approved for the treatment of ADHD in adults: ATX, mixed salts of amphetamine XR (Adderall XR), dexmethylphenidate XR (Focalin XR), lisdexamfetamine (Vyvanse), OROS-MPH (Concerta), and liquid MPH (Quillivant XR). Clinicians should be cautious about prescribing psychostimulants for adults with a comorbid substance abuse disorder. In these patients, it is preferable to use medications with lower abuse potential, such as ATX.

STIMULANT DRUGS

MPH, or methyl a-phenyl-2-piperidineacetate hydrochloride, is the active ingredient in the majority of stimulant medications prescribed in the United States. With the exception of the two *d*-methylphenidate (Focalin, Focalin XR) products, MPH's racemic mixture, composed of the *d*- and *l*-threo enantiomers, is used. The *d*-threo enantiomer is more pharmacologically active than the *l*-threo enantiomer. After the immediate-release tablet is swallowed, MPH absorption into the systemic circulation is rapid, so that effects on behavior can be seen within 30 minutes. Plasma concentration reaches a peak by 90 minutes, with a mean half-life of about 3 hours and a 3- to 5-hour duration of action. MPH is metabolized extrahepatically via de-esterification to alpha-phenyl-piperdine acetic acid (PPA, ritalinic acid), an inactive metabolite. About 90% of radiolabeled MPH is recovered from the urine.

Most children taking one IR-MPH dose just after breakfast will require a second dose at lunch (which for young children must be given by the school nurse) and a third dose after coming home from school in the afternoon to prevent loss of effectiveness and rebound crankiness and tearfulness. Long-duration preparations have been developed in the past 15 years to overcome the need for multiple daily MPH doses, and these preparations are now the mainstay of practice.

In clinical practice, IR-MPH tablets are often used to provide a boost in the morning for certain long-duration forms, such as OROS-MPH, or to smooth withdrawal in the late afternoon. When used as the main ADHD treatment, IR-MPH should be administered before school, at lunch, and at home prior to homework (Greenhill et al., 1996). IR-MPH should be initiated at low doses, 5 mg in the morning for children and 10 mg for adults, and increased every 3 days by adding a noontime and an afternoon dose until the three-times-daily schedule is achieved. Preschool children generally need a total daily dose of approximately 15 mg and school-aged children need about 30 mg daily (Greenhill et al., 1996). Although not FDA approved, some older children may require more than 60 mg/day.

Short- and long-duration MPH preparations demonstrate the same common adverse event profile during placebo-controlled RCTs. These include delay in sleep onset, appetite loss, weight decrease, headache, abdominal pain, and new-onset tics. Other adverse effects reported as infrequent are nausea, abdominal pain, dryness of the throat, dizziness, palpitations, headache, akathisia, dyskinesia, and drowsiness.

Rare, serious, and unexpected adverse events include angina, tachycardia, hypertension, visual hallucinations, auditory hallucinations, priapism, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme, and thrombocytopenic purpura. Also rare are tactile hallucinations, formication, phobias of insects, leucopenia, anemia, eosinophilia, transiently depressed mood, sudden unexpected death, and hair loss. Neuroleptic malignant syndrome has been reported very rarely and only when MPH is used in combination with drugs that are associated with neuroleptic malignant syndrome.

MPH interacts with a few medications, including MAO inhibitors (isocarboxazid, phenelzine, selegiline, and tranylcypromine), as well as antibiotics with MAO-inhibiting activity (linezolid), leading to blood pressure elevations and increase in MPH serum concentrations. For this reason, MAO-inhibiting medications are contraindicated in those taking stimulant medications. Furthermore, phenytoin, phenobarbital, tricyclic antidepressants, and warfarin increase the MPH serum concentrations. The effects of centrally acting antihypertensives (guanadrel, methyldopa, and clonidine) can be reduced by MPH. Neuroleptic malignant syndrome has been reported in patients treated with both venlafaxine and MPH.

Despite IR-MPH's effectiveness, its short, 3- to 5-hour duration of action means that a midday dose in school is necessary, which can expose children to peer ridicule. The short duration of action also requires administration by nonfamily members when children participate in after-school programs. Long-duration MPH preparations address these problems with a once-daily dosing formulation (Biederman, Lopez, Boellner, & Chandler, 2002; Greenhill, Findling, & Swanson, 2002; Greenhill et al., 2006b; McCracken et al., 2003; Pelham et al., 1999; Wolraich et al., 2001). An MPH transdermal patch (Findling et al., 2005) and an extended-release oral suspension of MPH (Wigal et al., 2103) have also been approved for the pediatric population. The long-duration MPH formulations differ in the number and shape of the MPH pulses released into the circulation. They include the older single-pulse MPH drugs, such as Ritalin SR and Metadate ER, and the newer dual-pulse beaded MPH products such as Metadate CD, Ritalin LA, Quillivant SR, and Focalin XR, as well as the complex release formulations, such as OROS-MPH (Concerta).

Single-pulse sustained-release, long-duration MPH formulations (Ritalin SR, Metadate ER) use a wax matrix to prolong delivery. They display a slower onset of action than IR-MPH, produce lower serum concentrations, and have up to an eight-hour duration of action (Birmaher, Greenhill, Cooper, Fried, & Maminski, 1989). Clinicians regard these as less effective in practice than the immediate-release or the dual-pulse, beaded MPH or OROS preparations. To compensate for reduced effectiveness and slow onset of action, the single-pulse drugs should be given twice daily or supplemented with an immediate-release tablet in the morning. Metadate ER and Methylin ER are referred to as "branded generics" because they are copies of Ritalin ER.

The beaded MPH products use an extended-release formulation with a bimodal release profile. In Ritalin LA, this is created using a proprietary Spheroidal Oral Drug Absorption System (SODAS) technology. MPH products using SODAS technology (Ritalin LA, Metadate CD, and Focalin XR) may help young children who have difficulty swallowing pills by allowing their bead content to be sprinkled on food. The capsule is opened, and contents—tiny medication spheres—can be sprinkled into a small amount of cold applesauce or pudding. The SODAS technology uses bead-filled capsules, mixtures of

immediate-release and enteric-coated delayed-release MPH beads (Metadate CD contains 30% IR-MPH beads and 70% delayed-release beads), providing a two-pulse release system that mimics the use of IR-MPH given in two doses 4 hours apart. Both Ritalin LA and Metadate CD 10-, 20-, 30-, and 40-mg capsules provide the same amount of MPH in a single dose as twice-daily IR-MPH dosages of 5, 10, 15, or 20 mg. Ritalin LA and Metadate CD given once daily exhibit a lower second peak concentration ($C_{max}2$), higher inter-peak minimum concentrations, and less peak-to-peak trough fluctuations in serum concentration of MPH than IR-MPH tablets administered 4 hours apart. This may be due to an earlier onset and more prolonged absorption of the delayed-release beads. The efficacy of Ritalin LA in the treatment of ADHD in children aged 6 to 14 meeting criteria for ADHD was established in one controlled trial in 2003 (Biederman et al., 2003).

Dexmethylphenidate hydrochloride (*d*-MPH, Focalin) is the *d*-threo-enantiomer of racemic MPH. The drug's plasma concentration increases rapidly after ingestion, reaching a maximum in the fasted state at about 1 to 1.5 hours postdose (Quinn et al., 2004; Wigal et al., 2004). Plasma *d*-MPH levels were comparable to those achieved following single racemic IR-MPH doses given as capsules in twice the total milligram amount. *d*-MPH (5, 10, or 20 mg/day total dose), racemic MPH (10, 20, or 40 mg/day total dose), and placebo, all administered twice daily, were compared in a multicenter, 4-week, parallel group study of 132 patients. Patients treated with *d*-MPH showed a statistically significant improvement in SNAP-IV teacher-rated symptom scores from baseline over patients who received placebo (Wigal et al., 2004).

Focalin XR (*d*-MPH) is an extended-release formulation of *d*-MPH with a bimodal release using the proprietary SODAS technology similar to that of Ritalin LA and Metadate CD. Each bead-filled Focalin XR capsule contains half the dose as immediate-release beads and half as enteric-coated, delayed-release beads. Focalin XR 5-, 10-, and 20-mg capsules provide in a single dose the same amount of *d*-MPH as dosages of 2.5, 5, or 10 mg of Focalin IR given twice daily. After administration of Focalin XR, the first peak, on average, was 45% higher in females, even though pharmacokinetic *d*-MPH parameters were similar for males and females. Focalin XR's effectiveness was shown in a randomized, double-blind, placebo-controlled parallel-group study of 103 pediatric patients, aged 6 to 17. Using mean change scores from baseline on teacher-rated Conners ADHD/*DSM-IV* scales (CADS-T), the study reported significantly greater decreases in ADHD scores for youth on the active Focalin XR than on the placebo (Greenhill et al., 2006b). The medication effectiveness for adult ADHD was reported in a 5-week, randomized, double-blind, parallel-group, placebo-controlled study of 221 adults, aged 18 to 60, who met ADHD criteria on the *DSM-IV* Attention Deficit/Hyperactivity Disorder Rating Scale (ADHD-RS-IV). Signs and symptoms of ADHD were substantially reduced for adults on 20, 30, or 40 mg of Focalin XR than for those randomized to placebo (Chavez et al., 2009).

The OROS-MPH caplet (Concerta) uses an osmotic delivery system to produce ADHD symptom reduction for up to 12 hours (Swanson et al., 2004; Wolraich et al., 2001). The caplet is coated with IR-MPH for immediate action. The long-duration component is delivered by an osmotic pump (OROS) that gradually releases the drug over a ten-hour period, producing slightly ascending MPH serum concentrations. Taken once daily, it mimics the serum concentrations produced by taking IR-MPH three times daily, but with less plasma level variation (Modi, Wang, Noveck, & Gupta, 2000). Claims have been made that long-duration preparations using the beaded dual-pulse technology have greater efficacy than OROS-MPH for controlling ADHD symptoms in the early morning hours (Swanson et al., 2004). However, two double-blind, placebo-controlled RCTs have tested the efficacy and safety of OROS-MPH compared with IR-MPH for ADHD children (Swanson et al., 2003; Wolraich et al., 2001), and both found equal efficacy. Another multisite trial showed that OROS-MPH (Concerta) has similar efficacy to IR-MPH over placebo and significantly reduced ADHD symptoms in adolescents when the upper dose range was extended to 72 mg/day (Wilens et al., 2006). The results show that once-daily OROS-MPH dosing matches IR-MPH in the robust reductions of ADHD symptoms. Low placebo response rates are similar to the rates reported in the MTA Study. In addition, OROS-MPH has been demonstrated in a small study ($N = 6$) to have a longer duration for reducing ADHD-induced driving impairments in the evening than IR-MPH given three times daily (Cox et al., 2004).

Short-duration branded MPH chewable tablets or solutions have been formulated for young children who have difficulty swallowing pills or capsules. Methylin chewable tablets show peak plasma MPH concentrations in 1 to 2 hours (T_{max}), with a mean peak concentration (C_{max}) of 10 mg/mL after a 20-mg chewable tablet. High-fat meals delay the peak by one hour (1.5 hours, fasted, and 2.4 hours, fed), similar to what is seen with an IR-MPH tablet. Methylin chewable tablets are available in 2.5-, 5-, and 10-mg doses. The Methylin oral solution is available in strengths of 5 and 10 mg/5 mL. Quillivant XR is a long-acting racemic MPH solution using LiquiXR technology that enables the continuous release of MPH in an oral liquid form; it has been approved by the FDA for use in children and adults.

In the transdermal MPH preparation (Daytrana), MPH is steadily absorbed after application of the patch, but it does not reach peak concentration until 7 to 9 hours later, with no noticeable action for the first two hours. Chronic dosing with the patch results in higher peak MPH levels than for equivalent OROS-MPH doses, suggesting increased absorption. Duration of MPH action for a 9-hour wear period is about 11.5 hours. A double-blind, placebo-controlled, crossover study conducted in a laboratory classroom showed significantly lower ADHD symptom scores and higher math test ratings on active versus placebo patch for postdose hours 2 through 9 (McGough et al., 2006). Transdermal MPH (Daytrana) appears to be as effective as other long-duration MPH preparations, but adverse effects, such as anorexia, insomnia, and tics, occur more frequently with the patch, and mild skin reactions are common. An advantage of the transdermal formulation is that it can be removed early in patients who suffer from insomnia.

Amphetamines are manufactured in a monoisomer dextro formulation, as in DEX (Dexedrine, ProCentra, Vyvanse), or in racemic forms, with mixtures of salts of *d*- and *l*-amphetamine (Adderall or Adderall XR). The efficacy of these amphetamine products resembles that of the MPH products for controlling overactivity, inattention, and impulsivity in ADHD patients. Some children who have adverse events associated with MPH may respond without such problems when taking amphetamine products. Absorption is rapid, and the drug's plasma level peaks 3 hours after oral administration. All amphetamines are hepatically metabolized. Taking the medication with ascorbic acid or fruit juice acidifies the urine and decreases absorption of amphetamine, whereas alkalinizing agents such as sodium bicarbonate increase it (Vitiello, 2006). Effects of DEX can be seen within 1 hour of ingestion, and the duration of action lasts up to 6 hours, somewhat longer than that of MPH. Nevertheless, twice-daily administration is needed to extend the effectiveness of the IR preparation throughout the school day.

Adderall and Adderall XR are amphetamine salt mixtures (MAS). Adderall XR is a dual-pulse capsule preparation that includes both immediate- and extended-release beads. There is no RCT evidence that MAS offer any advantage over MPH or DEX, but some patients can respond to one and not to another.

Lisdexamfetamine dimesylate (Vyvanse) is a pro-drug preparation that has been FDA approved for treatment of children and adolescents (6 to 17 years) and for adults. It is converted to DEX in the bloodstream upon cleavage of the covalently bonded lysine portion of the molecule. It was developed with the intention of creating a longer-lasting and less easily abused version of DEX. Due to the requirement of cleavage of lysine in the bloodstream, the medication may have a somewhat lower abuse and overdose liability if injected or inhaled. Also, requirement of the conversion into DEX via enzymes in the red blood cells increases its duration of action, regardless of the route of ingestion (Mattingly, 2010). It is available in 20-, 30-, 40-, 50-, 60-, and 70-mg capsules. The starting dose is 30 mg once daily in the morning. The dose can be raised in increments of 10 to 20 mg/day once per week, and the maximum dose is 70 mg/day.

Lisdexamfetamine dimesylate in doses between 30 and 70 mg for 3 to 4 weeks was shown to be both efficacious and well tolerated in two double blind, randomized, placebo-controlled clinical trials of children (6 to 12 years) with ADHD. The first was a phase II, double blind, placebo- and active-controlled crossover of 52 children, comparing the efficacy and safety of lisdexamfetamine dimesylate (30, 50, or 70 mg), with extended-release MAS (MAS XR) (10, 20, or 30 mg) included as a reference arm (Biederman et al., 2007a). There were significant reductions in ADHD symptoms as well as global clinical improvement in both the lisdexamphetamine and the MAS XR arms when compared to placebo. The second was a phase III, double-blind, placebo-controlled parallel study of 290 children with ADHD, randomly assigned to receive lisdexamfetamine dimesylate (30, 50, or 70 mg) with forced dose titration or to receive

placebo (Biederman et al., 2007b). As early as the first week, there were significant improvements on several parent- and teacher-validated efficacy measures with all doses of lisdexamphetamine as compared to placebo. The primary outcome measure was improvement in ADHD-RS-IV scores. Adverse effects occurred in at least 5% of the children assigned to active medication at a rate of twice that of the placebo group. The most common adverse effects included upper abdominal pain, decreased appetite, nausea, vomiting, decreased weight, dry mouth, irritability, and insomnia. In addition, children taking lisdexamphetamine had small but statistically significant increases in blood pressure and pulse.

In addition, lisdexamphetamine has been shown to be efficacious for both the short-term and maintenance treatment of adults with ADHD. Evidence for the short-term treatment came from two double-blind, randomized, placebo-controlled trials including a total of 562 adults (aged 18 to 55 years) with ADHD. In the first study, 420 adults with ADHD were randomized in a parallel design to receive 30, 50, or 70 mg lisdexamphetamine or placebo for a total of 4 weeks (Faraone et al., 2012). All lisdexamphetamine dose groups were found to be superior to placebo in the primary outcome measure (change in total score from baseline to endpoint in the investigator ratings on the ADHD-RS-IV). The second short-term study was a multicenter, randomized, placebo-controlled, crossover, modified study of lisdexamphetamine conducted in a setting designed to simulate a workplace environment in 142 adults with ADHD (Wigal et al., 2010). The study began with a 4-week open-label, dose-optimization phase with lisdexamphetamine (30, 50, or 70 mg/day in the morning). Subsequently, patients were randomized to one of two treatment sequences: lisdexamphetamine (optimized dose) followed by placebo, or placebo followed by lisdexamphetamine, each for one week. The primary outcome measure, the Permanent Product Measure of Performance (PERMP), a skill-adjusted math test that measures attention in ADHD, was assessed at the end of each week. Lisdexamphetamine treatment compared to placebo resulted in a statistically significant improvement in attention across all postdose time points, as measured by average PERMP total scores over the course of the day, as well as scores at each time point measured (up to 14 hours after the morning dose). Based on a 2012 study by Brams and colleagues, lisdexamphetamine has also been shown to be an effective maintenance treatment for adults with ADHD. This phase IV, double-blind, multicenter, placebo-controlled, randomized withdrawal design study assessed the maintenance of efficacy and safety in 123 adults with ADHD. Prior to enrollment, patients were required to have documented long-term treatment with lisdexamphetamine (30, 50, or 70 mg/day) for at least 6 months and have demonstrated treatment response. Subsequently, for 6 weeks, patients either were randomized to continue treatment or were switched to placebo. At the study endpoint, 8.9% of adults taking lisdexamphetamine and 75% taking placebo showed symptom relapse; most showed relapse after 1 and 2 weeks of the randomized withdrawal phase (Brams et al., 2012).

INITIATING STIMULANT DRUG TREATMENT IN PRACTICE

Predicting the individual drug response in ADHD children is difficult. While pretreatment patient characteristics (i.e., young age, low rates of anxiety, low severity of disorder, and high IQ) may predict a good response to MPH on global rating scales (Buitelaar, Van der Gaag, Swaab-Barneveld, & Kuiper, 1995), most research shows that neurological, physiological, or psychological measures of functioning have not been identified as reliable predictors of response to psychostimulants (Pelham & Milich, 1991; Zametkin & Rapoport, 1987). Once a child responds, there is no universally agreed-upon criterion for how much the symptoms must change before the clinician stops increasing the dose. Furthermore, there is no standard for the outcome measure. For example, should global ratings alone be used, or should they be combined with more "objective" academic measures such as percentage correct or percentage completed lists of math problems? Some have advocated a 25% reduction of ADHD symptoms, whereas others have suggested that the dose should continue to be adjusted until the child's behavior and classroom performance are normalized.

The concept of normalization has helped standardize the definition of a categorical responder across domains and across studies. Studies now determine whether the improvement from treatment is clinically meaningful using normal classroom controls, instead of just being statistically significant. Treatment was noted to remove differences

between ADHD children and nonreferred classmates on measures of activity and attention (Abikoff & Gittelman, 1985), but not for positive peer nominations (Whalen et al., 1989). Further advances occurred when investigators used statistically derived definitions of clinically meaningful change during psychotherapeutic treatment (Jacobson & Truax, 1991). Rapport and colleagues (1994) used this technique to calculate reliable change and normalization on the Abbreviated Conners Teacher Rating Scale (ACTRS) using national norms. They determined that a child would be normalized when his or her ACTRS score fell closer to the mean of the normal population than to the mean of the ADHD population. Using this technique in a controlled trial of four MPH doses in ADHD children, they found that MPH normalized behavior and, to a lesser extent, academics (94% vs. 53%). Similarly, DuPaul and colleagues (DuPaul & Rapport, 1993) found that MPH normalized behavior for all ADHD children treated, but only 75% of the ADHD children normalized for academics. In another study, the same group (DuPaul et al., 1994) reported that normalization in behavior and academics occurred less often when ADHD subjects were comorbid for high levels of internalizing disorders. Swanson applied this approach to the cumulative-distribution curves of the SNAP-IV parent and teacher ratings at the end of the MTA Study and found that 88% of classroom controls, 65% of ADHD children treated with combined treatment, and 55% of ADHD children treated with MTA medication strategies had mean symptom scores of 1 or less, equivalent to a "normal" response on those scales.

NEUROIMAGING STUDIES

To date, brain imaging has not been able to completely explain the mechanism by which stimulants reduce the level of ADHD symptoms. Although some studies in ADHD adults using positron emission tomography (PET) and [^{18}F]fluorodeoxyglucose show that stimulants lead to increased brain glucose metabolism in the striatal and frontal regions (Ernst & Zametkin, 1995), others (Matochik et al., 1993, 1994) could not find a change in glucose metabolism during acute and chronic stimulant treatment.

Structural magnetic resonance imaging (MRI) studies of children with ADHD have suggested volumetric disturbances in multiple cortical and subcortical regions (Durston, 2003). For example, in a study of 57 boys with ADHD and 55 matched healthy controls, total brain volumes were found to be 4.7% smaller in affected relative to unaffected boys (Castellanos et al., 1996). Analogous findings have been reported in girls with ADHD (Castellanos et al., 2001), and these findings were replicated in a sample of 152 boys and girls with ADHD (Castellanos et al., 2002). Likewise, a morphometric study examining the sizes and surface contours of the basal ganglia in 47 children with ADHD found volumetric reductions in the putamen, as well as abnormal surface morphology in other basal ganglia nuclei (Sobel et al., 2010). Earlier studies on the basal ganglia of children with ADHD have been inconsistent, with some research suggesting volumetric reductions in the left caudate (Filipek et al., 1997) and other research suggesting reductions in the size of the right, but not left, caudate (Castellanos et al., 1994). Interestingly, studies that have compared children with ADHD treated with stimulants versus untreated children suggest that stimulants may reduce, or normalize, some of the detected volumetric abnormalities (Castellanos et al., 2002; Sobel et al., 2010). These studies, however, have been cross-sectional in nature and the findings should be interpreted with caution. Replication with longitudinal, placebo-controlled designs is needed to better establish stimulant-induced change in brain structure.

Studies of ADHD using functional neuroimaging, which assesses neural activity in the context of specific cognitive operations, have focused largely on deficits in inhibitory and cognitive control, employing tasks that assess children's ability to restrain urges. Several functional MRI (fMRI) studies using tasks associated with cognitive control such as the Go No-Go, Stroop, or Stop-Signal Task have demonstrated that children with ADHD have altered task-related activations in frontostriatal circuits that encompass the dorsolateral prefrontal cortex, basal ganglia, and thalamus and are thought to underlie disturbances in impulsivity (Durston, 2003; Marsh, Maia, & Peterson, 2009; Paloyelis et al., 2007). There have, however, been inconsistencies in the direction of these abnormalities, with some studies suggesting hyperactivation of frontostriatal circuits in ADHD (Schulz et al., 2004, 2005; Pliszka et al., 2006b) and others suggesting hypoactivation of these circuits (Booth et al., 2005; Rubia et al.,

1999). Differences in the age ranges of the samples may have had important effects on the detected patterns of neural activity, underscoring the importance of longitudinal study designs.

The effects of stimulants on fMRI activations have been examined in ADHD by scanning patients in medicated and unmedicated states (Posner et al., 2011a, 2011b), comparing the effects of treatment with either placebo or stimulant employing randomized double-blind designs (Bush et al., 2008; Cubillo et al., 2012), and by comparing medication-naïve children to those who have received long-term stimulant treatment (Pliszka et al., 2006b). Taken together, these studies suggest that stimulants may normalize activation within the frontostriatal circuits, including the right inferior frontal and midcingulate cortices (Bush et al., 2008, Cubillo et al., 2012), as well as the striatum (Vaidya et al., 2005), although it remains unclear whether this normalization mediates symptom improvement. Additional fMRI studies have examined the effects of stimulants on neural circuits underlying emotional regulation and processing and suggest that stimulants may have a direct salutary effect on these circuits, offering a potential mechanistic explanation for stimulant-induced reductions in emotional lability (Posner, 2011a, 2011b).

Dopamine transporter (DAT) blockade is regarded as the putative mechanism for psychostimulants in the human central nervous system. For instance, MPH has high affinity for the DAT. PET scan data in adult substance abusers show that [^{11}C] MPH concentration is maximal in striatum, an area rich in DA terminals where DAT resides (Volkow et al., 1995). These scans reveal a significant difference in the pharmacokinetics of [^{11}C] MPH and [^{11}C] cocaine. Although both drugs display rapid uptake into striatum, MPH is more slowly cleared from brain. The authors interpret the slow reversal of binding to DAT to mean that MPH is not as reinforcing as cocaine and therefore is less likely to lead to self-administration. Therapeutic oral MPH doses significantly increase extracellular DA in the human brain. Volkow and colleagues (2001) have speculated that "Because DA decreases background firing rates and increases signal-to-noise in target neurons, the amplification of weak DA signals in subjects with ADHD by MPH would enhance task-specific signaling, improving attention and decreasing distractibility. (p. 3)"

ADVERSE EVENTS WITH STIMULANTS

Common adverse events frequently reported during stimulant use include delay of sleep onset, headache, appetite decrease, and weight loss. Infrequently observed adverse events include emotional lability and tics. All stimulant products carry a warning in the package insert that they should be used with care in patients with a history of drug dependence or alcoholism.

The most common adverse events associated with stimulant discontinuation in controlled trials included twitching (e.g., motor and vocal tics), anorexia, insomnia, and tachycardia, with reported incidence rates of approximately 1%. Motor or vocal tics have been reported in as many as 1% of children taking MPH (Ickowicz, Tannock, Fulford, Purvis, & Schachar, 1992). Nonetheless, a controlled MPH trial in ADHD children with chronic tic disorder (Gadow et al., 1995) reported significant improvement in ADHD symptoms for all subjects without consistent worsening or increase in tic frequency. However, the total daily MPH doses did not exceed 20 mg/day. These low doses and the short 8-week study do not resemble the higher doses or longer treatment duration found in clinical practice, where tics may appear after several months of MPH administration. More recently, a 2009 meta-analysis of 447 subjects with ADHD and comorbid tic disorders concluded that stimulants do not seem to worsen tics, with the exception of supratherapeutic doses of amphetamine (Bloch, Panza, Landeros-Weisenberger, & Leckman, 2009). The practitioner should keep in mind that transient tics are very common in children (8% to 20%) between the ages of 6 and 10. Furthermore, in a population with a tic disorder, ADHD is found in approximately 50% of patients. Although there is not a large increase in new-onset tics in children taking stimulants, there is the possibility that these medications may uncover a predisposition for tics. Although the clinical literature has held that MPH lowers the seizure threshold, MPH treatment of ADHD patients with seizures is not associated with an increase in seizure frequency (Klein, 1995).

Several clinical conditions have been worsened by stimulant treatment, including florid psychosis, mania, concurrent substance abuse, Tourette syndrome, and eating disorders. More recently, preexisting structural cardiac lesions and hypertensive states

were added as contraindications for using stimulants to treat ADHD.

Drug response may be altered by comorbid anxiety. Stimulant responsiveness and rates of side effects were originally thought to be affected by the presence of comorbid anxiety symptoms. Pliszka (1989) used MPH (0.25 to 0.4 mg/kg and 0.45 to 0.70 mg/kg) and placebo to treat ADHD in 43 subjects for 4 weeks. The 22 ADHD subjects with comorbid anxiety showed less efficacy when active stimulant treatment was compared with placebo, as judged by teachers' global ratings, with no increase in side effects. This might be explained by strong placebo response in this group. Tannock, Ickowicz, and Schachar (1995a) reported that ADHD children, some with (N = 18) and some without (N = 22) comorbid anxiety symptoms, treated in a double-blind, randomized, crossover design with three MPH doses (0.3, 0.6, and 0.9 mg/kg), showed equal decreases in motor activity; however, children comorbid for anxiety had an enhanced risk for tics and dysphoria and less improvement in memory. The group with comorbid anxiety also did more poorly on a serial addition task and had a differential heart rate response to MPH. DuPaul, Barkley, and McMurray (1994) found that 40 children with ADHD and comorbid anxiety were less likely to respond to MPH and showed more side effects for three doses of MPH (5, 10, and 15 mg). The study did not collect ratings for anxiety symptoms, so the direct effect of MPH on such symptoms was not recorded.

More recent data suggest that comorbid anxiety neither decreases the efficacy nor increases the side effects of psychostimulants. A controlled study (Gadow et al., 1995) that tested the MPH effects in children with ADHD and anxiety found equally good response in those with and without comorbid anxiety disorders. Using a flexible clinically appropriate titration trial, Diamond and colleagues (1999) found no difference in short-term outcome or side effects in children with or without anxiety, implying that a method variance may, in part, account for conflicting results in these studies. Analyses of the MTA Study by Arnold and colleagues (1997) suggested that there was no adverse effect of parent-reported child anxiety on medication efficacy for core ADHD symptoms or other outcomes. These divergent data leave open the question of whether comorbid anxiety symptoms predict poor response to stimulant treatment.

Growth Slowdown During Stimulant Treatment

Growth slowdown is another psychostimulant adverse reaction. Psychostimulant-induced reductions in growth velocity have been the most consistently researched long-term side effect (Greenhill, 1984). Even with the many studies in this area (Greenhill, 1981), a myriad of methodologic difficulties prevents an easy interpretation. Few studies employ the optimal controls needed, which include untreated children with ADHD, a psychiatric control group, and an ADHD group treated with a class of medications other than stimulants. Studies differ in quality of compliance measures, whether the children are off stimulants on weekends, and whether the stimulants are used through the summer. One large controlled study (Gittelman-Klein et al., 1988) reported reductions in growth rate among a subgroup of children taking stimulants but noted that growth resumed immediately after treatment was interrupted (Safer et al., 1975). Safer and Allen (Safer et al., 1972, 1975; Safer & Allen, 1973) first reported that treatment for two or more years with MPH and DEX could produce decrements in weight velocity on age-adjusted growth rate charts; stopping the medication produced a quick return to baseline growth velocities. DEX, with a half-life two to three times that of MPH, produces more sustained effects than MPH on weight velocity, as well as suppressing mean sleep-related prolactin concentrations (Greenhill, 1981). In MPH-treated ADHD children followed for 2 to 4 years, dose-related decreases in weight velocity were seen (Gittelman-Klein et al., 1988; Satterfield et al., 1979), with some tolerance of the suppressive effect developing in the second year. Hechtman and colleagues (1984) reported growth slowdown in untreated ADHD children, suggesting that there may be differential growth associated with the ADHD disorder itself. Spencer and colleagues (1996b) also detected similar different growth rates for ADHD children that could be associated with the disorder itself and not with stimulant treatment alone.

More recently, in the MTA Study, growth slowing for height and weight was reported for 288 children aged 7 to 10 with ADHD, combined subtype, treated with MPH at mean doses of 30 mg/kg per day (Swanson et al., 2002). School-age children grew 1.0 cm less per year and gained 2.5 kg less than

predicted from CDC growth charts. Similar effects were observed for preschool children in the NIMH PATS (Swanson et al., 2006), who grew 1.5 cm less and gained 2.5 kg less than predicted by CDC growth norms while treated with mean MPH doses of 14 mg/kg per day. Two major reviews (Faraone et al., 2008; Poulton, 2005) concluded that stimulant treatment most likely slows height acquisition in children, at least during the first 1 to 3 years of treatment. Patients randomized to the stimulant arm in the MTA Study showed significantly less height acquisition during the first two years compared to patients in the nonstimulant arms. Interestingly, when youth with ADHD entered the MTA Study or the PATS, they were typically heaver and taller than average at the start of treatment. Thus, clinicians may not observe growth slowdown as often as predicted because the ADHD-treated children do not slow down in height acquisition enough to become shorter than average.

The actual mechanism for any growth slowdown caused by psychostimulants is unknown. Early theories attributed the drug's putative growth-suppressant action on its effects on growth hormone or prolactin, but research studies on 13 children treated for 18 months with 0.8 mg/kg per day of DEX (Greenhill et al., 1981) and on 9 children treated for 12 months with 1.2 mg/kg per day of MPH (Greenhill et al., 1984) failed to demonstrate a consistent change in growth hormone release. The most parsimonious explanation is appetite suppression, leading to reduced caloric intake. No study, however, has collected the standardized diet diaries necessary to track calories consumed by ADHD children on psychostimulants (Greenhill et al., 1981). There is also evidence that even if height acquisition is reduced during the first year of stimulant treatment, these effects attenuate after that time (Faraone et al., 2008). Pliszka and colleagues (2006a) found that amphetamine affected the rate of weight acquisition more than MPH, but neither had significant effects on the rate of height acquisition. The AACAP Work Group on Quality Issues Guidelines (2007) for ADHD recommends that no change in treatment should occur until the patient has a change in height or weight percentile that crosses two percentile lines on the CDC chart. If this happens, the clinician can reduce the dose, switch to another ADHD medication, or temporarily stop stimulant treatment.

Rare, Serious Adverse Events

The package insert for all psychostimulants includes a black box warning concerning sudden death that may be associated with preexisting cardiac abnormalities or other serious heart problems. This is a rare adverse event. For adults, the warning includes sudden death and also extends to stroke and myocardial infarction. In addition, adults are warned that they should be cautious taking stimulants if they have preexisting hypertension, heart failure, recent myocardial infarction, or ventricular arrhythmia. Those with preexisting psychotic and bipolar psychiatric illness are cautioned against taking stimulants.

These concerns arose from a series of reviews conducted by the FDA of cardiovascular and psychiatric adverse events associated with use of approved stimulant medications. On June 30, 2005, the agency began this review by examining the passive surveillance reports concerning treatment with OROS-MPH (Concerta) (http://www.fda.gov/ohrms/dockets/ac/05/slides/2005-4152s2_06_McCune.pdf). The review uncovered 135 adverse events, including 36 psychiatric adverse events and 20 cardiovascular events. In particular, the reports documented 12 instances of tactile and visual hallucinations (classified under "psychosis") on OROS-MPH, the same clinical phenomena seen in cases of delirium. These OROS-MPH adverse event reports represent 135 per 1.3 million cases and thus seem to be rare events.

Most worrisome were the data that revealed 20 cases of sudden unexpected death with amphetamine or DEX (14 children, 6 adults) and 18 cases with MPH (14 children, 4 adults) (Villalaba, 2006). Based on U.S. postmarketing reports of sudden death, Health Canada suspended the sale of Adderall XR in February 2006. Of the fourteen cases of sudden cardiac death in children taking amphetamine or DEX, six had documented structural cardiovascular abnormalities or other predisposing factors for sudden death on autopsy (Villalaba, 2006). Data from the FDA's Adverse Event Reporting System estimated that the rate of sudden death in children being treated for ADHD during the exposure period January 1, 1992, to December 31, 2004, was 0.2/100,000 patient-years for MPH and 0.5/100,000 patient-years for amphetamine (Villalaba, 2006). Notably, the rate of sudden death in the general pediatric population has been estimated at 1.3 to 8.5/100,000 patient-years, whereas the rate of sudden death among those with a history of

congenital heart disease can be as high as 6% by age 20 (Liberthson, 1996). Therefore, the rate of sudden death in children taking stimulants for ADHD does not appear to exceed the rate of sudden death in the general population (AACAP, 2007).

In March 2006, the FDA's Pediatric Advisory Committee voted unanimously against adding a black box warning for all patients taking stimulants. Instead, the black box warning was targeted to specific high-risk children, such as those with structural heart defects, cardiomyopathy, or an arrhythmia. In 2011, Cooper and colleagues conducted a large retrospective cohort study with over 1 million children and young adults from four separate health plans and found no evidence that current use of an ADHD drug was associated with an increased risk of serious cardiovascular events (Cooper et al., 2011).

In summary, serious unexpected cardiac adverse events associated with stimulants have been known for years and are extremely rare. The rates of cardiac adverse effects are too low to prove a causal association with stimulants in patients with no history of previous heart disease. Routine electrocardiograms and echocardiograms are not indicated before starting stimulants in a patient who has an unremarkable history and physical examination. The physician prescribing stimulants should first ask patients and their families if they have a history of structural heart disease and whether they have consulted previously with a cardiologist. Known cardiac problems that raise a caution about using stimulants include a history of tetralogy of Fallot, cardiac artery abnormalities, and obstructive subaortic stenosis. Clinicians should be alert if the patient has hypertension or complains of syncope, arrhythmias, or chest pain, as these symptoms may indicate hypertrophic cardiomyopathy, which has been associated with sudden unexpected death (AACAP, 2007).

Stimulant Treatment for Children with ADHD and Subsequent Substance Use Disorder

Even though psychostimulants are the most widely researched and clinically effective treatment for childhood ADHD, controversy remains regarding their classification as drugs of abuse, which creates concern about their being administered to young children to treat a condition that has no readily available laboratory test validating the diagnosis. There is also the prominent question of whether children who take stimulants are at an increased risk for later substance use disorders. This subject can be challenging to study, as ADHD itself (particularly when comorbid with CD) is a risk factor for substance abuse. Children with ADHD are significantly more likely to develop substance use disorders in adolescence and adulthood than children without ADHD (Charach et al., 2011). A meta-analysis from 2011 demonstrated that children with ADHD have a 1.5-fold increased risk for developing any substance use disorder and a nearly three times greater risk for developing nicotine dependence (Lee et al., 2011). Nonetheless, there are data from several early long-term clinical studies that suggested that treatment with MPH during childhood reduces the risk of later addiction and substance abuse, including alcohol, nicotine, and drug abuse (Biederman et al., 1999). Several subsequent studies showed no such correlation (Wilens et al., 2003). A 10-year prospective follow-up study of 140 boys (ages 6 to 17 years) with ADHD showed no evidence that stimulant treatment increases or decreases the risk for subsequent substance use disorders in children and adolescents when they reach young adulthood (Biederman et al., 2008a). There was also no significant association between age at stimulant treatment onset and subsequent substance use disorders or any association between the duration of stimulant treatment and subsequent substance abuse disorders. Another recent meta-analysis of 15 long-term studies followed 2,565 children with ADHD from childhood into adolescence and young adulthood. Results suggested comparable outcomes between children with and without medication treatment history for any substance use disorder outcome across all substance types. These results provide an important update and suggest that ADHD treatment with stimulant medication neither protects against nor increases the risk of later substance use disorders (Humphreys et al., 2013).

NONSTIMULANT MEDICATION TREATMENTS FOR ADHD

Because of the controversy surrounding the use of scheduled drugs in children, clinicians and parents may prefer nonstimulant medications for ADHD treatment (Table 4.3). Besides the controversy, other problems face the family using stimulants for ADHD.

TABLE 4.3 Nonstimulant Drugs with FDA Indication for ADHD

Medication (Brand Name)	*Available Dose of Preparation*	*Starting Dose/ Maximum Dose*	*Indicated Age (Years) for Psychiatric Use*
Atomoxetine (*Strattera*) † *	10-, 18-, 25-, 40-, 60-, 80-, 100-mg tabs	**<70 kg**: 0.5 mg/kg/1.2 mg/kg **>70 kg**: 40 mg/day/100 mg/day (Maintain initial dose for minimum of 7 days prior to upward dose titration)	6+
Bupropion (*Wellbutrin; Wellbutrin SR, Wellbutrin XL*) †	*Wellbutrin*: 75-, 100-mg tabs *Wellbutrin SR*: 100-, 150-, 200-mg tabs *Wellbutrin XL*: 150-, 300-mg tabs	*Wellbutrin*: 100 mg b.i.d./150 mg/dose up to 450 mg/day *Wellbutrin SR*: 100 mg AM/400 mg/day *Wellbutrin XL*: 150 mg AM/450 mg/day	18+ (off-label for pediatric ADHD)
Clonidine (*Catapres*)		**27–40.5 kg**: 0.05 mg qhs/0.05 mg/dose up to 0.2 mg/day **40.5–45 kg**: 0.05 mg qhs/0.1 mg/dose up to 0.3 mg/day **>45 kg**: 0.1 mg qhs/0.1 mg/dose up to 0.4 mg/day	18+ (off-label for pediatric ADHD)
Guanfacine Immediate Release (*Tenex*)		**27–40.5 kg**: 0.5 mg qhs/0.5 mg/dose up to 2 mg/day **40.5–45 kg**: 0.5 mg qhs/1 mg/dose up to 3 mg/day **>45 kg**: 1 mg qhs/1 mg/dose up to 4 mg/day	18+ (off-label for pediatric ADHD)
Clonidine Extended Release (*Kapvay*) †		0.1 mg qhs/0.4 mg/day (divide doses >0.1 mg/day)	6+
0.1-, 0.2-, 0.3-mg tabs		1 mg/day (morning or evening)/4 mg/day	6+

†Must be swallowed (not crushed or chewed)

*FDA approved for treating adult ADHD

Short-acting stimulants require cooperation from the school personnel for midday dosing, and this may not always be possible. Stimulants, which cause insomnia, cannot be given too late in the day. MPH's attention-enhancing effects, which last only 3 to 4 hours, are often needed in the late evening to help school-age children with their homework but may result in delayed sleep onset and insomnia. Adverse effects, including weight loss, headaches, insomnia, and tics, can occur. March, Conners, Erhardt, and Johnson (1994) suggested that a nonstimulant may be used when there is an unsatisfactory response to two different stimulants; this recommendation is in congruence with the studies of Elia and colleagues (1991). Other ADHD treatment parameters, including the Texas Children's Medication Algorithm Program, recommend the use of nonstimulants when stimulants cannot be used because of inadequate response, unwanted side effects, or parental preference (Pliszka et al., 2000; Pliszka et al., 2006a).

ATX (Strattera) is a potent selective norepinephrine reuptake inhibitor and was approved in the United States in November 2002 for the treatment of ADHD in children (6 years and older), in adolescents, and in adults. Results from premarketing randomized placebo-controlled trials demonstrated effect sizes between 0.6 and 0.8 (Kelsey et al., 2004; Michelson et al., 2001, 2002; Spencer et al., 2002). A large parallel-group, placebo-controlled, double-blind study compared the acute treatment response of ATX versus MPH in the treatment of ADHD in children and adolescents. In this study, 561 children and adolescents (6 to 16 years) with ADHD were randomized to receive ATX (0.8 to 1.8 mg/kg per day), OROS-MPH (18 to 54 mg/day), or placebo for six weeks. The response rates for both ATX (45%)

and MPH (56%) were markedly superior to those for placebo (24%), but the response to OROS-MPH was superior to that for ATX (Newcorn et al., 2008). Following 6 weeks of treatment, patients treated with MPH were switched to ATX under double-blind conditions. Approximately one third of the patients responded preferentially to either ATX or to MPH. About half responded to both treatments, and 22% did not respond to either treatment. This finding suggests that a subgroup of patients may derive greater benefit from one or the other treatment. This may be attributable to differential sensitivity to the pharmacological mechanisms and individual metabolic and pharmacokinetic responses (Newcorn et al., 2008). There is also evidence for the efficacy of ATX for the maintenance treatment of ADHD in patients who responded to initial treatment with ATX (Michelson et al., 2004).

ATX's value as a treatment is for patients who have not responded to or cannot tolerate stimulants, or for those who do not want treatment with a schedule II stimulant ("Atomoxetine for ADHD," 2003). ATX is neither a controlled substance nor a stimulant. It is rapidly absorbed, with peak serum concentrations occurring in 1 hour without food and 3 hours with food. The drug undergoes hepatic metabolism with CYP2D6 isozyme and then is glucuronidated and excreted in urine. Plasma elimination half-life averages 5 hours for most patients, although 5% to 10% of patients have a polymorphism for the allele that codes for CYP2D6 and show ATX half-life as long as 24 hours. The pharmacodynamics differs from the pharmacokinetics in that the duration of action in reducing ADHD symptoms lasts much longer than the pharmacokinetic half-life, so once-daily dosing can manage ADHD symptoms. ATX is usually administered as a single morning dose but can, if necessary, be given in the evening, whereas stimulants cannot. ATX dosage for children and adolescents is weight-dependent. The recommended starting dose for youth weighing 70 kg or less is 0.5 mg/kg per day divided into two equal doses the first week and increased after 1 week to a target dose of 1.2 mg/kg per day to limit adverse events. In patients weighing more than 50 kg, treatment can be initiated with 18 mg during the first week, and those weighing more than 70 kg can start with 40 mg. Concurrent administration of CYP2D6 inhibitors, such as paroxetine, fluoxetine, metoprolol, or propranolol, requires lower dosages, as ATX levels can be increased three- to fourfold. ATX and MAO inhibitors should not be used together or within 2 weeks of each other. Dry mouth, somnolence, nausea, decreased appetite, and vomiting have occurred in children on ATX, particularly when the dose is increased from initial to top levels within three days. Slow metabolizers displayed higher rates of decreased appetite. Contraindications and relative contraindications include congenital or acquired long QT syndrome, a family history of prolonged QT interval, cerebral seizures or a history of seizures, and hepatic dysfunction.

Two warnings have been added to the ATX package insert instructions. The first warning was added on December 17, 2004, based on three spontaneously reported cases of reversible drug-induced liver injury that were deemed probably related to ATX. ATX should be discontinued in patients with jaundice or laboratory evidence of liver injury and should not be restarted (Bangs et al., 2008). The second warning was added in September 2005. Lilly Pharmaceuticals reported that 5 of 1,800 youth in ATX trials spontaneously reported suicidal ideation, whereas none randomized to placebo made such reports. The FDA required that ATX's label carry a black-box warning about its possible association with suicidality. A 2008 meta-analysis, including 14 pediatric clinical trials, demonstrated that the frequency of suicidal ideation was greater among ATX-treated (0.37%) than among placebo-treated patients (0%); however, no patients in these trials committed suicide. It is noteworthy that both warnings are based on spontaneous reports, not systematically elicited adverse events.

Bupropion, an antidepressant with noradrenergic activity, has been reported to be effective for some ADHD symptoms in placebo-controlled trials (Casat et al.,1989; Clay et al., 1988; Simeon et al., 1986). Barrickman and colleagues (1995) concluded that bupropion was equivalent to MPH in the treatment of 15 children with ADHD, who had equal improvements for both medications on the Clinical Global Impression scale, Conners teacher and parent ratings, the Continuous Performance Test, and ratings of anxiety and depression. The study shows an order effect, which suggests a carryover from one drug condition to the next. Also, subjects were not placed on placebo in the crossover, so the study is not placebo controlled. The multisite, double-blind, placebo-controlled trial of bupropion revealed that teachers could detect a reduction of ADHD symptoms at a significant level but parents could not (Conners et al., 1996). This

suggests that bupropion is a second-line agent for ADHD treatment.

Clonidine and guanfacine were initially developed and used clinically as centrally active antihypertensive agents, which exert their antihypertensive activity by decreasing sympathetic tone in the central nervous system and reducing vascular resistance. Clonidine is a central α_2-adrenergic pre- and post- synaptic receptor agonist with high affinity at each of the three postsynaptic α_2-receptor subtypes (α_2A, α_2B, α_2C), whereas guanfacine is selective for the α_2A-receptor subtype (15-60 times more selective for the α_2A than for α_2B and α_2C) (Stahl, 2013). In clinical practice, both clonidine and guanfacine have been used to treat ADHD, both alone and with psychostimulants, especially in patients unable to tolerate pychostimulants or in those who present clinically with comorbid disorders such as Tourette syndrome/tic disorders, impulsive aggression, or insomnia (Sallee, 2010; Scahill et al., 1999).

Only the extended-release formulations of clonidine (Kapvay) and guanfacine (Intuniv) are FDA approved as monotherapy or adjuvant therapy for children and adolescents (aged 6–17 years) with ADHD. Neither medication has an FDA indication for the treatment of adults. A meta-analysis of 11 small double-blind and open-label studies (fewer than 50 subjects) that reviewed the effects of treatment with immediate-release clonidine on symptoms of ADHD alone, or ADHD comorbid with developmental, conduct, or tic disorders, determined a moderate overall effect size of 0.58 ± 1.6 (Connor et al., 1999). The efficacy of extended-release clonidine monotherapy was evaluated in an 8-week double-blind placebo-controlled forced dose titration study in children and adolescents (aged 6 to 17 years) with ADHD. Subjects in the active arm were randomized to receive either 0.2 or 0.4 mg/day. Subjects were started on 0.1 mg at bedtime, and their doses were increased by 0.1 mg/week until the target dose (0.2 or 0.4 mg/day) was reached. Improvement from baseline in ADHD-RS-IV total score (primary efficacy variable) was significantly greater in both clonidine groups versus placebo, with an effect size of 0.71 for 0.2 mg/day and 0.76 for 0.4 mg/day (Jain et al., 2011). The significant limitation of this fixed-dose protocol was the high discontinuation rate in all treatment arms, particularly in the 0.4-mg/day group. Nonetheless, there was ample power to demonstrate a robust treatment effect (change from baseline of 15 to 16 points on the ADHD-RS-IV) (Sallee et al., 2013).

There are only limited data available for immediate-release guanfacine, including several small studies showing improvement in both parent and teacher ADHD rating scales (summarized in Sallee et al., 2013). Two short-term (8- and 9-week) studies showed both the efficacy and the safety of using extended-release guanfacine as monotherapy for ADHD. Both were multicenter, randomized, fixed-dose, placebo-controlled trials in children and adolescents (aged 6 to 17 years) (Biederman et al., 2008b; Sallee et al., 2009b). Both studies used fixed-dose protocols and demonstrated a significant reduction in the ADHD-RS-IV total score for the entire study population, except for the 13- to 17-year-old subgroups. Effect sizes ranged from 0.43 to 0.86, and there was a correlation between efficacy and dose strength (Biederman et al.: 0.64 [2 mg/day] and 0.86 [4 mg/day]; Sallee et al.: 0.43 [2 mg/day] and 0.62 [4 mg/day]).

In addition, there are data demonstrating the efficacy and safety of using either clonidine or guanfacine in combination with stimulants for ADHD. Two randomized, multicenter, double-blind placebo controlled trials looked at immediate-release clonidine given adjunctively with MPH (Palumbo et al., 2008; Sallee et al., 2013; Tourette's Syndrome Study Group, 2002). Both studies had identical designs but differed in their study populations (Sallee et al., 2013). The Tourette's Syndrome Study Group examined 136 children with ADHD and comorbid chronic tic disorders. The combination of immediate-release clonidine and MPH produced the maximum treatment benefit for both ADHD symptom reduction and improvement in tics. In a sixteen-week, randomized, multicenter, double-blind, placebo-controlled study by Palumbo and colleagues (2008), 122 children (aged 7 to 12 years) with ADHD were randomized to receive placebo, immediate-release clonidine monotherapy (maximum dose 0.6 mg/day; mean dose 0.24 ± 0.11 mg/day), immediate-release MPH monotherapy (maximum dose 60 mg/day; mean dose 30.2 ± 18.9 mg/day), or combination therapy (mean clonidine dose 0.23 ± 0.13 mg/day; mean MPH dose 25.4 ± 18.2 mg/day). Although clonidine alone demonstrated a clinical benefit, it was inferior to MPH alone or in combination with MPH as measured by the change from baseline on the Connor's Abbreviated Symptom Questionnaire for Teachers (primary

efficacy measure). In an eight-week, randomized, multicenter, double-blind, placebo-controlled trial, 198 children and adolescents (aged 6 to 17 years) with hyperactive- or combined-subtype ADHD, who had an inadequate response to a stimulant, were randomized to receive either extended-release clonidine or placebo in combination with their baseline stimulant regimen (short- or long-acting MPH or amphetamine treatment). To meet inclusion criteria, subjects had to have been treated with a stable dose of either MPH or amphetamine for four weeks prior to screening and had to have an ADHD-RS-IV total score of at least 26. During the first five weeks, clonidine was titrated by 0.1 mg/week to an optimal dose based on improvement on the ADHD-RS-IV total score (primary efficacy measurement) and tolerability. Beginning in week two, extended-release clonidine plus stimulant resulted in a significantly greater improvement in ADHD-RS-IV total scores compared to placebo plus stimulant. Although the overall effect size for extended-release clonidine plus stimulant (0.34) versus stimulant alone was lower compared to monotherapy trials versus placebo alone, there was still a clinically significant improvement with adjunctive treatment over stimulant alone. This study had several notable limitations. First, patients with significant Axis I psychiatric comorbidities (i.e., CD) were excluded. Second, participants' stimulant medication regimens were determined on the basis of their response to a specific regimen (i.e., MPH or amphetamine). Although clinically applicable, this design made it impossible to determine whether specific combinations of stimulant medications were more effective than others. Finally, dosages of stimulant medications were not optimized during the course of the study, so it is unclear what the effects of extended-release clonidine would have been if a formal optimization phase had been used (Kollins et al., 2011).

In 2012, Wilens and colleagues conducted a 9-week, multicenter, double-blind, placebo-controlled, dose-optimization trial of extended-release guanfacine given adjunctively to stimulants. This study examined 461 children and adolescents (aged 6 to 17 years) with ADHD and suboptimal but partial response to stimulants alone. Subjects continued on their stable morning stimulant (short- or long-acting MPH or amphetamine treatment), and they were subsequently randomized to receive optimized extended-release guanfacine(1 to 4 mg/day) in the morning or in the evening, or placebo. Ultimately, both guanfacine treatment groups showed significantly greater improvement from baseline on ADHD-RS-IV total scores compared to placebo. Notably, these results generalized to both younger and older patients. The effect size for morning guanfacine plus stimulant was 0.377; for evening guanfacine plus stimulant it was 0.447. Although the overall effect sizes were low compared to what has been demonstrated in extended-release guanfacine versus placebo trials, symptom improvement with adjuvant treatment was still demonstrated over stimulant alone. Similar to the limitation in the 2011 study by Kollins and colleagues, stimulant medication doses were not optimized (Wilens et al., 2012).

Immediate-release clonidine is FDA approved for the treatment of hypertension but not for the treatment of ADHD (Catapres, 2010). The typical dose of immediate-release clonidine used to treat hypertension in adults is 0.2 to 0.6 mg/day, divided and given two times a day (Catapres, 2010). This is approximately the same dose range used in ADHD studies (Sallee et al., 2013). Similarly, immediate-release guanfacine is FDA approved for the treatment of hypertension but not for the treatment of ADHD, and the typical dose ranges from 1 to 2 mg given once per day (Tenex, 2008).

Only extended-release clonidine (Kapvay) and extended-release guanfacine (Intuniv) are FDA approved as monotherapy or adjuvant therapy for children and adolescents (aged 6 to 17 years) with ADHD. According to prescribing information, extended-release clonidine dosing should begin at 0.1 mg/day given at bedtime. The dose can be increased by 0.1 mg/day weekly until optimal response is achieved. Doses higher than 0.1 mg/day should be administered twice a day with an equal or higher dose given at bedtime, and the approved dose range is 0.1 to 0.4 mg/day (Kapvay package insert, 2010). According to prescribing information, extended-release guanfacine dosing should begin at 1 mg/day. The dose can be increased in increments of no more than 1 mg/week until optimal response is achieved. Dosing of extended-release guanfacine should be maintained within the range of 1 to 4 mg/day for both monotherapy and adjunctive therapy to a stimulant. Clinically relevant improvements were observed beginning at doses in the range 0.05 to 0.08 mg/kg once daily in both monotherapy and adjunctive therapy. Efficacy increases with increasing weight-adjusted dose (mg/kg), and if well tolerated, doses up to 0.12 mg/kg

per day may provide additional benefit (Intuniv package insert, 2011).

The most commonly reported adverse events in clinical trials with α_2-agonists are fatigue, sedation, and hypersomnia (Newcorn et al., 2003), although there is a high likelihood that the initial somnolence will improve over time (Daviss et al., 2008). In general, the extended-release α_2-agonists are better tolerated than the immediate-release formulations. The rapid absorption of the immediate-release α_2-agonists leads to high-peak plasma concentrations that are associated with the side effects of sedation, dry mouth, and hypotension.

The adverse event profile of all guanfacine and clonidine formulations is similar to that which could be expected of any centrally acting α_2-adrenoagonist antihypertensive agent, including small but consistent decreases in pulse and in both systolic and diastolic blood pressure. Reductions in pulse and blood pressure are dose dependent across all studies, and the greatest effects are noted at higher doses (Biederman et al., 2008a; Sallee et al., 2009b). In a study addressing the concerns about the safety and tolerability of clonidine when used alone or in combination with a stimulant in youths, investigators examined changes in electrocardiograms and in vital signs, including orthostatic changes, in a large sample of children with ADHD. All subjects were participating in a randomized placebo-controlled trial of clonidine, with and without MPH. The most notable group difference in electrocardiographic outcomes was the higher rate of bradycardia (heart rate less than 60 beats per minute) in patients taking clonidine, although the bradycardia experienced by the majority of individuals was asymptomatic and of questionable clinical significance. There were no other significant changes in the electrocardiogram patterns between treatment groups (Daviss et al., 2008). Although there has historically been concern about the cardiovascular safety of combining clonidine with a stimulant, a recent extensive review of the literature has alleviated this concern (Sallee et al., 2013). Similarly, trials of both long- and short-acting guanfacine have failed to demonstrate any serious cardiac side effects when used alone or in combination with a stimulant. In long-term safety studies of extended-release guanfacine, cardiovascular adverse events were rare, although small reductions in mean blood pressure and pulse rate were evident at monthly visits (Biederman et al., 2008b; Sallee et al., 2009a). Caution should be used when prescribing guanfacine or clonidine to patients with a history of syncope or its predisposing factors, and patients should be advised to avoid dehydration. Prior to starting an α_2-agonist for the treatment of ADHD, baseline heart rate and blood pressure need to be taken and subsequently checked periodically during treatment or after a dose increase. In addition, patients must be cognizant of the importance of their not stopping treatment abruptly, as this could precipitate rebound hypertension (Sallee et al., 2013).

Modafinil (Provigil) is a centrally acting agent with sympathomimetic properties that is structurally and pharmacologically different from stimulant medications. It is a wakefulness-promoting agent that is FDA approved for the treatment of narcolepsy, obstructive sleep apnea/hypopnea syndrome, shift work sleep disorder, and fatigue associated with multiple sclerosis. It was found to be equivalent to 600 mg caffeine (approximately six cups of coffee) in maintaining alertness and performance in sleep-deprived normal volunteers (Wesensten et al., 2002). The precise mechanism of action has not been determined. Although data pooled from three double-blind, placebo-controlled studies showed modafinil to be an effective treatment for children and adolescents with ADHD (Biederman & Pliszka, 2008), the FDA found the drug to be unfit for use in this population. It was not approved for the ADHD indication primarily due to the severe cutaneous adverse reactions associated with modafinil, including erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, and drug rash with eosinophilia and systemic symptoms involving adult and pediatric patients. The FDA-approved label for modafinil now discourages its use in children for any purpose (FDA Drug Safety Newsletter, 2007).

Selective serotonin reuptake inhibitors are widely prescribed for the treatment of mood and anxiety disorders, but Castellanos (1996) found no signs of their efficacy in the treatment of ADHD symptoms in children in the seven studies ($N = 68$) he reviewed.

MONITORING TREATMENT

The AACAP Practice Parameters recommend that during a psychopharmacological intervention for ADHD, the patient should be monitored for treatment-emergent side effects. The effectiveness of regular monthly visits and dose adjustments based

on tolerability and lingering ADHD symptoms was shown in the MTA Study. Those assigned medication management by NIMH protocol had significantly lower ADHD symptom scores than those followed by providers in the community. Children in the MTA Study had five times the rate of kept appointments, increased feedback from the teacher to the provider, and higher mean MPH total daily doses than children treated in the community. Monitoring can be done through direct visits, by phone calls with the patient and family, or even by e-mail contact. Teacher input should be sought at least once in the fall and once in the spring for patients attending primary, middle, or high school. Monitoring should also follow a predetermined plan that is worked out with the patient, and if a child, with the parents as well. Generally, the schedule of monitoring visits should be weekly during the initial dose-adjustment phase and then should become monthly for the first few months of maintenance. After that, visits can be regularly scheduled but less frequent. During monitoring visits, the clinician should collect information about the exact dose used and the administration schedule for the stimulants, including times of day. The clinician should ask about skipped doses. Questions about common and less common as well as acute and long-term side effects should also be raised by the clinician. Family and clinician should agree whether the patient is to be continued on the same stimulant dose or started on another dose. A new prescription should be written and a new appointment scheduled. The patient should leave with a prescription, a plan for administration, and a possible schedule for telephone contact. Reports of lost medication or requests for early refills or multiple dose increases should be viewed in light of possible drug misuse or diversion. Clinicians should emphasize that the patient should never give medication to friends and relatives. When available, clinicians should check state registries to be sure that the patient is not getting psychostimulant prescriptions from multiple prescribers or pharmacies.

The practitioner and family should agree on the dosing schedule of stimulant treatment. Stimulant medication may be administered daily or only on schooldays, with weekends and holidays off drug. Those patients with more impairing ADHD symptoms may benefit from taking medication 365 days per year. Patients should have their need for continued treatment with stimulant medication verified once per year through a brief period of medication discontinuation. This should be planned for a part of the school year when academic testing is not in progress. Strategies for maintaining adherence to treatment are a key component of monitoring. These include the option to adjust stimulant doses to reduce treatment-emergent adverse events. When an adverse event occurs, the practitioner would do well to assess the impairment induced. Some adverse events may not interfere with the child's health or cause significant interruption of routine. If the adverse event worsens, then dose reduction is indicated. If the dose reduction helps the adverse event but results in an increase of ADHD symptoms, then the clinician may want to consider switching to another stimulant.

The AACAP Practice Parameters suggest that adjunctive pharmacotherapy can be used to deal with a troublesome adverse event when the stimulant treatment is particularly helpful. Stimulant-induced delay of sleep onset may benefit from the use of antihistamines, clonidine, or a bedtime dose of 3 mg melatonin (Tjon Pian Gi, Broeren, Starreveld, & Versteegh, 2003).

CHOICE OF MEDICATION

An international consensus statement (Kutcher et al., 2004), the AACAP ADHD Practice Parameters (2007), the Texas Medication Algorithm Project (Pliszka et al., 2006a), and the American Academy of Pediatrics (2011) all recommend stimulant medication as the first-line of treatment for ADHD. Direct comparisons of MPH and ATX in a double-blind, randomized, multisite trial (Buitelaar et al., 2007; Michelson, 2004) have shown a decided benefit for MPH and confirm the meta-analysis by Faraone and colleagues (2003), which suggested the MPH effect size (0.91) was greater than that of ATX (0.62). However, ATX might take precedence if the family had an aversion to stimulants or the patient had comorbid anxiety, suffered from chronic motor tics, or was an adolescent or adult with a substance abuse problem. The AACAP guidelines recommend that treatment begin with a long-duration formulation of either an amphetamine or an MPH-based stimulant. The specific drug can be chosen based on its rapidity of onset, duration of action, effectiveness in the specific patient under treatment, and insurance coverage. Short-acting stimulants can be used at first for small children or preschoolers if there is

no long-acting preparation available in a low enough dose. Dual-pulse MPH and amphetamine products have strong effects in the morning and early afternoon but tend to wear off by the late afternoon. These drugs work best for children with academic problems at the beginning and middle of the school day, for those whose appetite is strongly suppressed, and for those who have delay of sleep onset during stimulant treatment. Because transdermal stimulants are reported to have higher-than-average numbers of adverse events, orally administered stimulants should be used first. ATX should be employed only if the family does not want treatment with a controlled substance, or if the patient fails to respond to full-dose-range trials of both a long-duration MPH and a long-duration amphetamine preparation. The AACAP Practice Parameters for ADHD (2007) wisely point out that none of the extant practice guidelines should be interpreted as justification for requiring a patient to be a treatment failure (or experience adverse events) with one agent before allowing the trial of another.

CONCLUSIONS

Psychostimulant medications have become a mainstay in the treatment of ADHD, primarily based on their proven efficacy during short-term controlled studies. In fact, the majority of children with ADHD will respond to either MPH or DEX, so that nonresponders are uncommon (Elia et al., 1991). Although the long-term response of ADHD children to psychostimulants has not been examined in a controlled study much longer than 24 months (Jacobvitz et al., 1990), anecdotal reports suggest that patients relapse when their medication is withdrawn and respond when it is restarted. Optimal treatment involves initial titration to optimize dose, followed by regular appointments and a clinician who remains in frequent contact with the patient, parent, and school (Greenhill et al., 2001b). The combination of behavioral and medication therapies is only slightly more effective in reducing ADHD symptoms than medication alone (MTA Cooperative Group, 1999).

Although psychostimulant treatment research has flourished, there is ample opportunity for more studies. Not all patients respond to psychostimulants, in particular patients with comorbid psychiatric disorders. It is also important to determine medication effects on the acquisition of social skills in ADHD children (Hinshaw, 1991). Finally, there remains a need for more long-term psychopharmacological studies as well as studies that target populations with comorbid disorders (e.g., the child with ADHD and a comorbid anxiety disorder) to examine differential responses to medications in these patients.

PSYCHOPHARMACOLOGICAL TREATMENT FOR DISRUPTIVE BEHAVIOR DISORDERS

The psychopharmacological treatment of ADHD often includes managing patients' aggression or their symptoms of either ODD or CD. The essential features of ODD are a recurrent pattern of angry/irritable mood, argumentative/defiant behavior, or vindictiveness. ODD often precedes the development of CD. The essential features of CD are a repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated (American Psychiatric Association, *DSM-5*, 2013). Discussions of the treatment of these complex disorders involve not only the efficacy and safety of various medications but also the use of multiple psychopharmacological agents of different classes, the optimal behavioral measures to track clinical progress, and the need to target both overt physical aggression toward people or objects and verbal aggression and covert, nonconfrontational aggression (stealing or vandalism).

Disruptive behavior disorders (DBDs), including both ODD and CD, are the most common comorbidities associated with ADHD. Of children with ADHD referred to psychiatric clinics, up to 50% meet criteria for both ADHD and CD (Newcorn et al., 2001). In the MTA Study, 39.9% of the children with ADHD met criteria for comorbid ODD and 14.3% met criteria for CD (MTA Cooperative, 1999). A study that examined psychiatric comorbidities in both preschool- and school-age youth found that 63% of preschoolers with ADHD also had ODD, which was similar to the rate found in school-age children with ADHD (Wilens et al., 2002). In nonreferred community samples, up to 30% of children with ADHD exhibit this comorbidity, depending on the rater (Wolraich et al., 1998).

Children with ADHD frequently display impulsive aggression, which can be characterized as reactive, unplanned, and uncontrolled. Although children with ADHD exhibit disruptive behaviors at school and at home, impulsive aggression is not typically

pathognomonic of the condition. In the MTA Study, 267 of the original 579 children (46%) with ADHD displayed clinically significant aggression. Even after receiving medication treatment for ADHD, 44% of the aggressive subgroup remained symptomatic with aggression (Jensen et al., 2007b). Symptoms of impulsive aggression may include nonprofitable damaging of one's own property and a loss of control in front of other people. A second subtype of aggression, referred to as predatory aggression, is goal-oriented, planned, and controlled. Individuals exhibiting this subtype of aggression may hide their aggressive acts and may be able to control their own behavior (Vitiello & Stoff, 1997b). Notably, the more affective/impulsive and less predatory subtype of aggression is thought to be more responsive to pharmacological intervention (Malone et al., 1998).

Three major clinical consensus conferences have been held to address the pharmacological management of aggression in children and adolescents. These include the Treatment Recommendations for the use of Antipsychotics for Aggressive Youth (TRAAY; Pappadopulos et al., 2003; Schur et al., 2003), revision of the Texas Children's Medication Algorithm (Pliszka et al., 2006a), and Treatment of Maladaptive Aggression in Youth (TMAY; Scotto Rosato et al., 2012). As a general principle, expert opinion strongly supports the use of evidence-based psychosocial interventions (e.g., behavior therapy and parent management training) and parent education and training prior to using medication for maladaptive aggression. This discussion will focus on the current psychopharmacological treatments of choice for children and adolescents with DBDs (ODD and CD) and aggression, while the psychosocial treatments are discussed in a separate chapter 5.

Several assessment scales are frequently used to assess the efficacy of psychopharmacological treatment for DBDs. The Rating of Aggression Against People and/or Property Scale (RAAPP) (Kemph et al., 1993) is a global assessment of aggression completed by the clinician and scored on a five-point scale with 1 indicating "no aggression" and 5 indicating "intolerable aggression." Another scale is the Conduct Disorder Subscale on the Nisonger Child Behavior Rating Scale (NCBRF; Aman, Tassé, Rojahn, & Hammer 1996). The parent-completed NCBRF has various subscales that measure both positive social interactions and various problem behaviors. Higher scores on the problem behavior subscales indicate behavioral dysfunction. The Modified Overt Aggression Scale (MOAS; Kay et al., 1988) is a sixteen-item scale that asks the clinician to rate a patient's aggression (verbal aggression, aggression against property, auto-aggression, and physical aggression) over the previous week. Finally, the Children's Aggression Scale-Parent (CAS-P) and the Children's Aggression Scale-Teacher (CAS-T) (Halperin et al., 2002, 2003) retrospectively measure the frequency and severity of four types of aggression: verbal aggression, aggression against objects and animals, provoked physical aggression, and initiated aggression.

FDA-Approved Medications for ADHD: Psychostimulants, Alpha-2 Agonists, and Atomoxetine

Not only do psychostimulants significantly improve the core symptoms of ADHD, but they also reduce overt aggression in children and adolescents with non-comorbid ADHD, although the effect is less robust in the presence of comorbid ODD and CD (Connor et al., 2002). Connor's meta-analysis of 28 studies between 1970 to 2001 reported on the effect sizes for stimulants on overt and covert aggression-related behaviors in children with ADHD, separated from stimulant effects on the core symptoms of ADHD. The overall effect size was 0.84 for overt and 0.69 for covert aggression-related behaviors in ADHD. Comorbid CD was associated with diminishing stimulant effect size for overt aggression. For example, in a double-blind placebo-controlled RCT of 84 patients (aged 6 to 15 years) with CD, MPH was superior to placebo in reducing both core symptoms of ADHD and antisocial behaviors specific to CD. Nonetheless, symptoms of CD at endpoint were not generally normalized (Klein et al., 1997). Klein and colleagues hypothesized that stimulants are effective in treating both ADHD and CD because these medications target impulsivity, which may be the key pathologic abnormality in both disorders.

In addition to stimulants, α_2-agonists and ATX, both FDA-approved agents for the treatment of ADHD, have shown promise in reducing aggression in patients with ADHD and comorbid ODD or CD. There are few data from type 1 RCTs demonstrating the efficacy of these agents in treating children and adolescents with DBDs and comorbid ADHD (Table 4.4).

TABLE 4.4 FDA-Approved Medications Used for Disruptive Behavior Disorders

Study (Year)	N	Age Range	Inclusion Criteria	Medication Dosage (mean or range)	Design (Duration)	Primary Outcome Measure(s)	Treatment Response	Comment
Stimulants								
Klein et al. (1997)	84	6–15 years	CD	MPH 41.3 mg/day (divided into morning and noon administration)	Double-blind placebo-controlled RCT (5 weeks)	CPRS QRBC	MPH > Placebo	Comorbid ADHD: 69%; MPH effects on CD independent of severity of initial ADHD symptoms
Spencer et al. (2006)	308	6–17 years	ODD or ODD with comorbid ADHD	MAS XR* 10–40 mg/day	Double-blind placebo-controlled forced-dose escalation RCT. Randomized to MAS X*R 10, 20, 30, or 40 mg/day (4 weeks)	SNAP-IV ODD parent rating subscale	MAS XR* (30 and 40 mg/day) > Placebo	Comorbid ADHD: 79.2% Lack of treatment response when analysis limited to patients without comorbid ADHD (21%)
Sinzig et al. (2007)	85	6–16 years	ADHD with comorbid oppositional and aggressive behavior	MPH-MR† (20–30 kg, max 20 mg; 31–50 kg, max 40 mg; >50 kg, max 60 mg)	Double-blind placebo-controlled (5 weeks)	ODD/CD-symptom checklist	MPH-MR† > placebo in decreasing oppositional symptoms; degree of symptom improvement: school > home	Comorbid ODD/CD: 64.7%
Blader et al. (2010)	65	6–13 years	ADHD with comorbid DBD (CD or ODD) and stimulant-refractory aggression	OROS MPH 18–90 mg/day (mean dose for responders: 52.33 mg/day)	Open stimulant monotherapy optimization protocol	MOAS	Aggression among 49.3% of children was reduced sufficiently after stimulant dosage adjustment	All families received behaviorally oriented psychosocial treatment.
Alpha-2 Agonists								
Connor et al. (2000)	24	6–16 years	ADHD with comorbid DBD (CD or ODD)	Clonidine 0.17 mg/day MPH 32.5 mg/day	Double-blind RCT group comparison of MPH vs. clonidine vs. MPH + clonidine (12 weeks)	DBS	MPH = clonidine = MPH + clonidine in symptom reduction of ODD or CD symptoms on the DBS	

Hazell et al. (2003)	67	6–14 years	ADHD with comorbid DBD (CD or ODD)	Clonidine 0.10–0.20 mg/day	Double-blind placebo-controlled RCT of adjuvant clonidine added to stimulant for hyperactivity and aggression (6 weeks)	CPRS-RS (Conduct and hyperactivity subscales)	• Clonidine > Placebo in reducing conduct symptoms • Clonidine = Placebo in reducing hyperactive symptoms	Treatment effect on conduct scale not apparent until about 5th week
Connor et al. (2010)	217	6–12 years	ADHD with oppositional symptoms (ODD included)	Guanfacine XR 1–4 mg/day	Double-blind placebo-controlled dose-optimization RCT (9 weeks)	CPRS-RL (Oppositional subscale)	Guanfacine XR > Placebo	Medication washout (including stimulants) prior to randomization
Atomoxetine								
Bangs et al. (2008)	226	6–12 years	ADHD with comorbid ODD/CD	ATX 1.2–2.4 mg/kg per day	Double-blind placebo-controlled RCT (8 weeks)	SNAP-IV ODD and ADHD subscales	• ATX = Placebo for ODD at 8 weeks (end of study) but medication was superior to placebo at 2 and 5 weeks. • ATX > placebo for ADHD	Medication washout (including stimulants) prior to randomization
Dell'Agnello et al. (2009)	156	6–15 years	ADHD with comorbid ODD/CD and non-responders to previous 6-week parent support phase	ATX 1.10 ± (SD: 0.13) mg/kg per day	Double-blind placebo-controlled RCT (8 weeks)	SNAP-IV ODD and ADHD subscales	ATX > placebo for both ADHD and ODD	
Dittman et al. (2011)	180	6–17 years	ADHD with comorbid ODD/CD	ATX 1.2 mg/kg per day day administered in fast vs. slow up-titration	Double-blind placebo-controlled RCT (9 weeks)	SNAP-IV ODD and ADHD subscales	• ATX > placebo for both ADHD and ODD • Slow up-titration = fast up-titration in terms of efficacy • Slow up-titration > fast up-titration in term of tolerability	Medication washout (including stimulants) prior to randomization

*MAS XR: mixed amphetamine salts extended release (*Adderall XR*)

†MPH-MR: Medikinet retard® (modified-release MPH preparation with a two-step dynamic to release MPH: 50% immediate release, 50% sustained release; available in Germany and other European countries)

SCALES: CPRS: Children's Psychiatric Rating Scale, CPRS-RL: Conners' Parent Rating Scale–Revised Long Form, CPRS-RS: Conners' Parent Rating Scale–Revised Short Form, DBS: Disruptive Behavior Scale, MAOS: Modified Overt Aggression Scale, QRBC: Quay Revised Behavior Checklist, SNAP-IV: Swanson, Nolan, Pelham-IV.

Second-Generation Antipsychotics

Antipsychotic agents have also been used to control disruptive behavior (with or without comorbid ADHD), particularly when aggression is a core feature. In the 1980s, first-generation antipsychotics such as haloperidol, thioridazine, and molindone were studied in aggressive children with CD and were found to be superior to placebo. However, their side effect profile included sedation and extrapyramidal symptoms, making these agents difficult to tolerate, so the focus has shifted to second-generation antipsychotics (Findling, 2008). The efficacy and safety of these agents (also known as atypical antipsychotics), including risperidone, olanzapine, quetiapine, and aripiprazole, in treating aggressive children with CD and other DBDs has been examined by multiple studies in the past decade, although the majority of these trials are not type I RCTs. The pharmacological mechanism of action through which second-generation antipsychotics may inhibit aggression is not understood, but some investigators have suggested that they exert their antiaggressive action by blocking dopamine and serotonin (Schur et al., 2003).

Risperidone is the most frequently studied atypical antipsychotic and has the largest number of published type I RCTs for treating pediatric aggression in patients with both normal and low intellectual functioning. In addition, risperidone has the FDA indication for the treatment of irritability in children and adolescents (aged six to fifteen) with autism. The majority of patients examined in studies who have a diagnosis of DBD (CD, ODD, or DBD not otherwise specified with aggression) also have comorbid ADHD. There are seven randomized placebo-controlled trials that assessed the acute efficacy and safety of risperidone and one study that assessed time to symptom recurrence over a six-month period of maintenance treatment (Loy et al., 2012). In the earliest of these short-term trials, Findling and colleagues randomized 20 children and adolescents (aged 5 to 15 years) with average intelligence and primary CD to risperidone or placebo. The primary outcome measure used in this study was the RAAPP. Risperidone, in relatively low doses (0.75 to 1.5 mg/day), was superior to placebo in improving aggression on most measures and was reasonably well tolerated. None of the risperidone-treated youth developed extrapyramidal side effects, and the most common side effect was weight gain (Findling et al., 2000). In two additional small and short-term RCTs, youth with DBDs and subaverage intelligence (CD, ODD, and ADHD with persistent and overt aggression) who were randomized in a parallel fashion to either risperidone or to placebo showed significant improvement on the primary outcome measure (Buitelaar et al., 2001; Van Bellingham & Troch, 2001). Notably, in the Buitelaar study, the participants were selected from two inpatient settings, and their aggressive behavior had to have failed to respond to behavioral treatment approaches. In the Van Bellinghen study, patients were selected from residential care settings.

In addition, there are two larger scale 6-week outpatient multicenter double-blind placebo controlled trials in youth (aged 5 to 12 years) with DBDs and subaverage intelligence. Aman and colleagues conducted a parallel-group trial of risperidone in 118 children with severe DBDs, including CD, ODD, or DBD not otherwise specified, and subaverage intelligence (IQs 36 to 84). Fifty-nine percent of the subjects had comorbid ADHD and were permitted to remain on a psychostimulant if the dose had been stable for at least 30 days prior to the start of the study. Patients were randomly assigned to receive risperidone at a weight-adjusted dose of 0.02 to 0.06 mg/kg per day or placebo (mean dose at endpoint 1.16 mg/day) (Aman et al., 2002). By the first week of treatment, there was a significantly greater reduction in symptom severity with risperidone compared to placebo on the primary outcome measure (mean change from baseline on the Conduct Problem Subscale of the NCBRF). A parallel multicenter study by Snyder and colleagues that used the same selection criteria, experimental design, and dosing scheme enrolled a total of 110 patients (Snyder et al., 2002). Comparable to the Aman study, Snyder and colleagues reported a significantly large percentage of subjects with comorbid ADHD, specifically 80% of participants. The mean dose of risperidone was 0.98 mg/day, and there was a similar reduction in symptom severity on the Conduct Problem Subscale of the NCBRF. A subanalysis showed that the effect of risperidone was unaffected by diagnosis, presence/absence of ADHD, stimulant use, IQ, or somnolence (Snyder et al., 2002). Somnolence was the most commonly reported side effect with risperidone in both multicenter RCTs (Aman et al. 51%; Snyder et al. 41.5%). Nonetheless, somnolence was generally mild and transient in both studies and led to discontinuation in only two subjects. Notably, in both studies, the positive effects of risperidone on behavior measures were

shown to be independent of the sedative effects. In addition, there was significant weight gain with risperidone compared to placebo in both studies, with mean weight increases of 2.2 kg and 0.9 kg (Aman et al.) and 2.2 kg and 0.2 kg (Snyder et al.) in the risperidone and placebo groups, respectively. Finally, in both studies, prolactin levels increased with risperidone versus placebo, but there were no clinically significant adverse events related to elevated prolactin levels.

Although there are numerous type 1 RCTs supporting the clinical utility of risperidone for the acute treatment of DBDs (CD, ODD), particularly in youth with subaverage intelligence, there is only one RCT that examines the efficacy of long-term maintenance treatment in a sample of patients with average intelligence (Reyes et al., 2006). During the first 12 weeks of treatment, 527 patients (aged 5 to 17 years) of normal intelligence with DBDs (CD, ODD, or DBD not otherwise specified) received 6 weeks of open-label risperidone that was flexibly dosed based on body weight (acute phase). For patients weighing less than 50 kg, their dose range was 0.25 to 0.75 mg/day, and for patients weighing 50 kg or above, their dose range was 0.5 to 1.5 mg/day. Subsequently, responders entered continuation treatment, defined as 6 weeks of single-blind risperidone at the same dose taken during the acute phase. Of the initial 527 patients, 335 youth exhibited sustained response and were randomly assigned to 6 months of double-blind treatment with either risperidone or placebo. During the 6-month maintenance phase, patients randomized to risperidone were continued on the same dose they had been taking during the continuation phase, which could not be adjusted. The primary efficacy measure was the time to symptom recurrence, defined as deterioration of at least 2 points on the Clinical Global Impression Severity Rating Scale (CGI-I) or 7 points on the Conduct Problem Subscale of the NCBRF. Risperidone was effective for relapse prevention; the rate of relapse was significantly higher in the placebo group (42%) than in the risperidone group (27%). Youth who continued risperidone also had a significantly longer time to symptom recurrence compared to those switched to placebo. The time until 25% of the patients experienced symptom relapse was 119 days in the risperidone group versus 37 days in the placebo group (Reyes et al., 2006). Similar to the populations examined in the short-term RCTs of risperidone in the management of DBDs, there was a large percentage of patients in this study with comorbid ADHD (67%), and 24% of the overall population were taking stimulants.

As part of the 2012 Cochrane Review of atypical antipsychotics for disruptive behavior, data pooled from two trials (Aman et al., 2002; Findling et al., 2000) (combined N = 138) demonstrated that participants on risperidone gained 2.37 kg on average more than those in the placebo group over 6 to 10 weeks of treatment (Loy et al., 2012). Because there are very limited longer-term data, it is unclear whether the effect will weaken or worsen over time. There are also minimal data regarding metabolic side effects in these studies. In regards to potential long-term side effects, there does not seem to be an association between risperidone and adverse changes in height or pubertal development, which need to be considered when administering pharmacotherapy to children and adolescents. Dunbar and colleagues compared the observed versus the expected outcomes for height and sexual maturation in pooled data from five studies that included 700 children and adolescents (aged 5 to 15 years) with disruptive behavior disorders. Patients receiving up to 12 months of risperidone had an average increase in height that was 1.2 cm greater than the reference population. There was also no delay in sexual maturation, measured according to Tanner staging, in risperidone-treated patients.

Although elevated prolactin levels have been found to accompany treatment with risperidone, these elevated levels have not been associated with abnormal growth or delayed sexual maturation in short-term studies (Dunbar et al., 2004). In another examination of the data collected from five trials, Findling and colleagues looked at the possible association between adverse events and the elevated prolactin levels found in patients treated with risperidone over the long term. Although youth treated with risperidone had an initial increase in prolactin levels, predominantly during the first 2 months of treatment, prolactin levels slowly decreased over 1 year of treatment. At least one side effect hypothetically attributable to prolactin (i.e., amenorrhea and hirsutism in girls, erectile dysfunction and galactorrhea in boys, and breast enlargement, decreased libido, osteoporosis, and failure to enter or progress through puberty in both girls and boys) was reported in 2.2% of children, but no direct correlation between hyperprolactinemia and these side effects was found (Findling et al., 2003).

Quetiapine has shown benefit in treating DBDs and aggression. This includes one small RCT of 9 patients (aged 12 to 17) with CD, and one small 8-week open-label single-site study of 17 youth (aged 6 to 12) with CD and the corresponding 18-week open-label extension trial (Connor et al., 2008; Findling et al., 2006, 2007). Connor and colleagues randomized 9 youth with CD (co-morbid ADHD: 79%) to 7 weeks of quetiapine or placebo. Quetiapine was dosed twice daily and could be titrated through the end of week 5. The dose was held constant for the final 2 weeks of the study, and the mean dose of quetiapine was 294 ± 78 mg/day. Quetiapine was found to be superior to placebo on the primary outcome measures, Clinical Global Impressions-Severity (CGI-S) and -Improvement (CGI-I) scales.

Limited data exist for the treatment of DBDs with aripiprazole. Although there are no type 1 RCTs, there are two small open-label studies of aripiprazole for the treatment of CD. Findling and colleagues enrolled 23 youth (ages 6 to 15 years) in an open-label study to evaluate the dosing, safety, and effectiveness of aripiprazole in children and adolescents with CD. At the end of 15 days, approximately 52% of study participants responded to treatment, as evidenced by improvements in RAAPP scores and CGI-S scores based on clinician and parent observations (Findling et al., 2009). Kuperman and colleagues found a reduction in aggressive behavior in ten adolescent boys (aged 13 to 17 years) as measured by the total score on the MOAS and the CAS-P. In both studies, the initial aripiprazole dose depended on the weight of the patient: less than 25 kg, 1 mg/day; 25 to 50 kg, 2 mg/day; 51 to 70 kg, 5 mg/day; and more than 70 kg, 10 mg/day (Kuperman et al., 2011). The maximum dose was 15 mg/day and 20 mg/day in the Findling and Kuperman studies respectively.

There are scant published data on the use of olanzapine in treating DBDs, with no type 1 RCTs. Handen and colleagues conducted an 8-week open-label prospective trial of olanzapine in 16 adolescents (aged 13 to 17 years) with DBDs (CD, OD, DBD not otherwise specified, or ADHD with significant irritability and disruptive behavior). Dosing ranged from 5 to 20 mg/day, with an average dose of 13.7 mg/day. Although there was statistically significant improvement on the Irritability and Hyperactivity subscales of the Aberrant Behavior Checklist (ABC; Aman et al., 1985) and on the Conners' Parent Rating Scale Hyperactivity Index from the parent version of the Conners' Scale (Goyette et al., 1978), four subjects discontinued prematurely due to worsening symptoms or side effects. Weight gain was the most common side effect, with a mean weight gain of 12.7 pounds (Handen & Hardan, 2006). Masi and colleagues examined the efficacy and tolerability of olanzapine (mean dose 8 ± 3.2 mg/day) in a retrospective chart review of 23 youth with CD who had not adequately responded to mood stabilizers or nonpharmacological interventions. Subjects were followed for 6 to 12 months. Based on both an improvement of at least 50% on the MOAS, and a score of 1 or 2 on CGI-I, 60.9% of subjects responded to treatment with olanzapine. Mean weight gain at the end of the follow-up was 10 ± 6.6 pounds (Masi et al., 2006).

To date, there are no published studies examining the effects of ziprasidone on aggression. However, there are unpublished data investigating the efficacy, safety, and tolerability of ziprasidone versus placebo in the treatment of CD, ODD, and DBD not otherwise specified in older children and adolescents in an outpatient study (Shulz, unpublished data; http://clinicaltrials.gov/show/NCT00676429).

Psychostimulants Augmented with Second-Generation Antipsychotics

There is also limited evidence for the efficacy of combining psychostimulants with atypical antipsychotics in treating ADHD comorbid with DBDs. Importantly, no studies have specifically compared monotherapy with second-generation antipsychotics to combination treatment (Linton et al., 2013). In the sole randomized double-blind placebo-controlled study of combination therapy, Armenteros and colleagues added risperidone for treatment-resistant aggression in youth with ADHD who had not sufficiently responded to a psychostimulant alone. In this small pilot study, they randomized twenty-five children (aged 7 to 12 years) with ADHD and significant aggressive behaviors to receive either risperidone (mean dose: 1.08 mg/day) or placebo for 4 weeks. Youth were already in treatment with a constant dose of a stimulant medication for at least 3 weeks before entering the study and remained on this dose. Although ADHD symptoms may have improved, aggressive behaviors had failed to respond to stimulant medication alone. The primary efficacy measures were changes from baseline on the total scores of the CAS-P and the CAS-T (Halperin et al., 2002, 2003). After 4 weeks, risperidone augmentation of psychostimulant

treatment produced a significant reduction in aggressive behaviors (decrease of at least 30% in CAS-P total score) compared to augmentation with placebo. Nonetheless, there were no differences in the individual subscales of the CAS-P or in the CAS-T total score or in any of its subscales. There was also a large placebo response rate (Armenteros et al., 2007). Greater than 10% of the risperidone treatment group experienced abdominal pain and vomiting, but no one discontinued treatment. Notably, there was neither a significant difference in weight gain nor in BMI between treatment groups. This result is certainly unusual compared to the majority of studies with second-generation antipsychotics that have demonstrated a significant amount of weight gain, although the small size and brief duration of this study limit its ability to detect significant differences (Armenteros et al., 2007).

In another antipsychotic/stimulant combination study, Kronenberger and colleagues examined the efficacy and safety of adding quetiapine to OROS-MPH for comorbid ADHD and DBD. This was a prospective open-label study of adjuvant quetiapine for youth (aged 12 to 16) with ADHD and comorbid DBDs (CD or ODD) and moderate aggressivity who had not adequately responded to MPH monotherapy. Twenty-four youth received 3 weeks of OROS MPH monotherapy titrated up to 54 mg/day. Those subjects, who remained symptomatic, subsequently received 9 weeks of adjuvant quetiapine (mean dose: 392.2 mg/day). At the conclusion of the study, the addition of quetiapine to OROS-MPH effectively reduced ADHD and aggression (as per the CGI-I, RAAPP, and ADHD-RS-IV criteria for significant improvement) in individuals who did not respond sufficiently to OROS-MPH alone. Mild and transient sedation was reported by about half of treatment subjects. Initial weight loss (1.98 pounds) during MPH treatment was offset by weight gain (2.65 pounds) during combination treatment (Kronenberger et al., 2007). Similarly, two post hoc reviews of data from naturalistic cohort studies found that stimulant therapy did not provide a significant protective effect against the weight gain and metabolic changes associated with second-generation antipsychotics (Carlage et al., 2009; Penza et al., 2009).

Mood Stabilizers

Mood stabilizers, such as lithium and divalproex, have also been shown to be effective in treating aggression in youth with DBDs. In two small type 1 RCTs, lithium was superior to placebo in measures of global improvement and in reduction of aggression in children and adolescents with CD in an inpatient setting (Campbell et al., 1995; Malone et al., 2000). In the only negative RCT that reported that lithium was not more effective than placebo in reducing CD symptoms, lithium was administered for only 2 weeks versus 6 weeks in the studies showing efficacy (Rifkin et al., 1997). Clearly, one of the major downsides to treatment with lithium is the need to closely monitor blood levels to prevent toxicity.

Divalproex was found to be superior to placebo in a small crossover RCT of youth with DBDs, explosive temper, and mood lability (Donovan et al., 2000). Steiner and colleagues randomized 71 adolescents with CD who were living in a residential facility for juvenile offenders to either therapeutic or low doses of divalproex for 7 weeks. Both subjects and clinicians were blinded to treatment status. Symptom severity and global improvement ratings were more favorable after administration of higher/therapeutic doses (500 to 1,500 mg/day) than lower doses (up to 250 mg/day) of divalproex (Steiner et al., 2003).

Divalproex has also been examined as an augmenting agent with psychostimulants for reducing aggression among children with ADHD and a DBD, whose chronic aggression was refractory to optimized stimulant treatment alone. Youth (aged 6 to 13 years) diagnosed with ADHD and either ODD or CD were recruited into a treatment study with an open 5-week lead-in phase of stimulant monotherapy and family-focused behavioral management treatment (Blader et al., 2009), where the goal was to identify the optimal agent and dose for each child. Subsequently, subjects whose aggressive behavior persisted at the end of 5 weeks were randomized in a double-blind fashion to receive divalproex or placebo as an adjuvant treatment for 8 weeks. Adjuvant divalproex (mean dose: 567 mg/day; mean serum valproic acid level: 68 mg/liter) was more effective than adjuvant placebo in decreasing aggressive behavior: 57% of subjects randomized to divalproex met remission criteria compared to 15% of those assigned to placebo. Finally, carbamazepine was not superior to placebo for reducing aggressive behavior in the one double-blind placebo-controlled trial of subjects with aggressive CD (Cueva et al., 1996).

Before initiating psychopharmacological treatment to target impulsive aggression in children and

adolescents with DBDs, the clinician should consider using psychosocial interventions. This is particularly important since the second-generation antipsychotics like risperidone, which has the most data supporting its efficacy, can cause weight gain and or metabolic side effects.

Psychosocial Treatments for Conduct Disorder in Children and Adolescents

Alan E. Kazdin

Antisocial and aggressive behavior (conduct disorder [CD]) is a severe source of impairment among children and adolescents in light of the stability of the problem, the untoward long-term prognosis, and the diverse domains of dysfunction in the child, parent, and family with which the problem is associated. Significant advances have been made in treatment. Several psychosocial interventions with strong evidence in their behalf with children and adolescents are highlighted and include parent management training, multisystemic therapy, multidimensional treatment foster care, cognitively based treatments, functional family therapy, brief strategic family therapy, and the Good Behavior Game. The treatments have been very well studied with multiple replications. There are some commonalities among the treatments. Two that are salient are the use of techniques of applied behavior analysis (e.g., operant conditioning as a means of behavior change) and focus on the family. These are not part of all of the techniques covered but encompass most of them. Also, the set of treatments as a whole has addressed the full range of severity of dysfunction and age through childhood and adolescence. Thus, the evidence applies to oppositional and conduct problems in early childhood, severe aggressive and antisocial behavior at home and at school among children referred for either inpatient or outpatient treatment, and adolescents who have been adjudicated for serious acts of delinquency. Outcomes have been reflected on a range of measures and indices of antisocial behavior, including psychological measures of impairment and symptoms but also on dropping out of school, substance use, pregnancy rate, criminal activity, hospitalization, and readjudication. There remain questions about the long-term impact of treatments, the persons for whom one or more of these treatments is well suited, and how to optimize therapeutic change. Disseminating effective interventions to professionals in clinical practice and reaching the majority of children in need who do not receive treatment remain critical challenges. Even so, the extensive evidence indicates that there are several viable treatments for CD.

INTRODUCTION

Antisocial behavior in children refers to social rule violations and actions against others and includes such behaviors as fighting, lying, and stealing. Many such behaviors are evident in varying degrees over the course of child development. CD refers to antisocial behavior that clearly is beyond the realm of "normative" functioning in light of its frequency, persistence, intensity, and impact on others (e.g., parents, teachers, peers), and whether it leads to significant impairment of the child. CD is currently recognized as a psychiatric disorder with a constellation of symptoms, likely history, and long-term course.

The significance of CD as a clinical and social problem derives from several factors (e.g., Colman et al., 2009; Hill & Maughan, 2001; Loeber, Burke, & Pardini, 2009; Murray & Farrington, 2010). The

behaviors that constitute CD are among the most frequent bases of clinical referral in child and adolescent treatment services and encompass from one third to one half of referred cases. Moreover, children with CD often traverse multiple social services in childhood, adolescence, and adulthood (e.g., special education, mental health, juvenile justice). This contributes to the fact that CD is one of the most costly mental disorders in the United States. The estimated cost for a child with CD is $10,000 to $15,000 per year for social services over the course of childhood and adolescence (Bonin et al., 2011; Foster & Jones, 2005; Scott, Knapp, Henderson, & Maughan, 2001). These costs are 10 times greater than for a child without the diagnosis.

Fortunately, significant advances have been made in developing effective interventions, in relation to both treatment and prevention (see Baldwin et al., 2012; Christopherson & Vanscoyoc, 2013; Steele, Elkin, & Roberts, 2008; Weisz & Kazdin, 2010). This chapter reviews advances in psychosocial treatments for CD and aggressive and antisocial behavior more generally. The treatments were selected because they have been carefully evaluated in randomized controlled clinical trials with children and adolescents.[1] The chapter describes and evaluates the current techniques and highlights evidence in their behalf. Issues that influence interpretation of the evidence and current and future research directions are discussed.

CHARACTERISTICS OF CONDUCT DISORDER: OVERVIEW

Descriptive Features: Diagnosis and Prevalence

CD reflects a persistent pattern of behavior in which the rights of others and age-appropriate social norms are violated. Isolated acts of physical aggression, property destruction, stealing, fire setting, and running away are sufficiently severe to warrant concern and attention in their own right. Although these behaviors may occur in isolation, several are likely to appear together as a constellation or syndrome and form the basis of a clinical diagnosis. For example, in the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*; American Psychiatric Association [APA], 2013), the diagnosis of CD is merited if the child shows at least three of 15 symptoms within the past 12 months, with at least one symptom evident within the past 6 months. The symptoms include bullying others, initiating fights, using a weapon, being physically cruel to people or to animals, stealing items of nontrivial value, stealing while confronting a victim, forcing someone into sexual activity, fire setting, destroying property, breaking into others' property, staying out late, running away, lying, and truancy.

Using these diagnostic criteria or criteria from prior versions of the *DSM*, the prevalence of the disorder among community samples of school-age youth is approximately 2% to 10% (median 4%; APA, 2013). The lifetime prevalence rate is approximately 10% (Nock, Kazdin, Hiripi, & Kessler, 2006). One of the most frequent findings is that boys show approximately three to four times higher rates of CD than girls. The prevalence rates of CD are likely to underestimate the extent of the problem. The criteria for delineating individual symptoms and the diagnosis are recognized to be somewhat arbitrary. Youths who approximate but fail to meet the diagnosis, sometimes referred to as subsyndromal or subclinical, often are significantly impaired. CD is better represented as a spectrum disorder or set of continua based on the number, severity, and duration of symptoms and degree of impairment rather than as a condition achieved by a particular cutoff.

Subtypes and Patterns to Delineate Subgroups

Clearly, CD is not a homogeneous disorder. Indeed, given the diagnostic criteria mentioned previously, over 32,000 distinct symptom profiles can be identified that would qualify for the diagnosis. It is unlikely that CD results from a single cause or set of causes in principle because there is no single or circumscribed pattern that the diagnosis identifies. Research identifying different ways of delineating subgroups of CD makes up a large literature in an effort to refine how to view the disorder(s).

In *DSM-5*, subtypes are recognized based on the age of onset and life course. Box 5.1 summarizes the subtypes. The pattern that reflects a more severe form of the disorder is early onset, which includes aggressive behavior and a worse long-term prognosis than the more common adolescent onset. Longitudinal research has supported key facets of these patterns (Moffitt et al., 2001; Moffitt & Caspi, 2005; Reid, Patterson, & Snyder, 2002). Among the interesting patterns, the higher prevalence rate for of CD boys

BOX 5.1 Currently Delineated Subtypes of Conduct Disorder

Child Onset (a.k.a. Life-Course Persistent)
- Begins in childhood
- Associated with aggressive behavior
- More common among boys
- More likely to show deficiencies in planning, problem solving, and abstract reasoning
- Poor prognosis—more likely to continue into adulthood
- More dropping out of school, more violent crime
- Harsh parenting practices play an important role
- The more severe form of the disorder

Adolescent Onset (a.k.a. Adolescent Limited)
- Begins in adolescence
- More common than child onset
- Associated with vandalism and criminal behavior
- More equally distributed among girls and boys
- Less likely to continue antisocial behavior long term
- Peer group influences play a major role
- The less severe form of the disorder

Discontinuous Offending (a.k.a. Low Level, Chronic)
- Pervasive symptoms, looks like child-onset group
- Rate of the problems not as severe—more sporadic
- Socially isolated and tend to be withdrawn

DSM-5 recognizes the first two and has as a third type, "unspecified onset," when the information is not available. I have included "Discontinuous Offending" as a third type that has emerged in research but is not as well established or as frequent as the first two subtypes (see Moffitt et al., 2008, for a thorough discussion of CD and *DSM* subtypes and related matters).

is associated primarily with childhood-onset CD; the boy-to-girl ratio evens out for adolescent-onset CD. Although onset and life course have evidence in their behalf, the subtypes have not emerged in many analyses of CD, and there are common features that span these subtypes (e.g., Kendler, Aggen, & Patrick, 2013; Nock et al., 2006; Waldman et al., 2011). Also, within a given subtype (e.g., child onset), it is likely that vast distinctions need to be made.

Apart from subtypes, callousness-unemotional interpersonal personality style influences CD. A callous-unemotional style consists of lack of guilt and lack of empathy or remorse (Frick, Ray, Thornton, & Kahn, 2014; Rowe et al., 2010). CD children high in callous-unemotional style are considered to have more severe and persistent symptoms. Also, they are characterized by sensation seeking, less sensitivity to emotional stimuli, and lower levels of anxiety. Callousness has been an extremely active area of research. Overall, subtypes and interpersonal style are useful to convey that advances are being made in delineating facets that might help with the enormous heterogeneity of youth and symptom constellations that constitute CD. As yet, the subtypes and patterns that have been studied do not provide clear guidelines to suggest what treatments to provide or not to provide.

Scope of Dysfunction

If one were to consider "only" the symptoms of CD and the persistence of impairment, the challenge of identifying effective treatments would be great enough. However, the presenting characteristics of children and their families usually raise other considerations that are central to treatment. Consider the characteristics of children, families, and contexts that are associated with CD as a backdrop for later comments on treatment.

Child Characteristics. Children who meet criteria for CD are likely to meet criteria for other disorders as well. The coexistence of two or more disorders is referred to as comorbidity. Although comorbid disorders among youth with CD span the full range of psychiatric diagnoses (Nock et al., 2006), those involving other disruptive or externalizing behaviors (oppositional defiant disorder, attention-deficit/hyperactively

disorder) are especially likely. In my own work (and only one clinic), children referred for CD meet criteria for a mean of 2.4 disorders and occasionally extending up to five disorders (Kazdin, 2010). This conveys that the challenge of treatment is beyond pairing a given treatment with a given disorder.

Children with CD are likely to show academic deficiencies, as reflected in achievement level, grades, being left behind in school, early termination from school, and deficiencies in specific skill areas such as reading. Youths with the disorder are likely to evince poor interpersonal relations, as reflected in diminished social skills in relation to peers and adults, bullying, and higher levels of peer rejection. They are likely to show deficits and distortions in cognitive problem-solving skills, attributions of hostile intent to others, and resentment and suspiciousness. Clearly, CD is pervasive in the scope of child characteristics that are affected.

Parent and Family Characteristics. Several parent and family characteristics are associated with CD. Criminal behavior and alcoholism are two of the stronger and more consistently demonstrated parental characteristics. Harsh, lax, erratic, and inconsistent parent disciplinary practices and attitudes often characterize the families of CD children. Dysfunctional relations also are evident, as reflected in less acceptance of their children; less warmth, affection, and emotional support; and less attachment, compared to parents of nonreferred youths. Less supportive and more defensive communications among family members and less participation in activities as a family are also evident. In addition, unhappy marital relations, interpersonal conflict, and aggression characterize the parental relations of antisocial children. Poor parental supervision and monitoring of the child and knowledge of the child's whereabouts also are associated with CD.

Contextual Conditions. CD is associated with a variety of untoward living conditions such as large family size, overcrowding, poor housing, and disadvantaged school settings. Many of the untoward conditions in which families live place stress on the parents or diminish their threshold for coping with everyday stressors. The net effect can be evident in strained parent–child interactions in which the parent's behavior inadvertently sustains or exacerbates the child's antisocial and aggressive behavior (see Capaldi, DeGarmo, Patterson, & Forgatch, 2002). It is likely there are bidirectional effects in which parent stressors influence child behavior but also child behavior contributes to parental stress (Deater-Deckard, 2004).

Quite often the child's dysfunction is embedded in a larger context that cannot be neglected in conceptual views about the development, maintenance, and course of CD or in the actual delivery of treatment. For example, at our outpatient clinical service (Yale Parenting Center), it is likely that a family referred for treatment will experience a subset of these characteristics: financial hardship (unemployment. significant debt, bankruptcy), untoward living conditions (dangerous neighborhood. small living quarters), transportation obstacles (no car or car in frequent repair, state-provided taxi service), psychiatric impairment of one of the parents, stress related to significant others (former spouses, boyfriends, or girlfriends), and adversarial contact with an outside agency (schools, youth services, courts, debt collection). Many of these characteristics can be captured by standardized psychological measures that quantify stress or impairment. However, many characteristics that influence child and family functioning and indeed treatment are more qualitative, idiosyncratic, and not easily assessed (e.g., husbands who stalk their wives and monitor their calls and whereabouts; parents who buy weapons for their children with CD; parents who train their children to shoplift with them; and mothers who use their homes to sell alcohol and sex in the neighborhood). Such events are not always present. However, these are all real examples and, lamentably, not at all rare stories.

Prognosis of Conduct Disorder

Longitudinal studies have consistently shown that CD identified in childhood predicts a continued course of social dysfunction, problematic behavior, and poor school adjustment. The classic studies showed that antisocial child behavior predicts multiple problems in adulthood 30 years later (Robins. 1966, 1978). Youths who are referred for their antisocial behavior, compared to youths with other clinical problems or matched controls without clinical dysfunction, are likely to show psychiatric symptoms, criminal behavior, physical health, and social adjustment in adulthood. Even though CD portends a number of other significant problems, not all children with antisocial behavior will suffer impairment as adults: Among the

most severely antisocial children, fewer than 50% become antisocial adults. If diverse diagnoses are considered, rather than serious antisocial behavior alone, the picture of impairment in adulthood is much worse. Among youths referred for antisocial behavior, over 80% received a diagnosis of some psychiatric disorder as adults.

Additional longitudinal studies have replicated and extended these early findings (e.g., Fergusson et al., 2005; Moffitt et al., 2001; Murray & Farrington, 2010; Olino, Seeley, & Lewinsohn, 2010). The scope of physical as well as psychiatric consequences also has been elaborated. For example, many children with CD have been subjected to abusive parenting practices that predict higher morbidity and mortality rates from serious disease (e.g., heart attack, cancer, respiratory illness) in adulthood (Krug, Dahlberg, & Mercy, Zwi, & Lozano, 2002). In short, the scope of consequences, suffering, and impairment over the life course is quite astounding. Beyond what CD youths suffer as they move to adolescence and adulthood, the suffering of the victims of their acts (e.g., criminal activity, domestic violence) is enormous as well.

Risk Factors for Conduct Disorder

Decades of research have focused on characteristics, events, and experiences that place individuals at risk for CD. Risk factors are antecedents that correlate with a subsequent outcome. Numerous factors have been identified that predispose children and adolescents to CD. Box 5.2 highlights several risk factors. Risk factors convey important information in identifying cases and in generating hypotheses about processes involved in onset and course, and possible causal connections. Yet there are many cautions and complexities that are essential in evaluating these factors.

As for the cautions, unless otherwise demonstrated the risk factors are only correlates. It is easy to assume unwittingly that because risk factors come before the onset of the problem they play a causal role. Many interventions, both treatment and prevention, have focused on correlates as if they were pivotal to the disorder. The complexities convey why the focus is risky. First, a given factor and antisocial behavior may have bidirectional relations, so it is not clear which came first. For examples, parent stress, irritability, and punishment can both precede and follow child antisocial behavior.

Second, it has been tempting to consider risk factors to be part of either the child's genes or environment. However, the interplay here too is complex. Seemingly environmental influences (e.g., parenting practices in the home) have strong genetic components (Dodge, 2009). Similarly, genetic influences on the child may readily influence parental behaviors in ways that promote the occurrence of environmental factors that increase risk (Moffitt & Caspi, 2005). For example, genetically mediated antisocial behavior appears to influence the parenting practices of adoptive parents. Child deviance can promote adverse parenting practices. These comments do not signify that parenting practices are genetically controlled or fixed; they are in a dynamic relation with multiple influences.

Third, some risk factors are proxies for other variables—that is, they reflect and are accounted for primarily by some other variable. For example, teen marriage places the offspring at risk for CD. It is not likely that marrying early per se is the critical influence because teen marriage is associated with antisocial behaviors and delinquency in girls, liaisons with antisocial men, less schooling, and higher domestic violence, each or all of which might be the critical factor, or explain in whole or in part the predictive value of teen marriage.

Finally, an exciting advance in understanding risk factors is evaluation of gene–environment interactions. This area moved forward considerably by the pioneering finding that the effects of maltreatment of children are moderated by a genetic polymorphism (Caspi et al., 2002), Individuals with a history of abuse and a particular allele (related to serotonin) are at much greater risk for antisocial behavior. Among boys with the allele and maltreatment, 85% developed some form of antisocial behavior (diagnosis of CD, personality assessment of aggression, symptoms of adult personality disorder, or court conviction of violent crime) by the age of 26. Replication of these effects and similar findings has underscored the critical role of gene–environment interactions in antisocial outcomes (Foley et al., 2004; Jaffee et al., 2005). Additional work focused on genetic polymorphism related to dopamine has shown that a genetic influence is moderated by environmental experiences (e.g., Lahey et al., 2011). Larger-scale genome-wide associations are increasing and are generating promising leads

BOX 5.2 Factors that Place Youths at Risk for the Onset of Conduct Disorder

Child Factors

Difficult Child Temperament. A more difficult child temperament (on a dimension of "easy to difficult"), as characterized by more negative mood, lower levels of approach toward new stimuli, and less adaptability to change.

Neuropsychological Deficits and Difficulties. Deficits in diverse functions related to language (e.g., verbal learning, verbal fluency, verbal IQ), memory, motor coordination, integration of auditory and visual cues, and "executive" functions of the brain (e.g., abstract reasoning, concept formation, planning, control of attention).

Subclinical Levels of Conduct Disorder. Early signs (e.g., in elementary school) of mild ("subclinical") levels of unmanageability and aggression, especially with early age of onset, multiple types of antisocial behaviors, and multiple situations in which they are evident (e.g., at home, school, the community).

Hyperactive, Impulsive, Oppositional Defiant Disorder. One of these disorders increases risk of academic deficiencies and lower levels of intellectual functioning.

Poor Bonding and Attachment to Conventional Values. Little connection to family life and schoolwork or to others who are bonded to these values.

Parent and Family Factors

Prenatal and Perinatal Complications. Pregnancy- and birth-related complications, including maternal infection, prematurity and low birth weight, impaired respiration at birth, and minor birth injury.

Psychopathology and Criminal Behavior in the Family. Past or current criminal behavior, antisocial personality disorder, and alcoholism of the parent.

Untoward and Coercive Parent–Child Interaction. Harsh (e.g., severe corporal) punishment, inconsistent punishment, and coercive interchanges increase risk.

Poor Monitoring of the Child. Poor supervision, lack of monitoring of whereabouts, and few rules about where youth can go and when they can return.

Poor Quality of the Family Relationships. Less parental acceptance of their children, less warmth, affection, and emotional support, and less attachment.

Early Marriage. Teen marriage of the child's mother.

Marital Discord. Unhappy marital relationships, interpersonal conflict, and aggression of the parents.

Large Family Size. More children in the family.

Sibling with Antisocial Behavior. Presence of a sibling, especially an older brother, with antisocial behavior.

Few Family Activities. Little involvement of the family in activities (e.g., recreation, religious) together

Socioeconomic Disadvantage. Poverty, overcrowding, unemployment, receipt of social assistance (welfare), and poor housing.

School-Related Factors

Characteristics of the Setting. Attending schools where there is little emphasis on academic work, little teacher time spent on lessons, infrequent teacher use of praise and appreciation for schoolwork, little emphasis on individual responsibility of the students, poor working conditions for pupils (e.g., furniture in poor repair), unavailability of the teacher to deal with children's problems, and low teacher expectancies.

The list of risk factors highlights major influences. The number of factors, their influence, and their interactions are more complex than the summary statements noted here. For a more detailed discussion, other sources can be consulted (e.g., Boden, Fergusson, & Horwood, 2010; Hill & Maughan, 2001; Murray & Farrington, 2010).

on the underpinnings of CD (Dick et al., 2010). More generally, the work on gene–environment interactions provides leads in searching for mediators of action but also might provide a stronger basis for subtyping CD.

In general, no single characteristic or risk factor seems to be necessary or sufficient to account for the onset of the disorder. Even though some risk factors are more important than others, the accumulation of factors (i.e., number present) itself is important. One or two risk factors may not increase risk very much. With several risk factors, however, the likelihood of the outcome may increase sharply. Even with the presence of multiple risk factors, however, the outcome is not determined: Some individuals at high risk may not show any dysfunction. Many factors that contribute to reducing risk, referred to as protective factors, have been identified, but these are less well studied than risk factors.

General Comments

CD is conceived as a dysfunction of children and adolescents. The accumulated evidence regarding

the symptom constellation, associated features, and risk factors, as well as the course over the lifespan, attests to the heuristic value of focusing on characteristics of the child. At the same time, there is a child/parent/family/context gestalt that includes multiple and reciprocal influences that affect each participant (child and parent) and the systems in which the participants operate (family, school).

From the standpoint of treatment, the striking feature is the scope of child, parent, and family domains that seem in need of urgent attention. Understandably, treatment proponents often note that treatment must be multifaceted to address the multiple domains in which dysfunction are evident (e.g., Crenshaw & Mordock, 2005; Henggeler et al., 2009). This seemingly obvious conclusion is in great need of empirical attention, a point to which we will return. Even so, clearly the treatment of CD raises enormous challenges well beyond the presenting symptoms that lead to the diagnosis

EVIDENCE-BASED TREATMENTS

Overview

Many different treatments have been applied to youths with CD, including variations of psychotherapy; pharmacotherapy; psychosurgery; home-, school-, and community-based programs; residential and hospital treatment; and social services. Several treatments now have solid evidence on their behalf (primarily from randomized controlled trials [type 1], but also from single-case designs in which groups of individuals and their changes have been rigorously evaluated (Muffihy, Kidman, & Ollendick; 2010; Weisz & Kazdin, 2010).[2] I highlight major treatments below and refer to other sources (e.g., books and review articles) where each has been treated in greater detail.

Parent Management Training

Background and Characteristics of Treatment. Parent management training (PMT) refers to procedures in which parents are trained to alter their child's behavior in the home (Kazdin, 2009). The parents meet with a therapist or trainer, who teaches them to use specific procedures to alter interactions with their child, to promote prosocial behavior, and to decrease deviant behavior. Training derives from two views. The first is the position that conduct problem behavior is inadvertently developed and sustained in the home by maladaptive parent–child interactions. These interactions include directly reinforcing deviant behavior, frequently and ineffectively using commands and harsh punishment, failing to attend to appropriate behavior, and coercive exchanges that exacerbate child disruptive behavior (e.g., Patterson et al., 1992; Reid et al., 2002). The second view focuses on how to develop prosocial behaviors. This view underscores the advances in applied behavior analysis that can be used to alter behavior. Not all parents engage in interactions that promote child antisocial behavior, although they may once these behaviors become evident and all reasonable interaction patterns of influencing the child have been exhausted. The views are not incompatible, yet the latter view is the broader one and explains the utility of parent training across many domains (e.g., autism spectrum disorder, child anxiety, academic skills) and populations (e.g., children, adolescents, the elderly) (e.g., Kazdin, 2013a).

PMT alters the pattern of interchanges between parent and child so that prosocial, rather than coercive, behavior is directly reinforced and supported within the family. This requires developing several different parenting behaviors that include the skilled use of antecedents, behaviors, and consequences; establishing the rules for the child to follow; providing positive reinforcement for appropriate behavior; delivering mild forms of punishment to suppress behavior; negotiating compromises; and other procedures. These parenting behaviors are systematically and progressively developed within the sessions in which the therapist shapes (develops through successive approximations) parenting skills. The behavior-change programs that parents eventually implement in the home also serve as the basis for the focus of the sessions in which the procedures are modified and refined.

Many variations of PMT exist and have emanated from several programs of research and with varying names for the intervention, including Parent Management Training—Oregon Model (Forgatch, Patterson, & Gewirtz, 2013), The Incredible Years (Webster-Stratton & Reid, 2010), Triple P (Sanders, 2012), Parent-Child Interaction Therapy (Zisser & Eyberg, 2010), and PMT of others (Forehand & Long, 2010) and our group (Kazdin, 2009, 2010). While distinctions can be made among different programs,

some of which include additional treatment components, several common characteristics of PMT can be identified.

First, treatment is conducted primarily with the parent(s), who implement several procedures in the home. The parents meet with a therapist, who teaches them to use specific procedures to alter interactions with their child, to promote prosocial behavior, and to decrease deviant behavior. There may be little direct intervention of the therapist with the child. With young children, the child may be brought into the session to help train both parent and child how to interact and especially to show the parent precisely how to deliver antecedents (prompts) and consequences (reinforcement, time out from reinforcement). Older youths may participate to negotiate and to develop behavior-change programs in the home. Second, parents are trained to identify, define, and observe problem behaviors in new ways. Careful specification of the problem is essential for delivering reinforcing or punishing consequences and for evaluating whether the program is achieving the desired goals. Third, the treatment sessions cover social learning principles and the procedures that follow from them, including positive reinforcement (e.g., the use of social praise and tokens or points for prosocial behavior), mild punishment (e.g., use of time out from reinforcement, loss of privileges), negotiation, and contingency contracting. Fourth, the sessions provide opportunities for parents to see how the techniques are implemented, to practice using the techniques, and to review the behavior-change programs in the home. The immediate goal of the program is to develop specific skills in the parents. As the parents become more proficient, the program can address the child's most severely problematic behaviors and encompass multiple problem domains (e.g., school behavior). Over the course of treatment, more complex repertoires are developed, both in the parents and in the child. Finally, child functioning at school is usually incorporated into the program. Parent-managed reinforcement programs for child deportment and performance at school, completion of homework, and activities on the playground often are integrated into the behavior-change programs. If available, teachers can play an important role in monitoring or providing consequences for behaviors at school.

Evidence and Evaluation. Over the past 40 years, many randomized controlled studies of PMT have been completed with youths varying in age and degree of severity of dysfunction (e.g., oppositional, CD, delinquent youth). It is important to underscore that the evidence extends well beyond a handful of isolated type 1 studies. The Oregon Model, the earliest program of research, alone has generated scores of studies that have evaluated PMT, assessed factors that contribute to change, and replicated treatment effects across multiple samples and settings (Forgatch & Patterson, 2010). Other programs of research and scores of isolated studies have built on this foundation (see Lundahl, Risser, & Lovejoy, 2006; Weisz & Kazdin, 2010).

Treatment effects have been evident in marked improvements in child behavior on a wide range of measures, including parent and teacher reports of deviant behavior, direct observation of behavior at home and at school, and institutional (e.g., school, police) records. The effects of treatment have also been shown to bring problematic behaviors of treated children within normative levels of their peers who are functioning adequately in the community. Follow-up assessment has shown that the gains are often maintained for 1 to 3 years, but some reports have extended to 9 to 14 years (e.g., Forgatch, Patterson, DeGarmo, & Beldavs, 2009; Long, Forehand, Wierson, & Morgan, 1994).

The impact of PMT can be relatively broad. The effects of treatment are evident for child behaviors that have not been focused on directly as part of training. Also, siblings of children referred for treatment improve, even though they are not directly focused on in treatment. This is an important effect because siblings of children with CD are at risk for severe antisocial behavior. In addition, maternal psychopathology, particularly depression, decreases systematically following PMT (see Forgatch & Patterson, 2010; Kazdin, 2010). These changes suggest that PMT alters multiple aspects of dysfunctional families.

Several characteristics of the treatment contribute to outcome. Longer duration of treatment improves outcome. Programs vary in duration from weeks to months and have been applied to populations varying in age and severity of dysfunction. Second, specific training components, such as providing parents with in-depth knowledge of social learning principles and using time out from reinforcement in the home, enhance treatment effects. Third, families characterized by many risk factors associated with childhood dysfunction (e.g., socioeconomic disadvantage, marital discord, parent psychopathology, poor social

support) tend to show fewer gains in treatment than families without these characteristics and to maintain the gains less well, but this is not always the case. Socioeconomic disadvantage and maternal mental health problems are the more well-studied factors that attenuate responsiveness of the child to PMT. Attenuated or reduced effects does not mean that PMT has been ineffective but that treatment modifiers have been identified that influence outcome. This point also applies to other treatments highlighted later.

The extensive outcome evidence for the treatment of CD is bolstered by related lines of work. First, many of the core procedures (e.g., use of antecedents, reinforcement, shaping, and fading) have been developed in nonhuman animal research on operant conditioning. That research has allowed evaluation of specific behavior-change procedures (e.g., reinforcement schedules, time out) that translate to applied settings (Kazdin, 2013a). Second, early studies on family interaction established maladaptive interactions as a critical feature in the homes of many children and then demonstrated that changes in these patterns led to reduced aggressiveness in the home (Forgatch & Patterson, 2010). This was a strong move from mere correlates and risk factors of child dysfunction to causal relations supporting the procedures.

Third, and perhaps unique among evidence-based interventions, is application and evaluation of PMT well beyond the confines of conduct problems. The techniques that make up PMT (e.g., various forms of reinforcement and punishment practices) have been effectively applied with parents of children with autism spectrum disorder, language delays, intellectual disabilities, and medical disorders for which compliance with special treatment regimens is required, and with foster parents, military families with deployed parents, homeless parents, and parents who physically abuse or neglect their children (Cooper, Heron, & Heward, 2007; Gewirtz, Erbes, et al., 2011; Kazdin, 2013a). In addition to treatment, PMT has been used as a preventive strategy for children at risk for academic dysfunction and untoward mental health outcomes (e.g., Prinz et al., 2009; Sanders, 2008; Webster-Stratton & Reid, 2010). Finally, multiple variations of PMT from the programs listed previously have been extended internationally, with replicated trials attesting to their efficacy. Thus, independent replications well beyond the original sites have many exemplars.

In light of the diverse and extensive applications, a great deal is known about the procedures and parameters that influence the reinforcement and punishment practices that form the core of PMT. Consequently, very concrete recommendations can be provided to change behavior and to alter programs when behavior change has not occurred (Kazdin, 2013a). Many treatment manuals and training materials for PMT are available for parents and therapists, only a small number of which can be noted (e.g., Barkley, 2013; Cavell, 2000; Forehand & Long, 2010; Kazdin, 2009; Kazdin & Rotella, 2008; McMahon & Forehand, 2005; McNeil & Hembree-Kigin, 2010; Turner, Markie-Dadds, & Sanders, 2010; Webster-Stratton, 2006). In short, information about implementing the treatment procedures is readily available. Also, Internet-delivered versions of PMT are available and appear to be effective, as initially studied in randomized controlled trials (e.g., Enebrink, Högström, Forster, & Ghaderi, 2012).

Several limitations of PMT can be identified as well. First, as with any treatment, not everyone responds. Second, PMT makes several demands on the parents, such as mastering educational materials that convey major principles underlying the program, systematically observing deviant child behavior and implementing specific procedures at home, attending weekly sessions, and responding to frequent telephone contacts made by the therapist. For some families, the demands may be too great to continue in treatment. Finally, perhaps the greatest limitation or obstacle in using PMT is that there are few training opportunities for professionals to learn the approach. Training programs in child psychiatry, clinical psychology, and social work are unlikely to provide exposure to the technique, much less opportunities for formal training. PMT requires mastery of social learning principles and multiple procedures that derive from them, but how to implement them is really critical, so learning about the techniques is not likely to be of much value (Cooper et al., 2007; Kazdin, 2013a).

Multisystemic Therapy

Background and Characteristics of Treatment. Multisystemic therapy (MST) is a family systems–based approach to treatment (see Henggeler, 2011; Henggeler et al., 2009). Family approaches maintain that clinical problems of the child emerge within

the context of the family and focus treatment at that level. MST expands on that view by considering the family as only one, albeit a very important, system. The child is embedded in multiple systems, including the family (immediate and extended family members), peers, schools, neighborhood, and so on. Also, within a given system, different subsystem issues may be relevant. For example, within the context of the family, some tacit alliance between one parent and child may contribute to disagreement and conflict over discipline between the parents. Treatment may be required to address the alliance and sources of conflict in an effort to alter child behavior. Child functioning at school may involve limited and poor peer relations; treatment may address these areas as well. Finally, the systems approach entails a focus on the individual's own behavior insofar as it affects others. Individual treatment of the child or parents may be included in treatment. Many different treatment techniques are used to address the multiple foci of the case. Thus, MST can be viewed as a package of interventions deployed with children and their families. Treatment procedures are used "as needed" to address individual, family, and system issues that may contribute to problem behavior. The conceptual view focusing on multiple systems and their impact on the individual serves as a basis for selecting multiple and quite different treatment procedures.

Several family therapy techniques (e.g., joining, reframing, enactment, paradox, and assigning specific tasks) are used to identify problems, increase communication, build cohesion, and alter how family members interact. The goals of treatment are to help the parents develop behaviors of the adolescent, to overcome marital difficulties that impede the parents' ability to function as parents, to eliminate negative interactions between parent and child, and to develop or build cohesion and emotional warmth among family members. MST draws on many other techniques as needed, such as PMT, problem-solving skills training, and marital therapy, to alter parent–child interactions at home, the response repertoire of the child, and marital communication, respectively. In some cases, practical advice and guidance are also given to address parenting issues (e.g., involving the adolescent in prosocial peer activities at school, restricting specific activities with a deviant peer group). Although MST includes distinct techniques from other approaches, it is not a mere amalgamation of them. The focus of treatment is on interrelated systems and how they affect each other. Domains are addressed in treatment (e.g., parent unemployment) if they raise issues for one or more systems (e.g., parent stress, increased alcohol consumption) and affect how the child is functioning (e.g., marital conflict, child-discipline practices). In any given case, multiple interventions are likely to be applied.

Evidence and Evaluation. A large number of randomized control trials have evaluated MST, primarily with delinquent and substance-dependent youths with arrest and incarceration histories including violent crime (Henggeler, 2011; Henggeler et al., 2009). MST is superior in reducing delinquency, drug use, and emotional and behavioral problems and increasing school attendance and family functioning, in comparison to other procedures, including "usual services" provided to such youths (e.g., probation, court-ordered activities that are monitored such as school attendance), individual counseling, and community-based eclectic treatment. Apart from the sheer number of controlled studies, the strength of this literature stems from the breadth of application across age groups and clinical problems.

Follow-up examinations have repeatedly supported the impact of treatment. For example, a 22-year follow-up showed reduction in arrests, adult confinement, and family instability (e.g., divorce, paternity, child support suits) following treatment of delinquency (see http://mstservices.com/proven-results/proven-results). A cost-benefit analysis by the Washington State Institute on Public Policy found that the effects of MST result in net monetary benefits (benefits of program minus cost of program) of approximately $32,000 per participant when considering only taxpayer benefits, and more than $132,000 when considering victim benefits along with taxpayer benefits (Aos, Phipps, Barnoski, & Leib, 2001; http://mstservices.com/proven-results/cost-effectiveness).

Moderators have been identified. For example, therapist adherence to the MST treatment protocol has been related to both improvements in family relations and decreases in delinquent peer affiliation, which, in turn, are associated with decreases in delinquent behavior. Therapist adherence to MST is influenced by referral type (lower ratings for youths referred for both criminal offenses and substance abuse relative to youths referred for either offenses or abuse); lower adherence is related to greater pretreatment arrests and school suspensions; and higher ratings are related to greater family educational

disadvantage and caregiver–therapist ethnic and gender match (Schoenwald, Halliday-Boykins, & Henggeler, 2003; Schoenwald, Letourneau, & Halliday-Boykins, 2005). A positive ethnic match (therapist and caregiver matched on ethnicity) is related to greater symptom reduction, greater length of treatment (i.e., more treatment retention), and increases in the likelihood of case termination due to the meeting of treatment goals (Halliday-Boykins, Schoenwald, & Letourneau, 2005).

There are several remarkable features of MST. First, many of the youths who are treated are quite severely impaired (delinquent adolescents with history of arrest). As part of evaluations of MST with such youth, social impact measures (e.g., rearrest, family problems, dropping out of school) have been studied in addition to the usual and more familiar psychological symptom outcome measures. Second, few evidence-based treatments have follow-up data in several studies, including the virtually unheard of 22-year follow-up of MST mentioned previously.

Third, and possibly the most salient feature, is the dissemination of MST. For a period spanning decades, MST has had mechanisms in place for extending treatment, training, consultation, and supervision (Henggeler, 2011; Henggeler et al., 2009; http://www.mstservices.com). This has led to application of MST throughout the United States and in several other countries. When agencies, organizations, and states want to adopt an evidence-based treatment, MST has been available with contracting and training mechanisms well in place. Add to that a key attraction, namely the effectiveness with severely disturbed populations. In the short term MST has surpassed the effects of psychiatric hospitalization, which has augmented the appeal of the procedure as hospital services and reimbursement for them have declined. Overall, the evidence base of MST is very strong, as attested to by multiple replications.

There remain important challenges for the approach. First, the administration of MST is demanding in light of the need to provide several different interventions in a high-quality fashion. Individual treatments alone are difficult to provide; multiple combinations of different treatments invite all sorts of challenges (e.g., therapist training, ensuring treatments of high quality, strength, and integrity). Second, and related, MST is intensive. In some projects, therapists are available 24 hours a day, 7 days a week. Sometimes a team of therapists is involved rather than merely one therapist. It may be the case that this model of treatment delivery is precisely what is needed for clinical problems that are multiply determined, protracted, and recalcitrant to more abbreviated interventions.

Overall, MST is an evidence-based treatment with excellent evidence on its behalf. The outcome studies have included youths with different types of problems (sexual offenses, drug use). Moreover, MST has been extended to many other problems (e.g., acute psychiatric crises; suicide attempts; depression, anxiety, and thought disorder), further supporting the viability of the model as a way of intervening for serious dysfunction. Moreover, as noted above, a model for dissemination and adoption has been in place for decades and hence the treatment is readily available.

Multidimensional Treatment Foster Care Model

Background and Characteristics of Treatment. Multidimensional Treatment Foster Care (MTFC) is a community-based treatment program (Forgatch & Patterson, 2010; Leve et al., 2012a,b; Smith & Chamberlain, 2010). It began as an alternative to institutional, residential, and group-care placements for youths with severe and chronic delinquent behavior and has since been extended to work with children and adolescents referred from either mental health or child welfare service systems.

The program provides opportunities for youth to live successfully in their communities while at the same time providing them with intensive supervision, support, and skill development, and to prepare their parents (or other aftercare resource) to provide effective parenting. (Approximately 85% of the youths return to their families; the remaining 15% return to long-term foster care or residential placement.) The youths begin treatment while they are out of their homes. They are placed individually in a foster home and are provided with intensive support and treatment in that setting. Individual placement is important and departs from many programs where several youths with antisocial behavior might be placed together in one setting. Evidence that group-based treatments for youth with CD can make them worse has fostered concern about many programs (e.g., Dishion, McCord, & Poulin, 1999; Mager, Millich, Harris, & Howard, 2005). Once the foster program is in place, PMT is provided to the parents (biological

or other) to whom the child will return after foster care placement.

In foster placement (e.g., 6 to 9 months), several interventions are provided, including family and individual therapy, skill training, academic support, case management, and medication, as needed. The interventions are provided across home, school, and the community. The foster setting is designed both to change the behavior of the youths and to prepare them for return to their families or placement in a different home. Four key elements of treatment provide youths with the following:

1. A reinforcing environment where they are mentored and encouraged to perform specific behaviors that will increase their skills;
2. Daily structure that includes clear expectations, limits, and consequences;
3. Close supervision and monitoring of the youth's whereabouts; and
4. Prosocial peer contacts and support rather than associations with delinquent peers.

Each child is supervised by a team including a case manager, individual therapist for the child, family therapist for the aftercare parents, behavioral support specialist, and psychiatrist, who conducts the treatment intervention. The team facilitates implementing and coordinating interventions, which take place across multiple settings (i.e., foster care setting where the child is placed, school, family home to which the child returns, and community). The overall conceptual focus of treatment is social learning—that is, providing learning experiences in the context of a positive interpersonal environment and various systems (home, community, school).

Foster parents are trained to implement behavioral programs and focus on such behaviors as getting up on time, attending school, positive behavior in class and at home, following directions, maturity, and positive attitude. Interventions are those that constitute PMT, highlighted earlier in the chapter (e.g., clear goals, feedback, praise, points, response cost). Parents to whom the child returns also receive PMT. They are gradually exposed to the child under supervision before the child is returned home to oversee the practices of the parents in light of their PMT. Parents visit the foster setting and the child visits the home of the biological parents. The gradual exposure to the home environment ensures that the transition will be smooth when the child is placed and that the biological parents have the skills and new ways of interacting to sustain gains in their child.

Evidence and Evaluation. Several randomized trials (type 1) have been completed with youth referred from multiple sources, including child welfare and mental health services, as noted previously (see Forgatch & Patterson, 2010; Leve et al., 2012a,b; Smith & Chamberlain, 2010, for reviews). The samples usually include individuals with comorbid disorders, a history of trauma and abuse, and prior treatments and multiple placements. Those with the most severe conduct problems have included youth referred from juvenile justice departments (aged 12 to 17), who have been involved in serious and frequent offending, and who are mandated by the courts for out-of-home placement.

The outcome studies have shown that the MTFC program leads to significant reductions in crime and delinquent behavior relative to treatment as usual. In the first outcome trial, delinquent youths were studied and randomly assigned to MTFC or treatment as usual (Chamberlain & Reid, 1998). In the case of chronically delinquent youths, treatment as usual consists of group-care placement, as determined by parole or probation officers. The program includes individual, group, and family therapy, although these can vary in conceptual approach and degree across settings. This initial study and by now the many others that have followed (e.g., Eddy, Bridges-Whaley, & Chamberlain, 2004; Eddy & Chamberlain, 2001; Leve et al., 2012b; Van Ryzin & Leve, 2012) conveyed the strong benefits of the MTFC program compared with control conditions. The benefits have been reflected on important outcome measures, including the extent to which youths run away, records and self-report of criminal activity, arrest rates, days spent in locked settings (e.g., state training schools), and reduced pregnancy rates among adolescent females (Smith & Chamberlain, 2010; Smith, Chamberlain, & Eddy, 2010). Follow-up studies have supported the effectiveness of MTFC up to two years (e.g., Chamberlain et al., 2007; Leve, Chamberlain, & Reid, 2005). The program has been extended to many other countries (Smith & Chamberlain, 2010).

Monetary costs of the MTFC program for treating individuals from the juvenile justice system are approximately one-third less than placement and treatment in group care (treatment as usual; Chamberlain & Smith, 2003). A cost-effectiveness

evaluation estimated that the MTFC model saves taxpayers approximately $44,000 per participant in criminal justice and avoids victim costs (Aos et al., 1999). For every dollar spent on MTFC, approximately $23,000 of taxpayer benefits were estimated when compared with more commonly used programs.

The evidence on behalf of the program is impressive in light of applications to severely impaired youth and extensions to multiple samples drawn from different types of agencies. Moreover, there have been several independent replications (e.g., Bolle et al., 2012; Farmer et al., 2010; Westermark, Hansson, & Olsson, 2011). The intensive effort required to implement treatment is noteworthy. For example, the team includes a case manager who can oversee more than one case (e.g., approximately 10 families). The case manager coordinates all facets of treatment. The demands can be great, as the manager provides daily telephone contact, supervises weekly foster parent meetings, and is available 24 hours a day. Yet, evidence-based programs for foster care are difficult to find. Moreover, the intervention has focused on children in great need (e.g., victims of child abuse, those in the child welfare system) and has produced quite favorable outcomes in relation to such critical indices as substance use, delinquency, depression, and teen pregnancy.

Overall, this is a well-developed program. It draws on two evidence-based treatment literatures. First, the evidence for this program is solid in its own right. This literature continues to emerge in replications extending to programs in many states in the United States and to other countries. Second, PMT is pivotal to the foster and biological parent facets of the intervention. The strong PMT literature, much of which has emanated from the same center (in Oregon) from which this intervention emerged, provides further evidence underpinning this treatment program (Forgatch & Patterson, 2010). Yet, the MTFC clearly has made its own contribution and findings beyond research on many of the constituent techniques. As one example, the effectiveness of MTFC was recently shown to be mediated by reducing peer associations with other delinquent youth (e.g., Van Ryzin & Leve, 2012), which is a novel addition for understanding how the intervention may work.

Cognitively Based Treatments

Background and Characteristics of Treatment. *Cognitive processes* refer to a broad range of beliefs, perceptions, attributions, and means of coding experience. Children and adolescents who engage in aggressive behavior show distortions and deficiencies in various cognitive processes. Several cognitive processes have been studied. Examples include generating alternative solutions to interpersonal problems (e.g., different ways of handling social situations); identifying the means to obtain particular ends (e.g., making friends) or consequences of one's actions (e.g., what could happen after a particular behavior); making attributions to others of the motivation of their actions; perceiving how others feel; and expectations of the effects of one's own actions (Larson & Lochman, 2010; Mayer et al., 2011). Deficits and distortion among these processes are typically reflected in teacher ratings of disruptive behavior, peer evaluations, and direct assessment of overt behavior.

As an example, aggression is not merely triggered by environmental events but rather through the way in which these events are perceived and processed. The processing refers to the child's appraisals of the situation, anticipated reactions of others, and self-statements in response to particular events. Attribution of intent to others represents a salient cognitive disposition critically important to understanding aggressive behavior. Children and adolescents with aggressive behavior tend to attribute hostile intent to others, especially in social situations where the cues of actual intent are ambiguous (e.g., Dodge, 2010; Werner, 2012). Understandably, when situations are initially perceived as hostile, children are more likely to react aggressively.

Although many studies have shown that children with CD experience various cognitive distortions and deficiencies, the specific contribution of these processes to CD, as opposed to risk factors with which they may be associated (e.g., untoward living conditions, low IQ), have not been established. Nevertheless, research on cognitive processes among aggressive children has served as a heuristic base for conceptualizing treatment and for developing specific treatment strategies (Kendall, 2011). Variations of cognitively based treatments have been applied to aggression and conduct problems. Arguably the most well developed and best documented are the Anger Coping Program and the Coping Power Program (Lochman et al., 2010). The Anger Coping Program is delivered in a group format in which themes (e.g., use of a puppet to model self-control, problem solving, perspective taking) is conducted. Core features

of this program are designed to alter how youth with aggressive behavior encode social situations and respond on the basis of that encoding. Cognitive training and practice of prosocial solutions and problem solving are central (see Lochman et al., 2010, for a detailed description).

The Coping Power Program involves an extension in the amount of treatment and has separate group sessions for the parents that focus on the home environment. Many of the group sessions with parents draw on PMT techniques (e.g., social reinforcement of target behaviors in the child, clear instructions). Interestingly, other researchers have combined cognitively based treatment for the child with PMT in part to support the changes in treatment but also to controvert many parenting practices that may promote aggressive behavior of the child (e.g., Kazdin, 2010; Webster-Stratton, Reid, & Beauchaine, 2011).

Another treatment variation is cognitive problem-solving skills training. This intervention has been applied clinically to inpatient and outpatient treatment rather than in the schools and has focused on children with CD as well as multiple other disorders (Kazdin, 2010). The emphasis is on how children approach situations—that is, the thought processes in which the child engages to guide responses to interpersonal situations. The children are taught to engage in a step-by-step approach to solve interpersonal problems. They make statements to themselves that direct attention to certain aspects of the problem or tasks that lead to effective solutions. Second, the behaviors (solutions to the interpersonal problems) that are selected are important as well. Prosocial behaviors are fostered through modeling and direct reinforcement as part of the problem-solving process. Third, treatment uses structured tasks involving games, academic activities, and stories. Over the course of treatment, the cognitive problem-solving skills are increasingly applied to real-life situations. Fourth, therapists play an active role in treatment. They model the cognitive processes by making verbal self-statements, apply the sequence of statements to particular problems, provide cues to prompt use of the skills, and deliver feedback and praise to develop correct use of the skills by the child. Finally, treatment usually combines several different procedures, including modeling and practice, role playing, and reinforcement and mild punishment (loss of points or tokens). Many of the core assumptions and processes of problem-solving skills training align with and directly overlap with those of the Anger Coping Program and Control Coping Program (e.g., involvement of the parents).

Evidence and Evaluation. Several controlled clinical trials (type 1 and 2) have been completed with children and adolescents with impulsive, aggressive, and antisocial behavior (see Lochman et al., 2010; Sukhodolsky, Kassinove, & Gorman, 2004, for reviews). Cognitively based treatments have significantly reduced aggressive and antisocial behavior at home, at school, and in the community. At follow-up, gains have been evident up to four years after treatment (Lochman et al., 2010). In general, the program has produced sustained effects and has prevented later antisocial behavior (e.g., marijuana and tobacco use).

The Anger Coping Program and the Coping Power Program have been very well evaluated and with multiple replications. Also, the applications have focused on school samples but have been extended to clinical settings as well. The program began with a child component, then encompassed a parent component, and finally moved to providing teachers with training. Problem-solving skills training has been evaluated in randomized trials but does not have the range of replications of the two other programs. It has been applied to inpatient and outpatient cases with severe conduct problems. In all of those applications the intervention is delivered on an individual rather than group basis.

The strength of the evidence in the context of treatment for referred cases stands on its own in support of cognitive problem-solving approaches. Yet, early development of the intervention began over three decades ago in the schools and in the context of prevention (see Shure, 1997, 1999). Application in the classrooms both in early and current versions of treatment provides an intervention outside of the usual mental health service settings. There are features of cognitively based treatment that make it an extremely promising approach. First, several controlled outcome studies have shown that it leads to therapeutic change. Second, the treatment has drawn on research on cognitive processes of children and adolescents with aggressive behavior and other conduct problems and has integrated that into effective treatment. Finally, and on a more practical level, many versions of treatment are available in manual form (e.g., Friedberg & McClure, 2002; Larson & Lochman, 2010; Lochman et al., 2008; Mayer et al., 2011; Sukhodolsky & Scahill, 2012).

As mentioned previously, group treatment programs for antisocial youth have often been found to produce negative outcomes, a finding attributed to the socialization and connection that group members have with peers who further foster antisocial behavior, in citations noted previously. Group Anger Control Training has not shown such effects: It does not lead to worse outcomes than no treatment, indeed just the opposite. This is encouraging and raises important questions about when and under what circumstances group processes and peer connections can be problematic.

The cognitively based treatments highlighted here focus on cognitive deficits and distortions often evident in children with aggressive and antisocial behavior. A key question is whether children can still gain from treatment even if they have few or no such cognitive deficits. This is analogous to the issue raised with PMT. Harsh and inept parenting is often associated with conduct problems, but PMT as a behavior-change intervention does not require that parenting practices be harsh to effect change in parents or children.

Functional Family Therapy

Background and Characteristics of Treatment. Functional family therapy (FFT) reflects an integrative approach to treatment that relies on systems, behavioral, and cognitive views of dysfunction (Alexander & Robbins, 2010; Sexton, 2011). Clinical problems are conceptualized from the standpoint of the functions they serve in the family as a system, as well as for individual family members. Problem behavior evident in the child is assumed to be the way in which some interpersonal functions (e.g., intimacy, distancing, and support) are met among family members. Maladaptive processes within the family are considered to preclude a more direct means of fulfilling these functions. The goal of treatment is to alter interaction and communication patterns in such a way as to foster more adaptive functioning. Treatment also is based on learning theory and focuses on specific stimuli and responses that can be used to produce change. Social learning concepts and procedures, such as identifying specific behaviors for change, reinforcing new adaptive ways of responding, and evaluating and monitoring change, are included in this perspective. Cognitive processes refer to the attributions, attitudes, assumptions, and expectations of the family. Family members may begin treatment with attributions that focus on blaming others or themselves. New perspectives may be needed to help serve as the basis for developing new ways of behaving.

The underlying rationale emphasizes a family systems approach. Specific treatment strategies draw on findings that underlie PMT in relation to maladaptive and coercive parent–child interactions. FFT views interaction patterns from a broader systems view that also focuses on communication patterns and their meaning. As an illustration of salient constructs, research underlying FFT has found that families of delinquents show higher rates of defensiveness in their communications, in both parent–child and parent–parent interactions, blaming, and negative attributions, and also lower rates of mutual support than do families of nondelinquents. Improving these communication and support functions is a goal of treatment.

FFT requires that the family see the clinical problem from the relational functions it serves within the family. The therapist points out interdependencies and contingencies between family members in their day-to-day functioning and with specific reference to the problem that has served as the basis for seeking treatment. Over the course of treatment, the family is encouraged to see alternative ways of viewing the problem; in doing so, the incentive for the family to interact more constructively is increased.

The intervention is administered across three reciprocal and interdependent phases (Sexton & Alexander, 2002). The first, engagement and motivation, has a primary aim of increasing the perception of the intervention's credibility within the family, which includes fostering an expectation of change and establishing the alliance between therapist and family members. This is accomplished, in part, through therapists' reframing negative themes of presenting problems into positive themes, to develop a family-focused perception of the maladaptive behaviors and emotions that may be present within the family. The second phase, behavior change, aims to identify targets of change for each family member, with the idea that changes are tailored to the unique characteristics of the family member, and are appropriate for the cultural and contextual underpinnings of the family. Foci of behavior change are expected to encompass cognitive, interactive, and emotional domains of functioning. The last phase, generalization, aims to apply the

changes observed in the second phase to other problem areas and/or situations in the family system. The primary goal in this phase is for treatment to foster the family's ability to maintain changes observed in treatment, and prevent relapses in dysfunction.

Evidence and Evaluation. Several controlled trials have evaluated FFT and have focused on populations that are difficult to treat, including adjudicated delinquent and multiple offender delinquent adolescents and adolescents who abuse drugs (see Alexander & Robbins, 2010, Sexton, 2011; Waldron & Brody, 2010). FFT has led to greater change than other treatment techniques (e.g., client-centered family groups, psychodynamically oriented family therapy) and various control conditions (e.g., group discussion and expression of feeling, no-treatment control groups). Treatment outcome is reflected in improved family communication and interactions and lower rates of referral to and contact of youth with the courts.

Research has examined processes in therapy to identify in-session behaviors of the therapist and how these influence responsiveness among family members (see Sexton, 2011). For example, providing support and structure and reframing (recasting the attributions and bases of a problem) influence family members' responsiveness and blaming of others. The relations among such variables are complex insofar as the impact of various type of statements (e.g., supportive) can vary as a function of gender of the therapist and family member. Evidence of changes in processes proposed to be critical to FFT (e.g., improved communication in treatment, more spontaneous discussion) supports the conceptual view of treatment.

Several noteworthy points can be made about FFT. First, the outcome studies indicate that FFT can alter conduct problems among delinquent youth who vary in severity and chronicity of antisocial behavior (e.g., youths with status offenses; others with multiple offenses and who have served in maximum-security wards; youths who have suffered trauma). For example, in one comprehensive evaluation, FFT was estimated to reduce arrests by 22.6% for program participants within one year (Taxy et al., 2012).

Second, cost-effectiveness analyses have shown FFT to surpass alternatives such as detention and residential treatment for delinquents (Sexton, 2011). The reduction of arrest rates alone has enormous cost benefits. Each averted arrest is estimated to prevent $51,600 in associated victim harms and other savings (Taxy et al., 2012), accounting for more than 60% of all savings from averted crimes.

Third, the evaluation of processes that contribute to family members' responsiveness within the sessions, as well as to treatment outcome, represents a line of work rarely seen among treatment techniques for children and adolescents. Some of this process work has extended to laboratory (analogue) studies to examine more precisely how specific types of therapist statements (e.g., reframing) can reduce blaming among group members (see Sexton, 2011). Fourth, details of treatments, including treatment manuals, have been provided (Alexander et al., 2013; Sexton, 2011); Internet sources also are available (www.fftinc.com/). Along with that there is a mechanism for large-scale dissemination that is in place and active. The Web site notes that, currently, "300+ community, state, national and international organizations . . . provide FFT to over 20,000 families each year."

On balance, the treatment has several features in its favor. The evidence includes many studies. The samples included in the studies have been severely impaired delinquent youth, including youth who have suffered trauma. As with other treatment packages reviewed in this chapter, it is not clear whether all the treatments that constitute the FFT "package" are needed or are needed for some, most, or all of the cases.

Brief Strategic Family Therapy

Background and Characteristics of Treatment. Brief strategic family therapy (BSFT) has emerged from a programmatic series of studies with Hispanic youths (see Robbins & Gonzalo, 2007; Robbins, Harigian, Szapocznik, & Ucha, 2010). The program has systematically evaluated children (aged 6 to 11), early adolescents (12 to 14), and adolescents (13 to 18) and included youths from varied backgrounds (e.g., Cuban, Nicaraguan, Colombian, Honduran, and Puerto Rican). Although the groups vary widely, the approach is based on the view that as a group Hispanics show more family orientation and shared values and many immigration and acculturation experiences that make the grouping meaningful. The youths have included those referred for externalizing behaviors such as CD, drug abuse, and a broader range of problems as well.

BSFT views child behavior within the context of the family system. Integrated into a family approach is a cultural frame of reference that draws from the study of Hispanic families. Among the key foci of this frame of reference are the importance of strong family cohesion, parental control, and communication issues that may arise from cultural and intergenerational conflicts (e.g., individualism of the adolescent vs. family ties). Both family and individual behavior are considered as interdependent and interactive. Individuals are jointly responsible for the state of the family system and for the changes that are to be made in treatment. Patterns of interaction, conceptualized as the structure of the family system, are identified as the likely bases for maladaptive functioning. Thus, a child's "problem" brought to treatment is reconceptualized as dysfunction in relation to the family. Persistent maladaptive behavior in one or more family members must in some way be maintained by the family.

Treatment focuses on strategies that can be used to alter interaction patterns. The focus is on providing concrete and direct changes in the family situation to promote improved interactions. This is distinguished from more traditional strategies that have focused on insight and understanding. The treatment sessions are problem focused whenever possible. The therapist identifies what can be altered within the family to promote change. Formal assessment is provided by a set of family tasks (e.g., planning a menu, discussing a prior family argument) that allow the therapist to identify areas of focus. Structure of the family, alliance, conflict resolution, roles (e.g., patient, model child), and flexibility of the family are some of the dimensions that are examined in assessment and focused on in treatment. During treatment, the therapist challenges interaction patterns, reformulates (reframes) ways of considering interaction and communication patterns, and encourages new ways of interacting to break up established sequences.

Evidence and Evaluation. There have been many randomized controlled trials to develop and evaluate the intervention with youths referred for diverse problems. The results have shown improvements in child and family functioning as a result of treatment when compared with other treatment and control (e.g., minimal contact conditions) across several studies (see Robbins et al., 2010; Rowe, 2012). The benefits are reflected in reductions in parent-reported conduct problems and delinquency, substance use, and improved family functioning. Although the outcome focus of treatment emphasizes child and adolescent behavior, changes in the family are viewed as critical as well. Comparisons early in this program of research showed that even when two interventions (BSFT and psychodynamic therapy) were equally effective in reducing symptoms, BSFT also improves family functioning (Szapocznik et al., 1989).

Among the strengths of the program are efforts to engage the family in order to retain them in treatment (Ingoldsby, 2010). Special attention to the family early in treatment that addresses family and cultural barriers to treatment participation has been evaluated in randomized controlled trials; it significantly reduces dropping out of treatment. The engagement procedure and remaining in treatment, as might be expected, relate to treatment effectiveness.

Overall BSFT has been studied in a well-developed program of research. Treatment has been replicated in several studies and with children presenting diverse clinical problems. The research program is unique in directly developing a treatment sensitive to critical cultural issues and developing methods to assess these issues. The program has been extended to African American families and to other clinical problems than conduct problems (e.g., substance use, prevention of HIV). Apart from the accomplishments of the studies in relation to BSFT, the broader approach of assessing and studying cultural features of families and then integrating these features into therapy may reflect a model for developing ethnically relevant and sensitive treatment. There has been relatively little attention to ethnic issues in trials of psychotherapy with children and adolescents, and this program has been exemplary.

Good Behavior Game

Background and Characteristics. The interventions mentioned so far are within the realm of traditional models of psychotherapy in the sense of providing therapy in the context of treatment to individuals or to families. An exception is one of the cognitive therapy programs that has been routinely conducted in the schools. Another exception is PMT, which has been extended to schools to deliver the intervention to parents or to adopt the interventions for teachers. Other interventions have emanated from classroom applications and have strong evidence on their behalf as an intervention for aggressive behavior.

A classroom-based intervention referred to as the Good Behavior Game (GBG) has been effective for children with aggressive behavior. The class is divided into two (or more) teams. Classroom rules are posted that identify the target behaviors and reinforcers. When one of the rules is violated (e.g., talking out, hitting another person) the student is noted by name and the violation is stated specifically. The rule infraction leads to a loss of points from the team's total points. This loss can be noted by a point on a board or loss of a point—some public way of designating or tracking the number of infractions. At the end of the day and of the week, the team with fewer infractions earns a prize (e.g., could be a tangible reinforcer, a privilege, and praise as special recognition by the other team). Among the advantages of the system is the team competition, which adds an incentive to the usual group program. Essentially, this is a two-group program in one classroom and the two groups are in competition for which can behave better.

The principles underlying the program are based on those of applied behavior analysis, including reinforcement, mild punishment, careful specification of the target behaviors, and others (see Kazdin, 2013a). These principles and practices derived from them include many of the practices that underlie PMT and MTFC, highlighted previously. Thus, support for the intervention can draw from many other applications both for CD and other problem domains.

Evidence and Evaluation. The GBG has been used in elementary through high-school classrooms, in regular and special education classes, and with ethnically diverse samples (see Embry, 2002; Kleinman & Saigh, 2011; Tingstrom et al., 2006). In the typical study, the GBG is used as a strategy to help teachers manage classroom behavior and promote academic behavior. Many studies have demonstrated this use of the GBG with individual classrooms. However, in various applications the GBG has been extended to a large number of classrooms across several different schools, with impact on academic performance and disruptive behaviors (e.g., Dion et al., 2011; van Lier et al., 2004).

Multiple studies have attested to the effectiveness of the program in reducing aggressive behavior and improving classroom performance (e.g., attentive behavior, perseverance on tasks) while the program is in effect. Especially remarkable have been the follow-up results. When the program is implemented in early elementary school (first and second grades) the impact can be seen years later.

For example, a large-scale evaluation (e.g., first graders in 41 classrooms in 19 schools in Baltimore, Maryland) included multiple randomized trials to test the impact of early school intervention on later outcomes when the youth were aged 19 to 21 (Kellam et al., 2008; Poduska & Bowes, 2010). The impact of GBG relative to regular classrooms or regular classrooms with special reading achievement programs was remarkable. GBG youth, especially males who were more aggressive and disruptive in early grades, showed reduced rates of: drug and alcohol abuse and dependence, cigarette smoking, use of special school services (e.g., for problems with behaviors, drugs, alcohol), violent and criminal behavior; antisocial personality disorder, and suicide ideation and attempt. The effects have been replicated in other large-scale applications (Leflot et al., 2010, 2013).

Overall, the GBG has been shown to decrease behaviors such as aggression and classroom disruption and apparently interrupt the path to which these can lead for many children in terms of substance use and abuse and the other outcomes noted previously. The research, only highlighted here, conveys that the GBG can be used as a treatment (for the immediate effects) and preventive intervention for children with aggression and disruptive behavior for a host of untoward outcomes in adolescence and young adulthood. By implementation in the schools this can be used on a large scale (multiple classrooms and schools) and for treatment and prevention.

General Comments

I have highlighted several evidence-based treatments for youth with conduct problems. The treatments encompass young children through adolescents and a range of severity from oppositional and noncompliance to serious antisocial and criminal behavior. The research has included youths referred clinically, as well as from the courts, child welfare and protective services, and various agencies where such children may reside (e.g., foster care). Occasionally, critical evaluations of evidence-based treatments note that perhaps the participants are not like "real" patients referred for treatment, or perhaps they do not have serious or multiple disorders. Plainly the concern is incorrect in relation to evidence-based treatments

of CD. The treatments (e.g., PMT, MST, MTFC) include cases with all sorts of serious child, parent, family, and social problems. In terms of psychiatric diagnosis, our own studies show that comorbidity is the rule rather than the exception in our trials, with some children meeting criteria for five or six psychiatric disorders and that treatment is effective nevertheless (e.g., Kazdin & Whitley, 2006).

There are now multiple treatments available for youth with CD. Extending these to professionals and families in need is not the only task remaining, as I note in the sections that follow, but it is likely to be the most daunting. I have focused on the treatments that have been well established for some time (e.g., between three and five decades). More recent evidence makes the case stronger. Add to this that the cost and cost-benefits of the treatments have been quite favorable, and we can make the case that these treatments do not only "work" but are also worthwhile investments. Even so, there remain multiple issues regarding the impact of treatments and their dissemination.

CRITICAL ISSUES IN EVALUATING TREATMENTS

The treatments highlighted in the chapter have randomized controlled trials (type 1) on their behalf, including replications of treatment effects. The treatments encompass young school-age children through older adolescents and a range of youths varying in severity of aggressive and antisocial behavior (oppositional, CD, adjudicated delinquent and repeat offenders) and as included in or referred from various agencies (e.g., clinics, hospitals, courts). Some of the treatments have long-term follow-up (e.g., more than 20 years), which is rare across the full range of psychosocial therapies. The main conclusion is worth underscoring: *There are now several evidence-based treatments for conduct disorder.*

Interpretation of Findings of Evidence-Based Treatments

There are qualifiers about what we know and what can be said about evidence-based treatments that certainly apply to those related to CD. No single definition or set of criteria has been used to designate treatments as evidence-based. Several countries, professions, organizations within professions, and other parties (e.g., third-party payers; state, provincial, and federal governments) have delineated evidence-based treatments with varying criteria. Even so, commonly used criteria are that the treatment has been studied in randomized controlled trials, it has been shown to be more effective than another condition (e.g., no treatment, treatment as usual), and these effects have been replicated, preferably by independent research teams. "More effective" means that the treatment condition was statistically better than a control group. Often effect sizes complement tests of statistical significance to convey the magnitude of the relation between treatment and therapeutic change.

It is important to bear in mind that neither statistical significance nor effect size (even if large) has any necessary connection to the clinical or practical importance of the therapeutic change. It is easy to show that statistically significant differences between groups and large effect sizes can be readily obtained with little or no clinical benefit (Kazdin, 2013b). Thus, the clinical utility of evidence-based treatments and their superiority over other conditions (e.g., treatment as usual) are not so clear. The significance of this latter point is hardly trivial. In addition to knowing which treatments lead to greater therapeutic change than many control conditions, we must also understand whether and how this translates to client functioning in everyday life.

In some of the treatments I have reviewed (e.g., MST, MTFC, GBG), outcomes include social impact measures such as school dropout, rearrest, readjudication, hospitalization, days of confinement, criminal behavior, and pregnancy rates. These measures have clear practical referents in relation to the impact of treatment. It is likely that changes on these measures reflect palpable changes in children and adolescents and hence are "clinically significant." Such measures raise a related concept that might be referred to as "socially significant." I refer to social significance as a measure in which some meaningful outcome of broad interest to society (e.g., cost, use of resources) is affected by the treatment. Clearly more is needed in evaluating treatments for CD that establish palpable changes in the children and families and in the social impact of treatment. Yet, already, measurements in support of the techniques include but go beyond symptom ratings.

Another issue that qualifies interpretation of evidence-based treatments pertains to how the studies are reported. Typically, studies use multiple measures to evaluate therapeutic change. Frequently, some measures show the predicted differences in support of the treatment, whereas other measures do not. Researchers often consider the former to support the effectiveness of treatment, yet the measures that do not show the treatment effect often are excluded or minimized when drawing conclusions (see De Los Reyes & Kazdin, 2006). That is, there has been great inconsistency among investigators in reporting criteria in which measures are not all considered or specified in advance as primary or secondary measures.[3] The implication for rendering conclusions across many studies is not knowing which indicators have changed and which have not and, most importantly, what conclusions could be drawn if all available measurement data were considered.

These concerns illustrate some of the ambiguities regarding the interpretation of evidence-based treatments. However, this is not grounds for abandoning or dismissing these therapies in clinical practice. In many instances, as I have mentioned, these treatments have been shown to make a difference and to surpass the gains achieved through usual or more traditional interventions. Yet, the qualifiers about what we can say about these treatment are not minor; further research is needed to redress them.

Dissemination of Evidence-Based Treatments

Developing effective interventions does not mean they will be adopted or used in clinical practice. Even when techniques are used in clinical practice, their effectiveness drops sharply from what the results show in controlled treatment studies (see Wampold et al., 2011; Weisz, Ng, & Bearman, 2014). Beyond concerns regarding the fidelity of treatment application, the vast number of treatments now available means that the task of extending even a small set of these to a clinic or set of therapists is enormous. Moreover, most training programs (e.g., graduate work in clinical psychology or social work; residency training in psychiatry and child psychiatry) are not likely to include evidence-based treatments as part of course work, let alone supervised training and mastery of them. Finally, dissemination is not merely a matter of discussing treatment, completing a continuing education experience, or seeing the treatment in action: Many evidence-based treatments involve specialized knowledge and skill sets.

Providing the requisite training and experience is a formidable challenge. Possible solutions have been advanced (see Chorpita & Daleiden, 2010; Shafran & Craske, 2009; Weisz et al., 2014). These include identifying components of treatments or modules that can be more readily used than all the individual evidence-based treatments, developing unified treatment protocols for treatments that have impact across a diverse range of disorders, training many nonprofessionals on a national scale (e.g., United Kingdom) to address a few but highly prevalent clinical problems (e.g., depression and anxiety), developing research that begins with clinical practice settings rather than research settings, and providing training and certification in highly specialized interventions (e.g., behavior analysis, dialectical behavior therapy, PMT).

An excellent example of a novel way of providing treatment is providing one or more of three evidence-based modules to children referred for diverse clinical problems in outpatient services (Weisz et al., 2012). The modules included cognitive-behavioral therapy for depression, cognitive-behavioral therapy for anxiety, and behavioral parent training for conduct problems. Modules were provided as needed depending on the problems of the children. A comparison condition of treatment as usual was also included. The program included children with multiple and comorbid disorders, including CD. The results showed the benefits of a modular approach on symptoms and impairment at the end of treatment. The benefits of treatment on symptom scores were maintained at a two-year follow-up (Chorpita et al., 2013).

The model of providing treatment in modular form may greatly enhance the dissemination of evidence-based treatments. A small set of modules are likely to be applicable with a large range of clinical problems. Also, with a limited number of modules, rather than a long list of treatments, training clinicians in practice is much more feasible.

RESEARCH PRIORITIES AND FUTURE DIRECTIONS

Several topics are high priorities for research. In some cases the research foci are not new but the approaches used to address them are.

Moderators

Moderator refers to some characteristic that influences the direction or magnitude of the relation between the intervention and outcome. If treatment outcome varies as a function of characteristics of the child or therapist (e.g., sex, ethnicity, temperament, biomarkers) or treatment delivery (e.g., individual vs. group treatment), these characteristics are moderators. Historically, the dominant question that has guided psychotherapy has been about moderators, as illustrated by, "What treatment, by whom, is most effective for this individual with that specific problem, under which set of circumstances?" (Paul, 1967, p. 111). The question continues to receive prominence as the treatment agenda to guide research (e.g., Roth & Fonagy, 2005).

After decades of study, the literature is saturated with moderators for CD, but we rarely understand why they moderate, and it is nearly impossible to translate the findings to assign people to treatments for which they are well suited. For example, socioeconomic disadvantage and severity of conduct problems moderate the effects of treatment for CD (e.g., Kazdin, 2010; Leijten et al., 2013). Individuals with greater socioeconomic disadvantage, family stress, and severity of dysfunction respond less well to PMT. However, these findings on moderators of treatment do not help in relation to theory, research, or practice because we do not know whether the moderator is specific to a particular technique or would apply to any other evidence-based therapy. Also, without knowing why the moderator has an effect, there is not much we can do to controvert the process or influence the means by which the moderator exerts its effect. In the absence of further explanation, moderator research to date has not advanced our understanding of the underpinnings of treatment effects, nor has it been especially useful for selecting among treatments for CD.

Two lines of moderator research may point the way to future advances. First, efforts to understand moderators and how they relate to fundamental features of information processing may hold special promise. For example, biological features of how patients process information (e.g., neuromarkers) and psychological characteristics with which they are associated (e.g., processing social cues, working memory, emotion regulation) serve as moderators of treatment response (psychotherapy, medication) (e.g., Doehrmann et al., 2013; Furey et al., 2013). These moderators can relate to fundamental biological features of disorders and elucidate targets for psychosocial and biological treatments. Such work also has the potential of elaborating unifying processes across diverse treatments.

Second, the ways in which moderators are studied are likely to change in the coming years. Moderators (e.g., severity of dysfunction, comorbidity, culture) usually are studied one at a time in any individual study. Individual moderators tend to be weak in how they predict outcome (e.g., effect size) and may not emerge as statistically significant, even when they exert practically significant influences on treatment–outcome relations. Recently, methods for integrating and combining multiple moderators have been elaborated (Kraemer, 2013). When multiple moderators are combined, moderator × treatment interactions emerge that otherwise would not be evident (e.g., Frank et al., 2011; Wallace et al., 2013).

Improvements in moderator research are greatly needed to advance clinical practice and decision making. Few studies are theoretically driven to predict how and why moderators operate. In addition, it has been difficult to direct patients to treatments from which they are very likely to profit and away from those from which they are not. Therapy research would profit from selecting and evaluating moderators in ways that translate to better care.

Mediators and Mechanisms of Change

Notwithstanding the rich outcome literature, we have very little idea about how treatments "work" or lead to change. Without understanding how therapeutic change is achieved, we are at a disadvantage in knowing how we might optimize change through activation of specific components or processes. Research on mediators and mechanisms underlying therapeutic change aims to elaborate how treatment works.

Mediator is a construct that shows a statistical relation between an intervention and outcome. This is an intervening construct that suggests processes about why change occurs or on which change depends. Mediation is evident when several conditions are met: (1) the intervention leads to change in outcome measures, (2) the intervention alters the proposed mediator, (3) the mediator is related to outcome, and (4) outcome effects are not evident or significantly (statistically) less evident if the mediator did not change.

These relations convey that change was mediated (e.g., correlated with, depended on) by some construct. Even when these conditions are met, ambiguity can remain about the precise role of the mediator (Bullock, Green, & Ha, 2010; Kazdin, 2014). The mediator may not, and usually is not intended to, explain precisely how the change comes about. For example, cognitions may be shown to mediate change in therapy; however, this does not explain precisely how the change came about (i.e., what are the intervening steps between cognitive change and reduced stress or anxiety).

Mechanism refers to a greater level of explanatory specificity than mediator and reflects the steps or processes through which therapy (or some independent variable) actually unfolds and produces the change. Mechanism explains how the intervention translates into events that lead to the outcome or precisely what was altered that led to symptom change.

Psychotherapy research with adults outside of the context of treatment of CD in children has benefitted from advances in cognitive, affective, and social neuroscience, as well as the development of noninvasive neuroimaging and other biological assays to examine the structure, function, and activity of the brain that are associated with clinical dysfunction (especially anxiety and depression) and/or changes over the course of psychotherapy among adults (e.g., Frewen, Dozois, & Lanius, 2008; Porto et al., 2009; Quidé, Witteveen, El-Hage, Veltman, & Olff, 2012; Roffman et al., 2005). Much of this work, but certainly not all, is correlational when characterizing disorders or change processes. Yet, the strength of the research stems from multiple lines of converging evidence that move closer to identifying mechanisms of action. For example, from the reviews mentioned previously, research has

- Identified neurological characteristics associated with specific disorders and subtypes;
- Evaluated change in neural processes in "regions of interest" in light of characteristics associated with specific disorders;
- Induced or provoked symptoms (e.g., sadness manipulations in healthy samples; trauma stimuli in posttraumatic stress disorder patients) to demonstrate experimentally brain areas implicated in dysfunction;
- Demonstrated "normalization" of neurological structures, function, and activity after therapy is completed;
- Elucidated similarities and differences in specific brain processes altered by different interventions (e.g., medication, psychotherapy) for a given disorder (e.g., major depression); and
- Documented some similarities in what brain processes are altered by the same intervention (e.g., cognitive-behavioral therapy) as applied to different disorders (e.g., obsessive-compulsive disorders, depression).

Neuroimaging studies capitalize on a set of tools to elaborate processes involved in therapeutic change. Additional methods have been used to study brain receptors, intracellular signaling, and target genes that reflect dysfunction and change over the course of treatment (e.g., Duman, Schlesinger, Russell, & Duman, 2008; Sen, Duman, & Sanacora, 2008). Capitalizing on novel methods of assessment may help in identifying processes that change over the course of effective intervention as well as suggesting biomarkers that moderate treatment effects.

A clear research direction and priority will be elaborating biological changes that underlie and are associated with changes in symptoms, behaviors, and subjective experience. There is a concern that drawing on advances in neural assessment methods unwittingly will contribute to the "biologizing" of psychotherapy (i.e., reverting to biological and "reductionist" explanations). However, core psychological and biological processes increasingly are studied together (e.g., cognitive, social, and cultural neuroscience) to elaborate the connections, reciprocal relations, and conversions of experience and brain processes.

Transdiagnosis and Transtreatment

Developing evidence-based therapies has focused on matching treatments to specific dysfunctions. Psychiatric diagnosis has served as the basis for this and of course harbors the view that there are discrete entities (syndromes and disorders) such as CD, oppositional defiant disorder, major depression, bipolar disorder, and a few hundred more (e.g., APA, 2013; World Health Organization [WHO], 2010). Treatments were (and continue to be) developed with a disorder focus. Yet, an alternative view, referred to as transdiagnosis, has taken hold as a novel model for understanding clinical dysfunction, underlying

processes, and treatment. Transdiagnosis refers to the study of processes that span many different manifestations of clinical dysfunction (e.g., Harvey, Watkins, Mansell, & Safran, 2004; Kring & Sloan, 2009).

Several factors have served as impetus for a transdiagnostic conceptualization of clinical dysfunction. Among the key interrelated influences are findings that

- There are high rates of comorbidity so that individuals (children or adults) who meet criteria for one disorder are likely to meet criteria for at least one other disorder as well (e.g., Kessler et al., 1994; Wichstrøm et al., 2012);
- Underlying processes that maintain "different disorders" often are quite similar (e.g., Fairburn, Cooper, & Shafran, 2003; Green et al., 2010; Jagannath, Peirson, & Foster, 2013);
- Several disorders share common biological underpinnings as reflected in brain structures, neurotransmitters, and genes (e.g., Meyer-Lindenberg & Tost, 2012; Smoller et al., 2013);
- A number of evidence-based treatments (e.g., cognitive-behavioral therapy, mindfulness) are effective across a range of disorders, suggesting some common mechanisms or core processes (e.g., working memory, emotion regulation) (e.g., Johnston et al., 2013); and
- Broad characteristics such as a general psychopathology factor (a "p factor"), neuroticism, perfectionism, and tolerance of uncertainty might serve as underlying or mediating characteristics of many different disorders (Barlow et al., 2014; Caspi et al., 2014; Egan, Wade, & Shafran, 2011; McEvoy & Mahoney, 2012).

These findings have inspired efforts to search for core psychological (e.g., working memory, cognition), environmental (e.g., exposure to trauma, violence, parent with depressed affect), and biological processes (e.g., neuromarkers, genetic), and their interrelations (e.g., epigenetic) that unite several types of clinical dysfunction that have been viewed as discrete diagnostic entities. Budding efforts to focus diagnosis on core psychological and biological processes also are emerging in new diagnostic work that may inform disorders from a transdiagnostic perspective (e.g., Cuthbert & Insel, 2013).

Transdiagnostic conceptualizations have altered treatment and treatment research. Rather than adding to burgeoning lists of treatments for specific disorders, attention is now being directed to the search for transdiagnostic treatments. Terms such as transdiagnostic treatment, unified treatment protocol, and unified cognitive-behavior therapy are increasingly evident in treatment literature (e.g., Allen, McHugh, & Barlow, 2008). It is likely that research will continue to explore treatments that are broad in applicability across diverse disorders. As an example related to this chapter, PMT for decades has been used to treat conduct problems (externalizing behavior). Yet, the treatment has been successfully extended to quite different disorders (e.g., anxiety disorders, autism spectrum disorders). Transdiagnostic/transtreatment thinking no doubt will expand to address what we can treat effectively with what we know.

Reaching Children and Families in Need

The scope and impact of psychological dysfunction, whether conceived from a disorder-specific or transdiagnostic perspective, are extraordinary. Among children, adolescents, and adults, 20% to 25% of community samples meet criteria for at least one psychiatric disorder. Prevalence alone does not convey the burden to individuals or society. Mental disorders are more impairing than common chronic medical disorders, with particularly greater impairment in the domains of home, social, and close-relationship functioning (Druss et al., 2009).

A critical aspect to reducing the burden of mental illness is the ability of effective interventions to reach those in need of services. Recent years have seen an increase in the proportion of people in need who receive treatment in the United States, from 20.3% of individuals suffering from a disorder receiving treatment (e.g., psychiatry services, complementary and alternative medicine) between 1990 and 1992 to 32.9% of individuals with a psychiatric disorder receiving some form of treatment between 2001 and 2003 (Kessler et al., 2005). Despite these gains, 70% of individuals who need services are not receiving them. Ethnic disparities with respect to access to mental health care add important challenges to providing services. Ethnic minority groups (e.g., African, Hispanic, and Native Americans) have much less access to care than do European Americans (e.g., McGuire & Miranda, 2008; Wells, Klap, Koike, & Sherbourne, 2001). The lack of available services for most people and systematic disparities among those

services that are available underscore the importance of delivering services in ways that can reach many more people while targeting (and likely responding to the unique needs of) special groups.

The dominant model of delivery across varied therapy techniques is administration by a highly trained (e.g., master's or doctoral level) mental health professional in one-to-one, in-person sessions with a client who visits a particular setting (e.g., clinic, private office, health care facility). This is referred to as the dominant model because clinical practice, graduate training, clinical program accreditation, pre- and postdoctoral internships, and research on psychosocial interventions draw heavily on this model. The one-to-one, in-person model is enduring, in demand, and suitable to deliver many treatments to individuals and families who access them. With the exception of the school-based treatments I mentioned, most evidence-based therapies for CD (and other disorders) are delivered via this traditional model.

Within the mental health professions, models of delivering psychosocial interventions are expanding. Many of these involve the use of technology and online versions of treatment that draw on the Internet and other media, including video, phone, and application software (apps) for smartphones and tablets. Some uses of technology are variants of the dominant model in the sense that they are one-to-one and face-to-face programs (e.g., individual sessions by webcam) but extend to places where there may be no service or suitable facilities available (e.g., Wooton, 2003). Other extensions include self-help interventions and a vast array of techniques (e.g., online interventions, expressive writing techniques) that are available 24/7 and require little or no assistance from a trained professional (L'Abate, 2007). Several Internet, computer-based, self-help, and low-cost psychological interventions are evidence based and achieve effects (i.e., effect sizes) at least on par with the similar technique administered in person by a trained mental health professional, and are high in client adherence to and satisfaction with treatment (e.g., Andrews et al., 2010; Cartreine, Ahern, & Locke, 2010; Harwood & L'Abate, 2010).

Novel models of delivery are needed that include but go well beyond the use of technology. Models are needed that have such characteristics as

- Reach: Capacity to reach individuals not usually served or well served by traditional service delivery models;
- Scalability: Capacity to be applied on a large scale or larger scale than traditional service delivery;
- Affordability: Relatively low cost compared to the usual model that relies on individual treatment by highly trained (master's, doctoral degree) professionals;
- Expansion of nonprofessional workforce: Increase the number of providers who can deliver interventions;
- Expansion of settings where interventions are provided: Bring interventions to locales and everyday settings where people in need are likely to participate or attend already; and
- Feasibility and flexibility of intervention delivery: Ensure the interventions can be implemented and adapted to varied local conditions to reach diverse groups in need.

Several such models have emerged from global health care, from business models of delivering innovations, and from nontraditional forms of interventions for mental health treatment (see Kazdin & Rabbitt, 2013). As one illustration, task shifting is a method of strengthening and expanding the health care workforce by redistributing the tasks of delivering services to a broad range of individuals with less training and fewer qualifications than traditional health care workers (e.g., doctors, nurses) (see WHO, 2008). Task shifting is an evidence-based model of delivery that has been used extensively in treating and preventing physical disease but also has been extended to treat psychiatric disorders (e.g., anxiety, depression, schizophrenia) (e.g., Balaji et al., 2012; Patel et al., 2010; Rahman et al., 2008).

Research has focused almost exclusively on evidence-based *treatments*. In the coming years, much greater priority is likely to be given to evidence-based *models of delivery*. It is obvious we have many interventions that simply cannot get to the people in need. Even broad treatments (e.g., transdiagnostic treatments) and dissemination of current treatments to clinicians in practice will not have a palpable effect on reducing the burdens of mental illness until we can take these efforts to scale. We still need to attend to evidence, of course, but we must direct our attention to evidence that supports interventions that can be effective, can be administered on a large scale, and can reach many unserved segments of the populations in need (see Kazdin & Blase, 2011; Kazdin & Rabbitt, 2013).

CONCLUSION

The development of evidence-based treatments for aggression and antisocial behavior in children and adolescents is a major advance. There are effective interventions for CD and for a broad spectrum of disruptive behaviors, including oppositional defiant disorder, CD, and delinquent behaviors. Still, it is surprising how little we know about how treatments actually achieve the changes that are now well demonstrated. In the coming years, key issues that are likely to receive major attention include

- Disseminating and evaluating treatment in clinical practice settings;
- Identifying common ingredients or transdiagnostic treatments that may not only facilitate dissemination but also establish a new way to conceptualize interventions and clinical dysfunction;
- Elaborating moderators of treatment that can be clinically useful and guide decision making;
- Elucidating the mechanisms through which therapeutic change occurs; and
- Scaling up our interventions to reach people in need of services.

The notion of translational research from medicine captures broadly key issues and priorities for therapy research in the coming years. Translational research focuses on "bench to bedside" (i.e., laboratory to clinical application) and also "bedside to community" (i.e., scaling up interventions to have impact). Extending treatments to practice and communities on a larger scale increasingly will serve as points of departure for developing interventions. We now have several evidence-based treatments for conduct problems, and perhaps armed with that the challenges involved in having those in need actually receive them are more salient than ever.

NOTES

1. *Children* will be used to refer to both children and adolescents. When pertinent to the discussion, a distinction will be made and referred to accordingly.

2. This section provides only an overview of the treatments presented. The treatments are the topic of reviews and book chapters, books, and treatment manuals, as referred to in the treatment descriptions and references to other sources.

3. There has been increased concern about selective reporting of measures and how this can bias the conclusions in psychological research more generally outside the context of intervention research (Simmons, Nelson, & Simonsohn, , 2011). To combat this in the context of treatment, funding agencies (e.g., National Institutes of Health), organizations (e.g., World Health Organization) and a consortium of journal editors (the International Committee of Medical Journal Editors) require individuals to register their clinical trials in advance of the study. Investigators complete information to convey exactly what the measures are, what the primary measures will be, and how the measures will be examined. ClinicalTrials.gov in the United States is the largest clinical trials database, and as of this writing over 140,000 studies have been registered; they encompass all fifty U.S. states and 183 countries (http://clinicaltrials.gov/). As investigators are required to specify and prioritize outcomes in advance, interpretation of the effects of treatment ought to be enhanced.

Pharmacological Treatments for Schizophrenia

Atheir I. Abbas
Jeffrey A. Lieberman

Schizophrenia is a chronic mental disorder with a lifetime prevalence rate of approximately 1%. The first antipsychotic drug, chlorpromazine, was introduced in 1954, followed by several similar drugs. With the later introduction of clozapine, risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and more recently paliperidone, iloperidone, asenapine, and lurasidone, antipsychotic drugs are often classified as first-generation or typical (chlorpromazine-like) versus second generation or atypical (clozapine-like), although the distinction between the two classes, particularly with respect to efficacy, is not as meaningful as had initially been believed. Both of these broad classes of medications have been demonstrated to safely improve psychotic symptoms in the acute phase of the illness and reduce risk of relapse in the maintenance phase of treatment. Because of the limited efficacy of antipsychotic medication in resolving the full range of schizophrenic psychopathology, adjunctive treatments are often used to reduce morbidity. Concomitant medications such as benzodiazepines, lithium, carbamazepine, valproic acid, antidepressants, glutamate agonists, and dopamine agonists have been used alone and in combination with antipsychotic drugs to improve treatment response. In this chapter, we review controlled trials of the pharmacological agents used to treat schizophrenia.

BACKGROUND

According to the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* 5 (*DSM-5*), clinical diagnosis of schizophrenia is dependent on the presence of two of the following five symptom domains: delusions; hallucinations; disorganized speech; grossly disorganized or catatonic behavior; and negative symptoms such as avolition, blunted affect, impoverished speech, and anhedonia, with 6 months of continuous disturbance and symptoms that meet full criteria for at least 1 month, or less if successfully treated. These symptoms must take place in the presence of significant social and occupational impairment that often precedes the diagnosis for some years. A few changes have been made in the *DSM-5* compared to *DSM-IV-TR*, largely due to issues of specificity, reliability, and/or validity. First, there is now a firm requirement for two Criterion A symptoms, eliminating the possibility of a diagnosis of schizophrenia with just the presence of bizarre delusions or Schneiderian first-rank auditory hallucinations (two or more voices conversing). Also, at least one of three core positive symptoms of delusions, hallucinations, or disorganized speech must be present to diagnose schizophrenia. Notably, the *DSM-IV* subtypes of schizophrenia have been eliminated due to their limited diagnostic stability, low reliability, and poor validity. Other changes to the chapter on schizophrenia spectrum disorders include the requirement for schizoaffective disorder that a major mood episode be present for a majority of the disorder's total

duration after Criterion A has been met, the elimination of the requirement that delusions in delusional disorder be non-bizarre, and changes to the way catatonia is diagnosed.

Schizophrenic psychopathology has been characterized as divided into three symptom clusters: positive symptoms composed of delusions, hallucinations, and disorganization; negative symptoms such as anhedonia and avolition; and cognitive symptoms such as impairments in executive functioning, working memory, and attention (Liddle, Carpenter, & Crow, 1994). Approximately 75% of patients with schizophrenia have clinically meaningful deficits in at least two cognitive domains, and 90% have deficits in at least one domain (Palmer et al., 1997). Cognitive deficits antedate the clinical onset of the illness, may worsen over time, and are more strongly correlated with functional outcome then severity of positive symptoms (Green, 1996; Harvey et al., 1998; Marder & Fenton, 2004). In addition, patients with schizophrenia frequently exhibit affective symptoms during both the psychotic phase and the residual phase of the illness.

The course of schizophrenia is typically characterized by long-term social and occupational impairment punctuated by periods of decompensation during which psychotic symptoms worsen or reappear. Thus, treatment strategies need to target the acute psychotic phase of the disorder, achieve maintenance of symptom improvement or remission, and reduce relapse risk in long-term treatment. The illness course and outcome are variable among individuals, although complete symptom remission and return to premorbid function is not common. Progressive deterioration over time characterizes the course of illness for most patients, particularly in the first few years of the illness. The first antipsychotic drug, chlorpromazine, was introduced in 1954 and was followed by several similar drugs, including fluphenazine, haloperidol, loxapine, perphenazine, thiothixene, thioridazine, and trifluoperazine. With the later introduction of clozapine, risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, paliperidone, iloperidone, asenapine, and lurasidone, antipsychotic drugs have come to be classified as typical (chlorpromazine-like) or first-generation antipsychotics (FGAs) versus atypical or (clozapine-like) second-generation antipsychotics (SGAs). SGAs were initially thought to produce fewer extrapyramidal side effects (EPS) and cases of tardive dyskinesia than conventional drugs, to have greater efficacy in refractory patients and against negative symptoms, and to induce only limited prolactin elevation, although in recent years it has become clear that these differences are not as pronounced as initially thought and may not be clinically meaningful. Both FGAs and SGAs have been clearly demonstrated to be effective and safe for the acute and maintenance phases of treatment for schizophrenia. Notably, a landmark study by Kane, Honigfeld, Singer, and Meltzer (1988), which compared clozapine to chlorpromazine, demonstrated superior efficacy of clozapine in reducing symptoms in 30% of rigorously defined treatment-resistant patients, and the superiority of clozapine to other antipsychotics has been confirmed in a number of studies. Numerous studies have demonstrated that continuation of antipsychotic medication beyond treatment of the acute episode is necessary to reduce the risk of psychotic relapse, as evidenced by the fact that most patients will experience a clinical worsening if their treatment is discontinued (Carpenter et al., 1990; Davis, 1975; Gaebel et al., 1993; Herz et al., 1991; Hogarty, Ulrich, Mussare, & Aristigueta, 1976; Hogarty et al., 1988; Johnson, Ludlow, Street, & Taylor, 1987; Jolley, Hirsch, Morrison, McRink, & Wilson, 1990; Kane & Lieberman, 1987; Kane, Rifkin, Quitkin, Nayak, & Ramos-Lorenzi, 1982; Kane et al., 1983, 1993; Kane, Woerner, & Sarantakos, 1986; Marder et al., 1987; Robinson et al., 1999a; Schooler, Keith, Severe, & Mathews, 1993; Schooler et al., 1993). Concomitant medications such as benzodiazepines, lithium, carbamazepine, valproic acid, dopamine agonists, and glutamatergic agonists have been used alone and in combination with antipsychotic drugs to improve treatment response, although clear demonstration of the effectiveness of these strategies is lacking. In addition, antidepressants have been used extensively to treat depressive symptoms associated with schizophrenia. We will begin with a review of the controlled trial literature for FGAs and SGAs, followed by a review of the various augmentation strategies that have been evaluated.

FIRST-GENERATION ANTIPSYCHOTICS

The introduction of the prototypical conventional antipsychotic drug chlorpromazine in the 1950s, with the subsequent development of other antipsychotic agents with similar pharmacological activity, led to a revolution in the treatment of schizophrenia. These

drugs are credited with providing the first effective medical management strategy for schizophrenia and constitute one of the great medical advances of the 20th century. Early doubts regarding the efficacy of these compounds led to the design of rigorous clinical trials, such as the placebo-controlled, double-blind study with thoughtful subject inclusion and exclusion criteria, random treatment assignment, and the use of standardized rating instruments to prove the value of these drugs. More than 100 placebo-controlled trials have conclusively demonstrated the effectiveness of antipsychotic drugs (Davis, Barter, & Kane, 1989). A representative sample of methodologically rigorous acute treatment trials that demonstrate the efficacy of FGAs commonly used and currently available in the United States, compared with placebo, is given in Table 6.1. Placebo-controlled studies in which antipsychotic efficacy could not be demonstrated are generally restricted to poorly designed studies that involved doses of chlorpromazine less than 300 mg/day (Klein & Davis, 1969). Of the FGAs, haloperidol (Joy, Adams & Lawrie, 2006) and chlorpromazine (Adams et al., 2005) are the best characterized in terms of modern double-blind, randomized controlled trials (RCTs), although when FGAs have been compared to SGAs in high-quality studies there have not been clear differences in efficacy. Two of them, haloperidol and fluphenazine, are available in depot form. Despite improvement in psychotic symptoms, which is clinically important and was partly responsible for deinstitutionalization, patient functioning and social reintegration did not consistently improve with the use of FGAs. This disappointing observation was made soon after the introduction of these drugs into clinical practice (Schooler, Goldberg, Boothe, & Cole, 1967). Although a large number of antipsychotics have become available to clinicians in the United States since 1954, an extensive body of evidence has confirmed that most of these drugs, with a few notable exceptions, are essentially similar in their efficacy profiles, although an individual patient may show a better response to one particular drug than to another (Gardos, 1974). Table 6.2 lists the efficacy demonstrated in controlled clinical trials of a representative sample of antipsychotic drugs compared to the reference drugs chlorpromazine and haloperidol.

Accumulating data suggest that the time to onset of therapeutic effect of antipsychotic drugs during the treatment of an acute episode of schizophrenia may be quite variable. Davis and colleagues (1989) reported that onset of effect is usually manifest within the first 1 to 3 weeks and that most gains are noted within 6 to 8 weeks. Agid, Kapur, Arenovich, and Zipursky (2003) conducted a meta-analysis of 42 double-blind comparator-controlled studies and found that antipsychotic effect was evident within the first week of treatment and that improvement in the first 2 weeks was greater than during any subsequent 2-week period. In a double-blind, placebo-controlled study comparing intramuscular olanzapine with intramuscular haloperidol, Kapur and colleagues (2005) reported that onset of specific antipsychotic effect was evident within the first 24 hours, and that improvement in psychosis was independent of change in agitation and excitement. However, some patients, including first-episode patients (Lieberman, 1993; Robinson et al., 1999b), may require several months to achieve their full clinical response and symptom remission. In another study of patients with first-episode schizophrenia, Emsley, Rabinowitz, and Medori (2006) found that clinical response (greater than 20% improvement in total Positive and Negative Symptom Scale [PANSS] score) was achieved in 77% of the sample, although the time to response varied from 1 to greater than 8 weeks.

When a patient fails to respond to a standard course of treatment, clinicians generally employed maneuvers such as increasing the dose, switching to another typical antipsychotic, or maintaining the initial treatment for an extended trial. However, little early evidence from controlled clinical trials supports the efficacy of any of these strategies (Kinon et al., 1993; Levinson et al., 1990; Rifkin, Doddi, Karajgi, Borenstein, & Wachspress, 1991; Van Putten, Marder, & Mintz, 1990; Volavka et al., 1992). More recently it was shown in the large Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study that switching to a new medication yielded no advantage over staying on the previous medication (Rosenheck et al., 2009), and in another trial switching from olanzapine, quetiapine, or risperidone to aripiprazole led to reduction in weight and triglycerides but at the expense of higher discontinuation rates at 24 weeks (43.9% vs 24.5%) (Stroup et al., 2011). Similarly, switching from haloperidol decanoate or fluphenazine decanoate to risperidone long-acting injectable led to higher rates of discontinuation and no differences in psychopathology (Covell et al., 2012). Switching from antipsychotic polypharmacy to monotherapy also led to increased rates of discontinuation

at 6 months—86% among those staying on polypharmacy were still taking both medications compared to 69% taking the same medication among those switching to monotherapy—although symptom control was no different between the two groups. Nonetheless, two thirds of patients who switched were successful, and monotherapy resulted in weight loss (Essock et al., 2011), suggesting that discontinuing polypharmacy is a reasonable course of action in many instances, particularly if there is a compelling reason. This is consistent with an earlier meta-analysis that found that antipsychotic polypharmacy was associated with less study-specific inefficacy and all-cause discontinuation than switch to monotherapy (Correll, Rummel-Kluge, Corves, Kane, & Leucht, 2009).

Significant efforts are under way to identify factors that may be associated with antipsychotic treatment response and refractoriness. For example, a delay in the initiation of antipsychotic drug treatment following onset of psychosis in first-episode schizophrenia (Loebel et al., 1992), and in the treatment of acute exacerbations (May et al., 1976; Wyatt, 1995), may be associated with poorer clinical outcomes. Robinson and colleagues (1999b) reported that 87% of their sample of first-episode patients with schizophrenia or schizoaffective disorder responded to treatment within 1 year, with a median response time of 9 months. They demonstrated that male gender, a history of obstetric complications, poorer attention at baseline, more severe hallucinations and delusions, and the development of EPS during antipsychotic treatment were associated with a significantly lower likelihood of response.

Numerous studies have demonstrated that continuation of antipsychotic medication beyond treatment of the acute episode is necessary to reduce the risk of psychotic relapse, as evidenced by the fact that most patients will experience a clinical worsening if their treatment is discontinued (Davis, 1975; Kane & Lieberman, 1987). Controlled clinical trials of drug discontinuation demonstrate that after 1 year of maintenance treatment, 30% of patients will relapse on medication compared with a rate of 65% in patients who have undergone placebo substitution. Even those patients who have been successfully maintained in the community for 2 to 3 years on antipsychotic drugs will demonstrate a relapse rate of 66% by 1 year after their treatment is discontinued (Hogarty, Ulrich, Mussare, & Aristigueta, 1976). First-episode patients show a slightly lower relapse rate, with 40% of patients on placebo experiencing a relapse, compared with none while on medication during the year following initial recovery (Kane, Rifkin, Quitkin, Nayak, & Ramos-Lorenzi, 1982). Robinson and colleagues (1999a) showed that discontinuing drug therapy increased the risk of

relapse almost five times in a sample of patients with first-episode schizophrenia and schizoaffective disorder. This study also showed an 82% cumulative risk of relapse for patients who had recovered from a first episode of psychosis but were not continued on antipsychotic medication. Those who had one relapse within 5 years had a 78% chance of having a second relapse and an 86% chance of having a third. Thus, maintenance antipsychotic therapy seems justified, even for patients recovering from their first episode of schizophrenia. The benefits of maintenance antipsychotic drug treatment, however, are tempered by the inherent risk to the patient of long-term side effects such as the development of tardive dyskinesia and health sequelae of weight gain and dyslipidemia secondary to metabolic abnormalities caused by antipsychotics. Limiting antipsychotic drug exposure by introducing "drug holidays" or reducing the dose has intuitive appeal for minimizing side-effect risk. However, maintenance studies of the dose-response relationship for up to 1 year of continuous antipsychotic drug treatment indicate that standard drug doses (fluphenazine decanoate 12.5 to 50 mg biweekly; haloperidol decanoate 50 to 200 mg monthly) provide significantly greater prophylaxis against relapse than do doses of one half to one tenth as much (Hogarty et al., 1988; Johnson, Ludlow, Street, & Taylor, 1987; Kane et al., 1983; Kane, Woerner, & Sarantakos, 1986; Kane et al., 1993; Marder et al., 1987; Schooler, Keith, Severe, & Mathews, 1993), although the lower doses may be associated with better social adjustment and fewer EPS. A targeted approach that involves slowly titrating patients off maintenance medication with reintroduction of the medication rapidly during presumptive incipient relapsing has not been found to be more effective than the continuous administration of maintenance medication and is associated with risks of symptom exacerbation and relapse (Carpenter et al., 1990; Gaebel et al., 1993; Herz et al., 1991; Jolley, Hirsch, Morrison, McRink, & Wilson, 1990; Schooler et al., 1993).

SECOND-GENERATION ANTIPSYCHOTICS

SGAs initially offered hope for enhanced efficacy in the treatment of schizophrenic psychopathology with a reduced burden of extrapyramidal motor dysfunction. The number of double-blind studies comparing the acute treatment effects of atypical antipsychotics with the effects of their typical counterparts and the number of studies comparing effects in treatment-refractory populations have continued to grow rapidly. We will review the available evidence supporting the use of each drug in acute, chronic, and treatment-resistant schizophrenia. This is followed by summaries of the meta-analyses of published studies, the CATIE, and side-effect profiles of the SGAs.

Clozapine

Two reviews summarizing a total of 45 studies compared clozapine to FGAs in the treatment of non–treatment-resistant patients and hinted at the superiority of clozapine with respect to the proportion of patients responding to clozapine, the amount of their response, and a small albeit statistically nonsignificant advantage in long-term relapse rate (Baldessarini & Frankenburg, 1991; Wahlbeck, Cheine, & Essali, 2000). When studies that included only patients with treatment-resistant schizophrenia are selected, the superiority of clozapine over typical antipsychotics is most consistently demonstrated.

A pivotal study (Kane et al., 1988) of the effectiveness of clozapine in treatment-resistant schizophrenia entered 268 such patients into a double-blind comparison with chlorpromazine. Treatment resistance was defined as having failed to respond to at least three prior antipsychotics and without any period of good functioning in the past 5 years, and then not responding to a single-blind 6-week haloperidol prospective lead-in trial. At 6 weeks, 30% of the clozapine-treated group but only 4% of the chlorpromazine-treated group met the a priori response criteria of a reduction greater than 20% from baseline in the Brief Psychiatric Rating Scale (BPRS) total score plus either a posttreatment Clinical Global Impression (CGI) score of 3 (mild) or lower or a posttreatment BPRS total score of 35 or lower. Since the initial study by Kane and colleagues, several double-blind comparisons of clozapine and an FGA have been conducted in patients with treatment-resistant schizophrenia (Buchanan, Breier, Kirkpatrick, Ball, & Carpenter, 1998; Hong, Chen, Chiu, & Sim, 1997; Kane et al., 2001; Kumra et al., 1996; Rosenheck et al., 1997), as well as an open-label study with random treatment assignment and long-term follow-up (Essock, Hargreaves, Covell, & Goethe, 1996), and all have been consistent with the notion that clozapine displays superior efficacy in treatment-resistant schizophrenia. A meta-analysis of seven trials comparing clozapine to typical antipsychotic drugs in treatment-refractory schizophrenia (Chakos, Lieberman, Hoffman, Bradford, & Sheitman, 2001) showed an advantage for clozapine with regard to total psychopathology, categorical response to treatment (measure of the number of patients who met an arbitrary cutoff for response), EPS, tardive dyskinesia, and study completion rates. Finally, the efficacy of clozapine in the maintenance phase of treatment is supported by three open-label studies (Breier, Buchanan, Irish, & Carpenter, 1993; Meltzer, Burnett, Bastani, & Ramirez, 1990; Miller, Perry, Cadoret, & Andreasen, 1992) that suggest clozapine reduces rehospitalization rates.

Almost certainly because they are a preselected group of the most treatment-refractory individuals, a considerable proportion of patients treated with clozapine do not respond or respond only partially to clozapine and are left with substantial residual psychopathology. A review of data from clozapine clinical trials by Buckley, Wiggins, Sebastian, and Singer (2001) found that about half of patients with treatment-refractory symptoms do not respond to clozapine. An augmentation strategy for patients who have failed to respond to an adequate clozapine trial that has been evaluated in several controlled and open trials is the use of an antipsychotic with high D_2 antagonist affinity to supplement the low D_2 occupancy of clozapine. Three double-blind, placebo-controlled, randomized studies of augmentation of clozapine with risperidone have been published, with one suggesting benefit of risperidone augmentation of clozapine (Josiassen et al., 2005) and two finding no benefit (Honer et al., 2006; Yagcioglu et al., 2005). In summary, the controlled studies in aggregate do not lend support to augmentation of clozapine with other antipsychotics in patients who either have failed to respond or have had a suboptimal response to an adequate trial of clozapine alone.

Clozapine remains the only antipsychotic specifically approved by the U.S. Food & Drug Administration (FDA) for treatment-resistant schizophrenia. Clozapine is also approved for reduction of suicide risk in patients with schizophrenia. The controlled trial that led to this indication (Meltzer et al., 2003) included 980 patients who were at relatively high risk of suicide and were randomized to double-blind treatment with either clozapine or olanzapine and followed for up to 2 years; approximately 25% of the sample had treatment-resistant schizophrenia. Suicidal behavior was significantly less in patients treated with clozapine versus olanzapine, as reflected by fewer clozapine-treated patients attempting suicide, requiring hospitalization or rescue interventions to prevent suicide, or requiring concomitant treatment with antidepressants or anxiolytics.

Unfortunately, the reported incidence rate of 1% for clozapine-induced agranulocytosis (Alvir, Lieberman, Safferman, Schwimmer, & Schaaf, 1993) has limited the extent of the drug's use in clinical practice, although with appropriate monitoring of the granulocyte count (weekly for the first 6 months, every other week for the second 6 months, and every 4 weeks thereafter) the risk of morbidity and mortality from agranulocytosis is almost entirely eliminated. Clozapine has also been associated with an increased risk of myocarditis and a dose-dependent risk for seizures; other side effects that commonly occur include sedation, weight gain, hypotension, tachycardia, hypersalivation, and constipation. In summary, the demonstrated efficacy of clozapine among the subgroup of refractory patients, with no acute EPS and the absence of risk for tardive dyskinesia, represents a

landmark achievement in psychopharmacology. The success of clozapine provided the impetus for an enormous research effort that has resulted in the development of several other atypical antipsychotic drugs.

Risperidone

A number of double-blind RCTs have been published that compared the efficacy of risperidone to placebo and/or FGA or SGA in the treatment of acute schizophrenic exacerbations. In these studies, risperidone has been consistently superior to placebo. Some studies have shown the superiority of risperidone compared to haloperidol with respect to clinical efficacy (Chouinard et al., 1993; Marder & Meibach, 1994), while others have shown that the efficacies of risperidone and haloperidol are indistinguishable (Moller et al., 2008; Peuskens, 1995), including in first-episode patients (Schooler et al., 2005). Studies have been more consistent in showing that risperidone is superior to haloperidol with respect to EPS, although the difference may not be as pronounced at higher doses of risperidone (Chouinard et al., 1993; Marder & Meibach, 1994; Moller et al., 2008; Peuskens, 1995; Schooler et al., 2005). One smaller RCT with a total of 78 patients split across four treatment groups suggested that risperidone was superior to quetiapine and equivalent to olanzapine with respect to the percentage of patients discontinuing after 8 weeks (Hatta et al., 2009), and another larger RCT showed that risperidone and ziprasidone were equivalent with respect to efficacy but not side effects, with ziprasidone being superior in terms of EPS, prolactin elevation, and weight gain (Addington et al., 2009). Risperidone appears to be superior to haloperidol with respect to EPS liability, but it causes more prolactin elevation, more early weight gain, and similar weight gain at later endpoints (Schooler et al., 2005). It should be noted that addition of aripiprazole to risperidone (or quetiapine) in one RCT with a total of 323 patients did not demonstrate any improvement in psychiatric symptoms compared to risperidone alone (Kane et al., 2009). Furthermore, a rater-blinded, randomized controlled 4-week trial suggested that lack of response with risperidone at 2 weeks predicted lack of response at 4 weeks, a relationship that did not hold for olanzapine (Hatta et al., 2011).

Hunter, Joy, Kennedy, Gilbody, and Song (2003) conducted a review of all RCTs comparing risperidone to any FGA treatment for individuals with schizophrenia or other similar serious mental illnesses. In the short term, risperidone was more likely to produce an improvement in the PANSS compared with haloperidol (n = 2,368, nine RCTs). A similar, favorable outcome for risperidone was found in long-term studies (n = 859, two RCTs). Risperidone was also more likely to reduce relapse at 1-year follow-up compared with haloperidol (n = 367, one RCT). Fewer participants treated with risperidone left studies before completion, in both short-term (n = 3,066, 16 RCTs) and long-term trials (n = 1,270, four RCTs). Patients given risperidone had significantly fewer general movement disorders (including EPS) than those receiving FGAs (n = 2,702, 10 RCTs). Significantly fewer participants given risperidone used antiparkinsonian drugs (n = 2,524, 11 RCTs). Four studies (n = 1,708) found risperidone-treated patients were more likely to gain weight than were patients treated with FGAs. Risperidone was no more or less likely than haloperidol to cause sexual problems such as erectile dysfunction (n = 106, two RCTs).

The efficacy of risperidone compared with haloperidol in longer-term treatment has also been rigorously evaluated in RCTs. Some early trials suggested that risperidone might be superior to FGAs (usually haloperidol) with respect to relapse risk (Csernansky, Mahmoud, & Brenner, 2002). A naturalistic follow-up study showed that time to readmission to an inpatient psychiatric unit after 2 years was longer in risperidone and olanzapine-treated patients compared to those being treated with FGAs (Rabinowitz et al., 2001). Another RCT (Schooler et al., 2005) of risperidone and haloperidol in first-episode patients found that relapse rates were significantly lower in risperidone-treated patients (42% and 55%, respectively) over a median follow-up period of 206 days, and median time to relapse was longer in risperidone-treated patients (466 days for risperidone-treated patients vs. 205 days for haloperidol-treated patients). The advantage for risperidone in reducing relapse risk was evident even though both groups had comparable symptom improvement. On the other hand, in the CATIE study, patients who were switched from perphenazine to risperidone due to lack of efficacy had significantly shorter time to discontinuation (3.6 months) compared to switching to quetiapine (9.9 months) or olanzapine (7.1 months), possibly due to similarities in potency and side-effect profile between perphenazine and risperidone (Stroup et al., 2007). A large

RCT with a total of 404 patients demonstrated that continuing risperidone at the dose that was effective during acute exacerbation was superior to 50% dose reduction at 4 or 26 weeks (30.5% vs 19.5% vs 9.4%, respectively) (Wang et al., 2010). The efficacy of risperidone compared with conventional antipsychotics in treatment-refractory populations has also been studied, although to a lesser degree. Multiple rigorous RCTs have not been able to clearly demonstrate any utility of risperidone in treatment-refractory patients (Azorin et al., 2001; Volavka et al., 2002; Wirshing et al., 1999), although RCTs comparing risperidone with clozapine using less strict criteria for the definition of treatment-resistant schizophrenia (Bondolfi et al., 1998; Klieser et al., 1995) had somewhat more optimistic results for risperidone.

Risperidone has recently become available in a long-acting injectable formulation for intramuscular administration every 2 weeks. The efficacy and safety of long-acting risperidone have been evaluated in two large clinical trials (Fleischhacker et al., 2003; Kane et al., 2003). Kane and colleagues (2003), in a 12-week, randomized, double-blind, placebo-controlled, multicenter trial, treated 400 patients with schizophrenia with either long-acting risperidone (25 mg, 50 mg, or 75 mg every two weeks) or placebo injection; they found that long-acting risperidone was significantly more effective than placebo in terms of mean total PANSS, as well as mean positive and mean negative subscale scores. The 75-mg dose was associated with no efficacy advantage over the lower doses and was associated with an increased rate of adverse events; it is therefore not a marketed dose. Another small RCT suggested that risperidone long-acting injectable (LAI) (n = 26) was superior to oral risperidone in terms of adherence (89% vs 59%) (Weiden et al., 2009). A randomized, active-controlled, 2-year trial with 666 patients with schizophrenia suggested that risperidone LAI was superior to quetiapine in terms of relapse at 2 years (16.5% vs 31.3%) (Gaebel et al., 2010). A nationwide cohort study in Finnish schizophrenia patients (N = 2,588 total) found that the risk of relapse with risperidone LAI (and other depots) was one third of that for the equivalent oral formulation (Tiihonen et al., 2011). Similarly, a prospective observational schizophrenia study with 1,345 risperidone LAI-treated patients showed that risperidone LAI was superior to oral antipsychotics in treatment retention and CGI as well as reduction in number and days of hospitalizations (Olivares et al., 2009). However, a recent rigorous RCT with 369 total patients compared risperidone LAI to psychiatrist antipsychotic of choice and found no difference in hospitalization rate or efficacy, although risperidone LAI was inferior with respect to EPS (Rosenheck et al., 2011). Another smaller 6-month RCT followed by 6 months of naturalistic follow-up compared patients continued on haloperidol decanoate or fluphenazine decanoate to individuals switching to risperidone LAI and found a higher discontinuation rate in switchers, no differences in psychopathology, and more weight gain (Covell et al., 2012).

In summary, the available data suggest that risperidone may be somewhat more effective than typical antipsychotics in acute and maintenance treatment; however, its utility in treatment-refractory populations has not been convincingly established, although there is some evidence it may be superior to conventional antipsychotics but not as effective as clozapine in this population. Persistent prolactin elevation remains a problem with risperidone. The advantage of lower EPS liability compared with typical antipsychotics is diminished at higher doses (more than 6 mg/day), although higher doses are usually not necessary for therapeutic effect.

Olanzapine

The FDA approved olanzapine in 1996 for the treatment of schizophrenia. Since that time, many RCTs and large prospective studies have accumulated. At least one large RCT has demonstrated the superiority of olanzapine (Beasley et al., 1996) and olanzapine LAI (Lauriello et al., 2008) compared to placebo in the treatment of acute schizophrenia, and multiple large RCTs in acute schizophrenia have demonstrated either that olanzapine and haloperidol are similar in efficacy (Beasley et al., 1996) or that olanzapine may be superior to haloperidol with respect to improvement in positive and negative symptoms, although in some studies only at higher doses (Beasley et al., 1997; Tollefson et al., 1997). Olanzapine has similarly been shown to be superior to chlorpromazine with respect to efficacy in a recent RCT (Dossenbach et al., 2007). Olanzapine's side-effect profile also differed from haloperidol in that it had lower EPS liability and caused less prolactin elevation (Beasley et al., 1996, 1997; Tollefson et al., 1997) but more early weight gain (Tollefson et al., 1997). The aforementioned findings

are consistent with the findings of a meta-analysis that found that olanzapine was superior to typical antipsychotics (14 RCTs, $N = 3,344$) in terms of total PANSS as well as positive and negative symptom scores, and caused fewer EPS but significantly more weight gain. Olanzapine did not differentiate from other SGAs on efficacy outcomes, although it was associated with fewer EPS but caused greater weight gain (11 RCTs, $N = 1,847$). A number of more recent RCTs have also been unable to demonstrate superiority of olanzapine relative to other SGAs. In an 8-week RCT in acute schizophrenia with 75 total patients, there were no significant differences between quetiapine, risperidone, and olanzapine on PANSS total score (Sacchetti, Valsecchi, & Parrinello, 2008). Another RCT with 116 total patients showed no efficacy difference between olanzapine, risperidone, or molindone in the treatment of acute schizophrenia (Sikich et al., 2008). In contrast to most studies demonstrating no efficacy difference between olanzapine and other SGAs, one 6-week acute RCT with 703 patients suggested that olanzapine was superior to aripiprazole in terms of efficacy measures and time to discontinuation (Fleischhacker et al., 2009). Interestingly, a large ($N = 599$ patients) RCT using multiple doses of olanzapine (10, 20, and 40 mg) demonstrated no difference on the PANSS total but a dose-response effect with respect to prolactin elevation and weight gain, suggesting that 10 mg is a reasonable initial dose for non–treatment-resistant patients (Kinon et al., 2008). One post hoc reanalysis of a large multicenter double-blind RCT ($N = 1,996$) suggested that patients who showed little to no reduction in symptoms 2 weeks after starting olanzapine were unlikely to show a response of any kind at 4 to 6 weeks (Leucht, Shamsi, Busch, Kissling, & Kane, 2008), although the opposite was shown in another RCT (Hatta et al., 2011). It should also be noted that olanzapine oral tablets have been shown in a 13-week, randomized, open-label trial with 377 schizophrenic and schizoaffective patients to be equivalent in efficacy to risperidone LAI (Keks, Ingham, Khan & Karcher, 2007). In a 24-week RCT with over 1,000 patients, olanzapine LAI and oral olanzapine were noted to be equivalent with respect to exacerbation likelihood and efficacy (Kane et al., 2010).

The potential of olanzapine in maintaining long-term therapeutic effect in comparison with both FGAs and SGAs has also been studied extensively. Consistent with acute treatment studies, a recent 52-week RCT with 400 total patients split among olanzapine, quetiapine, and risperidone treatment groups showed that these medications appeared comparable with respect to effectiveness, although olanzapine held a small advantage with respect to positive symptoms at 12 and 52 weeks (McEvoy et al., 2007). However, a number of long-term studies comparing olanzapine to other antipsychotics have detected differences in clinical effectiveness (Tran, Dellva, Tollefson, Wentley, & Beasley, 1998). The data from the extension phases of three double-blind studies comparing olanzapine with haloperidol were pooled to form one group for each drug. Olanzapine-treated subjects experienced fewer relapses than haloperidol-treated subjects, and the Kaplan-Meier estimated 1-year risk of relapse was 19.7% with olanzapine and 28% with haloperidol. Similar advantages for olanzapine were evident in a study in patients with first-episode schizophrenia. Lieberman and colleagues (2003) conducted a double-blind, randomized study of olanzapine and haloperidol in first-episode patients and found that in treatment of the acute phase of the illness, both drugs were comparable in efficacy. However, at the last observation point (12 weeks), significantly more patients were still in treatment in the olanzapine arm versus the haloperidol arm (67% vs. 54%). Evidence for reduced discontinuation rates with olanzapine in comparison to FGAs has accumulated in both RCTs and prospective observational studies. As will be discussed in greater detail later, this was noted in the large CATIE trial, in which olanzapine had the longest time to discontinuation in comparison to perphenazine, risperidone, quetiapine, and ziprasidone (Lieberman et al., 2005). In a 3-year prospective, observational study with 7,728 patients, medication discontinuation rates were lowest with olanzapine (36.4%) and clozapine (33.8%) and higher for conventional oral FGAs (53.1%) and depot FGAs (50.2%) (Haro et al., 2007). Similarly, in an RCT with a total of 498 first-episode patients, discontinuation for any cause within 12 months was 72% for haloperidol, 40% for amisulpride, 33% for olanzapine, 53% for quetiapine, and 45% for ziprasidone (all significantly lower than haloperidol, despite indistinguishable efficacy) (Kahn et al., 2008). Another large observational study, the Schizophrenia Health Outcomes Observational (SOHO) study, with 1,688 patients, noted similar findings, namely that medication

maintenance at 3 years was highest with clozapine (57.6%) and olanzapine (48.3%) and lowest with quetiapine (19%). Treatment discontinuation was less frequent with olanzapine than with risperidone, depot FGA, oral FGA, or quetiapine, and similar to clozapine; and longer maintenance was associated with higher social abilities and better cognitive status (Ciudad et al., 2008). Findings were similar in the SOHO study in previously untreated patients initiating monotherapy (Haro, Novick, Suarez, & Roca, 2009) and another large observational study with 7,658 patients (Dossenbach et al., 2008). An exception to the trend of decreased rates of discontinuation in patients taking olanzapine may be in patients who have a substance use disorder, for whom all drugs appeared similar in terms of rates of discontinuation in the CATIE study ($N = 371$) (Swartz et al., 2008). Although most studies have not shown long-term differences in efficacy as measured by clinical scales, it was noted in the CATIE study that a higher proportion of olanzapine-treated patients maintained remission at 6 months (12.4%) in comparison to other antipsychotics (quetiapine, 8.2%; perphenazine, 6.8%; ziprasidone, 6.5%; and risperidone, 6.3%) (Levine, Rabinowitz, Ascher-Svanum, Faries, & Lawson, 2011).

The metabolic effects of olanzapine have also been studied and compared to a handful of other antipsychotics in mostly open-label or retrospective studies. In one study with 145 first-episode psychosis patients, metabolic changes were noted to be similar between haloperidol, olanzapine, and risperidone at 12 weeks (Perez-Iglesias et al., 2007), although using data from 246 patients in the CATIE study, it was found that olanzapine and quetiapine increased triglyceride levels, ziprasidone was neutral, and perphenazine and risperidone decreased triglycerides at 3 months (Meyer et al., 2008). In a retrospective chart review study with 296 patients, individuals started on SGAs had a three times higher incidence of metabolic syndrome than those started on FGAs, with the difference in incidence disappearing when olanzapine and clozapine patients were excluded from the analysis (De Hert et al., 2008). Finally, in another randomized, open-label prospective trial with 164 patients, it was noted that severity of weight gain increased from haloperidol to risperidone to olanzapine at 3 months, but there was no difference at 1 year (Perez-Iglesias et al., 2008).

A few studies have compared olanzapine with other antipsychotics in treatment-refractory patients with varying results. Conley and colleagues (1998), in a 6-week trial with 84 patients, described a study very similar in design to the original study by Kane and colleagues (1988) that established clozapine as a treatment for refractory schizophrenia. No differences were found between olanzapine and chlorpromazine for positive or negative symptoms or total psychopathology. Breier and Hamilton (1999), in a 6-week RCT of 526 patients who were determined to be partially responsive to FGAs, noted olanzapine to be superior to haloperidol in reducing positive and other symptoms in at least some patients. Volavka and colleagues (2002) also found olanzapine to be superior to haloperidol. A more recent small RCT ($N = 40$ patients total) also suggested that high-dose olanzapine was equivalent to clozapine with respect to efficacy at 6 weeks and 6 months (Meltzer et al., 2008), although another similarly sized RCT found that 66% of clozapine patients met response criteria whereas only 33% of olanzapine patients did, suggesting the superiority of clozapine (Kumra et al., 2008). On the whole, the available evidence suggests that olanzapine has some efficacy advantages over FGAs both in the acute and maintenance treatment phases of the illness and in the treatment of patients selected for prior treatment resistance to FGAs. However, substantial weight gain and metabolic disturbances have emerged as serious side effects.

Quetiapine

The FDA approved quetiapine in 1998, and its efficacy has been evaluated in several methodologically rigorous clinical trials. Two 6-week double-blind, placebo-controlled studies that enrolled 109 and 286 patients, respectively (Borison, Arvanitis, & Miller, 1996; Small, Hirsch, Arvanitis, Miller, & Link, 1997), and were composed of groups of patients with average treatment doses ranging from 209 mg to 407 mg, showed superiority of quetiapine to placebo in the treatment of psychotic symptoms. In a randomized, double-blind 6-week study (Peuskens & Link, 1997) that compared the efficacy of quetiapine to chlorpromazine among 201 patients, with doses up to 750 mg for each, no significant differences in efficacy were found.

Two 6-week RCTs in patients with schizophrenia have found quetiapine to be comparable to haloperidol with respect to efficacy but with fewer EPS (Arvantis & Miller, 1997; Copolov, Link, & Kowalcyk, 2000). Most of the studies comparing quetiapine to other SGAs, which include olanzapine and were described above, have suggested that quetiapine is comparable in efficacy to other SGAs (Sacchetti, Valsecchi, & Parrinello, 2008) although perhaps slightly inferior to olanzapine (McEvoy et al., 2007). On the other hand, quetiapine has demonstrated significantly inferior discontinuation rates to olanzapine, although not other SGAs, in the CATIE trial (Lieberman et al., 2005). Maintenance of remission at 6 months in the CATIE trial in quetiapine-treated patients was also inferior to olanzapine-treated patients (12.4% vs 8.2%) although similar to other SGAs and perphenazine (Levine, Rabinowitz, Ascher-Svanum, Faries, & Lawson, 2011). The findings in the SOHO study were even less favorable with respect to quetiapine, with medication maintenance at 3 years at 19% for quetiapine, which was the lowest of any medication examined in the study, including oral and depot typical antipsychotics, risperidone, olanzapine (48.3%), and clozapine (57.6%) (Ciudad et al., 2008). Finally, in an RCT of 498 first-episode patients, the 12-month discontinuation rate for quetiapine-treated patients was superior in comparison to haloperidol-treated patients, higher than for olanzapine-treated patients, and comparable to slightly higher than the rate for patients treated with other SGAs (Kahn et al., 2008).

The data for the effectiveness of quetiapine in treatment-resistant schizophrenia are very limited. Buckley, Goldstein, and Emsley (2004) reported a post hoc analysis of a double-blind randomized trial comparing quetiapine to haloperidol in 95 patients who had failed to improve with fluphenazine 20 mg/day in a 4-week, open-label phase. There was no clear advantage of quetiapine with respect to response rates based on the PANSS score (greater than 20% reduction) or CGI-improvement scale (CGI-I). Similarly, Conley and colleagues (2005) were not able to demonstrate a significant superiority of quetiapine or risperidone over fluphenazine in a small ($N = 38$) double-blind trial lasting 12 weeks in treatment-resistant patients. Overall, quetiapine appears to be similarly efficacious as conventional antipsychotics and is associated with minimal EPS and prolactin elevation. Sedation, orthostasis, and weight gain and other metabolic side effects may be problematic for some patients.

Ziprasidone

The FDA approved ziprasidone in February 2001 for the treatment of schizophrenia. Several studies have shown it to be effective against positive and negative symptoms of schizophrenia with little or no weight gain, a feature that distinguishes it from many of the current antipsychotics. Approval of ziprasidone was delayed by the FDA in 1998 pending more data on QT-interval changes in cardiac rhythm that theoretically could cause a dangerous arrhythmia called torsades de pointes. The drug was approved after the manufacturer submitted further safety data, including the fact that more than 4,000 patients had been treated in clinical trials with ziprasidone without evidence of torsades de pointes. This is supported by a more recent open-label study with 18,154 patients that showed no difference in non-suicide mortality between ziprasidone and olanzapine (Strom et al., 2011). The FDA does not require an electrocardiogram prior to treatment, and cardiac checkups during treatment are not mandated. To date, there has been no evidence from the clinical experience with ziprasidone that it is associated with cardiac toxicity.

The efficacy of ziprasidone in treating schizophrenia has been established in seven main studies: two versus placebo, one versus haloperidol, one versus risperidone, and three versus olanzapine. Keck and colleagues (1998) conducted a 4-week double-blind comparison of placebo and ziprasidone at 40 mg/day and 120 mg/day in 139 patients with schizophrenia and schizoaffective disorder, with ziprasidone at 120 mg/day producing statistically significant improvement in clinical symptomatology without causing movement disorders at a rate higher than placebo. Daniel and colleagues (1999) compared ziprasidone at 80 mg/day and 160 mg/day to placebo in a 6-week double-blind trial of 302 patients and demonstrated superiority of both doses to placebo in reducing clinical symptoms. Ziprasidone at 160 mg/day was also shown to significantly reduce depressive symptoms in patients with clinically significant depression at baseline. The drug was well tolerated and caused movement disorders and weight gain at rates similar to placebo.

In RCTs comparing ziprasidone to other antispychotics, ziprasidone has been shown to be equivalent in efficacy, often with a lower side-effect burden. Ziprasidone at doses of 160 mg/day has been shown to be equivalent in efficacy and superior with respect to EPS and prolactin elevation in comparison to haloperidol (Goff et al., 1998), indistinguishable from risperidone with respect to efficacy and side effects (Addington, Pantelis, Dineen, Benattia, & Romano, 2004), equivalent to olanzapine with respect to efficacy (Grootens et al., 2011; Simpson et al., 2005), and superior to olanzapine with respect to weight gain and lipid abnormalities (Meyer et al., 2008; Simpson et al., 2005). However, in a similar 28-week study, Breier and colleagues (2005) found that although both drugs were efficacious, olanzapine was superior to ziprasidone in the PANSS score (total and all subscales) as well as the CGI but inferior with respect to weight gain and lipid abnormalities.

The existing evidence on ziprasidone indicates that it is an effective antipsychotic, at least comparable to haloperidol in treating schizophrenia. It is associated with minimal weight gain and metabolic disturbances, is not sedating, and does not elevate serum prolactin. Further study and clinical experience are needed to determine whether this drug has a role in treatment-refractory schizophrenia or other special populations.

Aripiprazole

Aripiprazole was approved by the FDA in 2002 and has a mode of action that is distinct from those of currently available antipsychotic drugs. In addition to 5-HT_{2A} receptor antagonism, aripiprazole acts as a potent partial dopamine D_2 receptor agonist and a partial serotonin 5-HT_{1A} agonist. In Phase III comparative clinical studies, aripiprazole 15 to 30 mg/day was at least as effective as haloperidol and risperidone in short-term treatment of acute exacerbation of schizophrenia and superior to placebo. Consistent with the profile of most SGAs, aripiprazole has a low propensity to induce EPS. It is not associated with hyperprolactinemia and has a low liability for causing weight gain. Three short-term studies using Aripiprazole doses between 10 and 30 mg/day have established that aripiprazole is superior to placebo in terms of clinical improvement (Kane et al., 2002; Potkin et al., 2003; McEvoy, Daniel, Carson, McQuade, & Marcus, 2007).

A 26-week placebo-controlled trial in which aripiprazole 15 mg/day was administered to patients with stable chronic disease found that aripiprazole was significantly more effective than placebo in preventing relapse (34% vs. 57%), and there was no difference between treatments with respect to the overall incidence of adverse events (Pigott et al., 2003). The long-term efficacy and safety of aripiprazole (30 mg/day) relative to haloperidol (10 mg/day) was investigated in two 52-week, randomized, double-blind, multicenter studies with 1,294 patients with chronic schizophrenia who were in acute relapse (Kasper et al., 2003). Aripiprazole demonstrated long-term efficacy that was comparable or superior to that of haloperidol across all symptom measures, including significantly greater improvements for PANSS negative subscale scores and Montgomery-Asberg Depression Rating Scale (MADRS) total score. The time to discontinuation for any reason was significantly longer with aripiprazole than with haloperidol, and aripiprazole was associated with significantly lower scores than haloperidol on all EPS assessments. A 16-week RCT in 173 patients with schizophrenia or schizoaffective disorder showed that switching from olanzapine to aripiprazole led to significant weight loss, while continuation of olanzapine led to continued weight gain (Newcomer et al., 2008), although, as mentioned earlier, at the cost of higher discontinuation rates in switchers: 43.9% versus 24.5% (Stroup et al., 2011) or 16.8% versus 8.9% (Kane et al., 2009). Finally, aripiprazole has very recently become available in a depot formulation that has been shown to reduce the risk of impending relapse and to help patients maintain symptomatic clinical improvement in an RCT with 979 patients randomized to placebo maintenance or aripiprazole depot maintenance after an oral aripiprazole lead-in phase (Kane et al., 2009).

These data indicate that aripiprazole is effective in short- and long-term treatment of schizophrenia with efficacy that is at least comparable to that of other available antipsychotics. It also has a favorable side-effect profile that includes limited sedation, no prolactin elevation, and minimal weight gain. Aripiprazole has not been systematically evaluated in patients with treatment-resistant schizophrenia.

Paliperidone

Paliperidone, or 9-hydroxy-risperidone, a metabolite of risperidone, was approved by the FDA

for the treatment of schizophrenia in 2006 and schizoaffective disorder in 2009. It is available in oral and depot formulations, both of which have been studied in short- and long-term studies. In multiple 6 week, multicenter, double-blind RCTs, each with about 500 schizophrenia patients, paliperidone was superior to placebo in efficacy as measured by PANSS score and other clinical scales at multiple doses (3, 6, 9, 12, and 15 mg being the commonly studied doses) (Canuso et al., 2009; Davidson et al., 2007; Kane et al., 2007), including in patients who had previously received risperidone but were still acutely ill (Marder et al., 2007) and adolescents (Shah & Joshi, 2011). However, in at least one study lower-dose paliperidone (6 mg) was not superior to placebo in patients with schizoaffective disorder (Canuso et al., 2010). Paliperidone has also been compared in a few studies to other antipsychotics. In a 6 week RCT with 399 schizophrenia patients who received 2 weeks of monotherapy with paliperidone, quetiapine, or placebo, followed by the option to add another antipsychotic if needed for lack of efficacy, paliperidone was superior to quetiapine from days 5 through 14, and this superiority remained even if another antipsychotic was added (Canuso et al., 2009). In another RCT that allowed for periodic up-titrations due to lack of efficacy, the efficacy of paliperidone (maximum dose 12 mg) was comparable to olanzapine (maximum dose 20 mg) (Shah & Joshi, 2011). Furthermore, one RCT with 113 patients total suggested that the time to recurrence of a schizophrenia exacerbation was greater in paliperidone-treated patients compared to placebo (Kramer et al., 2007). Two studies have examined the side effects of paliperidone directly. In one study with 109 patients with schizophrenia or schizoaffective disorder, it was noted that the effect on QTc of daily doses of paliperidone extended-release 12 mg, the maximum recommended dose; paliperidone extended-release 18 mg; and quetiapine 800 mg were comparable (Hough et al., 2011). In a second RCT, paliperidone extended-release did not increase the ratio of triglycerides to high-density lipoproteins (TG/HDL ratio, a proxy measure for metabolic syndrome) or worsen insulin resistance, while olanzapine did both (Schreiner et al., 2012).

Paliperidone has also been studied extensively in the long-term treatment of schizophrenia, although mostly in open-label extension studies, typically 52 weeks in duration. In one open-label study with 215 paliperidone-treated patients, patients on paliperidone had fewer inpatient hospital days in the 52 weeks after starting the drug compared to the 52 weeks before, resulting in significant cost savings (Janicak, Wu & Mao, 2008). In another 52-week open-label study with 1,083 patients, many paliperidone-treated patients maintained their symptomatic improvements with few adverse events, with 47% of patients completing the open-label extension phase (Emsley et al., 2008), while in another flexibly dosed open-label extension study there was clinical improvement at 52 weeks in comparison to the start of the study (Kramer et al., 2010).

Paliperidone is also available in a depot formulation, paliperidone palmitate, which can be injected once a month. Paliperidone palmitate has been shown in at least three large placebo-controlled RCTs, typically 13 weeks in duration, to be effective in the treatment of acute exacerbations of schizophrenia (Gopal et al., 2010; Nasrallah et al., 2010; Pandina et al., 2010). In a fourth placebo-controlled RCT, paliperidone was shown to be superior to placebo and well tolerated; onset of action was as early as day 4 (Alphs, Bossie, Sliwa, Ma, & Turner, 2011). One longer-term RCT compared paliperidone palmitate (N = 379) to risperidone LAI (N = 370), finding that clinical improvement was greater in risperidone LAI compared to paliperidone palmitate, although this difference was thought to be due to suboptimal dosing of paliperidone (Fleischhacker et al., 2011). In a 52week open-label extension study with 388 patients, patients continued on paliperidone continued to improve clinically, with 74% completing the study, and the drug was tolerated with few adverse effects (insomnia, 7%; worsening of schizophrenia, nasopharyngitis, headache, and weight increase, 6% each; potentially prolactin-related adverse events, n = 13, 3%; extrapyramidal treatment-emergent adverse events, n = 25, 6%) (Gopal et al., 2011). In another study, data including 160 patients in a variable-duration, double-blind, randomized, relapse-prevention study followed by open-label extension in individuals with schizophrenia showed that hospitalizations decreased significantly for subjects receiving paliperidone palmitate as compared to the period before starting the medication (Kozma et al., 2011).

Lurasidone

Lurasidone is an antipsychotic that was approved for use in schizophrenia in 2010. It has been studied primarily in short-term (6 weeks) RCTs in acute schizophrenia. It has been shown to be superior to placebo at 40 mg, 80 mg, and 120 mg (Meltzer et al., 2011; Nakamura et al., 2009; Nasrallah et al., 2013; Ogasa, Kimura, Nakamura & Guarino, 2013). Lurasidone has also been compared to treatment with olanzapine (15 mg) in one of the aforementioned studies (Meltzer et al., 2011) and quetiapine extended-release (600 mg) in another (Loebel et al., 2013), and no differences in effectiveness as measured by PANSS and CGI were noted, although Meltzer and colleagues noted that dose-related akathisia was more common with lurasidone than with olanzapine.

In a 3-week, double-blind RCT, switching to lurasidone 120 mg in chronic and stable schizophrenia and schizoaffective disorder from other antipsychotic medications was as safe as switching to ziprasidone 80 mg twice daily, and both were associated with improvements in PANSS and small reductions in weight and cholesterol, although no changes were noted in triglycerides or electrocardiogram (Potkin, Ogasa, Cucchiaro, & Loebel, 2011). Similarly, in another 6-week RCT, cross-titration to lurasidone was well tolerated (McEvoy et al., 2013). Longer-term treatment with lurasidone was well tolerated and led to further improvements in PANSS in a 6-month open-label study with 254 patients who had started the study (Stahl et al., 2013). Similarly, continuation of flexibly dosed lurasidone in a 12-month, double-blind, noninferiority study in patients with chronic schizophrenia showed that lurasidone was not inferior to quetiapine extended-release with respect to relapse prevention and was superior with respect to the probability of hospitalization and remission rate (Loebel et al., 2013).

Iloperidone

Iloperidone is an SGA approved for the treatment of schizophrenia since 2009. It has been shown to be superior to placebo in the treatment of acute schizophrenia in doses ranging from 4 to 24 mg/day in at least four RCTs with a total of 2,536 patients (Cutler, Kalali, Weiden, Hamilton & Wolfgang, 2008; Potkin, Litman, Torres, & Wolfgang, 2008). Patients on iloperidone had lower rates of adverse events than those on ziprasidone (Cutler et al., 2008). In another RCT with 473 patients, EPS scores were noted to improve with iloperidone and worsen with the comparator haloperidol (Kane, Lauriello, Laska, Di Marino, & Wolfgang, 2008). Finally, a randomized open-label, multicenter study noted that iloperidone twice daily produced mean QTc changes similar to ziprasidone and higher than quetiapine, with once-daily dosing of iloperidone leading to QTc changes higher than ziprasidone.

Asenapine

Asenapine, which is taken as a sublingual tablet that dissolves under the tongue, was approved by the FDA in 2009. Asenapine has been shown to be superior to placebo in two 6-week RCTs with a total of 630 patients (Kane, Cohen, Zhao, Alphs, & Panagides, 2010; Potkin, Cohen, & Panagides, 2007). In a 26-week open-label study followed by a 26-week RCT in which patients were either continued on asenapine or switched to placebo, time to relapse/impending relapse and discontinuation for any reason were significantly longer with asenapine than with placebo, and incidence of relapse/impending relapse was lower with asenapine than placebo (12.1% vs 47.4%) (Kane et al., 2011). Asenapine was also studied in a 26-week RCT with a 26-week extension and noted to be inferior to the comparator olanzapine in terms of clinical effectiveness, EPS adverse events, and treatment discontinuation rates (Buchanan et al., 2012). The results were fairly consistent with another double-blind 1-year trial with 1,219 patients with schizophrenia and schizoaffective disorders in which asenapine patients, in comparison to olanzapine patients, exhibited lower trial completion rates, inferior clinical improvement, and greater EPS, although weight gain was greater with olanzapine (Schoemaker, Naber, Vrijland, Panagides, & Emsley, 2010). However, in another variable-length blinded extension study after a 52-week RCT in 440 schizophrenia and schizoaffective disorder patients, adverse events were lower in the extension than in the core study; body weight increase and incidence of EPS adverse events were negligible during extension; and clinical improvement was similar between asenapine and olanzapine (Schoemaker et al., 2012). Asenapine was also shown in an RCT to cause minimal change in QTc, similar to quetiapine (Chapel et al., 2009).

Summary of Meta-Analyses of Efficacy and Tolerability of Second-Generation Antipsychotics

In addition to meta-analyses for individual SGAs referenced earlier, several rigorous meta-analyses have been published (Davis, Chen, & Glick, 2003; Geddes, Freemantle, Harrison, & Bebbington, 2000; Leucht, Pitschel-Walz, Abraham, & Kissling, 1999; Leucht, Wahlbeck, Hamann, & Kissling, 2003) about the relative efficacy and safety/tolerability of SGAs compared with FGAs, and compared with other SGAs. In general, the studies included in these meta-analyses were conducted mostly in patients with an acute exacerbation, did not include treatment-resistant patients, were of relatively short duration, and assessed limited efficacy and safety outcome measures. Results have been variable, with some meta-analyses finding superiority of SGAs to FGAs with respect to efficacy and EPS liability (Leucht et al., 1999), others finding superiority of SGAs only with respect to efficacy but not tolerability (Davis et al., 2003; Leucht et al., 2003), and still others suggesting only slight superiority of SGAs with respect to tolerability but not efficacy (Geddes et al., 2000). A very recent meta-analysis, however, did note evidence of a continuum of efficacy of FGAs and SGAs, with the most effective antipsychotics on multiple different measures being SGAs (Leucht et al., 2013). At the present time the preponderance of the evidence suggests that while clozapine has superior efficacy in treatment-refractory populations, antipsychotics do not otherwise clearly separate from one another with respect to efficacy. Adverse side effect profiles do, however, differ substantially among the various medications.

Impact on Cognitive Functioning of Second-Generation Antipsychotics

The superiority of SGAs in improving cognitive function in schizophrenia relative to FGAs is not well established. Iatrogenic impairments in cognitive test performance in patients on the older drugs may result from EPS, anticholinergic effects, and sedative effects (Green & Braff, 2001; Mortimer, 1997; Velligan & Miller, 1999). The improvement reported in cognitive functioning with the SGAs relative to conventional agents may at least in part be attributable to elimination or relative reduction of some of these deleterious effects of FGAs. In general, patients on SGAs have demonstrated improvement in verbal fluency, digit symbol substitution, executive function, and fine-motor control (Green et al., 1997; Meltzer & McGurck, 1999). A large long-term RCT with 533 patients suggested the superiority of risperidone to haloperidol with respect to improvement in cognitive symptoms in first-episode patients (Harvey, Rabinowitz, Eerdekens, & Davidson, 2005), a 12-week RCT in 35 schizophrenia patients suggested superiority of olanzapine (Lindenmayer, Khan, Iskander, Abad, & Parker, 2007), and a meta-analysis by Keefe, Silva, Perkins, and Lieberman (1999) found a significant overall advantage for atypical antipsychotics on cognitive test performance. However, many studies have found no advantage for SGAs over FGAs. The CATIE trial noted similar cognitive improvements at 8 weeks between the two classes. Another RCT noted improvement in cognition at 12 and 52 weeks, with no differences between antipsychotics (Keefe et al., 2007), and other studies similarly found no differences (Green et al., 2002; Keefe et al., 2004, 2006). Furthermore, in one RCT with 188 patients, neurocognitive improvements in patients with schizophrenia and healthy controls were similar at 2 months, suggesting a practice effect (Goldberg et al., 2007). Overall, there is inconsistent evidence that antipsychotics lead to mild improvements in cognitive functioning, and there is no clear evidence that there is any difference between FGAs and SGAs with respect to cognitive improvement.

Clinical Antipsychotic Trials of Intervention Effectiveness

Many of the studies cited thus far, or used in meta-analyses, are of short-term duration and designed primarily for regulatory approval. Comparators are typically a placebo or a single fixed-dose active agent. Results are often not generalizable because the studies lack representative patient samples, clinical settings, and treatment conditions. The CATIE trial, funded by the National Institute of Mental Health, was a randomized comparison of the long-term effectiveness of olanzapine, risperidone, quetiapine, ziprasidone, and perphenazine (Stroup et al., 2003). The trial was designed to mimic clinical practice and was conducted between January 2001 and December 2004. It included approximately 1,500 patients with schizophrenia, using broad inclusion and minimal exclusion criteria, from 57 community sites, public health

systems, and academic settings. The primary outcome of CATIE was time to all-cause treatment discontinuation; secondary outcomes included discontinuation due to lack of efficacy, tolerability, patient decision, physician decision, psychopathology, safety, neurocognitive functioning, and cost-effectiveness. Patients in Phase 1 were initially randomly assigned to receive olanzapine (7.5 to 30 mg/day), perphenazine (8 to 32 mg/day), quetiapine (200 to 800 mg/day), or risperidone (1.5 to 6 mg/day) under double-blind conditions and followed for up to 18 months or until treatment was discontinued for any reason. Ziprasidone (40 to 160 mg/day) was approved for use by the FDA after the study began and was added to the study in January 2002. Patients whose assigned treatment was discontinued could switch and receive other treatments in Phases 2 and 3. With the exception of additional antipsychotic agents, concomitant medications were permitted throughout the trial.

In Phase 1 of the study (Lieberman et al., 2005), olanzapine was found to be superior to risperidone and quetiapine in terms of the time to *all-cause* discontinuation. Olanzapine was not statistically superior to ziprasidone or to perphenazine in time to all-cause discontinuation after adjustments for multiple comparisons. The percentage of patients who discontinued their medications for any cause prior to 18 months ranged from 64% (olanzapine) to 82% (quetiapine), with an overall discontinuation rate of 74%. The time to the discontinuation of treatment for *lack of efficacy* was longer in the olanzapine group than in the perphenazine, quetiapine, risperidone, and ziprasidone groups; however, the difference between the olanzapine and ziprasidone groups was not significant after adjustment for multiple comparisons. Patients taking olanzapine had the lowest rate of hospitalization for an exacerbation of schizophrenia (11%) versus 15% to 20% for the other agents. Patients taking olanzapine showed the highest rate of discontinuation due to side effects (18%), whereas risperidone had the lowest rate (10%). More patients discontinued perphenazine because of extrapyramidal effects (8% vs. 2% to 4% for the other agents). Quetiapine was associated with a higher rate of anticholinergic effects than any of the other agents (31% vs. 20% to 25%). There were no significant differences among the groups in the incidence of EPS, akathisia, or movement disorders as reflected by either the Simpson-Angus Extrapyramidal Signs Scale or the AIMS Global Severity Scale. There were no substantially different effects of the medications on the corrected QT interval on electrocardiography, and no patients developed torsades de pointes. There were no significant differences among the groups in the incidence of new cataracts, suicide attempts, or suicidal ideation. There were few substantial differences among the groups in the rates or types of medications added during the study. Patients in the olanzapine and risperidone groups were the least likely to receive additional anxiolytic agents, and patients on perphenazine were most likely to receive anticholinergic drugs. Nine percent of patients discontinued olanzapine because of weight gain or metabolic effects versus a 1% to 4% discontinuation rate for patients taking the other four drugs. Patients in the olanzapine group gained more weight than patients in any other group, with an average weight gain of 2 pounds (0.9 kg) per month, whereas patients taking perphenazine and ziprasidone showed a small weight loss per month. A larger proportion of patients (30%) in the olanzapine group gained 7% or more of their baseline body weight, higher than patients taking any of the other agents (7% to 16%). Olanzapine was also associated with greater increases in glycosylated hemoglobin, glucose, total cholesterol, and triglycerides than the other study drugs after adjustment for the duration of treatment. Ziprasidone was the only medication associated with improvement in each of these metabolic variables. Only risperidone was associated with a substantial increase in prolactin levels. The main findings of Phase 1 were that perphenazine, a typical antipsychotic, was similar in effectiveness to risperidone, quetiapine, and ziprasidone and only modestly less effective than olanzapine, and that all drugs were associated with a high rate of discontinuation. Limitations included a dose of olanzapine that was higher than the maximum approved dose, which may have conferred an efficacy advantage to olanzapine, and the fact that patients with tardive dyskinesia (approximately 200) were not randomized to perphenazine for obvious ethical reasons. Because patients with tardive dyskinesia may be more resistant to treatment, the study design may thus have favored perphenazine.

In Phase 2 of the study, subjects who had discontinued their first assigned treatment were offered entry into one of two possible treatment arms. If the drug in Phase 1 was discontinued primarily due to efficacy failure, patients were offered entry to a randomized trial that would compare open-label clozapine

treatment with blinded treatment with an atypical antipsychotic not previously received in Phase 1 of the trial (McEvoy et al., 2006). Patients were randomly assigned to open-label treatment with clozapine ($n = 49$) or to blinded treatment with olanzapine ($n = 19$), quetiapine ($n = 15$), or risperidone ($n = 16$). Time until treatment discontinuation *for any reason* was the primary outcome measure and was significantly longer for clozapine (median = 10.5 months) than for quetiapine (median = 3.3 months) or risperidone (median = 2.8 months), but not for olanzapine (median = 2.7 months). Time to discontinuation because of *inadequate therapeutic effect* was significantly longer for clozapine than for olanzapine, quetiapine, or risperidone. At 3-month assessments, PANSS total scores had decreased more in patients treated with clozapine than in patients treated with quetiapine or risperidone but not olanzapine. Thus, for these patients with schizophrenia who prospectively failed to improve with an atypical antipsychotic, clozapine was more effective than switching to another atypical antipsychotic. These advantages for clozapine were strong enough to achieve statistical significance despite the small sample sizes (McEvoy et al., 2006) and to underscore the superior therapeutic effect of clozapine in treatment-resistant populations.

In the other arm of Phase 2 (Stroup et al., 2006), subjects ($N = 444$) who had discontinued the first atypical antipsychotic due to either inadequate therapeutic effect or tolerability issues in Phase 1 of the CATIE investigation were randomly reassigned to double-blind treatment with a different atypical antipsychotic (olanzapine, 7.5 to 30 mg/day [$n = 66$]; quetiapine, 200 to 800 mg/day [$n = 63$]; risperidone, 1.5 to 6.0 mg/day [$n = 69$]; or ziprasidone, 40 to 160 mg/day [$n = 135$]). The time to treatment discontinuation was longer for patients treated with risperidone (median, 7.0 months) and olanzapine (6.3 months) than with quetiapine (4.0 months) and ziprasidone (2.8 months). There were no differences in the incidence of EPS among the drugs as reflected by rating scale measures of severity or reasons for discontinuing treatment. Patients receiving olanzapine gained more weight than did patients receiving any of the other drugs, with a mean of 1.3 pounds per month. Patients receiving ziprasidone had a mean loss of 1.7 pounds per month. Those receiving risperidone and quetiapine had negligible mean changes in weight over the course of Phase 2. Olanzapine was associated with substantial increases in total cholesterol and triglycerides, whereas risperidone and ziprasidone were associated with decreases in these parameters, even after adjusting for drug exposure. Patients receiving risperidone experienced substantial increase in prolactin levels and higher rates of adverse effects involving sexual functioning (29%) relative to the other groups (11% to 17%). Risperidone was also associated with higher rates of gynecomastia or galactorrhea (5%) relative to the other groups (less than 1%). More patients receiving quetiapine experienced orthostatic faintness (13%) relative to the other groups (4% to 7%). In summary, both risperidone and olanzapine were superior to quetiapine and ziprasidone on the primary outcome measure in this group of patients with chronic schizophrenia who had discontinued previous therapy with a different atypical antipsychotic.

Summary of Safety and Tolerability of Second-Generation Antipsychotics

The biggest advance in the side-effect profile of SGAs is the lower risk of acute EPS. Among the types of EPS, acute dystonia is very rare, whereas akathisia still occurs, albeit to a lesser degree, with perhaps lurasidone and asenapine being the most likely to cause akathisia. Within the group, clozapine and quetiapine have the lowest (almost absent) risk of parkinsonism, whereas risperidone, paliperidone, iloperidone, and, to a lesser extent, olanzapine, lurasidone, and asenapine are associated with dose-related parkinsonism. Ziprasidone and aripiprazole can also occasionally induce EPS, although it is not clear whether there is a dose relationship with these drugs. Lower rates of tardive dyskinesia have also been reported with risperidone compared with haloperidol (0.6% vs. 4.1%, respectively) in a 1-year double-blind study (Csernansky et al., 2002), and for olanzapine (Beasley et al., 1999) compared with haloperidol (0.5% vs. 7.4%, respectively). A review of eleven long-term studies of SGAs by Correll, Leucht, and Kane (2004) supported a lower risk of tardive dyskinesia for SGAs as a group compared with FGAs.

Weight gain has emerged as a major problem with some of the SGAs (Newcomer, 2005). Olanzapine and clozapine are most notorious in this respect, and in some patients rapid and massive weight gain can occur. Quetiapine, risperidone, paliperidone, and iloperidone are intermediate in weight gain liability, and

ziprasidone, aripiprazole, lurasidone, and asenapine rarely cause significant weight gain (Newcomer, 2005). Weight gain in patients with schizophrenia is especially problematic because these patients are usually overweight at baseline, have high rates of smoking, and are usually physically inactive. This combination of risk factors along with an increased risk of glucose dysregulation and hyperlipidemia reported to varying degrees with these agents (Newcomer, 2005) can create a potentially fatal constellation of risk factors for cardiovascular disease and stroke. These adverse effects, in their entirety, may well be worse than tardive dyskinesia, which was the primary concern for the older antipsychotics (Casey et al., 2004). The diabetes risk appears to be greatest for clozapine and olanzapine, less for risperidone and quetiapine, and lowest for ziprasidone and aripiprazole (Newcomer, 2005). Risperidone causes sustained prolactin elevation, and therefore patients who previously developed prolactin-induced side effects (galactorrhea, gynecomastia, menstrual irregularities, and sexual dysfunction) on older agents should probably be tried first on one of the other atypical antipsychotics. Ziprasidone is associated with QT prolongation, although the significance of this is not clear because related adverse events have not materialized after 5 years of clinical use. Iloperidone is associated with similar levels of QT prolongation to ziprasidone. Clozapine, in addition to agranulocytosis risk, is associated with significant orthostasis, tachycardia, seizures (dose-related), myocarditis, constipation (at times severe), and various other side effects, making it a challenging drug to use in clinical practice.

OTHER PHARMACOLOGICAL TREATMENTS

Because of the limited efficacy of antipsychotic medication in resolving the full range of schizophrenic psychopathology, and the frequently occurring comorbid symptoms that occur over the course of the illness (e.g., anxiety, depression, mood lability, and motor unrest), adjunctive treatments are often used to reduce morbidity. In the next section we review controlled trials of pharmacological agents other than antipsychotic medications that have been used to treat patients with schizophrenia. We report on the efficacy of these drugs when used either in combination with an antipsychotic drug or as a lone treatment, to treat both schizophrenic psychopathology and comorbid conditions. The classes of medication described are antianxiety/hypnotics, antidepressants, mood stabilizers, dopamine agonists, and glutamatergic agents. In addition, we briefly review the efficacy of electroconvulsive therapy as a treatment for schizophrenic psychopathology. The use of adjunctive pharmacological treatments in schizophrenia patients has been the subject of numerous reviews (Christison, Kirch, & Wyatt, 1991; Donaldson, Gelenberg, & Baldessarini, 1983; Johns & Thompson, 1995; Lindenmayer, 1995; Meltzer, 1992; Meltzer, Sdommers, & Luchins, 1986; Rifkin, 1993; Siris, 1993; Wolkowitz, 1993). Given our space limitations, and the large number of studies involved, where applicable, recent review articles are summarized and updated with reports of subsequently published methodologically rigorous studies.

Benzodiazepines

Benzodiazepines have been used to treat patients with schizophrenia since the early 1960s. Wolkowitz and Pickar (1991) reported that 9 of 14 studies using benzodiazepines alone to treat schizophrenic psychopathology showed significant improvement, whereas 11 of 16 studies using antipsychotic and adjunctive benzodiazepine showed utility of the adjunctive treatment. Benzodiazepines have also been compared with antipsychotics and a combination of both classes of drugs in the management of acute agitation and psychosis in acutely relapsed patients over the first few hours or days, and there is evidence from RCTs that benzodiazepines both alone and in combination with antipsychotics reduce aggression, agitation, and assaultive behavior (Barbee, Mancuso, Freed, & Todorov, 1992; Salzman et al. 1991), and benzodiazepine augmentation may be useful in limiting the quantity of antipsychotics used for the acute treatment of schizophrenia (Bodkin, 1990). Battaglia and colleagues (1997) conducted a prospective, randomized, double-blind, multicenter trial of 98 psychotic, agitated, and aggressive patients comparing lorazepam treatment, haloperidol treatment, and combination treatment. All three treatments were effective in achieving significant reductions in scores on the Agitated Behavior Scale after 1 hour and in a modified Brief Psychiatric Rating Scale after 2 and 3 hours, with combination treatment of lorazepam and haloperidol superior to either alone.

Another RCT with 53 patients with schizophrenia provided some evidence that diazepam, when given for indications of disturbed sleep, increased anxiety or other dysphoric affect, agitation and irritability, increased suspiciousness, and peculiar perceptual experiences thought to be prodromal of an impending psychotic exacerbation, was superior to placebo and comparable to fluphenazine in preventing a psychotic relapse (Carpenter, Buchanan, Kirkpatrick, & Breier, 1999). Indeed, there is some evidence to suggest that schizophrenia patients with anxiety, depression, hostility, irritability, and motor unrest may benefit from benzodiazepines (Kellner, Wilson, Muldawer, & Pathak, 1975; Wolkowitz & Pickar, 1991). Despite the evidence of benefits in some patients, there are reports that benzodiazepines may result in a "disinhibiting" effect (Karson, Weinberger, Bigelow, & Wyatt, 1982) or worsening of psychopathology in some patients (Wolkowitz & Pickar, 1991). Nevertheless, benzodiazepines appear to be useful adjuncts to antipsychotics in the treatment of agitation or anxiety, especially during acute psychotic relapse, as well as in managing the prodromal symptoms of an impending psychotic exacerbation.

Antidepressants

The efficacy of antidepressant medication for the treatment of schizophrenic psychopathology, used either alone or as adjuncts to antipsychotics, was first comprehensively reviewed by Siris, Van Kammen, and Docherty (1978) in an analysis of the results of double-blind, controlled studies. Their review suggested little utility in the use of antidepressants to treat schizophrenic psychopathology, although they cautioned that the overwhelming preponderance of negative findings might have resulted from weaknesses in study design, in particular inadequate antidepressant dosages. There is some evidence from RCTs that antidepressants (tricyclics were used in most but not all of the studies) are effective in relieving depressive symptoms (Hogarty et al., 1995; Plasky, 1991; Siris, 1991) and negative symptoms (Silver, Barash, Aharon, Kaplan, & Poyurovsky, 2000; Silver & Nassar, 1992; Siris, Pollack, Bermanzohn, & Stronger, 2000) outside of acute exacerbations, with some evidence that antidepressants may worsen psychosis during acute exacerbations (Plasky, 1991). Berk, Ichim, and Brook (2001) conducted a 6-week randomized, placebo-controlled trial of mirtazapine and haloperidol versus placebo and haloperidol in 30 patients with schizophrenia and found clinical improvement in negative symptoms but not depressive symptoms. In a meta-analysis of seven randomized controlled trials ($N = 202$), the combination of antidepressants and antipsychotics was suggested to be superior to antipsychotics alone in the treatment of negative symptoms (Rummel, Kissling, & Leucht, 2005). One long-term RCT suggested the utility of antidepressant treatment in preventing relapse of patients with schizophrenia or schizoaffective disorder into either depression or psychosis (Siris, Bermanzohn, Mason, & Shuwall, 1994). Overall, the available data suggest that adjunctive antidepressant treatment is warranted when a patient reports persistent symptoms of depression when not in an acute episode of his or her illness, and for those with prominent negative symptoms.

Mood Stabilizers

Lithium

Lithium salts have been used both alone and as an adjunct to antipsychotics in the treatment of schizophrenia patients (Atre-Vaidya & Taylor, 1989; Christison et al., 1991). Atre-Vaidya and Taylor (1989) reported on three small studies (Carman, Bigelow, & Wyatt, 1981; Growe, Crayton, Klass, Evans, & Strizich, 1979; Small, Kellams, Milstein, & Moore, 1975) that examined lithium as an adjunct to antipsychotics for treatment-refractory patients and found greater improvement with adjunctive lithium compared with antipsychotics alone. Most later studies, however, find no utility of adjunctive lithium in treating psychotic symptoms in patients with schizophrenia (Hogarty et al., 1995; Schulz et al., 1999; Small, Klapper, Malloy, & Steadman, 2003; Terao et al., 1995; Wilson, 1993), although there is some evidence that some patients with schizoaffective disorder with inadequate response to antipsychotic medication alone may achieve greater symptom reduction with adjunctive lithium (Schulz et al., 1999; Small et al., 2003). Not surprisingly, in a more recent meta-analysis (Leucht, Kissling, & McGrath, 2004) that included 20 controlled studies of lithium alone or as an augmentation agent in treatment of schizophrenia/schizoaffective disorder, it was found that lithium as a sole agent was ineffective, and as an

augmentation strategy it was effective only in patients with prominent affective symptoms.

In summary, most of the available literature suggests that in the absence of affective symptoms, augmentation of antipsychotics with lithium is not effective in the treatment of schizophrenia. However, because there have been reports of a benefit in some treatment-refractory patients, a trial of lithium should be considered if the patient has not adequately responded or was unable to tolerate clozapine. Earlier concern about potentially toxic interactions between an antipsychotic and lithium (Cohen & Cohen, 1974) appears not to be supported by the vast majority of the published literature (Rifkin, 1993). However, patients co-administered lithium and clozapine may be at higher risk of neurotoxicity.

Carbamazepine

Christison and colleagues (1991) reviewed five double-blind studies published through 1989 in which either carbamazepine or placebo was added to a stable antipsychotic regimen and found modest positive results in three. Leucht, Wahlbeck, Hamann, and Kissling (2003) reviewed 10 RCTs (N = 283) comparing carbamazepine (as a sole or an adjunctive compound) and found no benefit from monotherapy or adjunctive treatment with carbamazepine. Overall, there is some evidence to support carbamazepine as an adjunctive agent to antipsychotics in the treatment of schizophrenia, particularly in a subpopulation of aggressive, agitated patients. Due to carbamazepine's ability to upregulate hepatic enzymes, plasma antipsychotic levels may drop with concomitant carbamazepine use, requiring antipsychotic dose adjustment.

Valproic Acid

Valproic acid as an adjunct to antipsychotics has been the focus of a few controlled studies. While two small RCTs have shown benefit in terms of psychopathology with adjunctive valproic acid (Linnoila, Viukari, & Kietala, 1976; Wassef et al., 2000), other RCTs, including a large RCT with 249 patients with schizophrenia, have shown no benefit at study endpoint (Casey et al., 2003; Ko, Korpi, Freed, Zalcman, & Bigelow, 1985), although there may be some early benefit in terms of reducing hostility. Basan, Kissling, and Leucht (2004) conducted a meta-analysis of five (N = 379) RCTs comparing valproate as an adjunctive compound for patients with schizophrenia or schizophrenia-like disorders and found no overall superiority of valproate augmentation at study endpoints. Overall, the preponderance of the evidence suggests that valproic acid is not useful in the treatment of schizophrenia.

Dopamine Agonists

Dopamine agonists have been associated with an exacerbation of psychotic symptoms in 40% to 60% of schizophrenia patients; however, these agents have also been used as a treatment for patients with prominent negative symptoms. This strategy is consistent with the hypothesis that a hypodopaminergic state is responsible for the negative symptoms of the illness (Davidson et al., 1991). The efficacy of L-dopa has been assessed in three small, low quality, double-blind treatment studies (Christison et al., 1991; Brambilla et al., 1979), two of which used it as an adjunct to antipsychotics (Gerlach & Luhdorf, 1975; Inanaga et al., 1975). These studies suggested possible utility of L-dopa in treating negative symptoms in particular.

Other dopamine agonists have been studied with inconsistent results in RCTs suggesting no utility of adjunctive bromocriptine (Gattaz, Rost, Hubner, & Bauer, 1989) or mazindol, a dopamine reuptake inhibitor (Carpenter et al., 2000), some affective and cognitive benefit of a single dose of dextroamphetamine (Barch & Carter, 2005; Goldberg, Bigelow, Weinberger, Daniel, & Kleinman, 1991), and minimal to moderate improvement on negative and other symptoms with adjunctive selegiline (Jungerman, Rabinowitz, & Klein, 1999). Dopamine agonists have been the subject of too few controlled studies to allow us to draw definitive conclusions, and the above studies do not suggest clear utility of these medications, although clinicians' hesitancy to use these agents due to concern about exacerbating psychotic symptoms may not be warranted if patients are maintained on antipsychotics (Perovich, Lieberman, Fleischhacker, & Alvir, 1989).

Glutamate Agonists

Phencyclidine was first observed by Luby, Cohen, Rosenbaum, Gottlieb, and Kelly (1959) to produce a syndrome similar to schizophrenic psychosis with its

associated emotional withdrawal, apathy, and cognitive impairment. A later study by Anis and colleagues (1983) demonstrating that phencyclidine blocks the N-methyl-D-aspartic acid (NMDA) subtype of the glutamate receptors in a noncompetitive manner led to an intensified effort to understand the role of glutamate receptors in schizophrenia. Because phencyclidine inhibits the neurotransmission of glutamate through NMDA receptors (i.e., is an NMDA antagonist), it was hypothesized that reduced glutamate activity (possibly through NMDA receptor hypofunction) caused the symptoms of schizophrenia (Javitt & Zukin, 1991), and from this hypothesis it was inferred that agents that facilitate the stimulation of NMDA receptors would be therapeutic in schizophrenia. In this context, four glutamate agonists have been studied to date: glycine, D-cycloserine, D-serine, and sarcosine (Table 6.3).

Seven double-blind studies have evaluated the use of glycine as an adjunctive treatment to antipsychotic medications, with some studies suggesting benefit of adjunctive low-dose glycine (15 g/day) with respect to psychiatric symptoms (Potkin et al., 1992); others suggesting improvement in negative symptoms at 30 g/day of adjunctive glycine (Javitt, Zylberman, Zukin, Heresco-Levy, & Lindenmayer, 1994) or improvement in negative, depressive, or cognitive symptoms at up to 60 g/day of adjunctive glycine (Heresco-Levy et al., 1996, 1999; Heresco-Levy, Ermilov, Lichtenberg, Bar, & Javitt, 2004); and still others failing to show any benefit (Evins, Fitzgerald, Wine, Rosselli, & Goff, 2000; Potkin, Jin, Bunney, Costa, & Gulasekaram, 1999). Despite some encouraging results, glycine is known to have poor central nervous system bioavailability, and the doses needed to effect clinical benefit (30 to 60 g/day) are very difficult to administer.

D-cycloserine (DCS) freely crosses the blood–brain barrier and acts as a partial agonist at the glycine regulatory site on the NMDA receptor. Because of this latter feature, DCS stimulates NMDA receptor function at low doses but inhibits endogenous glycine activity

TABLE 6.3 Glutamate Agonists

Drug	*Positive vs. Negative Results*	*Author*	*Comments*
Glycine	Positive	Potkin et al. (1992) Javitt et al. (1994) Heresco-Levy et al. (1996) Heresco-Levy et al. (1999) Heresco-Levy et al. (2004)	Poor central nervous system bioavailability; doses needed to for clinical benefit (30–60 g/day) difficult to administer
	Negative	Potkin et al. (1999) Evins et al. (2000)	
D-cycloserine	Positive	Goff et al. (1999) Evins et al. (2002) Gottlieb et al. (2011)	Narrow therapeutic range; outside of this range, D-cycloserine is at best not effective, at worst may worsen psychosis
	Negative	Goff et al (1995) Rosse et al. (1996) Evins et al. (2002) Buchanan et al. (2007) Goff et al. (1999)	
D-serine	Positive	Tsai et al. (1998) Heresco-Levy et al. (2005) Lane et al. (2010)	Full NMDA agonist with greater central nervous system bioavailability than glycine
	Negative	Tsai et al. (1999) Gottlieb et al. (2011)	
Sarcosine (N-methylglycine)	Positive	Tsai et al. (2004) Lane et al. (2005)	Endogenous antagonist of glycine transporter-1, which potentiates glycine's action
	Negative	N/A	

at higher doses, thus lowering NMDA receptor function. There is some evidence from RCTs that the drug is effective in treating negative symptoms in a narrow therapeutic range when added to FGA regimens (Evins, Amico, Posever, Toker, & Goff, 2002; Goff et al., 1999b), but other RCTs have established that very low or high doses are either not effective or may worsen psychosis (Evins et al., 2002; Goff et al., 1995; Rosse, Fay-McCarthy, Kendrick, Davis, & Deutsch, 1996). Notably, however, a more recent study has suggested that DCS can help facilitate cognitive-behavioral therapy for delusions in schizophrenic patients by reducing delusional distress and severity if given before starting cognitive-behavioral therapy (but not halfway through) (Gottlieb et al., 2011). Despite early evidence that adjunctive DCS was effective in treating negative symptoms within a narrow therapeutic range, some large, high-quality RCTs have had negative results (Buchanan et al., 2007), and adjunctive DCS did not improve symptoms when added to clozapine treatment (Goff, Henderson, Evins, & Amico, 1999a).

Another glutamate agonist candidate for the treatment of schizophrenia is D-serine (DS), which is a full NMDA agonist with greater central nervous system bioavailability than glycine. A study by Tsai, Yang, Chung, Lange, and Coyle (1998) evaluated the use of DS in 29 patients (25 treated with FGAs and 4 treated with risperidone) with deficit syndrome schizophrenia and found improvements in positive, negative, and cognitive symptoms. In a later add-on study of clozapine, Tsai and colleagues (1999) found that symptoms did not improve with adjunctive DS. In a double-blind, placebo-controlled, 6-week crossover trial with DS 30 mg/kg per day added to the antipsychotic medication of 39 patients with schizophrenia (21 on risperidone and 18 on olanzapine), DS administration resulted in significant improvements in negative, positive, cognitive, and depression symptoms (Heresco-Levy et al., 2005). The results for more recent studies have been conflicting, with one RCT showing add-on of DS (30, 60, and 120 mg/kg) leading to significant improvement in PANSS positive, negative, total, and general symptoms, and on the MATRICS composite score at higher doses (60 mg/kg or more) (Lane et al., 2010), whereas another RCT with 195 patients found no effect of 2 g/day DS as adjunctive therapy to antipsychotics (Gottlieb et al., 2011), possibly limited by low dosing.

The glycine transporter-1 is a novel target for the pharmacotherapy to enhance NMDA function. Inhibition of the glycine transporter-1 would be expected to increase synaptic glycine levels and augment NMDA receptor function. N-methylglycine (sarcosine) is an endogenous antagonist of glycine transporter-1, which potentiates glycine's action on the NMDA glycine site, and in one 6-week RCT with 38 patients, sarcosine as an add-on to antipsychotics (mostly risperidone) led to significant improvement in positive, negative, cognitive, and general psychiatric symptoms and was well tolerated (Tsai, Lane, Yang, Chong, & Lange, 2004). Lane, Chang, Liu, Chiu, and Tsa (2005) conducted a 6-week randomized, double-blind, placebo-controlled trial to determine whether DS (2 g/day) or sarcosine (2 g/day) had better efficacy when added to risperidone treatment in 65 patients with acute exacerbation of schizophrenia. The sarcosine group was superior to both the placebo and DS groups in improvement in PANSS total scores, Scale for the Assessment of Negative Symptoms (SANS) scores, PANSS depressive, and PANSS general subscales. Unlike other studies that have found a benefit for DS, in this study adjunctive DS with risperidone did not differ significantly from risperidone monotherapy in all efficacy domains.

Glycine, DCS, DS, and sarcosine all show some benefit for the treatment of negative, cognitive, and psychotic symptoms when dosed appropriately. Although dosing challenges with glycine and DCS may make them impractical for clinical use, studies with these compounds provide strong support for the role of glutamate in the pathophysiology of schizophrenia, as well as furthering the understanding of the unique pharmacological mechanism of clozapine. DS is the most promising agent in this group based on the current findings. This line of research will, we hope, lead to improved symptom reduction for patients with schizophrenia and clues leading to the development of other novel therapeutic agents.

Electroconvulsive Therapy

Electroconvulsive therapy (ECT), which was an acceptable treatment option for schizophrenia before the introduction of antipsychotic medication, has been the subject of few controlled studies. Information gathered from open trials suggests that ECT works best in schizophrenia patients in the early stages of their illness, in those with catatonic or affective symptoms, and in conjunction with an antipsychotic (Salzman, 1980). ECT is rarely used in the

treatment of schizophrenia patients today except in the most refractory cases.

Three double-blind, controlled studies of schizophrenia patients maintained on antipsychotics who received either ECT or sham ECT have produced consistent results. These studies, each with approximately 20 patients treated with antipsychotics augmented by ECT or sham treatment, found evidence of more rapid early improvement that disappeared at later time points (Abraham & Kulhara, 1987; Brandon et al., 1985; Taylor & Fleminger, 1980). Interestingly, May and colleagues (1981), in a 5-year prospective study of 228 first-episode schizophrenia patients who received one of five treatments by random assignment (antipsychotics, ECT, psychotherapy, psychotherapy plus antipsychotic, or milieu), found that the outcomes in all groups were poor, but that the ECT-treated group fared best.

Chanpattana, Chakrabhand, Buppanharun, and Sackeim (2000) conducted a double-blind comparison of three different stimulus intensities (seizure threshold, two times seizure threshold, and four times seizure threshold) of bilateral ECT plus flupenthixol in the treatment of 62 patients with schizophrenia. They concluded that treatment with high-dosage bilateral ECT speeds clinical response in patients with schizophrenia. Chanpattana and colleagues (1999) compared flupenthixol alone, continuation ECT alone, and combined continuation ECT and flupenthixol in a 6-month single-blind study of 58 patients with treatment-resistant schizophrenia who had met response criteria after an acute phase of treatment with bilateral ECT and flupenthixol (12 to 24 mg/day). Patients treated with the combination of bilateral ECT and flupenthixol relapsed at a rate of 40% (6/15), whereas patients in the bilateral ECT-alone and flupenthixol-alone groups relapsed at a rate of 93% (14/15). All 8 of the patients treated with the combination of the two treatments maintained therapeutic benefits at follow-up of 3 to 17 months.

Tharyan and Adams (2005) reviewed 26 RCTs that compared ECT with placebo (sham ECT), nonpharmacological interventions, and antipsychotics for people with schizophrenia, schizoaffective disorder, or another chronic mental disorder. When ECT was compared with sham ECT, more people improved in the real ECT group ($N = 392$, 10 RCTs). There was no evidence that this early advantage for ECT was maintained over the medium to long term, however. When ECT was compared with antipsychotic drug treatments (total $N = 443$, 10 RCTs), results favored the medication group. Limited evidence suggested that ECT combined with antipsychotic drugs results in greater improvement in mental state ($N = 40$, one RCT) than with antipsychotic drugs alone. When continuation ECT was added to antipsychotic drugs, the combination was superior to the use of antipsychotics alone ($n = 30$) or continuation ECT alone ($n = 30$). Unilateral and bilateral ECT were equally effective in terms of global improvement ($N = 78$, two RCTs). One trial showed a significant advantage for 20 treatments over 12 treatments in terms of the number of patients manifesting global improvement at the end of the ECT course ($N = 43$). The authors concluded that the evidence suggested that ECT, combined with treatment with antipsychotic drugs, may be considered an option for people with schizophrenia, particularly when rapid global improvement and reduction of symptoms are desired, as well as for those with schizophrenia who show limited response to medication alone.

CONCLUSIONS

Pharmacological treatment has had a profoundly positive impact on the course of schizophrenia, with the vast majority of patients now no longer requiring chronic institutionalization. Nevertheless, schizophrenia remains a major public health concern, with patients over the course of their illness displaying varying degrees of social and vocational disability and remaining susceptible to psychotic exacerbations even when compliant with medication. A large number of high-quality studies in recent years have established that the clearest differentiation between FGAs and SGAs is with respect to tolerability rather than efficacy, although there are unequivocal data to suggest that clozapine is superior to other antipsychotics, particularly in treatment-resistant patients, and some evidence for an efficacy advantage of olanzapine as well. However, metabolic side effects have proven to be serious side effects of a number of the newer agents. It should also be noted that the importance of continuing long-term antipsychotics at doses that are efficacious during acute exacerbations during the relapse prevention phase has been established. Furthermore, although switching agents has been shown to be relatively safe, it has been associated with an increased risk of relapse, so the risks and

benefits should be weighed carefully when considering switching. There is some evidence for the use of adjunctive medications to treat other psychiatric symptoms in patients with schizophrenia. Although antipsychotics have been very effective in treating positive symptoms in many patients, they have been shown to be considerably less effective with respect to the treatment of cognitive and negative symptoms, and patients have thus remained relatively disabled in their everyday lives.

Accumulating evidence indicating the value of treating patients with schizophrenia as early in the course of the illness as possible, and reducing the duration of untreated psychosis has led to early detection and intervention strategies to optimally treat patients in their first acute episode of illness and potentially while in the prodromal phases. This strategy offers great hope for limiting the cumulative morbidity and disability of schizophrenia for future generations of patients. At the same time, continued efforts are being made to develop new treatments acting at novel targets that may have either superior antipsychotic efficacy or efficacy in treating cognitive and negative symptoms as well.

Cognitive and Social Cognitive Interventions for Schizophrenia

Matthew M. Kurtz

Cognitive remediation (CR) and social cognitive training (SCT) are increasingly studied behavioral interventions for improving disorder-linked cognitive and social cognitive deficits in schizophrenia. They appear to hold considerable promise for improving disorder outcome. A synthetic, critical review of the extant literature on these treatments for schizophrenia revealed over 80 controlled studies on CR and 20 controlled studies on SCT. Results for both classes of interventions have been largely positive. Seven meta-analyses of CR and one meta-analysis of SCT have been conducted to date. Conclusions from the most recent meta-analysis of CR included 40 studies, the majority of which were type 1; the meta-analysis revealed moderate-sized effects on cognitive outcomes (d = .45) and measures of functioning (d = .42). Strongest effects of CR on functioning were evident when the intervention was paired with other psychosocial treatments. A meta-analysis consisting of 19 studies of SCT revealed moderate treatment effects on specific outcomes targeted by the interventions, including facial affect recognition (d = .71) and Theory-of-Mind (d = .46), as well as evidence of the extension of treatment effects to functioning (d = .78). While SCT has been one key element of effective, integrated programs of psychosocial intervention, only four type 1 studies using broad-based, sustained, standalone programs of SCT have been completed to date. Preliminary results are promising.

INTRODUCTION

As opposed to many of the treatment modalities discussed in this book, cognitive and social cognitive interventions for people with schizophrenia are (1) novel, emerging in a systematic manner only over the past 10 to 15 years, and (2) largely understudied to date. Thus, research on central questions regarding mechanisms of treatment action, whether treatment should be focused on compensatory training to create "workarounds" for existing deficits or employ strategies for improving deficits directly, and the science of who responds to these interventions and who doesn't is still in an inchoate state. Additional, important questions regarding how these interventions can be integrated most effectively with extant, evidence-based psychosocial and pharmacological practices in schizophrenia have been studied more, but the total number of studies still remains very small. Results of controlled and frequently randomized and blinded trials of cognitive remediation have been both impressive in individual studies and remarkably robust in their effects across studies, despite widely varying strategic treatment approaches, control conditions, duration of interventions, selection of outcome measures, sample characteristics, and adjunctive treatments, (e.g., McGurk, Twamley, Sitzer, McHugo, & Mueser, 2007; Wykes, Huddy, Cellard, McGurk, & Czobor, 2011). Nonetheless, motivational deficits remain a key feature of the disorder and impede the ability of all people with the diagnosis to benefit equally from these treatments (Medalia & Richardson, 2005; Medalia & Saperstein, 2011). Controlled trials of social cognitive therapies,

while smaller in number, have shown considerable promise as well (e.g., Kurtz & Richardson, 2012). Cognitive and social cognitive therapies thus represent an exciting new frontier in the study of psychosocial treatment for schizophrenia. Their promise suggests a high probability of inclusion in the armamentarium of the next generation of interventions for the promotion of optimal recovery in schizophrenia.

COGNITIVE REMEDIATION

Cognitive remediation (CR) for schizophrenia was well defined at a meeting of the Cognitive Remediation Experts Workshop (Florence, Italy, April 2010) as "a behavioral training based intervention that aims to improve cognitive processes (attention, memory, executive function, social cognition or meta-cognition) with the goal of durability and generalization." CR for schizophrenia has seen a remarkable growth in research interest over the past 20 years. This growth can be seen in the rapidly accelerating cumulative number of controlled trials in the field and a 100% increase in the number of randomized trials over the past four years alone (Fig. 7.1).

Historical Antecedents

Cognitive Impairment in Schizophrenia

Emil Kraepelin and Eugen Bleuler, both widely considered to have formulated the first modern diagnostic conceptions of schizophrenia at the end of the 19th and beginning of the 20th centuries, described deficits in attention, memory, and other cognitive functions as a key feature of their newly defined disorder. Indeed, Kraepelin's first term for schizophrenia, described in the fifth edition of his clinical textbook *Psychiatry* in 1896, was *dementia praecox*, meaning literally a dementia with early onset (Kraepelin, 1920; Shorter, 1997). Similarly, Bleuler, who coined the term *schizophrenia*, thought that all manifestations of the disorder were secondary to four fundamental symptoms (the four As) of which one was *association*, or the appropriate linking of ideas. As Bleuler states:

> The schizophrenic is not generally demented but he is demented with regard to certain periods, to certain constellations, and to certain complexes. In mild cases, the defective functions are the exception. In most severe cases, those who sit around in our mental institutions taking no part in anything, the defective functions are the rule…The mildest case can commit as great a piece of folly as the most severe, but he commits it far more rarely. (pp. 73–74, E. Bleuler, 1950, *Dementia Praecox*)

Bleuler's ideas were particularly prescient in that they anticipated three key facts about cognitive deficits in schizophrenia: (1) they are a core feature of the disorder, (2) there is a great deal of heterogeneity in these deficits from person to person with the diagnosis, and (3) they are closely linked to functional outcome.

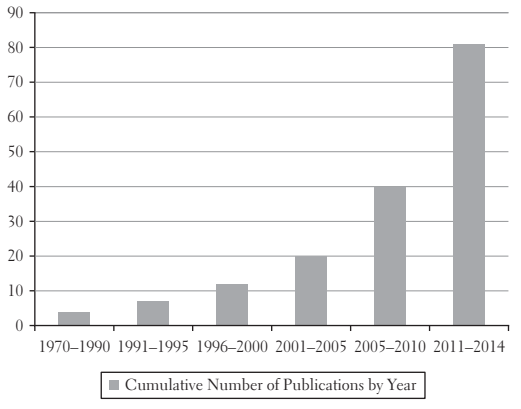

FIGURE 7.1 Cumulative number of controlled studies on cognitive remediation interventions in schizophrenia.

Cognitive Remediation in Schizophrenia

The two foundational studies in the study of CR in schizophrenia were motivated by theories regarding the role of behavioral reinforcement and cognition in the control of overt behavior in healthy populations. They presaged the importance of these factors in contemporary research for promoting strong outcomes in CR studies in schizophrenia. Wagner (1968) investigated the role of contingent reinforcement and task practice on several neurocognitive outcome measures, including measures of abstraction, vocabulary, and nonverbal memory, in eight individuals with schizophrenia. In a counterbalanced, within-subject design, results revealed that contingent reinforcement produced improvement in four of the five neurocognitive measures; these findings could not be accounted

for by simple task practice alone. Using a very different approach, Meichenbaum and Cameron (1973) evaluated the role of self-instructional training procedures, which consisted of verbalizing the nature and demands of a task, mentally rehearsing these demands to maintain task focus, and giving self-instruction and self-reinforcement to enhance both concentration and motivation for task performance, in a sample of hospitalized individuals with schizophrenia. Results revealed improvements in working memory, sustained attention, and processing speed greater in magnitude than repeated exposure to and practice with the cognitive outcome measures. Thus, both of these studies provided early evidence that a variety of cognitive deficits in people with schizophrenia were modifiable with appropriate training.

Neurocognition in Schizophrenia

Anecdotes describing superior intellectual function and singular creative accomplishment in people with schizophrenia abound and support the popular, socially constructed myth of the "mad genius." Probably the best example of this concept is expressed in the life of John Nash, the renowned Princeton mathematician, Nobel Prize winner, and focus of both a major biography and biographical film, *A Beautiful Mind*. Nash was diagnosed with schizophrenia in his 30s and likely developed major symptoms of the disorder, such as auditory hallucinations and crystallized delusions (which included beliefs that he was receiving coded messages from extraterrestrials through *The New York Times*), well before this time (Green, 2003). Despite such powerful case studies, a wealth of evidence conducted over the past 25 years has starkly contradicted these commonly held views about schizophrenia and revealed a broad range of substantial and persistent deficits in neurocognition.

It has been known for some time that IQ measures are, on average, lower in people with a diagnosis of schizophrenia than the general population (e.g., Aylward, Walker, & Bettes, 1984). Furthermore, deficits of a magnitude of one to two standard deviations relative to healthy controls are evident on both standardized clinical neuropsychological assessment tools and experimental psychopathological measures in the domains of attention, verbal and nonverbal memory, working memory, language, problem solving and inhibition, and sensory and motor skills, among others (e.g., Goldberg, David, & Gold, 2011; Heinrichs & Zakzanis, 1998). These deficits are evident in clinical high-risk states and thus presage the disorder. They are also seen in an attenuated form in first-degree relatives without the illness and without exposure to psychotropic medications (e.g., Cannon, Bearden, Hollister, Rosso, Sanchez, & Hadley, 2000), are evident at illness onset (Mesholam-Gately, Giuliano, Goff, Faraone, & Seidman, 2009), and persist through middle age and into senescence (Irani, Kalkstein, Moberg, & Moberg, 2011). Indeed, several recent studies suggest that virtually all people with schizophrenia have some level of cognitive impairment if levels of premorbid intellectual functioning are accounted for (Kurtz, Donato, & Rose, 2011) and the presence of cognitive impairment is more common than estimates of the presence of delusions that are frequently used to diagnose the disorder (Harrow & Jobe, 2010). These deficits persist in the face of optimal pharmacotherapy for positive symptoms, emphasizing the need for novel, adjunctive treatments (Green, Kern, Braff, & Mintz, 2000). For all of these reasons, neurocognitive deficits are viewed as a core feature of the disorder.

Neurocognition and Functional Status in Schizophrenia

A key rationale for the development and assessment of novel CR interventions in schizophrenia has been derived from research showing a substantial and well-replicated link between measures of neurocognitive skills and functional status in schizophrenia. These links became a fundamental concept in the field of schizophrenia research through a series of highly cited critical, integrative review papers by Michael Green and his colleagues at UCLA (Green, 1996; Green et al., 2000, Green, Kern, & Heaton, 2004). While these relationships had been noted in previous work (e.g., Heaton & Pendleton, 1981), the powerful influence of Green's reviews lay in the careful documentation of relationships among a wide range of indices of neurocognitive function. Those indices included sustained vigilance, verbal learning and memory, verbal fluency, concept formation and conceptual flexibility, psychomotor speed and elementary sensory processing, and a variety of domains of functional status in schizophrenia, including ratings from patient- and informant-reported

community function scales, laboratory-administered and performance-based measures of social and everyday adaptive life skills, and the measurement of progress in psychosocial rehabilitation programs. Indeed, across studies, cognition accounted for anywhere from 20% to 60% of the variance in these different indices of functional status, suggesting substantial overlap between these key disorder domains. These findings have been buttressed by (1) a growing body of longitudinal data that has linked cognitive skills in people with schizophrenia in similar stages of illness as predictors of functional status measured as long as a decade later (e.g., Stirling et al., 2003) and (2) increasing data suggesting that neurocognitive skills play an important, rate-limiting step in the acquisition of elementary social skills and work-related skills in work therapy and supported employment programs and in comprehensive outpatient therapy programs (Kurtz, 2011). These links provide support for the possibility that improving cognitive skills may improve outcome in the disorder. An important limitation of this rationale is that these relationships are correlative and additional variables could be playing important causative roles in these associations.

Methods of Cognitive Remediation

For the purposes of this chapter we divide CR approaches into four major intervention categories.

Strategy-based approaches focus on the acquisition of skills for circumventing cognitive difficulties. In most cases, in an approach that has been labeled *scaffolding*, the therapist will provide cognitive supports for a task at first. These supports are reviewed with the client, and then the client is allowed to practice cognitive strategies as the therapist gradually removes these supports. These approaches place considerable emphasis on verbally mediated coaching and extensive client–therapist interaction. A key value of this approach is that the skills taught are generalizable. Thus, training is tailored directly to cognitive skills used in everyday life tasks and often specific sessions will be devoted to applying skills. The best-studied version of this approach in the research literature is Cognitive Remediation Therapy (CRT; e.g., Wykes et al., 2007a, 2007b), developed by Til Wykes and her colleagues at the Institute of Psychiatry in London.

Restorative approaches target cognitive deficits directly through repeated task practice, careful titration of task difficulty, and maintenance of high levels of accurate performance. This approach can be likened to the approach of a physical therapist, prescribing consistent and sustained exercise for muscle groups that have atrophied due to disuse or structural damage. In these interventions task practice is typically organized hierarchically, with elementary aspects of sensory processing or attention trained first, followed by training in higher-order memory and problem-solving skills. These approaches often rest on the assumption that improvements in cognition are mediated by neural plasticity and lead to more accurate sensory representations of environmental stimuli, thereby enhancing the output of computational cognitive systems.

Motivational approaches usually consist of an admixture of both restorative drill-and-practice training and strategy acquisition as a technique for improving cognitive function. The specific training method is considered secondary to the promotion of an intrinsic motivational set that is evoked through careful attention to the learning environment, therapist approach, and training materials. It is this enhanced motivational set that leads to greater task engagement and improved outcomes by this approach.

Hybrid approaches typically offer treatment in neurocognitive skills along with a package of other skills training modules, including social cognition (the ability to accurately decode the mental states of others) and/or social skills (Kurtz, 2012).

For each class of intervention we describe both the methods used for improving cognitive function and the empirical basis for intervention efficacy.

Strategy-Based Cognitive Remediation Training

To date, the best-studied strategy-based remediation intervention has been CRT (Delahunty et al., 2002; Wykes et al., 2007a, 2007b). CRT is based on three key principles: (a) teaching new, efficient information-processing strategies; (b) individualizing therapy; and (c) aiding the transfer of cognitive gains to the real world. The program includes several modules: cognitive flexibility, working memory, and planning. Each module consists of a series of exercises graded from "extremely easy" to "easy" to minimize task-related errors and promote errorless learning. In the cognitive flexibility module clients

are given practice in engagement, disengagement, and reengagement with a particular cognitive task or between two tasks. The working memory module requires the person to maintain two sets of information simultaneously and to carry out cognitive operations on this retained information. The planning module consists of tasks in which the participant tries to achieve a goal by planning a series of preparatory moves. The emphasis in this module is to organize information and to create and use subgoals. Within each module information-processing strategies are incorporated into each task at first (e.g., performance speed on a task may be regulated by the therapist by pointing to each test item at a fixed rate). The information-processing strategy is then discussed with the client, who then practices the strategy with the therapist (e.g., slowing down performance speed) overtly and then covertly. CRT has shown effectiveness in the earliest phases of the illness (Wykes et al., 2007a), with evidence that the intervention effects persist over time (Wykes et al., 2003) and that improvements can be linked to improvements in work quality measures (Wykes et al., 2012).

In another example of strategy-based training, Twamley and colleagues (2008) have developed a manualized intervention that is unique in the field of compensatory training. It uses modules that combine internal (use of acronyms and visual imagery) and external supports (writing down lists, placing lists in a convenient and visible location in the home environment) in many instrumental everyday tasks identified as important by consumers, family members, and therapists. Skills training modules are grouped into four general domains of prospective memory, attention and vigilance, learning and memory, and executive function. The types of everyday tasks trained in the program include remembering to go to work or school (prospective memory), focusing attention in class (attention and vigilance), learning and remembering names of supervisors (learning and memory), and self-monitoring work performance (executive function). Results from a recent type I randomized controlled trial of this intervention with 69 chronic outpatients with schizophrenia showed positive effects of the intervention on measures of attention and verbal memory and performance-based measures of function (e.g., writing a check, planning a trip to the beach), as well as negative symptoms and quality of life, relative to a control group treated with routine pharmacotherapy (Twamley, Vella, Burton, Heaton, & Jeste, 2012).

Restorative Cognitive Remediation Training

Two restorative CR programs have been studied most intensively to date: Neurocognitive Enhancement Therapy (NET), developed by Wexler, Bell, and their colleagues, and the PositScience Brain Fitness program, which has been evaluated in a series of randomized controlled trials by Sophia Vinogradov and her colleagues. Both are computer-assisted, hierarchically organized programs with simpler neurocognitive functions trained prior to more complex functions, both rely heavily on task practice, and both carefully titrate task difficulty according to the participant's ability level. The primary hypothesis of the approach is that minimizing invocation of verbally mediated guidance and other superordinate executive cognitive mechanisms, and instead placing emphasis on implicit practice-related learning, will facilitate acquisition of elementary cognitive skills in schizophrenia. A corollary assumption is that any evident improvements in elementary cognition will extend to other key disorder features. NET uses Bracy's PSS CogRehab software (Bracy, 1995) coupled with a weekly group discussion for social information processing and has been merged with on-site hospital work therapy programs. Cognitive training consists of a series of exercises first focused on sustained attention, then divided and shifting attention, and then working and episodic memory as well as problem solving. Exercises are started at individually determined levels of difficulty at which each client is successful (e.g., 80% accuracy) to presumably engage underfunctioning brain systems and maintain high levels of positive reinforcement. Several large sample randomized controlled trials have shown that NET in combination with work therapy improves working memory, executive function, and affect recognition (Bell, Bryson, Greig, Corcoran, & Wexler, 2001); these effects generalize to improved work performance as measured by hours worked and wages earned (Bell, Zito, Greig, & Wexler, 2008).

The Brain Fitness program is composed of exercises that place a much greater emphasis on sensory processing than the Bracy exercises (Fisher, Holland, Merzenich, & Vinogradov, 2009); thus, it trains at a more elementary level of cognitive function. The first part of the training program is targeted at auditory

sensory processing and consists of practice in distinctions between frequency-modulated sound sweeps as the sweeps become faster and are separated by shorter and shorter intervals. Subsequent exercises train processing phonemes. The last set of exercises targets verbal and working memory and focuses on accurately identifying increasing lists of syllables in spatial and sequential contexts or listening to a series of verbal instructions and carrying them out. By improving the speed and accuracy of auditory information processing it is hypothesized that the mental representations that encoding and rehearsal processes operate upon will be strengthened, leading to improved cognitive function. Preliminary findings from this intervention were very strong. Fisher and colleagues (2009) reported large effect-size improvement in verbal episodic learning and memory (d = .86 and .89, respectively) in a sample of clients with schizophrenia randomly assigned to the Brain Fitness program. These effects persisted at a six-month follow-up (Fisher et al., 2010). More recent data from a multisite international randomized controlled trial (n = 55), however, while showing improvement on tasks trained in the Brain Fitness program, failed to find any effects of training on cognitive or functioning measures not directly trained in the protocol (Murthy et al., 2012).

Motivationally Focused Programs

Disruptions in motivation, which refers to the ability to initiate and sustain goal-directed activities, is a primary feature of schizophrenia that affects a broad array of dimensions of psychosocial function in the disorder and presumably plays a key role in the ability to persist and benefit from these highly effortful, comprehensive, and sustained programs of CR. The manualized Neuropsychological Education and Rehabilitation (NEAR) CR program developed by Medalia and her colleagues (Medalia, Revheim, & Herlands, 2009) places the emphasis of cognitive training on the motivational processes required for acquisition of cognitive skills. They hypothesize that the central stumbling block for acquisition of novel cognitive skills in schizophrenia involves deficits in motivation and volition that are both a central feature of the disorder and the consequence of repeated failure experiences secondary to cognitive and social impairments. Thus, by this view, for CR to have an impact on cognitive skills in schizophrenia, the intervention must be administered in a manner that enhances motivation. Features that improve motivation include client choice in CR exercises, multimodal exercises that are engaging and intrinsically rewarding, and contextualization for the client. The key factor for these exercises, according to the NEAR model, is that they promote independence and self-efficacy. NEAR is most often offered in groups of up to 10, in which clients meet two to three times per week in 45-minute sessions, working on computerized exercises at their own pace. While a range of different computerized interventions have been used in this approach, exercises are often "top down" in that they train a range of cognitive skills within the same task. As opposed to restorative programs, they do not place emphasis on sequential, hierarchical training of elementary neurocognitive function. For example, with respect to problem-solving training, these researchers have investigated the "Where in the USA is Carmen San Diego" software. Participants are asked to solve a crime through planning, organization, and inference based on clues offered by the program on how to identify and track a criminal. Participants travel around the United States conducting interviews to support a warrant for the suspect. The program simultaneously provides practice on problem-solving skills as well as more basic skills in attention, memory, and concentration.

In support of this approach, these researchers have manipulated personalization, choice, and contextualization in an experimental paradigm and found that these factors together influenced the degree to which people with schizophrenia acquired arithmetic skills from an arithmetic training task, as well as the extension of effects of this training to a measure of attention (Choi & Medalia, 2010). To date this approach has received additional empirical support from other type 1 randomized controlled trials, with evidence of improvement on neuropsychological measures distinct from those trained and durability in which treatment effects persist for four weeks after the cessation of treatment (Medalia, Revheim, & Casey, 2002a, 2002b).

Hybrid Programs

Cognitive Enhancement Therapy (CET), developed by Gerard Hogarty and his colleagues, is an intensive intervention that represents an admixture

of cognitive and social cognitive training exercises (see section below on social cognitive training). It consists of 75 hours of training in elementary attention function along with 56 group social cognitive treatment sessions focused on increasing mental stamina, promoting active rather than passive social information processing, and learning to abstract the superordinate emotional character of social relationships. Group exercises are focused on understanding social cues, including recognizing affect in others, making accurate attributions about mental states, and emotion regulation. Results from type 1 randomized controlled trials have revealed that the intervention produces improvements in composite neurocognitive measures and behavioral measures of social cognition, cognitive style, and social adjustment relative to an active, enriched supportive therapy condition. Larger effects of the intervention were evident after a second year of treatment, and effects of treatment on composite measure of cognition, along with cognitive style, social cognition, and adjustment, are durable at a year after cessation of treatment (Hogarty et al., 2004; Hogarty, Greenwald, & Eack, 2006).

Integrated Psychological Therapy (IPT), as developed and studied by Brenner, Roder and his colleagues in Europe (Roder, Mueller, Mueser, & Brenner, 2006), and Spaulding and his colleagues at the University of Nebraska (Spaulding, Reed, Sullivan, Richardson, & Weiler, 1999), integrates neurocognitive, social-cognitive, and psychosocial rehabilitation into a comprehensive psychosocial treatment program consisting of five modules for people with schizophrenia. (IPT targeted at schizophrenia shares no relationship to Interpersonal Therapy developed for depression [e.g., Stewart et al., 2014].) Cognitive differentiation, the first training module, is designed to remediate cognitive deficits in schizophrenia. The next two modules are targeted at cognition in a social context (social perception and verbal communication), and the last two are intended to train social skills (specifically, social skill and interpersonal problem solving). Training is conducted in 30- to 60-minute sessions, two or three times per week in groups of five to seven clients. Cognitive training in IPT is similar in certain respects to computer-assisted restorative interventions in that training is targeted at specific cognitive deficits that are impaired in schizophrenia; it differs from this approach because it takes place in a group interactive format. It also shares elements with CR strategy in that strategies are practiced for achieving goals and tasks used are more directly integrated into the acquisition of ecologically relevant behavior such as social skill, which is then trained directly at a different juncture in the treatment protocol. A meta-analysis including 29 studies of IPT showed that effect sizes for measures of neurocognition were in the moderate to large size (d = .61); importantly, effects were also evident, at a reduced magnitude, on measures of psychosocial functioning (d = .41).

Meta-Analyses of the Efficacy of Cognitive Remediation on Cognition, Function, and Symptoms

To facilitate comparisons of findings across different studies, this section of the chapter will present standardized estimates of effect-size impairment in samples of people with schizophrenia treated with CR versus those not treated with CR (Cohen's d) from peer-reviewed, published meta-analyses of CR treatment. For effect-size calculations, the mean score of one group (e.g., mean scores on an outcome measure at the end of an intervention period from a group of people with schizophrenia treated with CR) is subtracted from that of a second group (e.g., mean scores on an outcome measure at the end of an intervention period in people with schizophrenia not treated with CR). The participant-to-participant variability in scores within each condition on the outcome measure is quantified, pooled across groups, and included as part of the statistic. This permits research results across studies to be compared directly since the results of each study can be expressed in standardized units of separation, regardless of interstudy differences in the specific measure selected for that study and the range of values for that measure in a specific study. We use the commonly accepted metric of small, d = .2 to .4, medium d = .4 to .8, and large effect size (d > .8) change (Cohen, 1977). It is important to note that at an individual participant level, even a large effect size of .8 still indicates an overlap of 53% of individual scores between two populations; thus, scores on a specific measure will only differentiate people in the treatment condition slightly less than 50% of the time from people not in the treatment condition. While this might suggest poor discrimination, if a substantial (e.g., approximately 50%) proportion of people with schizophrenia improve on a specific measure of outcome after a new treatment in this research area, the

treatment would still be considered beneficial, assuming other indices of statistical significance are found and adverse effects of the new treatment are low.

To date seven quantitative meta-analyses of CR in schizophrenia have been published, with all but one (Pilling et al., 2002) supporting the efficacy of CR for improving cognitive outcomes targeted by these interventions (Fig. 7.2). More recent meta-analyses have also provided support for moderate effect size improvements in function after CR when compared to a control condition—but only when CR is paired with other psychosocial interventions. Modest effects on symptoms have also been reported.

McGurk and colleagues (2007) conducted the first large-scale meta-analysis in this research area; it consisted of 26 randomized, controlled studies of CR and 1,151 participants with schizophrenia. Results revealed that CR produced moderate-sized effects on cognitive outcomes (d = .41) and small effect size improvements in psychosocial (d = .36) outcomes and symptoms (d = .28). Despite marked differences in study sample and treatment characteristics, there was little evidence that duration of CR training, inpatient versus outpatient status, age, or other variables influenced observed cognitive outcomes. The effects of CR on function were considerably stronger when CR was paired with other rehabilitation interventions (d = .47 vs. d = .05).

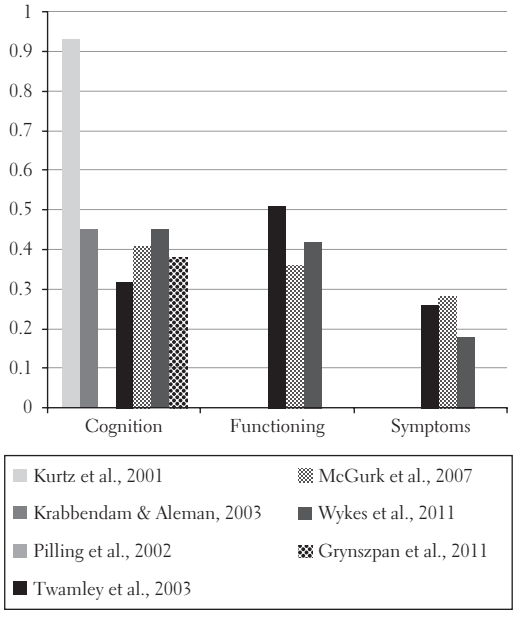

FIGURE 7.2 Effects of cognitive remediation on cognition, function, and symptoms in schizophrenia: results from effect size and formal meta-analyses.

These findings were confirmed in a more recent meta-analysis of 40 controlled studies of CR consisting of 2,104 participants (Wykes et al., 2011). Results revealed that CR produced moderate effect size improvement in cognitive outcomes (d = .45) and function (d = .42). This analysis was particularly important as it was the first to evaluate the impact of methodological rigor of CR studies on observed findings. Treatment factors such as duration, computer presentation, adjunctive psychiatric rehabilitation, and whether training was largely restorative or strategy-based were also evaluated. As in the study by McGurk and colleagues, effects on function were found to be larger when CR was administered as one element of a more general rehabilitation program, and there was some evidence for an advantage of strategy over restorative interventions on functioning, but not cognitive outcomes. There was also some evidence that having more symptoms leads to weaker treatment effect; however, even clients with high levels of symptoms showed some benefit. Other illness, demographic, and treatment factors did not influence treatment response, and the quality of the design methodology had no impact on observed treatment effects.

Predictors of Response to Cognitive Remediation

A small but growing number of studies have investigated the relationship of demographic features such as age, illness features such as positive and negative symptoms and amotivation, treatment characteristics such as duration and intensity of CR interventions, cognitive factors such as baseline level of cognitive skill at the start of CR treatment, and regional measures of brain volume from structural magnetic resonance imaging (MRI) to CR treatment response. In the first study of its kind, using 58 individuals with schizophrenia, Fiszdon and colleagues (2005) evaluated the relationship of demographics, symptoms, treatment, and neurocognition to the probability of showing normalized performance (improvement to within one standard deviation of healthy control performance) after CR training on a memory task that was an element of the comprehensive, computer-assisted, drill-and-practice remediation program selected by

the authors. The authors predicted that stronger sustained vigilance at study entry would predict normalized performance after the remediation intervention. As expected, results revealed that sustained visual vigilance, along with immediate verbal memory, time between termination of intervention and follow-up assessment, and clinical measures of hostility, accounted for 70% of the variance in normalization on the selected memory task.

Medalia and Richardson (2005) investigated the role of motivation, among other factors, in an analysis of three client databases in which CR "improvers" were distinguished from "non-improvers." They reported that motivation (as measured by voluntary participation in CR sessions), participant work style, and clinician experience were related to a positive response to NEAR CR treatment. Among neurocognitive measures, sustained attention was related to improvement across three samples of psychiatric inpatients and outpatients (these samples did not exclusively consist of people with schizophrenia). Participants were classified as "improved" if they improved on any proximal measure of neurocognitive function to a degree that could have occurred by chance only five times or less out of 100.

Kurtz and colleagues (2008) explored the relationship of four measures of neurocognitive function (crystallized verbal ability, auditory sustained attention and working memory, verbal learning and memory, and problem solving); two illness variables (total positive and negative symptoms); and the treatment variables of treatment intensity and duration to improvement on a measure of adaptive everyday life skills (UPSA) after a year of computer-assisted, restorative CR. CR was offered as part of intensive outpatient rehabilitation treatment that included exercise, case management, supportive group therapy, psychoeducation, and vocational counseling. Results of a linear regression model in 36 participants with schizophrenia revealed that auditory attention and working memory predicted a significant amount of improvements in performance-based measures of everyday life skills after CR, even when other neurocognitive variables in the model were accounted for.

Age was investigated as a moderating variable in studies of strategy-based CR in a pair of recent papers by Til Wykes and her colleagues (Kontis, Huddy, Reeder, Landau, & Wykes, 2013; Wykes et al., 2009). In both studies, participants were divided into younger (<40) and older (40 and up) samples. Wykes and colleagues (2009) evaluated a sample of 85 participants with schizophrenia in a randomized controlled trial, with memory, cognitive flexibility, and planning as primary cognitive outcomes and symptoms and self-esteem as secondary outcomes. The authors reported evidence of greater improvement in planning and cognitive flexibility in the younger group, along with improvements in negative symptoms. The follow-up study by Kontis and colleagues (2013) of 134 individuals with schizophrenia pooled across two studies revealed that when cognitive reserve estimates, as measured by premorbid IQ and vocabulary, were taken into account in addition to age, age remained a significant predictor of treatment response: Participants under 40 showed improvement in working memory after CR while those 40 and older failed to show a significant response. Proxy measures of cognitive reserve only predicted the likelihood of showing practice effects on the working memory outcome measure in younger participants regardless of treatment condition (CR or control).

In a particularly novel study employing structural neuroimaging indices, Keshavan and colleagues (2011) investigated the relationship of gray matter volume and cortical surface area to treatment outcome in 50 people with schizophrenia randomly assigned to a hybrid CR program, CET, or enriched supportive therapy. The authors hypothesized that greater pretreatment cortical volumes in key illness-linked brain regions (labeled by the authors as "brain reserve"), specifically in the frontal and temporal lobes, would predict cognitive/social cognitive outcomes over a two-year period in individuals in an early phase of illness. Results revealed that gray matter volumes and surface areas at baseline were linked to improved social cognitive task performance, but not cognitive task performance, at a one-year assessment. Both groups were similar in the magnitude of their treatment response to CET by the second year of treatment. Importantly, all relationships were specific, with structural neuroimaging measures predicting response to the active intervention when compared directly to the predictive value of these measurements for change in the control training condition.

In summary, age (under 40), sustained attention and memory, clinical ratings of hostility, therapist training, and client motivation and work style have all been linked to a positive response to CR. Two key limitations of this literature limit firm conclusions. First, programs of CR in these studies have varied widely;

for example, predictors of response to stand-alone restorative CR training may be quite different from predictors of response to hybrid programs consisting of CR and other treatment elements such as social cognitive training and social skills training. Second, only two studies in this section explicitly compared predictors of response to CR to a control condition, so the specificity of these predictor variables to CR response remains largely unknown. These findings do suggest that modifications of existing CR programs will likely be necessary to address the needs of clients with particularly low motivation for treatment, poor cognitive function, and older age. Indeed, with respect to motivation, recent research suggests that intrinsic motivational levels remain a significant stumbling block to CR participation and directly predict CR learning outcomes, and these effects are larger than those seen for more extrinsically motivated psychosocial interventions for schizophrenia (e.g., supported employment programs; Medalia & Saperstein, 2011). The good news is that intrinsic motivational levels in schizophrenia are dynamic rather than static and can be manipulated by increasing a sense of agency and self-efficacy in the context of CR and contextualizing learning by making the goals of CR more personally relevant (Choi & Medalia, 2010).

Cognitive Remediation + Adjunctive Pharmacotherapy

In a novel research avenue with considerable promise, two randomized controlled trials during the past 2 years have combined adjunctive medications designed to enhance neural plasticity with CR procedures. In both reports, an *N*-methyl-D-aspartate receptor (NMDAR) agonist or enhancer was used to promote neural plasticity in the context of CR. The rationale for the approach is that medications that enhance neural plasticity may have little effect on measures of neurocognition if they are administered in isolation to people with schizophrenia in the context of impoverished social environments with little cognitive stimulation. Only when cognitive functions are stimulated through repeated practice may the effects of enhanced neural plasticity be capitalized upon. In both studies the medications affecting the NMDAR system were selected for two reasons: (1) the clear role of the NMDARs in promoting neural mechanisms of plasticity that have been associated with long-term memory and fear extinction and (2) the hypothesized role of NMDAR dysfunction in the genesis of the disorder. Studies have shown evidence of NMDAR dysfunction in schizophrenia and the simulation of many key symptomatic features of schizophrenia in healthy participants following NMDAR blockade (e.g., Krystal & Moghaddam, 2011).

In the largest sample study to date, D'Souza and colleagues (2013) conducted a blinded, randomized, placebo-controlled type 1 study of 104 people with schizophrenia at two sites in the United States and India. Participants were assigned to one of four groups: (1) CR plus the NMDAR agonist d-serine, (2) CR plus placebo, (3) control CR plus d-serine, and (4) control CR plus placebo. CR consisted of 20 computer-assisted, restorative training tasks targeted at attention, memory, verbal and visuospatial working memory, and executive function. It was administered for five hours a week in two or three weekly sessions over 12 weeks. Participants were assessed with a battery of neurocognitive instruments at baseline, at the end of the trial, and at a 24-week follow-up. Results revealed that a sustained intervention consisting of combined pharmacotherapy and CR is feasible and well tolerated by individuals with schizophrenia, with completion rates of the 12-week trial over 80%. Consistent with previous research, results revealed effects of the CR intervention on verbal working memory, but no evidence of d-serine enhancement effects on primary indices of cognition and function. The authors concluded that overly low dosages of d-serine along with limited trial power and inflated placebo effects associated with this type of trial design may have limited detection of the effects of the combined treatment.

In a related study, Cain and colleagues (2014) investigated the effects of an eight-week CR intervention offered in combination with d-cycloserine, another NMDAR agonist with more specific effects on a subgroup of NMDAR receptors that include an NR2C subunit (relative to other NMDAR agonists such as d-serine). NMDAR receptors that include the NR2C subunit are thought to be particularly crucial for facilitating the neural plasticity associated with fear learning in animal models and to show reduced expression in the prefrontal cortex of people with schizophrenia (Krystal & Moghaddam, 2011). Forty chronic outpatients with schizophrenia treated with antipsychotic medications were randomly assigned to one of two conditions: once-weekly d-cycloserine

plus CR or placebo plus CR. CR consisted of either three- or five-times-per-week restorative CR based on participant choice (Brain Fitness, PositScience, San Francisco, CA). Outcome measures included an auditory discrimination task that was trained in CR, standardized neurocognitive measures (MATRICS battery) that were not trained directly in the CR program to assess the breadth of effects, and symptom and functioning measures. Completion rates for the trial were over 85%. Results revealed that d-cycloserine facilitated performance on the auditory discrimination task trained as one of the key elements of the CR program, but that participants assigned to the placebo group showed improved performance on an overall index of neurocognition from the neurocognitive test battery. The latter finding suggests that d-cycloserine may have in fact attenuated the effects of CR on nontrained neurocognitive measures in this study. The authors concluded that d-cycloserine may serve to enhance specific neuroplasticity for the acquisition of a trained task but may not enhance or may even interfere with CR effects more generally on untrained cognitive tasks. Taken together, these findings suggest that lengthy, combined CR and adjunctive pharmacotherapy treatment trials are feasible and well tolerated by people with schizophrenia. Results to date using NMDAR agonists have been negative with respect to enhancement of restorative CR effects on cognitive outcomes not directly trained in the CR program, with some evidence of enhancement of performance on trained tasks. The number of studies to date has obviously been small, and the results provide a rationale for additional, more highly powered treatment trials with perhaps other pharmacological agents designed to promote neural plasticity and facilitate CR effects.

SOCIAL COGNITIVE TRAINING

Social Cognition in Schizophrenia

Social cognition is defined as those cognitive processes necessary for the perception, interpretation, and processing of social stimuli (Fiske & Taylor, 1991). Social cognition is typically conceived as a complex set of cognitive operations that are built upon elementary skills in neurocognition discussed in the previous section of this chapter, but are not solely defined by these skills. For example, an employer may have a Superior level IQ score and outstanding attention and memory skills but still fare quite poorly when negotiating a delicate interaction with a supervisee regarding the supervisee's work product if the employer's social cognitive skills are underdeveloped. In contrast, a person with borderline IQ, along with attendant impairments in attention, memory, and problem solving, is likely to have a difficult time negotiating social situations without the requisite skills in attending to and remembering facial expression, voice prosody, and other paralinguistic expressions.

Social cognition is distinguished from nonsocial cognition on the basis of the following:

1. The content of information that is operated on—namely, socially relevant stimuli that are usually personally relevant, that are often affectively charged, and that focus on either perceptions of individuals in the social environment or the steps involved in negotiating complex social situations;
2. The products of social cognitive processes, which are focused on inferring traits or dispositions in others, rather than on a computational outcome;
3. Less emphasis placed on performance deficits as compared to healthy controls; instead there may be differences in biases in the way social information is processed in clinical populations as compared to healthy controls; and
4. Social stimuli are typically not static but reflexive, influencing the perceptions of the perceiver (Penn, Corrigan, Bentall, Racenstein, & Newman, 1997).

Over the past 10 years there has been increasing focus on component skills that make up social cognition in schizophrenia. A consensus statement by a group of experts on social cognition convened by the National Institute of Mental Health (Green, Olivier, Crawley, Penn, & Silverstein, 2005) identified five key areas of social cognition: *Theory-of-Mind (ToM)*, or the ability to infer another's perspective or mental state based on his or her speech and behavior; *social perception*, or the ability to decode environmental cues regarding the appropriate application of social rules and roles; *social knowledge*, which refers to the possession of knowledge regarding appropriate social rules and roles that govern social interaction; *attributional bias*, which reflects a style of attribution that focuses on the source of positive

or negative social events relating to internal (self), external (other), or situational factors; and *emotional processing*, the ability to understand and manage emotion as perceived in others or in oneself through a variety of behavioral and verbal cues. A recent meta-analysis of 112 studies of social cognition in schizophrenia that included nearly 4,000 individuals with schizophrenia and 3,500 matched controls showed that people with schizophrenia experienced large effect size impairments on skills in social perception (g = 1.04), ToM (.96), and emotion perception (g = .89) and processing (g = .88; Savla, Vella, Armstrong, Penn, & Twamley, 2013). Thus, deficits in social cognition in schizophrenia are substantial and widespread across a variety of component social cognitive processes.

Social Cognitive Deficits and Functional Status in Schizophrenia

Over the past 10 years a growing number of studies have investigated the relationship of a variety of domains of social cognition to a variety of indices of functional measures in schizophrenia. One conceptual model linking social cognitive deficits to a variety of measures of outcome has been delineated by Penn and his colleagues (Penn, Sanna, & Roberts, 2008). According to their view, when skills in emotion and social perception are disrupted, misperceptions of facial affect and other nonverbal cues result, leading a person with social cognitive deficits or nonadaptive information processing biases to misinterpret, for example, anxiety for anger in a coworker. Systematic biases in attribution in turn lead people with social cognitive impairment to assume that the anger is directed toward themselves, leading to reciprocal anger targeted at the coworker. The coworker then withdraws from social interactions based on this expression of anger. In turn, anger in the person with social cognitive impairment disrupts ongoing activity in his or her work life and decreases subjective quality of life. In this way, disruptions in elementary social cognitive processing can cascade, creating a variety of downstream effects on different indices of psychosocial function.

Conclusions from synthetic reviews of relationships between social cognition and functioning (e.g., Couture, Penn, & Roberts, 2006) provide support for this conceptual model, suggesting numerous and replicated links between specific aspects of social cognitive skill and different aspects of functional status. Results from one review of 23 largely cross-sectional studies that investigated four domains of social cognitive skill (social perception, emotion perception, ToM, and attributional style) and four measures of functional status (social behavior within a treatment milieu, community functioning, social skill, and social problem solving [the ability to generate solutions to everyday social problems]) revealed a consistent relationship between social perception and social problem solving, community functioning, and behavior in the milieu. Emotion perception had a consistent albeit modest relationship with community function, social skills, and social behavior in the milieu. Results also revealed a link between ToM and social skills. More recent work has confirmed these findings longitudinally by showing that social cognitive deficits in emotion processing, ToM, and social perception in a first episode of schizophrenia predicted work function at a 1-year follow-up after controlling for differences in work function explained by symptoms (Horan et al., 2012).

Other reviews (Schmidt, Mueller, & Roder, 2011) have suggested that impairments in social cognition in schizophrenia may in fact mediate the relationship between elementary neurocognitive function and psychosocial functioning. That is, neurocognition may exert its effect on psychosocial function by affecting social cognitive skills negatively; this in turn diminishes psychosocial function. This is important in that it might suggest that interventions targeting social cognitive skills directly could have a greater impact on functioning than those targeting neurocognition, since they are influencing skills more proximal to the disability itself. In a review of 15 studies of the role of social cognition as a mediator of the effects of neurocognition on function, 14 of these studies showed that, despite wide differences in indices of social cognition and neurocognition and a range of functioning measures, including social behavior in the milieu, community function, social problem solving, and social skills, there was a mean, standardized indirect effect size of .20 for social cognitive measures as mediators of the effects of neurocognitive skills on function.

Methods of Social Cognitive Training in Schizophrenia

Evidence of replicated links between skills and information processing biases in domains of social

cognitive function and aspects of psychosocial status, along with the mediating effects of social cognition on the relationship between neurocognition and function, give currency to the idea that social cognitive skills may be a crucial function to target for novel therapies for improving functional outcome in schizophrenia. As can be seen in Figure 7.3, while still in an inchoate stage of research, there have been a growing number of controlled studies investigating the effectiveness of social cognitive training (SCT) interventions, with a quadrupling of the cumulative number of published studies over the past eight years.

SCT programs have typically been considered "targeted" or "broad-based." Targeted programs treat one dimension of social cognitive deficits (e.g., facial affect recognition), whereas broad-based interventions treat several dimensions of social cognition in the same intervention or treat one or more areas of social cognition as well as other dimensions of the disorder such as cognitive or social skill deficits. Programs are best conceptualized along a continuum rather than rigidly categorized as one approach or the other; for example, an SCT program targeting two dimensions of social cognition would be somewhere toward the middle of this continuum. While social cognitive processes include biases in information processing as well as performance deficits, to date most programs have focused on remediation strategies for performance that are analogous to those in CR, including drill-and-practice and strategy training to enhance performance in areas of social cognition; debiasing strategies have been much less frequently employed.

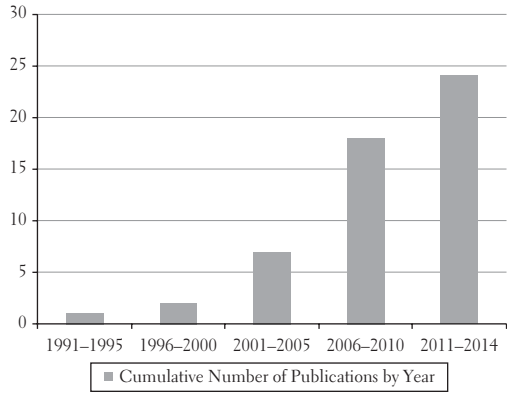

FIGURE 7.3 Cumulative number of controlled studies on social cognitive interventions in schizophrenia.

Targeted Programs

To date, targeted SCT programs have addressed two major areas of social cognitive deficit: ToM and facial affect recognition. In a pilot study ($n = 14$) Kayser and colleagues (2006) investigated the use of verbalization strategies in which individuals with chronic schizophrenia provided descriptions of 12 20- to 70-second scenes from French cinema. If descriptions were not offered spontaneously, therapists prompted participants to describe what they had seen in the film. If participants made attributions regarding the mental/emotional state of characters, participants were asked how they came to their conclusions. If they offered only concrete details of the scene and failed to mention the characters' intentions, participants were prompted by the therapist to describe the characters' mental/emotional state. Results revealed improvement on a nonverbal ToM outcome task that used stimuli that were distinct from the training videos (the Intentions Inference Task) in the verbalization group but not in the nonverbalization treated control group.

With respect to affect recognition training, early studies investigating the effects of reinforcement in the form of monetary compensation for correct performance and facial mimicry of emotional faces revealed that both interventions improved facial affect recognition immediately after the intervention, but effects were not durable at a one-week follow-up (Penn & Combs, 2000). Subsequent interventions have targeted facial affect recognition deficits through attentional shaping, in which visual scan paths in individuals with schizophrenia are modified through the use of attentional prompts (the brief presentation of a large cross on the screen) that focuses the attention of the participant on the eyes and mouth of the face, areas likely to provide the most information regarding the affective valence of a face (Combs et al., 2008). Other studies have investigated the use of didactic instruction on differentiating emotions that may appear to be overlapping, with corrective feedback and repetition to improve identification of briefly presented "microexpressions" (15-ms "flashes" of facial affect). These effects are substantial, enhancing performance to that of healthy controls, and are beyond those associated with passive exposure to faces expressing affect (Russell, Green, Simpson, & Coltheart, 2008). More sustained 12-session training programs in affect recognition have also been employed with improvements in affect recognition

skills that are specific and evident relative to active control conditions (Wolwer et al. 2005).

Taken together, targeted studies of SCT show that difficulties in two aspects of social cognitive skills (ToM and facial affect recognition) are modifiable with brief interventions that target impairments directly. These interventions have varied widely in method from simple task practice and corrective feedback to didactic instruction, verbalization, mimicry, and motivational enhancement through monetary reinforcement of correct responses.

Broad-Based Programs

In recent years, an exciting development in SCT programs has been the formulation and initial assessment of two broad-based, sustained training programs that comprehensively target a broad array of social cognitive skills in schizophrenia: Social Cognition and Interaction Training (SCIT), developed by David Penn and his colleagues at the University of North Carolina-Chapel Hill, and a novel integrated social cognitive training program derived partially from SCIT called Social Cognitive Skills Training (SCST), developed by William Horan and his colleagues at UCLA.

SCIT is a 20-week group intervention that includes three interrelated modules. Module One is devoted to emotion recognition using practice-based remediation, didactic instruction, verbalization skills, and corrective feedback and includes specific training in identifying and managing paranoid feelings. A second module, targeting ToM and attributional style, is aimed at making clients better social detectives, providing practice in questioning assumptions, generating alternative hypotheses regarding others' thoughts and feelings, distinguishing facts from assumptions in drawing conclusions about social situations, and acquiring the social skills to ask questions and gather additional information before making assumptions about the source of other people's behavior. In the last module, skills in applying techniques in the first two phases of the program to everyday life situations are taught and practiced. Initial findings from non-randomized type 2 designs have been promising, showing evidence that the program elevates skills in social cognition relative to control conditions (e.g., Roberts & Penn, 2009). The first type 1 randomized controlled trial of the intervention was conducted in the United States and has been published. It included 66 people with chronic schizophrenia and revealed that individuals treated with SCIT showed improved social functioning, negative symptoms, and hostile attributional bias relative to a treatment-as-usual control group, with evidence that clients attending more treatment sessions showed greater benefit. Thus, SCIT produced generalized improvements in the treated group. Somewhat surprisingly, there were only small, non-significant effects of SCIT on measures of affect recognition and ToM treated directly in this study (Roberts et al., 2014).

A recent type 1 randomized controlled trial of the related treatment program SCST has shown efficacy as well, with improvements in facial affect recognition and emotion perception, but not symptoms or neurocognition, in SCST-treated participants relative to active control groups treated with neurocognitive remediation or illness management training (Horan et al., 2009, 2011).

Meta-analysis of Effects of Social Cognition Training on Social Cognition, Function, and Symptoms in Schizophrenia

As shown in Figure 7.4, a recent meta-analysis of 19 studies of SCT (Kurtz & Richardson, 2012) revealed preliminary support for the efficacy of these interventions for improving social cognitive function, psychosocial functioning and some aspects of psychiatric symptoms. The meta-analysis included both targeted and broad-based programs of SCT. With respect to social cognitive measures, the meta-analysis revealed reliable, moderate and statistically significant effect size improvements in facial affect recognition (d = .71; 14 studies) and ToM (d = .46; 7 studies), relative to a control condition. Further, preliminary evidence of generalization with improvement on measures of total symptoms (d = .68; 7 studies) and psychosocial function (d = .78; 6 studies) was observed. Indeed, moderate-sized effects of these interventions on these more distal outcome measures were particularly noteworthy since they were similar in magnitude to those of social cognitive measures directly trained in these interventions. This finding suggests a close relationship between improvements in social cognitive skill and a variety of indices of functional outcome and generalized symptoms. Effects of these interventions on measures of social

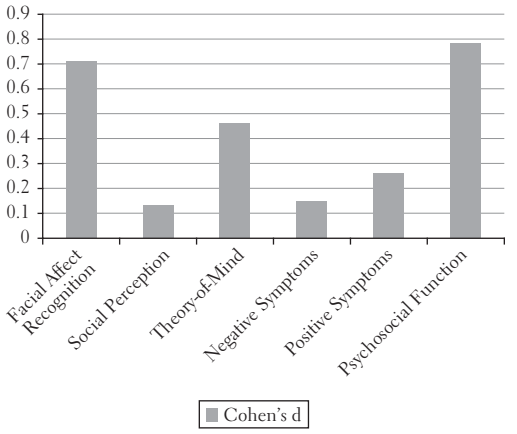

FIGURE 7.4 Meta-analysis of effects of social cognitive training on social cognitive, symptom, and function measures in schizophrenia from nineteen controlled studies.

perception and positive and negative symptoms were nonsignificant. These latter findings suggest that these training programs improve more generalized symptoms of anxiety and depression rather than symptoms that are more closely linked to the diagnosis of schizophrenia, including delusions, hallucinations, and social withdrawal. There was no evidence from the meta-analysis of effects of social cognitive training effects on measures of attributional bias. At the time of the analysis, however, only four studies had investigated the effects of these training programs on this index of social cognition. Moderator analyses revealed that clients with a longer duration of illness were more likely to benefit on measures of facial affect recognition and ToM, and younger, more medicated samples showed more general effects of SCT on measures of function and general symptoms.

CONCLUSIONS AND FUTURE RESEARCH

A wide range of cognitive interventions have been developed to address persistent deficits in neurocognition and social cognitive functioning in schizophrenia. These deficits are thought to impair successful psychosocial functioning and to be resistant to pharmacotherapy of schizophrenia. With respect to cognitive training programs, these methods differ in terms of whether they (1) teach strategies that work around cognitive deficits, (2) undertake restorative, drill-and-practice training, (3) maximize motivational set, or (4) represent hybrid programs that consist of cognitive training procedures with accompanying training in more molar social cognitive and social skills. Results from meta-analyses consisting of many type 1 research studies have revealed (1) strong support for moderate (d = .46; Wykes et al., 2011) improvements on measures of neurocognitive function distinct from the tasks trained as part of specific remediation protocols and (2) generalization of these effects to function (d = .42; Wykes et al., 2011) when offered along with other evidence-based psychosocial treatment programs. These findings suggest that these training interventions produce improvement in the underlying neurocognitive skills necessary to complete neurocognitive tasks, rather than simply teaching skills to the specific test. Even more importantly, these findings indicate that these improvements in cognition generalize to broader psychosocial function by boosting the effects of psychosocial interventions targeted at key areas of functioning in schizophrenia. A corollary to this conclusion is that there is little evidence that stand-alone CR programs enhance functioning. Taken together, these findings are remarkable given the wide differences in sample composition, method of remediation, type of adjunctive psychosocial treatment, and duration and intensity of intervention administration in studies in this research area.

However, there are several areas of concern that the CR field needs to address to be accepted as a front-line, evidence-based practice. First, the multitude of different strategies that have been used to intervene with cognitive deficits makes it unclear which interventions are most effective. These differences in methods in the CR literature have been identified by opinion leaders in the field as a crucial limitation of this treatment research area. In fact, the most recent Patient Outcomes Research Team (PORT) psychosocial treatment recommendations, commissioned by the U.S. Department of Health and Human Services, concluded that "while the literature to date provides a foundation for further research, more work is needed before a concrete recommendation for cognitive remediation can be offered to the field. There are…principal considerations underlying this conclusion…that the variation among

cognitive remediation models and programs is too great to allow identification of key elements of the intervention" (Dixon et al., 2010, p. 60).

Second, while there has been substantial growth in research over the past decade, a continued limitation in the field is the still-small number of CR studies assessing the generalization of cognitive training effects to functional outcome measures distal from the remediation intervention. In the meta-analysis by Wykes and colleagues (2011), 18 studies included functional outcome measures. These measures varied widely in terms of whether they were clinician-rated, performance-based (based on a laboratory assessment of life or social skills), or global ratings of function. It seems highly unlikely that CR interventions would produce equivalent effects on such diverse outcome measures bearing such different relationships to neurocognitive functioning. To improve our understanding of the mechanisms of action of remediation interventions, future studies will benefit from the use of a set of outcome measures that vary systematically in terms of their proximity to the locus of the remediation intervention. Furthermore, the specific relationship and any "threshold effects" between improvements on specific CR training tasks and improvements on cognitive outcome measures distinct from these training tasks, and in turn the relationship of improvement in these measures to improvements in functioning, is understudied and remains largely unknown. This absence has served as an impediment to the field. One recent report has tied CR-related improvements in neurocognitive function (planning skills) directly to improvements in work quality related to a work therapy program, but effects were modest (Wykes et al., 2012). Further study of these relationships will be crucial for the field to move forward in understanding the mechanisms of CR effects as well as how to maximize these effects.

Third, amotivation, a central feature of schizophrenia since its definition at the turn of the 20th-century, influences the ability of all clients to benefit equally from these time- and effort-intensive interventions. Levels of intrinsic motivation play a large role in client outcomes in CR and likely explain why some estimates suggest that as many as 40% to 69% of people who participate in CR interventions are "non-responders" (Medalia & Richardson, 2005). Findings that motivational states are mutable in schizophrenia (Medalia & Saperstein, 2011) suggest an important future direction for increasing the accessibility of these CR programs.

Fourth, self-reported life satisfaction and self-esteem, constructs that are central to any concept of client recovery from severe mental illness, have been evaluated only rarely as treatment endpoints. Accordingly, the relationship between these measures and changes in performance-based and clinician-rated measures of functional status after rehabilitation interventions remains unclear and even paradoxical in some studies (Brekke, Kohrt, & Green, 2001; Edmondson, Pawha, Lee, Ho, & Brekke, 2012). Indeed, improvement in cognitive functions may facilitate upward social comparisons, which lead to a consequently diminished sense of competence in adaptive everyday function and social relations. Thus, the effects of CR on self-reported quality of life remain largely unknown, do not clearly co-vary with improvements in objective psychosocial function, and should be an important focus of future study.

Fifth, at least one report has suggested a role of clinician training in the likelihood of response to CR interventions (Medalia & Richardson, 2005), but the question is largely understudied. Thus, the role of training in disseminating this family of interventions to clinical practice remains unclear. Training requirements are likely to differ based on approach. Computer-assisted restorative approaches, for example, are likely to require a much lower level of clinician training than the one-on-one training that is characteristic of many strategy-based programs (e.g., CRT).

Compared with cognitive treatments, the development and careful empirical validation of SCT programs are in a much earlier state of development, although interest and corresponding efforts are intensifying rapidly in light of the key role of social cognition in a variety of domains of psychosocial function. A growing number of targeted social cognitive interventions, including many type 1 studies, has revealed strong support for the idea that deficits are modifiable and that improvements in the key social cognitive domains of affect recognition and ToM can be attained with very brief motivational, attentional, didactic, and self-verbalization strategies. Importantly, in some cases these effects are durable. While SCT has been a key element of several validated, multimodal treatment programs consisting of CR, social skills training, and other interventions (e.g., Roder et al., 2006), for the first time two

sustained, comprehensive, stand-alone SCT packages have been developed (SCIT and SCT). Both have shown promise for improving social cognition in four type 1 and several type 2 studies. Studies to date, however, are small in number and have been largely preliminary and focused on development and feasibility. Thus, the ultimate value of these treatments will depend on the results of larger, ongoing and future, well-powered treatment trials.

In conclusion, CR and SCT have rapidly gained an evidentiary basis that suggests they will be key elements of the next generation of empirically supported treatments for schizophrenia. In light of the specificity of treatment effects to date, with generalization elusive in the absence of multimodal treatments, efforts geared toward understanding methods of integration of CR and SCT with other psychosocial and neuroscience-based pharmacological treatments represent the next frontier for enhancing recovery processes in schizophrenia. Indeed, these novel treatments, along with methods of cognitive-behavioral therapy tuned to the treatment of psychosis, and well-supported treatment mainstays such as social skills training, supported employment, and family interventions, all serve as an increasingly large bulwark against the therapeutic nihilism that has pervaded the application of psychological treatments over the past century for this highly underserved and still ill-understood population.

Pharmacological Treatments for Bipolar Disorder

Paul E. Keck Jr.
Susan L. McElroy

The vast majority of clinical trials in patients with bipolar disorders have been conducted in groups with bipolar I illness, although a few trials have recently emerged specifically in patients with bipolar II disorder. The pharmacological management of bipolar disorder involves the treatment of acute manic, hypomanic, mixed, and depressive episodes, as well as the prevention of further episodes and subsyndromal symptoms. Lithium, divalproex, carbamazepine, haloperidol, risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and asenapine have demonstrated efficacy in the treatment of acute mania in randomized controlled (type 1) trials. Although the pharmacological treatment of acute bipolar depression remains understudied, data from randomized controlled trials indicate that lithium, olanzapine, olanzapine–fluoxetine, quetiapine, lurasidone, tricyclics, monoamine oxidase inhibitors (MAOIs), and fluoxetine have efficacy in this phase of the illness. The optimal duration of antidepressant treatment, in combination with mood stabilizers, is still unknown. Lithium, lamotrigine, olanzapine, aripiprazole, quetiapine, and risperidone (long-acting, injectable) have been shown to have efficacy in relapse prevention. Less extensive data suggest that divalproex and carbamazepine are also efficacious as preventive treatments.

INTRODUCTION

Bipolar disorder is a common, severe, and recurrent psychiatric illness. In the United States, the 12-month prevalence rate of bipolar I and II disorders is estimated at 2.6% (Kessler, Chiu, Demler, Merikangas, & Walters, 2005). In 1990, bipolar disorder was the sixth leading cause of disability worldwide and was projected to remain so in the first two decades of this century (Murray & Lopez, 1996). Bipolar disorder is characterized by disturbances in mood, cognition, and behavior and is often associated with psychotic symptoms (McElroy, Keck, & Strakowski, 1996b). Untreated bipolar disorder carries substantial risks of morbidity and mortality (Mitchell, Slade, & Andrews, 2004). Morbidity is not simply limited to mood episodes themselves; for example, full recovery of functioning often lags behind remission of symptoms by many months (Dion, Tohen, Anthony, & Waternaux, 1988; Keck et al., 1998). In addition, recurrent mood episodes may lead to progressive deterioration in functioning between episodes, and the number of episodes, in turn, may adversely affect subsequent treatment response and prognosis (Prien & Gelenberg, 1989; Swann, Bowden, Calabrese, Dilsaver, & Morris, 1999). Thus, morbidity due to the illness is not limited to acute mood episodes but may linger and lead to prolonged deficits in social and vocational functioning (Calabrese et al., 2003b; Fagiolini et al., 2005). Bipolar disorder can also be a

lethal illness: Suicide attempts are made by at least 25% of patients (Hopkins & Gelenberg, 1994).

Bipolar disorder is a highly heritable illness (Gershon, 1989). Concordance rates between monozygotic twins for bipolar disorder range from 65% to 75% compared with concordance rates for dizygotic twins of approximately 14% (Gurling, 1995). In family studies, the lifetime prevalence rates of mood disorders among first-degree relatives of bipolar probands are elevated compared with prevalence rates for these disorders in first-degree relatives of people without psychiatric illness (Gurling, 1995).

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM*-5; American Psychiatric Association [APA], 2013) delineates seven classifications of bipolar disorder: bipolar I disorder, bipolar II disorder, cyclothymic disorder, substance/medication-induced bipolar and related disorder, bipolar and related disorder due to another medical condition, other specified bipolar and related disorder, and unspecified bipolar and related disorder. There are several changes from *DSM-IV* (APA, 1987) in the bipolar disorder section. Bipolar disorder not otherwise specified is eliminated as a diagnosis. Moreover, bipolar and related disorders are separated nosologically for the first time from depressive disorders, and positioned between "schizophrenia spectrum and other psychotic disorders and depressive disorders in recognition of their place as a bridge between the two diagnostic classes in terms of symptomology, family history, and genetics" (APA, 2013, pp. 123). As in *DSM-IV*, the *DSM-5* criteria for manic, hypomanic, and depressive episodes are summarized in *DSM*-5. Mixed episodes have been replaced by the specifier "with mixed features" (APA, 2013, pp. 127). The criteria for bipolar I disorder require the presence of at least one manic episode; the manic or depressive episode is not better accounted for by schizoaffective disorder, schizophrenia, schizophreniform disorder, delusional disorder, or other specified or unspecified schizophrenia spectrum and other psychotic disorder. The criteria for bipolar II disorder require at least one hypomanic episode and one or more current or past major depressive episodes. The criteria for cyclothymic disorder require, for at least 2 years (in children and adolescents for at least 1 year), the presence of numerous periods of hypomanic and depressive symptoms that do not meet respective criteria for hypomanic or depressive episodes; the person has not been without hypomanic or depressive symptoms for more than 2 months at a time and the hypomanic and depressive symptoms have been present for at least half the time; and no major depressive, manic, or hypomanic episode has been present; the symptoms in Criterion A are not better explained by a schizophrenia spectrum disorder, are not attributable to the physiological effects of substances or another medical condition, and the symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. Recent studies suggest that the duration criterion for hypomania of 4 days is arbitrary and longer than many patients with bipolar II disorder experience hypomanic symptoms (Benazzi & Akiskal, 2003).

The vast majority of psychopharmacological treatment research has focused on patients with bipolar I disorder. Thus, this chapter will review, primarily, the treatment of bipolar I disorder. The few studies that included patients with bipolar II disorder will be noted as such. Since the pharmacological treatment of bipolar I disorder involves the acute treatment of manic, mixed, and depressive episodes, as well as maintenance treatment to prevent cycling, recurrent mood episodes, and subsyndromal symptoms, we review below studies of both acute and long-term treatment. Finally, because studies of the pharmacological treatment of bipolar disorder vary in design, we will make careful distinction between conclusions based on randomized controlled trials and open trials, case series, and case reports.

PSYCHOPHARMACOLOGICAL TREATMENT FOR ACUTE MANIC AND MIXED EPISODES

Lithium

In 1970, lithium was the first drug approved by the U.S. Food and Drug Administration (FDA) for the treatment of "manic episodes of manic-depressive illness" (Goodwin & Jamison, 1990). Six controlled studies demonstrated that lithium was superior to placebo for the treatment of acute mania (Bowden et al., 1994, 2005; Goodwin, Murphy, & Bunney, 1969; Maggs, 1963; Schou, Juel-Nielson, Stromgren, & Voldby, 1954; Stokes, Shamoian, Stoll, & Patton, 1971). Early lithium trials had several methodological limitations that were addressed in more recent

studies. For example, only two studies (Bowden et al., 1994, 2005) used a parallel design, whereas the earliest four studies were crossover trials of varying duration (Goodwin et al., 1969; Maggs, 1963; Schou et al., 1954; Stokes et al., 1971). Two studies used nonrandom assignment to lithium or placebo (Goodwin et al., 1969; Stokes et al., 1971), and the diagnostic criteria used to define bipolar disorder in the early lithium studies (Goodwin et al., 1969; Maggs, 1963; Schou et al., 1954; Stokes et al., 1971) were not necessarily comparable to those of the *DSM-IV* (APA, 1987) or *DSM-5* (APA, 2013).

In the first placebo-controlled, crossover study, Schou and colleagues. (1954) reported a definite response in 12 (40%) and a probable response in 15 (50%) of 30 patients with typical bipolar disorder based on a global impression of improvement. In the first study to use formal rating scales and to analyze data statistically, 28 patients with mania were randomized to three consecutive 14-day periods of lithium-rest- placebo or placebo-rest-lithium (Maggs, 1963). Results were based only on the 18 study completers. In this group, lithium was superior to placebo during the second week of treatment.

In the first United States study, Goodwin and colleagues (1969) compared the longitudinal efficacy of lithium with placebo in 12 patients with mania; 8 (67%) displayed a complete response and 1 (8%) a partial response to lithium. Stokes and colleagues (1971) used a crossover design with alternating 7- to 10-day trial periods on lithium or placebo. These brief trial periods may have limited the opportunity for patients to display a more substantial lithium response, while the equally brief placebo period may have been confounded by residual lithium effects. With these caveats, Stokes and colleagues (1971) reported a 75% response rate (partial or full) with lithium, compared with 40% on placebo.

Two more recent studies used lithium as an active comparator in placebo-controlled, parallel-group trials of divalproex (Bowden et al., 1994) and quetiapine (Bowden et al., 2005). In both trials the mean improvement in lithium-treated patients at study endpoint was superior to placebo and comparable to the investigational agent. Response rates among active treatment groups were also comparable after 3 weeks (divalproex 48% lithium 49%, Bowden et al., 1994; quetiapine 53%, lithium 53%, Bowden et al., 2005). Significant differences in improvement in manic symptoms were evident in patients receiving lithium or divalproex compared with placebo at day 10 (Bowden et al., 1994), and in patients receiving lithium or quetiapine compared with placebo at day 7 (Bowden et al., 2005). Several post hoc analyses have attempted to identify predictors of acute lithium response. Clinical features associated with favorable lithium response include family history of lithium response (P. Grof et al., 2002), pure mania with minimal concurrent depressive symptoms (Swann et al., 1997), and relatively few lifetime mood episodes (Swann et al., 1999).

Lithium has been compared with first-generation (typical) antipsychotic agents (FGAs) in nine controlled trials in the treatment of acute bipolar mania (Garfinkel, Stancer, & Persad, 1980; Johnson, Gershon, Burdock, Floyd, & Hekiman, 1971; Johnson, Gershon, & Hekiman, 1968; Platman, 1970; Prien, Caffey, & Klett, 1972; Segal, Berk, & Brook, 1998; Shopsin, Gershon, Thompson, & Collins, 1975; Spring, Schweid, Gray, Steinberg, & Horwitz, 1970; Takahashi, Sakuma, Itoh, Itoh, & Kurihara, 1975). Interpretation of the results of some of these studies is difficult due to the inclusion of manic patients with schizoaffective disorder; the lack of standardized rating scales for mania; lack of use of last observation carried forward or comparable analyses; and the possibility of a type II error (failure to find a significant difference between treatments because of insufficient sample size; Johnson, Gershon, & Hekiman, 1968; Johnson et al., 1971; Platman, 1970; Segal et al., 1998; Shopsin et al., 1975). Two studies also titrated lithium to serum concentrations to the low end of the therapeutic range (Shopsin et al., 1975; Takahashi et al., 1975). Common side effects associated with lithium in these studies were nausea, vomiting, tremor, somnolence, weight gain, and cognitive slowing.

In summary, data from the controlled trials reviewed above indicate that lithium is superior in efficacy to placebo, with an onset of action within 7 to 10 days with gradual titration, and usually requires a 2- to 4-week trial at therapeutic levels to reach maximum effect. These data also suggest that lithium is superior to FGAs for amelioration of mood symptoms and exerts improvement in psychosis in tandem with improvement in the overall manic syndrome (Prien et al., 1972). On the other hand, FGAs had a more rapid onset of action and were more effective initially in agitated patients (Prien et al., 1972).

First-Generation (Typical) Antipsychotics

Prior to the introduction of lithium, antipsychotic medications were one of the few available classes of medications for the treatment of acute mania and as maintenance treatment for patients with bipolar disorder (Baldessarini, 1985). However, the emergence of lithium, valproate, carbamazepine, and second-generation antipsychotics (SGAs, atypicals) has limited the role of FGAs to the acute treatment of psychotic mania or psychotic depression in conjunction with thymoleptic agents. This is due in part to the neurological and neuroendocrinological side effects associated with FGAs as well as evidence that their use may increase the risk of postmanic depressive episodes, compared with SGAs. There is one double-blind, placebo-controlled trial of an FGA, chlorpromazine, in the treatment of bipolar mania (Klein, 1967). Not surprisingly, chlorpromazine (1,200 mg/day) was superior to imipramine (300 mg/day) or placebo in a 7-week trial involving only 13 patients rated globally for improvement. Most other studies examining FGAs in the treatment of acute mania have included these agents as active comparators in trials of lithium, valproate, carbamazepine, or SGAs reviewed elsewhere in this chapter.

Valproate

Valproate and its divalproex formulation have been shown to be effective in the treatment of acute mania in nine controlled trials (Bowden et al., 1994; Brennan, Sandyk, & Borsook, 1984; Emrich, Von Zerssen, & Kissling, 1981; Freeman, Clothier, Pazzaglaia, Lesem, & Swann, 1992; Hirschfeld, Allen, McEvoy, Keck, & Russell, 1999; Pope, McElroy, Keck, & Hudson, 1991; Post, Berretini, Uhde, & Kellner, 1984; Tohen et al., 2002a; Zajecka et al., 2002). These nine studies include comparisons of valproate with placebo in crossover trials (Brennan et al., 1984; Emrich et al., 1981; Post et al., 1984), with placebo in a parallel-group trial in treatment-refractory patients (Pope et al., 1991), with lithium in two parallel-group trials (Freeman et al., 1992; Hirschfeld et al., 1999), with placebo and lithium in a parallel-group trial (Bowden et al., 1994), and with olanzapine in two parallel-group trials (Tohen et al., 2002a; Zajecka et al., 2002).

In the most rigorous placebo-controlled trials, response rates to valproate ranged from 48% (Bowden et al., 1994) to 53% (Pope et al., 1991). The onset of antimanic response was evident by day 7 in each trial, despite gradual titration from baseline. Both lithium comparison trials were underpowered to detect a potential difference in efficacy between the two agents (Freeman et al., 1992; Hirschfeld et al., 1999). Nevertheless, Freeman and colleagues (1992) reported that patients with mixed mania were more likely to respond to valproate than to lithium. This observation is consistent with a post hoc analysis of findings from the study by Bowden and colleagues (1994) reported by Swann and colleagues (1997). Two randomized placebo-controlled trials examined the efficacy of the extended-release formulation of divalproex in patients with acute bipolar mania (Bowden et al., 2006; Hirschfeld et al., 2010). One study found significantly greater efficacy of this formulation in reduction in manic symptoms compared with placebo (Bowden et al., 2006); however, the second trial (Hirschfeld et al., 2010) did not, with possible limitations in this latter trial of high dropout rates (>80%) and lower-than-expected dosing.

Hirschfeld and colleagues (1999), and Hirschfeld, Baker, Wozniak, Tracy, and Sommerville (2003) specifically addressed the tolerability of divalproex oral loading (30 mg/kg per day for 2 days, then 20 mg/kg per day) and observed no significant differences in adverse events among patients randomized to divalproex loading, divalproex gradual titration, or lithium gradual titration. These findings confirmed earlier observations from open trials suggesting that divalproex oral loading was well tolerated (Keck, McElroy, Tugrul, & Bennett, 1993; McElroy, Keck, Tugrul, & Bennett, 1993; McElroy et al., 1996a).

Divalproex was compared with olanzapine in two head-to-head trials (Tohen et al., 2002a; Zajecka et al., 2002). Tohen and colleagues (2002a) found a significantly greater mean reduction in manic symptoms in patients treated with olanzapine compared with divalproex at 3 weeks. In contrast, Zajecka and colleagues (2002) did not find significant differences in efficacy between the two agents at 3 weeks. Both studies found overall better tolerability in patients receiving divalproex compared with olanzapine. These studies differed in the starting dose of each agent and in sample size. Tohen and colleagues (2002a) compared olanzapine 15 mg/day as a starting dose with divalproex gradual titration in a study adequately powered to yield significant differences in efficacy. Zajecka and colleagues (2002) compared divalproex loading with

olanzapine 10 mg/day as a starting dose in a study not adequately powered to yield potentially significant differences in efficacy. Taken together, the results of these two trials suggest that olanzapine may have a slight edge over divalproex in short-term efficacy in acute mania, but divalproex may have a slight edge in tolerability.

McElroy and colleagues (1996a) compared divalproex loading with haloperidol in an open randomized trial specifically in patients with psychotic mania. There were no significant differences in mean improvement in manic or psychotic symptoms between the two treatment groups. The improvement in psychosis observed with divalproex was consistent with findings in other studies (Bowden et al., 1994; Pope et al., 1991), and with improvement in manic psychosis with lithium in earlier studies.

Valproate has been studied as treatment adjunctive to FGAs in the treatment of acute bipolar mania (Muller-Oerlinghausen, Retzow, Henn, Giedke, & Walden, 1999). In this multicenter, double-blind, parallel-group, three-week trial, 136 patients receiving FGAs were randomized to valproate or placebo. By study endpoint, significantly more valproate-treated patients displayed a decrease in the need for concomitant antipsychotic medications. In summary, data from the controlled trials reviewed above indicate that valproate has a broad spectrum of efficacy in acute manic and mixed episodes, with or without psychosis, and appears to be comparable to lithium in overall antimanic efficacy.

Lastly, McElroy and colleagues (2010a) reported superior efficacy of divalproex extended-release loading monotherapy compared with placebo among outpatients with bipolar spectrum disorder displaying moderate to severe hypomania or mild mania.

Valproate-associated side effects in these studies include somnolence, nausea, vomiting, tremor, weight gain, and cognitive slowing. Rare serious side effects include hepatic transaminase elevations, hepatic failure, pancreatitis, thrombocytopenia, polycystic ovarian syndrome, and hyperammonemic encephalopathy in patients with urea cycle disorders.

Carbamazepine

Although a number of double-blind controlled trials provided preliminary evidence of carbamazepine's efficacy in the treatment of acute mania (Keck, McElroy, & Nemeroff, 1992), these findings were substantiated only several years later by large, multicenter, randomized, placebo-controlled, parallel-group trials (Weisler et al., 2004, 2005). In the first such trial, Weisler and colleagues (2004) randomized 204 inpatients hospitalized for a manic or mixed episode to an extended-release formulation of carbamazepine or placebo over 3 weeks. The carbamazepine-treated patients displayed significantly greater mean improvement in manic symptoms compared with patients receiving placebo by day 14. In addition, significantly more patients in the carbamazepine group were responders (42%) compared with the placebo group (22%). In a subgroup analysis, there was no significant difference in mean reduction of manic symptoms in patients with mixed episodes who received carbamazepine compared with placebo, due in part to a high placebo response in this subgroup.

Weisler and colleagues (2005) conducted a second, similar trial in which 239 bipolar inpatients with manic or mixed episodes were randomized to extended-release carbamazepine or placebo for up to 3 weeks. In this trial, patients in the carbamazepine group displayed a significantly greater mean reduction in manic symptoms compared with patients receiving placebo beginning at the time of the first rating following baseline, corresponding to day 7. At study end point, 61% of patients receiving carbamazepine were responders compared with 29% receiving placebo (last observation carried forward, day 21).

Unlike the first trial (Weisler et al., 2004), response rates were significantly greater in both manic and mixed patients receiving carbamazepine compared with placebo. Aside from the subgroup analyses in these two trials, there are no consistent data regarding clinical predictors of acute response to carbamazepine.

Carbamazepine has been compared with lithium (Lerer, Moore, Meyendorff, Cho, & Gershon, 1987, Small, 1990) and chlorpromazine (Grossi, Sacchetti, & Vita, 1984; Okuma et al., 1979) in head-to-head trials. These studies, although individually limited by sample sizes likely too small to detect significant differences in efficacy, nevertheless found generally comparable antimanic activity among patients receiving carbamazepine, lithium, or chlorpromazine.

Somnolence, fatigue, diplopia, blurred vision, and ataxia were commonly reported side effects of carbamazepine. Rare serious side effects include agranulocytosis, aplastic anemia, thrombocytopenia,

pancreatitis, hepatic failure, and Stevens-Johnson syndrome and toxic epidermal necrolysis. These latter systemic cutaneous reactions appear to be more common among individuals with the HLA-B*1502 allele, which, in turn, is prevalent among Asian and South Asian Indians (Hung et al., 2006). The FDA now recommends testing for the presence of this allele in these higher-risk ethnic groups.

Risperidone and Paliperidone

The efficacy of risperidone in the treatment of acute bipolar manic and mixed episodes has been established as monotherapy in two randomized, placebo-controlled trials (Hirschfeld et al., 2004; Khanna et al., 2005); as adjunctive therapy with lithium or divalproex in one placebo-controlled trial (Sachs, Grossman, Ghaemi, Okamato, & Bowden, 2002) and one open-label trial (Vieta et al., 2002a); and in comparison trials with olanzapine, haloperidol, and lithium (Brown, Ahmed, & Schuh, 2004; Segal et al., 1998; Smulevich et al., 2005). Risperidone was not superior to placebo in combination with lithium, carbamazepine, or divalproex in one trial (Yatham, Grossman, Augustyns, Vieta, & Ravindran, 2003). However, since this study included patients receiving carbamazepine, it is possible that there may have been significant reductions in plasma risperidone concentrations in these patients, undermining risperidone's efficacy. Hirschfeld and colleagues (2004) observed a significant mean reduction in manic symptoms by day 3 of the 3-week trial. In addition, risperidone exerted comparable efficacy in patients with manic and mixed episodes and with or without psychotic symptoms. Risperidone treatment was associated with low rates of extrapyramidal side effects when administered at average doses of less than 4 mg/day (Hirschfeld et al, 2004; Sachs et al., 2002; Yatham et al., 2003) but not when administered at average doses of 6 mg/day (Khanna et al., 2005; Segal et al., 1998).

Two placebo-controlled trials of paliperidone (9-hydroxyrisperidone), an active metabolite of risperidone, in acute bipolar mania yielded mixed findings (Berwaerts et al., 2012; Vieta et al., 2010a). Vieta and colleagues (2010a) found significantly higher remission rates among manic and mixed patients receiving paliperidone flexibly dosed 3 to 12 mg/day (52%) compared with placebo (29%). However, Berwaerts and colleagues (2012) found no differences in remission rates among patients randomized to receive placebo (37%) or paliperidone at fixed doses of 3 mg/day (37%), 6 mg/day (42%) or 12 mg/day (45%). It is possible that the multiple arms of this fixed-dose trial contributed to higher-than-expected placebo response rate. Berwaerts and colleagues (2011) compared paliperidone with placebo as an adjunctive treatment to lithium or valproate in patients with an inadequate response to these latter agents as monotherapy, but there was no significant difference in outcome measures between the paliperidone and placebo groups.

Common side effects from risperidone and paliperidone include akathisia, extrapyramidal signs, somnolence, appetite increase, weight gain, nausea, and prolactin elevation.

Olanzapine

In monotherapy trials, olanzapine was superior to placebo (Tohen et al., 1999, 2003) and divalproex (Tohen et al., 2002a), and comparable to lithium (Berk, Ichim, & Brook, 1999), divalproex (Zajecka et al., 2002), haloperidol (Tohen et al., 2003a), and risperidone (Brown et al., 2004) in mean improvement in manic symptoms in randomized controlled trials ranging from 3 to 6 weeks. Olanzapine-treated patients displayed significantly greater improvement in manic symptoms compared with patients receiving placebo by day 7 in one trial (Tohen et al., 2000), and day 21 in another (Tohen et al., 1999). The addition of olanzapine was also superior to placebo in patients who had partially responded to lithium or divalproex monotherapy for at least 2 weeks (Tohen et al., 2002b). There were no significant differences among patients with manic or mixed, rapid or nonrapid cycling or psychotic or nonpsychotic symptoms in studies in which sample sizes allowed post hoc comparisons (Baldessarini, Tondo, & Hennen, 2003). Initial starting doses of 15 mg/day appeared to exert more rapid antimanic efficacy compared with 10 mg/day (Tohen et al., 1999, 2000). In addition, one study found significant improvement in agitation within 1 day in patients receiving olanzapine alone in doses of 20 to 40 mg/day compared with 10 mg/day augmented by benzodiazepine use (Baker, Kinon, Maguire, Liu, & Hill, 2003). These results are consistent with a study of the intramuscular formulation of olanzapine, in which patients receiving olanzapine 10 mg given

intramuscularly displayed significant reductions in manic agitation within 2 hours of administration compared with patients receiving intramuscular placebo (Meehan et al., 2001).

Olanzapine-associated side effects in clinical trials were somnolence, constipation, appetite increase, weight gain, metabolic syndrome, headache, dry mouth, and dizziness.

Quetiapine

Quetiapine was superior to placebo in two monotherapy 12-week trials (Bowden et al., 2005; McIntyre, Brecher, Paulsson, Huizar, & Mullen, 2005) and in three studies in combination with lithium or divalproex (DelBello, Schwiers, & Rosenberg, 2002; Sachs et al., 2004; Yatham et al., 2004), and comparable to divalproex in one head-to-head comparison in adolescents (DelBello et al., 2006). The two placebo-controlled monotherapy trials also included active comparators of lithium (Bowden et al., 2005) or haloperidol (McIntyre et al., 2005). In these trials, there was no significant difference in efficacy between patients receiving quetiapine and either lithium or haloperidol, although the studies were not powered to detect such a difference if one existed. Significant differences in efficacy in favor of quetiapine over placebo were evident by day 4 in the two monotherapy trials, and patients receiving quetiapine displayed cumulative improvement in manic symptoms at 3 and 12 weeks (Vieta, Mullen, Brecher, Paulsson, & Jones, 2005b). The mean modal dose of quetiapine associated with antimanic efficacy in most studies was approximately 600 mg/day (Vieta et al., 2005b). Many of these trials excluded patients with mixed episodes (Bowden et al., 2005; McIntyre et al., 2005; Sachs et al., 2004; Yatham et al., 2004), so a comparative analysis of response between manic and mixed patients could not be conducted. There were no significant differences in response rates to quetiapine in patients with or without psychotic symptoms (Vieta et al., 2005b).

The emergence of hypomanic or mild manic symptoms in patients with bipolar I disorder or with other bipolar spectrum disorders presents a common clinical challenge but until recently had not been systemically studied in a controlled treatment trial. In an 8-week study among outpatients with bipolar spectrum moderate to severe hypomania or mild mania, quetiapine monotherapy (mean dose 232 mg/day) was marginally superior to placebo ($p = 0.06$) in reduction of Young Mania Rating Scale (YMRS) scores and significantly better than placebo in measures of overall global improvement and global improvement in manic symptoms (McElroy et al., 2010b). In a similar trial, the anxiolytic effects of extended-release quetiapine (50 to 300 mg/day) were compared with extended-release divalproex (500 to 3000 mg/day) and placebo in an 8-week, double-blind trial of outpatients with bipolar disorder and co-occurring generalized anxiety or panic disorder (Sheehan et al., 2013). The extended-release quetiapine (mean dose 186 mg/day) displayed significantly greater improvement in a measure of anxiety compared with the extended-release divalproex and placebo groups.

Side effects associated with quetiapine in acute bipolar mania trials included somnolence, constipation, weight gain, metabolic syndrome, headache, dry mouth, and dizziness.

Ziprasidone

In two 3-week, placebo-controlled, monotherapy trials, ziprasidone (mean dose 120 to 130 mg/day) produced significant reductions in manic symptoms by day 2 of treatment (Keck et al., 2003c; Potkin, Keck, Segal, Ice, & English, 2005). Ziprasidone-treated patients also had significantly higher response rates compared with patients receiving placebo. Vieta and colleagues (2010b) conducted a 12-week, haloperidol- and placebo-controlled trial (with efficacy assessment at week 3 and a 9-week extension active treatment comparison phase). Both ziprasidone and haloperidol groups had significantly greater improvement in manic symptoms, with greater efficacy for haloperidol, compared with placebo. In the 9-week extension, responses were maintained comparably for patients continuing to receive haloperidol (mean dose 16 mg/day) or ziprasidone (mean dose 121 mg/day), with better tolerability and lower discontinuation rates associated with ziprasidone. Ziprasidone was equally effective in patients with manic and mixed episodes and with and without psychotic symptoms.

Ziprasidone was not superior to placebo as an adjunctive treatment with lithium in a study designed to prove superior onset of action by day 14 (Weisler, Dunn, & English, 2003). However, patients receiving ziprasidone in combination with lithium had

significantly greater improvement in manic symptoms by day 4 compared with patients receiving placebo in combination with lithium. A second placebo-controlled, adjunctive trial to lithium and divalproex, designed to assess efficacy from baseline to week 3 of treatment, also found no significant difference in efficacy between the two study groups (Sachs et al., 2012a). However, enrollment of a substantial proportion of patients who did not meet eligibility criteria may have contributed to the negative findings in this study (Sachs et al., 2012b).

Common side effects associated with ziprasidone in studies of its efficacy and safety in acute bipolar mania were dizziness, akathisia, extrapyramidal signs, somnolence, and headache.

Aripiprazole

Aripiprazole was superior to placebo in three 3-week randomized controlled trials in patients with manic and mixed episodes (Kanba et al., 2012; Keck et al., 2003a) and comparable in efficacy to haloperidol in two twelve-week, adequately powered comparison trials (Vieta et al., 2005a; Young et al., 2009), one of which (Young et al., 2009) included a placebo arm wherein both active agents were comparably superior. In a fixed-dose, three-arm, aripiprazole, placebo-controlled trial there was no significant difference in efficacy between the aripiprazole and placebo groups (El Mallakh et al., 2010). In the three positive trials, initial target doses ranged from 24 to 30 mg/day with good tolerability, and patients displayed significantly greater improvement in manic symptoms compared with placebo by day 4 of both trials. The aripiprazole groups also had significantly higher response rates compared with the placebo groups. The mean dose of aripiprazole in the haloperidol comparison was 23 mg/day. There were no significant differences in response to aripiprazole among patients with manic and mixed episodes, and with or without psychotic symptoms. Adjunctive aripiprazole was superior to placebo in reduction of manic symptoms from week 1 on in a 6-week trial in patients with bipolar mania who had an inadequate response to lithium or valproate monotherapy at therapeutic concentrations (Vieta et al., 2008b).

Common aripiprazole side effects in these short-term trials were headache, nausea, vomiting, constipation, insomnia, and akathisia.

Asenapine

In two 3-week, double-blind, placebo-controlled trials of asenapine (mean dose 18 mg/day) in the treatment of acute manic or mixed episodes, each with an olanzapine noninferiority comparison arm, patients receiving asenapine displayed significantly greater improvement in manic symptoms as measured by the YMRS compared with the placebo group, with differences evident by day 2 (McIntyre et al., 2009a, 2010). Patients with manic and mixed symptoms had comparable improvement with asenapine. However, there were no significant differences between the asenapine and placebo groups in response or remission rates in these two studies, and olanzapine efficacy was superior to asenapine. In a 12-week, placebo-controlled, adjunctive treatment trial, adding asenapine to lithium or valproate was superior to placebo addition (Szegedi et al., 2012).

Asenapine-associated side effects reported in these trials included somnolence, insomnia, extrapyramidal signs, headache, akathisia, dizziness, weight gain, and triglyceride elevation.

Other Agents

Cariprazine (mean dose 7.4 mg/day; modal dose 12 mg/day), a dopamine D_2/D_3 partial agonist, was superior to placebo in three, 3-week, placebo-controlled trials in patients with bipolar manic and mixed episodes in reduction of manic symptoms as measured by the YMRS, and in response rates (Keck et al., 2013). Cariprazine side effects reported were headache, nausea, vomiting, constipation, insomnia, and akathisia. At press, this agent is not yet approved for this indication by the FDA. The protein kinase C (PKC) inhibitor, tamoxifen, approved for the treatment of breast cancer, has been reported to exert significant antimanic efficacy in two pilot monotherapy trials (Yildiz et al., 2008; Zarate et al., 2007) and one adjunctive therapy trial in patients receiving lithium (Amrollahi et al., 2010). These intriguing results indicate the need for a large, definitive trial, addressing in particular optimal dosing and duration of treatment. Similarly intriguing preliminary findings have been reported for adjunctive allopurinol, a xanthine oxidase inhibitor approved for the treatment of gout, compared with placebo in the treatment of acute mania (Akhondzadeh et al., 2006; Machado-Vieira et al., 2008). In an 8-week, placebo-controlled trial, allopurinol was superior to placebo added to lithium and haloperidol in 82 patients

hospitalized for acute mania (Akhondzadeh et al., 2006). In the second study, adjunctive allopurinol was superior to placebo in a trial that also included a dipyramidole arm, each added to lithium over 4 weeks (Machado-Vieira et al., 2008).

N-acetyl cysteine (NAC), a glutamate modifying drug that is available both by prescription and over the counter, was compared with placebo in a small ($N = 15$) pilot, 24-week, placebo-controlled trial in patients with manic symptoms (Vieira et al., 2013). The NAC group demonstrated an improvement in manic symptoms with worsening of depressive symptoms in the placebo group.

In randomized controlled trials in patients with acute bipolar mania, several agents have failed to demonstrate significant antimanic activity to date. These agents include gabapentin (Frye et al., 2000; Pande, Crockatt, Janney, Werth, & Tsaroucha, 2000), topiramate (McElroy & Keck, 2004a), and verapamil (Janicak, Sharma, Pandey, & Davis, 1998; Walton, Berk, & Brook, 1996). In addition, several agents—lamotrigine (Anand, Oren, & Berman, 1999; Frye et al., 2000; Ichim, Berk, & Brook, 2000), oxcarbazepine (Emrich, Dose, & VonZerssen, 1985; Muller & Stoll, 1984; Wagner et al., 2006), tiagabine (Grunze et al., 1999; Suppes et al., 2002), and levetiracetam (Bersani 2004; Braunig & Kruger, 2003; Grunze, Langosch, Born, Schaub, & Walden, 2003; Post et al., 2005)—have been studied in randomized controlled trials that have yielded mixed or insufficient evidence of antimanic efficacy thus far.

Akhondzadeh, Mohajari, Reza, and Amini (2003) conducted a randomized, placebo-controlled trial of the 5-HT_2 antagonist ritanserin as adjunctive treatment with lithium and haloperidol in 45 treatment-naïve patients with acute bipolar mania. Patients receiving adjunctive ritanserin had significantly better improvement in manic symptoms and had lower rates of extrapyramidal side effects compared with patients receiving adjunctive placebo. These intriguing findings require replication.

PSYCHOPHARMACOLOGICAL TREATMENTS FOR ACUTE BIPOLAR DEPRESSION

Lithium and Antidepressants

After years of being understudied, the pharmacological treatment of bipolar depression received renewed attention in a number of recent type 1 randomized controlled trials (Keck, McElroy, & Nelson, 2003b). The majority of controlled trials to date have assessed the efficacy of lithium in comparison to placebo or tricyclic antidepressants (Baron, Gershon, Rudy, Jonas, & Buchshaum, 1975; Donnelly, Goodwin, Waldman, & Murphy, 1978; Fieve, Platman, & Plutchnik, 1968; Goodwin et al., 1969; Goodwin, Murphy, Dunner, & Bunney, 1972; Greenspan, Schildkraut, Gordon, Levy, & Durrell, 1979; Keck, Welge, Strakowski, Arnold, & McElroy, 2000b; Mendels, 1976; Nemeroff et al., 2001; Noyes, Dempsey, Blum, & Cavenaugh, 1974; Stokes et al., 1971). All but one (Nemeroff et al., 2001) of these placebo-controlled trials used crossover designs with short time intervals, ranging from 1 to 28 days of lithium or placebo exposure. These short intervals limit the interpretation of the study results because of the potential confounding effects of lingering lithium activity during the placebo period and because optimal lithium response may have required a longer trial (Zornberg & Pope, 1993). Abrupt discontinuation of lithium may have contributed to a more rapid rate of episode recurrence than that attributable to the natural course of the illness (Suppes, Baldessarini, Faedda, & Tohen, 1991). Moreover, these studies did not exclusively enroll patients with bipolar depression, and they did not report switch rates into hypomania, mania, or mixed states. Primary outcome measures were also often not specified at the outset of these trials (Muzina & Calabrese, 2003). With these limitations in mind, pooled results from five crossover studies that provided sufficient data to assess degree of response revealed that 29 (36%) of 80 patients with acute bipolar depression displayed an unequivocal response to lithium; 63 (79%) patients had at least partial improvement (Zornberg & Pope, 1993).

Two controlled studies assessed the efficacy of lithium against tricyclic antidepressant monotherapy (Donnelly et al., 1978; Watanabe, Ishino, & Otsuki, 1975). Neither trial found significant differences in efficacy between patients receiving lithium or imipramine. A number of other controlled studies examined the efficacy of tricyclics in comparison to other classes of antidepressant agents (Altshuler et al., 1995; Ashberg-Wistedt, 1982; Baumhackl et al., 1989; Cohn, Collins, Ashbrook, & Wernicke, 1980; Himmelhoch, Thase, Mallinger, & Houck, 1991; Kessel & Holt, 1975; Levine et al., 1995; Nemeroff et al., 2001; Sachs et al., 1994; Silverstone, 2001).

The most recent trial comparing imipramine, paroxetine, or placebo added to lithium for breakthrough bipolar depressive episodes did not find a significant difference in acute efficacy among the three groups (Nemeroff et al., 2001). A post hoc analysis revealed that patients with lithium levels of less than 0.8 mEq/L displayed significantly greater improvement in depressive symptoms when randomized to paroxetine compared with placebo. However, in patients with lithium levels greater than 0.8 mEq/L, there were no significant differences in mean reduction of depressive symptoms. Two previous controlled trials comparing serotonin reuptake inhibitor (SRI) antidepressants with tricyclics had significant methodological limitations (Ashberg-Wistedt, 1982; Cohn et al., 1980). In the first study, a double-blind, randomized comparison of fluoxetine and imipramine with placebo, only 64 (72%) of 89 patients remained in the trial after 3 weeks, and only 44 (49%) completed the 6-week study because of side effects or lack of efficacy (Cohn et al., 1980). Furthermore, 7 (16%) subjects completing the study received lithium, but the remainder did not. If treatment dropouts were counted as treatment failures, the response rates in this study were not significantly different for fluoxetine (60%) and imipramine (40%). Both were superior to placebo. The second SRI comparison trial involved only 4 patients in a 4-week crossover trial of zimelidine and desipramine, with no conclusive findings due to the small sample size (Ashberg-Wistedt, 1982).

Two studies compared tricyclic antidepressants with reversible MAOIs (Baumhackl et al., 1989; Silverstone, 2001) and one with an irreversible MAOI (Himmelhoch et al., 1991). In the most methodologically rigorous of these studies, tranylcypromine had significantly greater efficacy than imipramine in 56 patients (bipolar I, $N = 24$; bipolar II, $N = 32$) treated for 4 weeks without lithium or another mood stabilizer (Himmelhoch et al., 1991). Of 26 tranylcypromine-treated patients, 21 (81%) displayed a significant antidepressant response compared with 10 (48%) of 21 imipramine-treated patients. Response rates did not differ between bipolar I and bipolar II patients. Silverstone (2001) compared the reversible MAO-A inhibitor moclobemide with imipramine, either as monotherapy or added to ongoing mood stabilizers, in an 8-week trial of 156 patients (75% outpatients) with bipolar I depression. In the moclobemide group, 46% of patients were receiving lithium (two in combination with carbamazepine). In the imipramine group, 49% were receiving lithium (five in combination with carbamazepine and one with valproate). Both treatment groups had significant mean reductions in depressive symptoms from baseline, but without a significant difference in efficacy between groups. More patients switched into mania in the imipramine group (11%) than in the moclobemide group (4%), and they switched earlier in treatment, although these differences were not significant. The authors did not report whether switches occurred less commonly among patients receiving mood stabilizers. Baumhackl and colleagues (1989), in an earlier, smaller ($N = 32$), 4-week, monotherapy comparison trial between moclobemide and imipramine, similarly failed to find a significant difference in efficacy between the two agents.

A number of other small pilot trials of antidepressants, usually in combination with mood stabilizers, have been conducted in patients with bipolar depression. Young and colleagues (2000) compared the efficacy of adjunctive paroxetine with a second mood stabilizer (lithium or divalproex) in a 6-week trial in 27 outpatients with breakthrough bipolar depressive episodes (type I, $N = 11$; type II, $N = 16$) despite treatment with therapeutic doses of lithium or divalproex for at least 3 months. In the combination mood stabilizer group, patients receiving lithium were randomized to divalproex and vice versa. Both adjunctive treatment groups displayed significant reductions in depressive symptoms, but without significant differences in efficacy between groups. Because of the small sample size and the limited duration of the trial, no conclusions could be reached about the relative efficacy of the different strategies.

Kessel and Holt (1975) compared maprotiline and imipramine in 14 patients for 6 weeks, with no significant differences in response rates. Sachs and colleagues (1994) compared desipramine with bupropion in 19 patients with bipolar I depression and found that although both agents produced comparable response rates, patients treated with desipramine (50%) were significantly more likely to switch into hypomania or mania than patients receiving bupropion (10%).

Two preliminary placebo-controlled, randomized adjunctive trials assessed the efficacy and safety of the dopamine D_2/D_3 receptor agonist pramipexole in the treatment of bipolar I and bipolar II depressed patients (Goldberg, Burdick, & Endick, 2004; Zarate et al., 2004b). Goldberg and colleagues (2004) randomized 22 patients (bipolar I, $N = 15$; bipolar II,

N = 7) to pramipexole (mean maximum dose, 1.7 mg/day) or placebo added to existing mood stabilizers for 6 weeks. Eight (67%) patients receiving pramipexole and two (20%) patients receiving placebo had more than a 50% reduction in depressive symptoms at study endpoint. Pramipexole-treated patients also had greater improvement in mean percentage reduction of depressive symptoms from baseline compared with patients receiving placebo. One patient in the pramipexole group experienced hypomanic symptoms, compared with none in the placebo group. Zarate and colleagues (2004b) conducted a 6-week trial of similar design except that only patients with bipolar II disorder were included (N = 21). The response rate (greater than 50% improvement in depressive symptoms from baseline) was significantly higher in the pramipexole group (60%) compared with the placebo group (9%). One patient on pramipexole and two on placebo experienced hypomanic symptoms. These intriguing findings suggest that pramipexole may have efficacy as an adjunctive treatment for bipolar depression and are consistent with open-label reports in patients with bipolar (Perugi, Ruffolo, Frare, & Toni, et al., 2001; Sporn, Ghaemi, Sambur, & Rankin, 2000) and unipolar depression (Lattanzi et al., 2002; Sporn et al., 2000).

Antidepressant-induced mood switching or cycle acceleration is an important risk of antidepressant treatment in patients with bipolar depression. Reported switch rates among patients with bipolar depression treated with antidepressants have ranged widely, from 4% to 70% (Sachs, Koslow, & Ghaemi, 2000). These disparate estimates reflect differences in data collected from naturalistic compared with controlled trials, whether or not patients were receiving concomitant mood stabilizers, the duration of study, and the specific type of antidepressant and mood stabilizer combinations. A number of studies have attempted to clarify the switch rates and the degree to which mood stabilizers reduce this risk in patients with bipolar depression. Bottlender and colleagues (2001) reviewed the medical records of 158 patients with bipolar I depression to determine the incidence of mania and hypomania in relation to treatment. The overall switch rate was 25%. Among those patients who experienced a mood switch, 80% were receiving tricyclic antidepressants, a significantly higher proportion than those not switching who were not receiving tricyclics (51%). Overall switch rates were 34% for patients receiving tricyclic agents, 12% for those receiving SRIs, 8% for MAOIs, and 14% for other agents. The protective effect of a mood stabilizer was most apparent for patients receiving tricyclics, in whom twice as many switched when not receiving a concomitant mood stabilizer. These findings are consistent with earlier studies suggesting that co-administration of lithium reduced the risk of antidepressant-associated switching by approximately 50% (Boerlin, Gitlin, Zoellner, & Hammen, 1998; Henry, Sorbara, Lacoste, Gindre, & Leboyer, 2001; Prien et al., 1984; Rouillon, Lejoyeaux, & Filteau, 1992).

Post and colleagues (Post et al., 2001, 2004) analyzed switch data from the Stanley Foundation Bipolar Network trial comparing adjunctive sertraline, bupropion, or venlafaxine with mood stabilizers in patients with bipolar depression. Thirteen (14%) of 95 patients experienced a mood switch during the 10-week acute treatment trial: 7% into hypomania and 7% into mania. During the subsequent maintenance trial up to 1 year, 33% switched: 20% into hypomania and 13% into mania (Post et al., 2001). The switch rate with venlafaxine was slightly but significantly higher than with the other two agents (Post et al., 2004). This finding is consistent with an earlier report by Vieta and colleagues (2002b), who also found a higher switch rate in patients receiving adjunctive venlafaxine compared with paroxetine in an open-label comparison trial. Because of the lack of placebo control groups in these studies, it is difficult to compare these rates with those associated with spontaneous rates from the illness, but the switch rates into mania were lower than anticipated.

In a meta-analysis of the rate of treatment-emergent switch into mania, with data derived from clinical trials comparing SRIs (fluoxetine, fluvoxamine, paroxetine, and sertraline), tricyclics, or placebo in 415 patients with bipolar depression, Peet (1994) reported that manic switch occurred significantly more commonly with tricyclics (11%) than with SRIs (4%) or placebo (4%). Data from the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) revealed that among 338 patients with bipolar disorder and with prior antidepressant treatment, 44% reported at least one switch into mania or hypomania associated with antidepressant treatment (Truman et al., 2007). Predictors of increased switch risk were a shorter duration of illness and a history of multiple antidepressant trials. Among classes of antidepressants, switch was least common with treatment with electroconvulsive therapy or MAOIs. Tricyclics

were associated with the highest risk, with intermediate risk from treatment with SSRIs or bupropion. These findings are limited by the retrospective, self-report nature of data collection. However, in prospectively gathered data, combination treatment with a mood stabilizer and an antidepressant was not superior to treatment with a mood stabilizer alone for patients with bipolar depression (Goldberg et al., 2007). Moreover, adjunctive antidepressant use was associated with significantly higher mania symptom severity at the 3-month follow-up assessment.

Quetiapine

Calabrese and colleagues (2005) examined the efficacy of quetiapine 300 mg/day, 600 mg/day, or placebo in an 8-week trial involving 542 outpatients with bipolar I (N = 360) or bipolar II (N = 182) depression. Both quetiapine groups had significantly greater improvement in depressive symptoms compared with the placebo group from week 1 onward. Responder rates (proportion of patients with greater than 50% improvement in depressive symptoms from baseline to endpoint) were also significantly higher in the quetiapine 300 mg/day (58%) and 600 mg/day (58%) groups compared with placebo (36%). Treatment-emergent mania rates were similar for the quetiapine (3%) and placebo (4%) groups. Patients with bipolar I depression had greater improvement with quetiapine compared with bipolar II patients. There were no significant differences in efficacy between the two quetiapine dosage groups, but the 300 mg/day group had better overall tolerability. Thase and colleagues (2006) replicated these findings in a nearly identically designed trial.

Two other pivotal double-blind, placebo-controlled, 8-week studies examined the efficacy and safety of quetiapine for patients with acute bipolar (I and II) depression (McElroy et al., 2010c; Young et al., 2010). The first trial compared quetiapine at 300 mg/day and 600 mg/day with lithium 600 to 1800 mg/day and placebo (Young et al., 2010). Patients in both quetiapine groups displayed significantly greater improvement in depressive symptoms, as well as overall improvement and reductions in anxiety symptoms compared with lithium and placebo. The second trial examined the same two doses but included a group receiving paroxetine 20 mg/day as well as a placebo group (McElroy et al., 2010c). Both quetiapine groups again had significantly greater improvement in depressive symptoms compared with paroxetine and placebo. The most common adverse events associated with quetiapine were somnolence, dry mouth, and dizziness. These results are consistent with the results seen in trials of quetiapine as monotherapy or adjunctive therapy in major depressive disorder (McIntyre et al., 2009b).

Olanzapine and Olanzapine–Fluoxetine Combination

Three controlled trials examined the efficacy of combination olanzapine and fluoxetine (Amsterdam & Shults, 2005; Brown et al., 2006; Tohen et al., 2003c). Tohen and colleagues (2003c) compared olanzapine (mean dose 9 mg/day), the combination of olanzapine (mean dose 7 mg/day) and fluoxetine (mean dose 38 mg/day), and placebo in an 8-week trial in 833 patients with bipolar I depression. Both active treatment groups displayed significantly greater improvement in depressive symptoms than the placebo group, beginning at week 1. In addition, the olanzapine–fluoxetine group displayed significantly greater improvement in depressive symptoms compared with the olanzapine group at weeks 4, 6, and 8. There were no significant differences in switch rates: olanzapine 6%, olanzapine–fluoxetine 6%, placebo 7%. The response to olanzapine–fluoxetine in this study was also consistent with the antidepressant response reported by Shelton and colleagues (2001) for patients with treatment-refractory nonpsychotic major depressive disorder.

Amsterdam and Shults (2005) compared switch rates among patients with bipolar I (N = 32) and bipolar II (N = 2) depression randomized to fluoxetine (10 to 30 mg/day), olanzapine (5 to 20 mg/day), or olanzapine (5 to 15 mg/day) and fluoxetine (10 to 40 mg/day) combination for up to 8 weeks. They found comparable efficacy and induction of mania among all three treatment groups. These investigators also reported low switch rates in open-label monotherapy trials of venlafaxine (Amsterdam & Garcia-Espana, 2000) and fluoxetine (Amsterdam, Shults, Brunswick, & Hundert, 2004) in depressed patients with bipolar II and bipolar disorder not otherwise specified. Brown and colleagues (2006) conducted a 7-week, head-to-head comparison of olanzapine–fluoxetine with lamotrigine (titrated to 200 mg/day) in 205 depressed patients with bipolar I disorder. Patients receiving

olanzapine–fluoxetine had significantly greater improvement than lamotrigine-treated patients across the 7-week treatment period. The lamotrigine group may have had a greater response with a longer trial, given the need for gradual lamotrigine titration. There were no significant differences in switch rates between the olanzapine–fluoxetine (4%) and lamotrigine (5%) groups.

Tohen and colleagues (2012) examined the efficacy of olanzapine monotherapy (5 to 20 mg/day) compared with placebo in a 6-week randomized trial of patients with acute bipolar I depression. Patients receiving olanzapine had significantly greater improvement in depressive symptoms, overall improvement, and response and remission rates compared with the placebo group.

Lurasidone

Lurasidone has been examined in one monotherapy (Loebel et al., 2012a) and one adjunctive therapy (Loebel et al., 2012b) trial, each compared with placebo over six weeks in patients with bipolar I depression. In the monotherapy trial (Loebel et al., 2012a), two dose ranges (20 to 60 mg/day: mean modal dose 35 mg/day; 80 to 120 mg/day; mean modal dose, 91 mg/day) of lurasidone were compared with placebo. Lurasidone-treated patients in both study arms displayed significantly greater improvement in depressive and anxiety symptoms, measures of disability and quality of life, and response and remission rates compared with the placebo group. Side effects of nausea, akathisia, insomnia, somnolence, sedation, and dizziness occurred slightly more frequently in the higher-dosage-range group. In the adjunctive therapy trial (Loebel et al., 2012b), lurasidone (20 to 120 mg/day; mean dose, 66 mg/day) or placebo was added to lithium or valproate, each of which had been first maintained at therapeutic levels for at least 28 days without an adequate antidepressant response. The lurasidone group had significantly greater improvement in depressive and anxiety symptoms, measures of disability and quality of life, and response and remission rates. There were no significant differences in switch rates among the treatment groups in either trial.

Other Second-Generation Antipsychotics

Shelton and Stahl (2004) randomized 30 patients with bipolar I ($N = 21$) or bipolar II ($N = 9$) depression despite treatment with a stable and therapeutic dose of a mood stabilizer to adjunctive treatment with paroxetine, risperidone, or the combination over 12 weeks. All three groups displayed significant reductions in depressive symptoms from baseline to endpoint without significant differences among groups. One patient in the paroxetine group developed hypomanic symptoms during the trial. The results of this trial are limited by the small sample size, heterogeneity in mood stabilizer treatment, and significant difference in mean maximum paroxetine dose between the paroxetine group (35 mg/day) and the paroxetine–risperidone group (22 mg/day). The lower paroxetine dose in the combination group may have been due to inhibition of paroxetine metabolism by risperidone.

Two randomized, placebo-controlled, 8-week studies of aripiprazole monotherapy (10 mg/day, then flexibly dosed at 5 to 30 mg/day) for patients with bipolar I depression did not find greater efficacy of aripiprazole compared with placebo at study endpoint (Thase et al., 2008), despite significant differences in efficacy in favor of aripiprazole during weeks 1 to 6. Aripiprazole was associated with greater rates of akathisia, insomnia, nausea, fatigue, restlessness, and dry mouth. A small ($N = 23$) 6-week, adjunctive trial of aripiprazole compared with placebo in patients receiving lithium or valproate for at least one week and also openly treated with citalopram for 6 weeks (begun during the double-blind phase of the trial) found no difference in efficacy between the two groups (Quante et al. 2010). This results of this study are limited by the small sample size and potential confounding effects of citalopram.

Adjunctive ziprasidone (20 to 80 mg/day) did not separate from placebo in a 6-week randomized controlled trial, each added to patients receiving therapeutic doses of lithium, lamotrigine or valproate (Sachs et al., 2011). Possible methodological limitations identified post hoc included the enrollment of a substantial number of subjects with low diagnostic confidence, low quality of depressive symptom ratings, and by what the study authors described as "overzealous reporting of symptoms" by study subjects. These same methodological limitations may have affected the results of another, negative study in which ziprasidone adjunctive therapy did not separate from placebo in patients with bipolar I depression (Lombardo et al., 2012).

Lamotrigine

Two published randomized, placebo-controlled trials examined the efficacy of lamotrigine in the treatment of acute bipolar depression (Calabrese et al., 1999; Frye et al., 2000). Calabrese and colleagues (1999) randomized 195 patients with bipolar I depression to lamotrigine monotherapy 50 mg/day, 200 mg/day, or placebo. Both lamotrigine doses were superior to placebo. Although the difference between the two doses was not significant, there was a trend toward a modest advantage for the higher-dose group, an advantage that may have become more apparent with a longer trial, given the gradual titration required. Switch rates were not significantly different among the three groups: placebo, 5% lamotrigine 50 mg/day, 3% and lamotrigine 200 mg/day, 8%.

Frye and colleagues (2000), in a crossover trial previously described, reported that patients displayed significantly greater improvement in depressive symptoms while receiving lamotrigine (mean dose 274 mg/day) compared with placebo. The design of this trial did not allow for the examination of possible differences in switch rates. Taken together, the results of these two trials suggest that monotherapy with lamotrigine at 50 to 275 mg/day was efficacious in the treatment of bipolar depression.

Lamotrigine was compared with placebo as adjunctive treatment to lithium in an 8-week trial in patients with bipolar (I or II) depression (Van der Loos et al., 2009). Patients in the combination therapy group displayed significantly greater improvement in depressive symptoms and response rates compared with the placebo–lithium group, with no differences in switch rates into hypomania or mania.

Carbamazepine

Three small controlled studies evaluated the efficacy of carbamazepine in the treatment of patients with unipolar and bipolar depression (Kramlinger & Post, 1989; Post, Uhde, & Roy-Byrne, 1986; Small, 1990). In the first of these studies, a placebo-controlled crossover trial (median 45 days per treatment interval), Post and colleagues (1986) reported marked improvement in 12 (34%) of 35 patients (24 bipolar, 11 unipolar) with treatment-resistant depression. A trend toward greater improvement in patients with bipolar than unipolar depression was observed, and the switch to placebo was associated with deterioration in carbamazepine responders. In the second study, Small (1990) compared the response of 28 patients (4 bipolar, 24 unipolar) with treatment-resistant depression in a 4-week trial of lithium, carbamazepine, or their combination. All patients were then treated with both agents for an additional 4 weeks. Of patients receiving carbamazepine or the combination, 32% displayed moderate or marked improvement compared with 13% of lithium-only-treated patients. These results are consistent with those of Post and colleagues (1986), although the cohort studied by Small had significantly fewer bipolar patients. Finally, Kramlinger and Post (1989) evaluated the antidepressant effect of lithium versus placebo augmentation of carbamazepine and found that six (46%) of 13 patients who had not responded to carbamazepine alone responded to lithium augmentation.

Valproate

The antidepressant activity of divalproex has been examined in two small placebo-controlled trials in patients with bipolar depression (Davis, Bartolucci, & Petty, 2005; Sachs, Collins, & Altshuler, 2001). In a multisite study, Sachs and colleagues (2001) randomized 45 patients with bipolar disorder, type I, type II, and not otherwise specified, to divalproex (mean serum concentration, 62 mcg/mL) or placebo and found higher response rates in the divalproex group (43%) compared with the placebo group (27%). However, these differences were not significant, and there was no significant difference in mean reduction of depressive symptoms from baseline to endpoint between the two groups. The divalproex group had significantly greater improvement in depressive symptoms at weeks 2, 4, and 5 only. Davis and colleagues (2005) conducted a single-site, 8-week study of similar design involving 25 outpatients with bipolar I depression, but with a higher mean valproic acid concentration (81 mcg/mL). In this latter study, patients receiving divalproex had significantly greater reductions in depressive and anxiety symptoms than patients receiving placebo. These positive results require confirmation in a larger trial. Muzina and colleagues (2011) examined the efficacy of extended-release divalproex compared with placebo in depressed, predominantly rapid-cycling (67%) bipolar I and II patients in a 6-week trial. The divalproex group displayed significantly greater improvement in depressive symptoms from week 3 on compared with the placebo group.

Modafanil and Armodafanil

Armodafanil (150 mg/day) was compared with placebo in a large ($N = 257$) 8-week adjunctive trial in patients with bipolar I depression who had not responded to monotherapy with lithium, olanzapine, or valproate (Calabrese et al., 2010). Patients receiving armodafanil had significantly greater improvement in depressive symptoms compared with the placebo group. However, there were no significant differences between the groups on secondary outcome measures. Patients receiving armodafanil reported greater rates of headache, diarrhea, and insomnia. There was no difference in switch rates between the two groups. The results of this study are consistent with those of an earlier 6-week adjunctive trial of modafanil, which was superior to placebo in the reduction of depressive symptoms in patients with bipolar I and II disorder (Frye et al., 2007).

Other Agents

Two placebo-controlled trials evaluated the efficacy of formulations of omega-3 fatty acids in the treatment of bipolar depression (Keck et al., 2006b; Stoll et al., 1999). Stoll and colleagues (1999) reported significant improvement in depressive symptoms in patients who received a combination of EPA/DHA adjunctively or as monotherapy for 4 months compared with placebo. In contrast, Keck and colleagues (2006b) did not find significant efficacy for EPA 6 g/day compared with placebo used adjunctively with ongoing mood stabilizers.

In a study comparing inositol with placebo in patients with both bipolar and unipolar depression, Levine and colleagues (1995) found inositol superior to placebo in the overall group, but the number of patients with bipolar depression was too small ($N = 6$) to detect meaningful treatment effects.

Zarate and colleagues (2005) reported preliminary evidence that the glutamate-modulating agent riluzole was effective in improving depressive symptoms from baseline to endpoint when added to mood stabilizers in an open-label trial in 14 patients with bipolar I and II disorder. There were no switches into hypomania or mania. These results were consistent with similar open-label findings reported in patients with treatment-resistant major depressive disorder (Zarate et al., 2004a).

NAC 1 g/day, an orally bioavailable precursor to glutathione, was compared with placebo as adjunctive treatment in 75 patients with treatment-resistant bipolar (I and II) depression over 24 weeks (Berk et al., 2008). Patients receiving NAC displayed significantly greater improvement in depressive symptoms by 8 weeks of treatment. There were no significant differences among the two treatment groups in adverse events. This intriguing proof-of-concept trial requires replication.

A two-week, crossover randomized controlled trial examined the efficacy of adjunctive ketamine intravenous administration in patients with treatment-resistant bipolar depression (Diazgranados et al., 2010). Patients receiving ketamine during the active phase of the crossover trial displayed a rapid (within 40 minutes) and substantial antidepressant response, with improvement remaining significant, compared with placebo at day 3 after the infusion. Ketamine is an inhibitor of the NMDA-type glutamate channel that has generated a great deal of excitement in depression treatment studies because it appears to reduce depression symptoms almost immediately. Extensive studies of ketamine in the treatment of depression are under way.

Nahas, Kozel, Li, Anderson, and George (2003) compared daily left prefrontal repetitive transcranial magnetic stimulation (rTMS) for 2 weeks with sham rTMS in 23 depressed patients with bipolar I ($N = 12$) or bipolar II ($N = 9$) disorder. No manic switches were observed, but there were also no significant differences in responder rates between the two groups. A trend in favor of mean improvement in depressive symptoms in the active rTMS group may have been significant with a larger sample size.

In a 6-week, placebo-controlled trial, the anticonvulsant levetiracetam was comparable to placebo as adjunctive treatment in 32 patients with bipolar depression (Saricicek et al., 2011).

MAINTENANCE PSYCHOPHARMACOLOGICAL TREATMENT

Lithium

During the late 1960s and 1970s, 10 double-blind, placebo-controlled studies involving 514 patients with bipolar disorder demonstrated that lithium was superior to placebo in preventing recurrent affective episodes (Hopkins & Gelenberg, 1994). The average relapse rate over 1 year was 34% for lithium-treated

patients compared with 81% for those receiving placebo. These data also revealed that lithium exerted greater efficacy in preventing mania than in preventing depressive episodes. Of these 10 studies, 4 were discontinuation trials (Keck et al., 2000a, 2000b; Maj, 2000). Because abrupt discontinuation of lithium appears to precipitate relapse (Baldessarini et al., 1996), this design may have artificially elevated the recurrence rate in patients receiving placebo. Geddes, Burgess, Hawton, Jamison, and Goodwin (2004) conducted a systematic review and meta-analysis of randomized controlled trials comparing lithium and placebo in the long-term treatment of bipolar disorders as part of the Cochrane Collaboration. They identified five randomized controlled trials involving 770 patients. Lithium was more effective than placebo in preventing all relapses (random effects relative risk = 0.65, 95% CI = 0.50 to 0.84) and manic relapses (relative risk = 0.62, 95% CI 0.40 to 0.95). However, the protective effect of lithium on depressive relapses was smaller and less substantial (relative risk = 0.72, 95% CI 0.49 to 1.07). Subsequent naturalistic treatment studies of patients maintained on lithium for more than 1 year indicate that a substantial number of patients do not respond adequately to lithium prophylaxis and that complete prevention of mood episode recurrence is a relatively rare outcome (Baldessarini, Tondo, & Hennen, 2002; Maj, 2000).

Analyses of suicide risk in patients treated with lithium suggest that lithium may exert a specific long-term preventive effect on suicide (Baldessarini, Tondo, & Hennen, 2003b). This risk reduction appears to exceed that predicted by the effects of no treatment and of treatment with divalproex (Goodwin et al., 2003; Tondo, Hennen, & Baldessarini, 2001). Nevertheless, this apparent benefit has not been definitively established in a large, prospective treatment trial controlling for a number of potential confounding effects.

Identification of clinical predictors of response to lithium prophylaxis has been an important area of inquiry over the past several decades. Predictors of favorable response to lithium prophylaxis include a family history of bipolar disorder (Mander, 1986; Mendlewicz, Fieve, & Stallone, 1973; Prien, Caffey, & Klett, 1974), a family history of lithium response (P. Grof et al., 2002), and an illness course characterized by a mania–depression–euthymia episode sequence (Faedda, Baldessarini, Tohen, Strakowski, & Waternaux, 1991; E. Grof et al., 1987; Haag et al., 1986; Koukopoulos et al., 1980). Conversely, predictors of poor maintenance efficacy include rapid cycling (Dunner, Fleiss, & Fieve, 1976), multiple prior episodes (Swann et al., 1999), co-occurring anxiety or alcohol or substance use disorder (Feske et al., 2000; Himmelhoch, Neil, & May, 1980), and familial negative affective style (Miklowitz, Goldstein, Neuechterlein, Snyder, & Mintz, 1988; Miklowitz et al., 2000). With other choices for maintenance treatment becoming available, assessment for these predictors is becoming increasingly important (Keck & Licht, 2000).

In patients successfully treated with lithium prophylaxis, the risks of discontinuing lithium appear to be substantial. For example, in a meta-analysis by Suppes and colleagues (1991) of 14 studies involving a total of 257 bipolar patients who discontinued lithium, the risk of recurrence was approximately 28 times higher per month without medication than with medication. More than 50% of patients who discontinued successful maintenance treatment experienced a relapse (more often of mania than of depression) within 6 months. Other studies found that the risk of recurrence is significantly lower if lithium is discontinued gradually (Baldessarini et al., 1996).

The optimal lithium serum concentration is also directly relevant to successful lithium prophylaxis. Gelenberg and colleagues (1989) found that the risk of relapse was 2.6 times higher in bipolar patients randomized to low (0.4 to 0.6 mol/L) serum concentrations than those with standard (0.8 to 1.0 mol/L) levels. However, patients treated with standard concentrations experienced significantly more side effects. In a second analysis of data from this study, Keller and colleagues (1992) found that patients randomly assigned to the lower range of lithium levels were more likely to experience subsyndromal symptoms, and that their symptoms were more likely to worsen at any time than were the symptoms of patients in the standard-level group. Furthermore, the first occurrence of subsyndromal symptoms increased the risk of full-episode relapse fourfold. Perlis and colleague (2002) also reanalyzed data from the original study and found that patients who had a drop in lithium levels, either due to random assignment to the lower level group or during the trial, were most likely to relapse, and that this was the most powerful predictor of relapse. Finally, in a review of all studies examining maintenance treatment with lithium and lithium serum levels, Hopkins and Gelenberg (2000)

concluded that therapeutic response is correlated with lithium concentration within the range of 0.6 to 1.2 mol/L, as are side effects. Taken together, these studies suggest that lithium should be optimally titrated to the highest level within the therapeutic range consistent with adequate tolerability and that eradication of subsyndromal symptoms, not just prevention of full affective episodes, is an important treatment goal.

Lamotrigine

Lamotrigine was the second medication, after lithium, to receive approval for the long-term treatment of bipolar disorder by the FDA. This indication was based on the results of two 18-month, placebo-controlled lithium comparison studies in which patients entered the trials following stabilization of an acute hypomanic or manic (Bowden et al., 2003) or depressive (Calabrese et al., 2003a) episode, respectively. These designs were chosen because of data suggesting that prior mood episode predicts subsequent episode polarity in relapse (Calabrese et al., 2004; MacQueen et al., 2002). In the study by Bowden and colleagues (2003), patients were randomized to lamotrigine (100 to 400 mg/day), lithium (0.8 to 1.1 mEq/L), or placebo as double-blind maintenance treatment for up to 18 months following an 8- to 16-week open-label phase during which treatment with lamotrigine was initiated and other psychotropics were discontinued. Of 349 patients who entered the open-label phase, 175 met stabilization criteria and entered the randomization phase. Both lamotrigine and lithium were superior to placebo in prolonging the time to intervention for any mood episode. Lamotrigine, but not lithium, was superior to placebo in prolonging time to a depressive episode, whereas lithium, but not lamotrigine, was superior to placebo in prolonging time to a manic, hypomanic, or mixed episode. The second study (Calabrese et al., 2003a) was of similar design, except that there were three fixed-dosage lamotrigine groups (50, 200, or 400 mg/day). The findings of this study were entirely consistent with the results of the study by Bowden and colleagues (2003) and with an earlier 1-year open-label continuation study (McElroy et al., 2004b).

Lamotrigine was compared with placebo in the only published randomized, controlled parallel-group trial conducted specifically in patients with rapid-cycling bipolar I and II disorders (Calabrese et al., 2000). There was no significant difference in efficacy between lamotrigine and placebo in time to additional pharmacotherapy for emerging symptoms, the primary outcome measure in this 6-month trial involving 324 patients. However, significantly more patients remained stable on lamotrigine (41%) compared with placebo (26%) at the end of 6 months. Although not statistically significant, there was a trend toward better response in patients with bipolar II compared with bipolar I disorder.

Olanzapine

Olanzapine has also received an indication for relapse prevention in patients with bipolar disorder. Three randomized controlled trials evaluated the efficacy of olanzapine monotherapy in the long-term prevention of mood episodes in patients with bipolar disorder (Tohen et al., 2003b, 2005, 2006). The first long-term study was a 47-week maintenance of effect comparison with divalproex in patients who had initially responded to either agent for acute mania (Tohen et al., 2003b). The median times to manic relapse were 270 days for the olanzapine group and 74 days for the divalproex group. These differences were not significant. There were also no significant differences in relapse rates between the olanzapine (45%) and divalproex (52%) groups. The second long-term trial was a relapse-prevention study comparing olanzapine with lithium in 543 patients with bipolar I disorder who were initially stabilized on the combination of the two agents following a manic or mixed episode for 6 to 12 weeks (Tohen et al., 2005). Of the initial 543 patients, 431 met symptomatic remission criteria and were randomized to olanzapine (5 to 20 mg/day) or lithium (0.6 to 1.2 mEq/L) for up to 1 year. Significantly more olanzapine-treated patients (47%) completed the trial than lithium-treated (33%) patients. Although there were no significant differences in overall relapse rates into a mood episode between the olanzapine (30%) and lithium (39%) groups, patients receiving olanzapine had significantly fewer manic relapses (14%) compared with patients receiving lithium (28%). Relapse rates into depression were similar for the olanzapine (16%) and lithium (15%) groups. Tohen and colleagues (2006) also conducted a 48-week placebo-controlled trial of olanzapine monotherapy in relapse prevention of bipolar I disorder. Patients

who met criteria for symptomatic remission from a manic or mixed episode at two consecutive weekly visits following 6 to 12 weeks of open-label treatment with olanzapine (5 to 20 mg/day) were randomized to olanzapine (N = 225) or placebo (N = 136) for up to 48 weeks. Patients receiving olanzapine had a significantly longer time to symptomatic relapse (median 174 days) compared with patients receiving placebo (median 22 days). Time to symptomatic recurrence of manic, mixed, and depressive episodes was also significantly longer in the olanzapine group. The overall relapse rates for olanzapine-treated patients were significantly lower (47%) compared with patients receiving placebo (80%). The findings from these trials indicate that olanzapine has efficacy in relapse prevention in patients with bipolar I disorder and suggest that it may be superior to lithium in preventing manic recurrence. Long-term treatment with olanzapine may be associated with significant weight gain, however.

Aripiprazole

The efficacy of aripiprazole in relapse prevention in recently (less than 3 months) manic patients with bipolar I disorder was examined in one 6-month, placebo-controlled trial (Keck et al., 2006a). A total of 633 patients enrolled in the trial; 567 entered the stabilization phase and received aripiprazole 15 or 30 mg/day, of whom 206 (37%) completed. A total of 161 patients entered the 6-month randomization phase after meeting stabilization criteria, which included symptomatic remission for at least 6 weeks on aripiprazole monotherapy. Aripiprazole was superior to placebo in delaying time to relapse into any mood episode and in percentage relapses (aripiprazole, 25%; placebo, 43%). Within mood episodes, aripiprazole was superior to placebo primarily in the prevention of manic or mixed episodes, probably because most of the patients enrolled had been recently manic or mixed.

Three studies examined the efficacy of aripiprazole compared with placebo as adjunctive therapy in the long-term treatment of patients with bipolar I disorder recovering from an acute manic or mixed episode (Carlson et al., 2012; Marcus et al., 2011; Woo et al., 2011). Aripiprazole or placebo was added to lithium or valproate in two studies (Marcus et al., 2011; Woo et al., 2011) and to lamotrigine in one study (Carlson et al., 2012). Aripiprazole displayed significantly greater efficacy in delaying time to relapse to any mood episode in only one of these three trials, when added to lithium or valproate (Marcus et al., 2011).

Quetiapine

In the first of two quetiapine adjunctive maintenance trials (Vieta et al., 2008a), patients received open-label quetiapine (400 to 800 mg/day, flexible, divided doses) in combination with lithium or divalproex at therapeutic plasma concentrations for up to 36 weeks in order to achieve at least 12 weeks of clinical stability. After this 12-week stabilization period, patients were randomized to receive quetiapine or placebo in combination with lithium or divalproex for up to 104 weeks. The combination treatment group had significantly greater time to recurrence of any mood event and a smaller proportion of patients experiencing a mood event compared with the placebo–lithium or placebo–divalproex group. The second quetiapine trial (Suppes et al., 2009), was nearly identical in design, and the adjunctive quetiapine group again displayed significantly longer time to any mood event and risk reductions in mood events, mania, and depression.

In a monotherapy trial (Weisler et al., 2011), continuation of quetiapine among quetiapine responders was superior to placebo and comparable to lithium in patients randomized among the three treatment groups.

Ziprasidone

Ziprasidone (80 to 160 mg/day) was compared with placebo as adjunctive treatment to lithium and valproate following an 8-week period of mood stability on therapeutic levels of lithium or valproate (Bowden et al., 2010). Patients were then randomized to ziprasidone or placebo for 6 months. Patients in the ziprasidone combination group had significantly longer times to intervention for a mood episode and significantly lower rates of intervention for a mood episode compared with the placebo–lithium or placebo–valproate group. In addition, the time to discontinuation was significantly longer for the ziprasidone group.

Risperidone (Long-Acting) and Extended-Release Paliperidone

The efficacy and safety of risperidone long-acting injectable (RLAI) for preventing recurrent mood

episodes in patients with bipolar I disorder was examined in three randomized, placebo-controlled trials (Macfadden et al., 2009; Quiroz et al., 2010; Vieta et al., 2012). The first study randomized patients with a history of at least four mood episodes in the past 12 months, and after 16 weeks of mood stability on RLAI and treatment-as-usual medications for bipolar I disorder, to a 52-week blinded study phase of randomization to RLAI plus treatment as usual or placebo plus treatment as usual (Macfadden et al., 2009). Time to relapse was significantly longer in the group randomized to RLAI. In the second study, patients with bipolar I disorder with a current or recent manic episode were treated with open-label oral risperidone for 3 weeks, and open-label RLAI for 26 weeks (Quiroz et al., 2010). Patients who maintained response were then randomized to placebo injection or to continue RLAI. Time to recurrence for any mood episode was significantly longer in the RLAI group, with time to recurrence significant for a manic but not depressive episode compared with placebo.

In the third trial, after a 12-week open-label period of treatment with RLAI, patients with bipolar I disorder who did not experience a recurrence entered into an 18-month randomized, double-blind treatment arm consisting of RLAI, placebo injection, or oral olanzapine 10 mg/day (Vieta et al., 2012). Time to recurrence of any mood episode was significantly longer in the RLAI group compared with placebo injection, again with the significant difference driven mainly by prevention of manic compared with depressive recurrence. However, RLAI demonstrated less efficacy compared with olanzapine in preventing relapse.

In a 3-month continuation, placebo- and olanzapine-controlled trial, continued extended-release paliperidone had significantly greater efficacy compared with placebo in preventing relapse in prior paliperidone responders treated for acute mania (Berwaerts et al., 2012). However, olanzapine had greater efficacy than paliperidone.

Carbamazepine

Nine controlled studies have assessed the efficacy of carbamazepine for the maintenance treatment of patients with bipolar disorder (Bellaire, Demish, & Stoll, 1988; Coxhead, Silverstone, & Cookson, 1992; Denicoff et al., 1997; Greil et al., 1997; Hartong et al., 2003; Lusznat, Murphy, & Nunn, 1988; Okuma et al., 1981; Placidi et al., 1986; Watkins, Callendar, & Thomas, 1987). However, the efficacy of carbamazepine in the prevention of mood episodes has been controversial (Dardennes, Even, Bange, & Heim, 1995; Murphy, Gannon, & McGennis, 1989). This controversy stems in part from the heterogeneity in design, sample size, liberal use of rescue medications, and other factors affecting trial outcomes among the controlled maintenance studies, and the availability of only one placebo-controlled maintenance trial (Okuma et al., 1981). Interpretation of this latter study is further limited by the use of rescue medications other than lithium or carbamazepine to treat breakthrough symptoms. The use of these adjunctive medications limits the degree to which relapse rates can be directly attributable to carbamazepine or placebo in this study.

Hartong and colleagues (2003) conducted one of the most rigorous trials of carbamazepine prophylaxis in treatment-naïve patients with bipolar I disorder. Patients ($N = 94$) with at least two prior mood episodes in the previous 3 years were randomly assigned to receive lithium or carbamazepine using a double-dummy parallel-group design beginning with an index episode of hypomania, mania, or depression and followed for up to 2 years. No adjunctive thymoleptic medications were allowed. Fewer patients receiving lithium (27%) developed a mood episode compared with patients receiving carbamazepine (42%). Most relapses in the lithium group occurred within the first 3 months of the trial, whereas the relapse rate in the carbamazepine group was approximately 40% per year. However, slightly more patients treated with lithium (36%) than carbamazepine (26%) dropped out of the study, yielding 36% of lithium-treated patients completing 2 years with no episodes compared with 32% on carbamazepine.

Valproate

A 1-year randomized, double-blind, placebo-controlled, lithium-comparator trial of divalproex by Bowden and colleagues (2000) did not find a significant difference in time to any mood episode among the three groups. A post hoc survival analysis that included both time to any mood episode and time to early discontinuation for any reason as

treatment failure events found that patients in the divalproex group had significantly longer time in study compared with the lithium group (Bowden, 2003). The more substantial benefits in relapse prevention for divalproex and lithium were for mania rather than depression (Bowden, 2003). In contrast, time to depression was longer and the need for rescue intervention with antidepressants was significantly less in the divalproex group compared with the lithium and placebo groups (Gyulai et al., 2003).

Revicki and colleagues (2005) conducted an open-label one-year study of the clinical effectiveness (efficacy and tolerability) of divalproex compared with lithium in 201 patients with bipolar I disorder randomized to either drug initially for the treatment of an acute manic or mixed episode requiring hospitalization. Divalproex-treated patients (12%) were less likely to discontinue study medications for lack of efficacy or adverse events compared with lithium-treated patients (23%). No other significant differences in clinical outcome measures were evident between the two groups.

Combination Therapy

The efficacy of mood stabilizer combinations compared with mood stabilizer monotherapy is a remarkably understudied aspect of the long-term treatment of bipolar disorders. Only two such prospective randomized double-blind trials have been reported: a 1-year pilot trial comparing the combination of lithium and divalproex with lithium and placebo (Solomon et al., 1997), and a large 18-month trial comparing the combination of olanzapine with lithium or divalproex versus placebo with lithium or divalproex (Tohen et al., 2004). Solomon and colleagues (1997) found lower relapse rates in patients receiving divalproex and lithium ($N = 5$) compared with patients receiving placebo and lithium ($N = 7$) but higher rates of side effects in the combination treatment group. Tohen and colleagues (2004) reported significantly lower relapse rates in patients receiving combination olanzapine with lithium or divalproex compared with placebo plus lithium or divalproex. The greatest protective effect in the combination group was in the prevention of manic relapse. Again, not surprisingly, side effects, in particular weight gain, were more common in the combination group. The results of this study need to be considered in light of the original cohort selection, which was based on patients who were partial nonresponders to monotherapy with lithium or divalproex after 2 weeks of treatment for manic or mixed symptoms (Tohen et al., 2002b).

The Bipolar Affective Disorder Lithium/Anticonvulsant Evaluation (BALANCE) Study was a 2-year, open-label comparison of the long-term efficacy of lithium monotherapy, divalproex monotherapy, and the combination following an initial treatment period with the combination (Geddes et al., 2010). Both the combination and lithium monotherapy were superior to divalproex monotherapy in preventing relapse. Interpretation of the results of this study must be considered in light of the fact that the patients were discontinued from combination therapy before randomization and the open-label design.

Three large naturalistic studies found the combination of lithium and carbamazepine superior to lithium monotherapy in preventing bipolar disorder relapse, although these studies were enriched for carbamazepine responders, and the side effect burden was not unexpectedly greater in the combination therapy groups (Baethge et al., 2005; Bocchetta, Chillotti, Severino, Ardau, & Del Zompo, 1997; Denicoff et al., 1997).

Two studies addressed the impact of antipsychotic discontinuation on relapse in patients initially treated with the combination of an antipsychotic (usually an FGA) and an antimanic mood stabilizer for acute mania (Saksa, Baker, & Woods, 2004; Zarate & Tohen, 2004c). Zarate and Tohen (2004c) randomized 37 patients receiving perphenazine in combination with lithium, carbamazepine, or valproate to remain on perphenazine or switch to placebo for 6 months immediately after remission of an acute manic episode for which they received both agents. Patients who continued on the combination of perphenazine and mood stabilizer were significantly more likely to have a shorter time to depressive relapse, to discontinue the study, and to have increased rates of dysphoria, depressive symptoms, and extrapyramidal symptoms. The study by Saksa and colleagues (2004) was limited by a high dropout rate, but two of five patients randomized to discontinue adjunctive antipsychotic therapy relapsed into psychotic and manic recurrence, respectively, within 1 month of the antipsychotic taper.

CO-OCCURRING PSYCHIATRIC DISORDERS

Patients with bipolar disorders have among the highest rates of psychiatric comorbidity of all primary psychiatric illnesses (McElroy et al., 2001). The presence of co-occurring psychiatric disorders can affect treatment selection. Unfortunately, very few studies have specifically addressed the long-term treatment of patients with bipolar disorder and psychiatric comorbidity. Frankenburg and Zanarini (2002) conducted a 6-month placebo-controlled trial of divalproex in 30 female patients with bipolar II disorder and co-occurring borderline personality disorder. Divalproex was superior to placebo in reducing measures of interpersonal sensitivity, anger, hostility, and aggression. In an 8-week, placebo-controlled trial of outpatients with bipolar disorder and co-occurring generalized anxiety disorder or panic disorder, patients treated with risperidone did not display improvement in measures of anxiety symptoms compared with placebo (Sheehan et al., 2009).

Salloum and colleagues (2005) conducted a 24-week, double-blind, placebo-controlled trial of adjunctive divalproex or placebo in 59 patients with bipolar I disorder and co-occurring alcohol dependence receiving lithium and psychosocial treatment. Patients receiving divalproex had a significantly lower proportion of heavy drinking days and a trend toward fewer drinks per heavy drinking day compared with patients receiving placebo. Higher serum valproic acid concentrations correlated with better alcohol use outcomes. There were no significant differences between the two groups in mood symptom improvement. In two related studies, adjunctive quetiapine was compared with placebo in reducing heavy drinking days in a 12-week study of patients with bipolar I disorder and alcohol dependence who were also receiving lithium or divalproex at therapeutic concentrations (Brown et al., 2008; Stedman et al., 2010). There were no significant differences between the two treatment groups in reduction of heavy drinking days or in secondary measures of first two consecutive weeks of abstinence, changes in proportion of nondrinking days, or other measures. Kemp and colleagues (2009) conducted a 6-month randomized controlled trial comparing the combination of lithium and divalproex with lithium monotherapy among patients with bipolar disorder, recently manic and rapid cycling with co-occurring substance use disorder who initially responded to combination therapy. Only 31 of 149 patients who entered the open-label phase of this study were subsequently randomized, and of these 55% relapsed, with no significant differences between treatment groups. These findings are limited by the small sample size of patients who entered the randomized phase of the trial. This group (Wang et al., 2010) conducted a similar trial of lamotrigine compared with placebo as adjunctive therapy to lithium for 12 weeks in patients with rapid-cycling bipolar disorder and co-occurring substance use disorder. Only 8 patients per treatment arm completed the trial.

The treatment of bipolar disorder and co-occurring stimulant use disorders has been studied in two randomized clinical trials to date (Brown et al., 2007; Nejtek et al., 2008). In the only placebo-controlled trial, a 12-week study involving 44 patients with bipolar I or II disorder and co-occurring cocaine dependence, citicoline, an over-the-counter psychostimulant, added to ongoing mood stabilizer treatment, significantly improved some aspects of declarative memory and cocaine use, but not mood compared with placebo (Brown et al., 2007). Nejtek and colleagues (2008) randomized 80 patients with bipolar disorder and co-occurring cocaine or methamphetamine dependence to treatment with quetiapine or risperidone for 20 weeks. Both treatment groups displayed improvement in manic and depressive symptoms, as well as drug craving and use, with no significant difference between groups. This study did not include a placebo arm and the sample size was likely too small to detect potential treatment differences.

FUTURE RESEARCH AND CONCLUSIONS

There have been substantial advances in the pharmacological treatment of bipolar disorder in the past two decades. Well-done randomized controlled trials have established the efficacy of lithium, divalproex, carbamazepine, chlorpromazine, haloperidol, risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and asenapine in the treatment of acute mania. Research into neglected but important aspects of the management of bipolar disorder—the treatment of acute bipolar depression and the long-term prevention of relapse—has finally gained momentum. Four agents have FDA indications for relapse prevention of bipolar I disorder: lithium, lamotrigine, olanzapine, and aripiprazole. Studies of the efficacy of quetiapine and

ziprasidone in the long-term treatment of bipolar disorder are under way. Although only one formulation, the combination of olanzapine and fluoxetine, has an indication for acute bipolar depression, evidence is beginning to emerge that some other agents, most notably quetiapine and lamotrigine, may also be efficacious in this pole of the illness without increasing the risk of hypomanic or manic switch. Recent studies have also shed light on the lack of efficacy of some agents initially hypothesized to have potential in the treatment of bipolar disorder, for example gabapentin and topiramate. The thymoleptic properties of the anticonvulsants levetiracetam, oxcarbazepine, and zonisamide require careful delineation in randomized controlled trials.

Important therapeutic questions remain unanswered. For example, the optimal duration of antidepressant treatment in combination with antimanic mood stabilizers, balanced against the risk of switch induction, is unclear from the available research. Very few data exist regarding the efficacy and effectiveness of long-term treatment of bipolar disorder with combinations of mood-stabilizing agents, even though this is common practice. Entirely novel treatment approaches such as tamoxifen, allopurinol, NAC, and rTMS have not been adequately explored in patients with bipolar disorder. Moreover, studies of patients with bipolar disorder and co-occurring illnesses have only just begun.

REFERENCES

The following coding system, with codes provided at the end of each reference entry, indicates the nature of the supporting evidence from each citation:

1. Randomized, prospective, clinical trial. A study must include comparison groups with random assignment, blinded assessments, clear presentation of inclusion and exclusion criteria, state-of-the-art diagnostic methods, adequate sample size to provide statistical power, and clearly described statistical methods.

2. Clinical trial. A study in which an intervention is made but some aspect of the type 1 study criteria is missing.

3. Clinical study. A study that has clear methodological limitations. These studies include open treatment studies designed to obtain pilot data, naturalistic studies, and case-control studies.

4. A review with secondary data analysis (e.g., meta-analysis or comparably designed trials).

5. A review without secondary data analysis designed to convey an impression of the available literature.

6. A textbook, reference manual, case reports, small case series, and opinion papers.

Treatments for Pediatric Bipolar Disorder

Pablo H. Goldberg
Prerna Martin
Carolina Biernacki
Moira A. Rynn

The past two decades have seen significant advances in the development of evidence-based treatments for pediatric bipolar disorder (PBD). Practice guidelines recommend pharmacotherapy with mood stabilizers or second-generation antipsychotics (SGAs) as the first-line treatment for PBD. Currently, lithium, risperidone, aripiprazole, quetiapine, and olanzapine are approved by the U.S. Food & Drug Administration (FDA) for treating bipolar disorder in children and adolescents. The pharmacological literature suggests that SGAs are faster and more effective than mood stabilizers in treating acute manic or mixed episodes; however, they have significant side effects and require careful monitoring. While mild to moderate PBD can be treated with monotherapy, combination pharmacotherapy with an SGA and a mood stabilizer is recommended for youth with severe PBD. A growing body of literature also suggests the efficacy of psychosocial interventions with family psychoeducation and skills building as adjunct treatments to pharmacotherapy. More type 1 studies for both pharmacotherapy and psychosocial treatments are needed to better inform treatment recommendations.

BACKGROUND

PBD is a chronic, disabling illness characterized by significant symptoms, comorbidity, recurrence, and suicide risk leading to serious disruption in the lives of children and adolescents affected by it (Birmaher et al., 2009). The symptoms of PBD include but are not limited to disturbance in mood, poor judgment, grandiosity, aggressive behaviors, sleeplessness, hypersexual behavior, racing thoughts, and pressured speech. Children and adolescents with PBD often underperform academically, are disruptive in school, and have neurocognitive deficits (Henin et al., 2007; Pavuluri et al., 2006b). They may have poor social skills and social networks and experience frequent victimization by their peers (Geller et al., 2002; Goldstein et al., 2006). Within families, they experience significant conflict with parents and siblings, lower levels of family cohesion, and increased chronic stress (Geller et al., 2000; Kim et al., 2007; Wilens et al., 2003). Interpersonally, youth with PBD also demonstrate low self-esteem, hopelessness, and poor coping skills (Rucklidge, 2006). Bipolar disorder seems to be more severe in children and adolescents than adults in terms of morbidity, mortality, and affected quality of life (Freeman et al., 2009), thus carrying a poorer prognosis (Leverich et al., 2007). The description of PBD has been in existence for a century (Carlson & Glovinsky, 2009; Kraepelin, 1921), but research on PBD and its treatment has become more rigorous in the past 15 to 20 years. There has also been a forty-fold increase in the diagnosis of PBD between

1994 and 2003. PBD has likely been underdiagnosed in the past due to poor conceptualization of the disorder, including lack of age-specific and clear diagnostic criteria, low concordance across informants, and diagnostic uncertainty related to high comorbidity of attention-deficit/hyperactivity disorder (ADHD) in the pediatric population (Moreno et al., 2007).

EPIDEMIOLOGY AND RISK

Lifetime prevalence of adult bipolar disorder (BD) has been reported to be 3.9% (Perlis et al., 2004). The prevalence of PBD has not been well studied, perhaps due to its complex presentation in this population. There have been more reports of comorbidity in PBD than in adults with BD: 32% of youth with PBD have comorbidities compared to 3% in adults (Moreno et al., 2007). The first epidemiological data on PBD appeared in the Epidemiological Catchment Area Study (0.8% to 1.4% depending on the city, 1980–1985) (Robins & Price, 1991). In the 1990 National Comorbidity Survey (Kessler et al., 1994) the rate of BD appeared to be slightly lower in adolescents aged 15 to 17 (1.3%) compared to the full sample (1.7%) (Merikangas et al., 2010). Rates of PBD have also varied by country, from 0.3% to 1.7% (Merikangas et al., 2010; Weissman et al., 1996). According to the National Institute of Mental Health's Methods for the Epidemiology of Child and Adolescent Disorders (MECA) Study, the six-month prevalence was 1.6% for mania and 0.6% for hypomania in a population-based sample of children and adolescents (Lahey et al., 1996). In the biggest sample to date, Lewinsohn, Klein, and Seeley (1995) determined that BD (primarily bipolar II disorder and cyclothymia) had a lifetime prevalence of 1% in older adolescents ($N = 1{,}709$, aged 14 to 18 years) from nine senior high schools representing rural and urban districts of western Oregon. The risk factors for PBD include lifetime history of mood disorders, history of BD in the family (Hodgins et al., 2002), antidepressant-induced mania, episodic mood lability, early-onset depression, presence of psychosis, and episodic aggressive behavior (Youngstrom et al., 2009).

DIAGNOSTIC CRITERIA

There has been considerable debate regarding how BD is conceptualized in children and adolescents. This could be due to the developmental differences in phenomenology of this illness and/or overlap with other conditions that present with similar symptoms, such as ADHD, oppositional-defiant disorder, and conduct disorder. There has been ongoing controversy as to whether the diagnosis of PBD should be confined to patients who have discrete episodes of mania and depression versus patients who have a more chronic emotional dysregulation (Carlson & Glovinsky, 2009). The National Institute of Mental Health research roundtable on prepubertal BD proposed the classification of PBD in "narrow" or "broad" phenotypes (Nottelmann, 2001). Patients with narrow phenotypes fit the classic definition of bipolar I disorder (BD I) and bipolar II disorder (BD II) described in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (*DSM-IV*; American Psychiatric Association [APA], 1994). In contrast, those with the broad phenotype present with severe irritability, affective storms, mood lability, severe temper outbursts, symptoms of depression, anxiety, hyperactivity, poor concentration, and impulsivity without clear episodicity. Due to the controversies about symptomatology, duration, and comorbidity in children, Leibenluft and colleagues (2003) proposed three main phenotypes of PBD: *narrow phenotype* (with the mania definition adjusted to fit the *DSM* definition and the hallmark symptoms of grandiosity or elevated mood); *broad phenotype* (chronic, nonepisodic symptoms of severe irritability and hyperarousal, without the hallmark symptoms of elevated mood and grandiosity); and *intermediate phenotype*, with two subcategories: (hypo)mania not otherwise specified (1 to 3 days in duration) and irritable (hypo)mania (fitting the BD not otherwise specified symptoms).

Defining the Disorder

According to the *DSM-5* (APA, 2013), a diagnosis of BD I requires the presence of a manic episode that may be preceded or followed by a hypomanic or major depressive episode. The diagnosis of BD II requires the presence of at least one major depressive episode and a hypomanic episode. A cyclothymia diagnosis is given to children who experience a full year of both hypomanic and depressive periods but do not meet full criteria for a hypomanic or major depressive episode. The *DSM-5* also includes a group of bipolar and related disorders that are induced by substances

or medications or occur due to a medical condition. The classic symptoms of mania in BD include grandiosity, insomnia, pressured speech, racing thoughts, inattention, and increase in goal-directed activity (e.g., hypersexuality). To meet criteria for a manic episode, patients must have at least three symptoms (four if the mood is only irritable) lasting at least a week, nearly every day (or for any duration if the patient is hospitalized). In hypomania, the same symptoms last for at least four consecutive days (APA, 2013). The presentation of BD in children seems to differ when compared to adults, as children often present with nonepisodic chronic irritability, aggression, mood lability, and impulsive behaviors, which may last from a few hours to a few days. There seems to be much more cycling in children than in adults (Geller et al., 2000).

Special considerations are necessary when making the diagnosis of PBD. Since children of the same chronological age may be at different developmental stages, it is difficult to define with precision what is "normal" or "expected" at any given point. Therefore, each child should be assessed according to his or her own baseline of functioning and symptom presentation. The age of onset of PBD remains controversial. If the broad phenotype is considered, then the condition is understood to start as early as during preschool (Carlson & Meyer, 2010). Considering all bipolar disorders, at least half of the cases start before age 25 (Kessler et al., 2005). Despite these controversies, the validity of the *DSM-IV* and *DSM-5* diagnoses has been supported by substantial evidence (APA, 2000, 2013).

Depressive symptoms are common in youth with BD. The criteria for having a major depressive episode remain mostly the same in the *DSM-5* and consist of depressed mood and/or loss of interest or pleasure in life activities for at least 2 weeks, along with five or more of the following symptoms causing significant impairment in functioning: (1) depressed mood (or irritability in children and adolescents), (2) marked diminished interest or pleasure in daily activities, (3) significant weight loss, weight gain, or decrease or increase in appetite, (4) insomnia or hypersomnia, (5) psychomotor agitation or retardation, (6) fatigue or loss of energy, (7) feelings of worthlessness or guilt, (8) decreased concentration or indecisiveness, and (9) recurrent thoughts of death or suicide (APA, 2013). More than 50% of youth with BD I have had a prior history of a major depressive episode (Axelson et al., 2006). Psychotic symptoms are present in 16% to 60% of children and adolescents with BD, with auditory hallucinations being the most common (Pavuluri et al., 2005). To enhance the accuracy of diagnosis and facilitate earlier detection in clinical settings, the criteria for manic and hypomanic episodes now include an emphasis on changes in activity and energy as well as mood. The *DSM-IV* diagnosis of BD I, mixed episode, requiring that the individual simultaneously meet full criteria for both mania and major depressive episode, has been removed. Instead, a new specifier, "with mixed features," has been added, which can be applied to BD when depressive features are present or to major depressive disorder with manic or hypomanic features.

DSM-5 allows the specification of particular conditions for "other specified bipolar and related disorders," including categorization for individuals with a past history of major depressive disorder who meet all criteria for hypomania except the duration criterion (i.e., at least four consecutive days). A second condition that is conceptualized within this category occurs when too few symptoms of hypomania are present to meet criteria for the full bipolar II syndrome, although the duration is sufficient at four or more days. Other conditions in this category include hypomania alone without major depression and short-duration cyclothymia (less than 24 months). The specifier "with anxious distress" has been added to the *DSM-5*, along with rapid cycling, melancholic features, atypical features, mood-congruent psychotic features, mood-incongruent psychotic features, catatonia, peripartum onset, and seasonal pattern (APA, 2013). Finally, disruptive mood dysregulation disorder differs from BD in terms of episodicity and should not be included in the PBD diagnosis (APA, 2013).

PHARMACOLOGICAL TREATMENT FOR PEDIATRIC BIPOLAR DISORDER

The two main classes of biological agents used to treat PBD are mood stabilizers and SGAs. Due to the limited number of randomized controlled trials (RCTs) of psychopharmacological treatments of PBD, some open trials and chart reviews have been included judiciously to take into account the past five to six years of research in the field. The fundamental landmark studies are also discussed. In this review, medication trials for PBD are classified based on the following

treatment phases (Hirschfeld et al., 2002; Kowatch et al., 2005). *Acute treatment trials* usually refer to the first 6 to 8 weeks of treatment, during which the goal is to stabilize acute mania symptoms in order to allow the patient to return to his or her baseline level of psychosocial functioning. This section includes monotherapy and combination treatment trials, pediatric bipolar depression trials, and trials for PBD comorbid with other conditions such as ADHD, anxiety, and substance abuse. *Maintenance or continuation treatment trials* refer to treatment that is provided following remission of an acute manic episode. After remission, patients may remain at a particularly high risk of relapse for up to 6 months. This phase of treatment is sometimes referred to as *continuation* treatment and is considered part of the *maintenance* phase. The goals of maintenance treatment include prevention of relapse and recurrence; reduction of subthreshold symptoms, suicide risk, affective cycling, and mood instability; reduction of vocational and social morbidity; and promotion of wellness. The maintenance phase can last up to 24 months. Table 9.1 provides a summary of pharmacological trials for treating PBD, including indications for study type, sample size, and treatment outcomes.

ACUTE TREATMENT FOR MANIC AND MIXED EPISODES

Monotherapy Trials

Mood Stabilizers: Lithium

Lithium was the first drug to be approved by the FDA for the treatment of mania in children 12 years and older; approval followed its success in treating adults. Lithium should be titrated to 30 mg/kg per day in two or three divided dosages (Kowatch et al., 2011). Lithium has a narrow therapeutic index (0.8 to 1.2 mEq/L), and higher dosages are needed to obtain a therapeutic level (Findling et al., 2008a). Lithium's narrow therapeutic range can precipitate significant adverse effects, particularly at toxic levels, as noted by the FDA's black box warning (FDA, 2011). To achieve an accurate lithium level, blood should be drawn 12 hours after a dose. A physical examination should be completed before the start of the lithium treatment, with careful attention to ruling out any renal conditions. Bloodwork should include a lithium level, blood urea nitrogen, creatinine concentration, thyroid function tests, electrolytes, and a complete blood count. This should be repeated every three months once a steady state is achieved, which is usually after 1 week of starting the medication in children. Pregnancy tests should be obtained for adolescents of childbearing age. Education on reliable contraception should be reviewed due to lithium's potential to cause birth defects such as Ebstein's anomaly. Patients should be educated to maintain adequate fluid intake to prevent dehydration. Lithium can lead to significant weight gain and requires careful monitoring. Adverse effects of lithium include nausea, vomiting, diarrhea, hypothyroidism, renal function abnormalities, polyuria, polydipsia, leukocytosis, tremors, and acne. If toxicity occurs, the dose should be either discontinued or lowered. The symptoms of lithium toxicity include loss of balance, increased diarrhea, vomiting, anorexia, weakness, ataxia, blurred vision, tinnitus, polyuria, coarse tremor, muscle twitching, irritability, and agitation. The drugs that can increase lithium levels are carbamazepine, nonsteroidal anti-inflammatories (NSAIDs), tetracycline, and thiazide diuretics. Theophylline and caffeine promote lithium excretion, resulting in lower serum levels at the same oral dose (Findling & Pavuluri, 2008).

There are only two studies in children that have evaluated lithium as a monotherapy with rigor, using a double-blind controlled design for acute treatment of mania or mixed episodes. In 1998, Geller and colleagues randomized 25 patients (aged 12 to 18 years) with comorbid PBD, manic or mixed episode, and secondary substance dependence to receive lithium (0.9 to 1.3 mEq/L) or placebo over a period of six weeks. Results of this trial indicated clinically significant improvement in patients taking lithium, with response rates for lithium (46%) separating from placebo (8%) as measured by a score of 65 or greater on the Children's Global Assessment Scale (CGAS). However, when assessing improvement using the Schedule for Affective Disorders and Schizophrenia for School Aged Children (Puig-Antich & Ryan, 1986), there was no significant difference between active and placebo groups.

The Collaborative Lithium Trials (CoLT) consisted of two multiphase trials (CoLT 1 and CoLT 2) that examined the safety and efficacy of lithium for the treatment of children and adolescents (aged 7 to 17 years) diagnosed with BD I, manic or mixed

TABLE 9.1 Summary of Pharmacologic Trials for Treatment of Bipolar Disorder in Children and Adolescents

Type of Pharmacologic Treatment	*Citation*	*Design/Duration*	*Class Type*	*Sample Size (N)*	*Age Range*	*Results/Outcome Measure*
Acute Treatment for Manic or Mixed Episodes (Monotherapy Trials)						
Li vs. PBO	Geller et al., 1998	RCT 6 weeks	1	25	12–18	Li = PBO (↓YMRS) Li > PBO (↑ CGAS) Response rate 46% (Li), 8% (PBO)
Li vs. DVPX vs. CBZ	Kowatch et al., 2000	Open label 6 weeks	2	42	8–18	Response rate 38% (Li), 53% (DVPX), 38% (CBZ)
DVPX-ER vs. PBO	Wagner et al., 2009	RCT 28 days	1	150	10–17	DVPX-ER = PBO (↓YMRS) Response rate 24% (DVPX-ER), 23% (PBO)
DVPX	Pavuluri et al., 2005	Open label 6 months	3	34	5–18	↓YMRS, ↓CDRS-R Response rate 73.5%, remission 52.9%
Li vs. DVPX vs. PBO	Kowatch et al., 2007	RCT 8 weeks	1	153	7–17	DVPX > PBO, Li = PBO Response rate 54% (DVPX), 42% (Li), 29% (PBO)
CBZ-ER	Joshi et al., 2010	Open label 8 weeks	3	27	6–12	↓YMRS (mean YMRS score at study endpoint 21.8 ± 12.2)
OCBZ vs. PBO	Wagner et al., 2006	RCT 7 weeks	1	116	7–18	OCBZ = PCBO (↓YMRS) Response rate 42% (OCBZ), 26% (PBO)

Arip = aripiprazole; CBZ = carbamazepine; CBZ-ER = carbamazepine extended-release; CLO, clozapine; DVPX, divalproex sodium; DVPX-ER = divalproex sodium extended-release; Li = lithium; LTG = lamotrigine; OCBZ = oxcarbazepine; OLZ = olanzapine; MAS = mixed amphetamine salts; MPH = methylphenidate; MS = mood stabilizer; PBO = placebo; QTP = quetiapine; RCT = randomized controlled trial; RIS = risperidone; SGA = second-generation antipsychotics; TPM = topiramate; ZPS = ziprasidone.

episode. As established in the written request to the FDA, the goals of the studies were to (1) establish evidence-based dosing strategies for lithium; (2) characterize the pharmacokinetics and biodisposition of lithium; (3) examine the acute efficacy of lithium in pediatric bipolarity; (4) investigate the long-term effectiveness of lithium treatment; and (5) characterize the short- and long-term safety of lithium (Findling et al., 2008a). Both CoLT studies provided up to a maximum of 52 weeks of treatment and had four phases: acute treatment, long-term stabilization, discontinuation, and restabilization. The purpose of CoLT 1 was to develop dosing strategies for lithium in children and adolescents with PBD. In CoLT 2, the first phase began with an 8-week double-blind, placebo-controlled trial where 81 subjects were randomized to receive either lithium or placebo. This initial efficacy phase was followed by an open-label long-term phase of either 16 or 24 weeks in duration, depending on the treatment that the patient received during the first double-blind phase. Study participants were eligible to enter phase 2 if they responded partially or fully to lithium, or did not respond fully to placebo. At the end of phase 2, participants who met criteria for remission of psychotic features and mood symptoms (as measured by Young Mania Rating Scale [YMRS] score <10 and the Children's Depression Rating Scale–Revised [CDRS-R] score ≤ 35) and were determined stable entered phase 3 (discontinuation phase), where they were blindly randomized to either continue on their present lithium treatment or gradually switch to placebo over a period of 28 weeks. Finally, participants who relapsed entered phase 4 (restabilization phase) and received 8 weeks of open-label treatment with lithium (Findling et al., 2008a; IRB, personal communication, July 5, 2012). The CoLT 1 and CoLT 2 studies have been completed and the results are being analyzed.

Several open trials have been conducted using lithium to treat pediatric mania, showing improvement in both mania and depression after 4-6 weeks. For example, Kowatch and colleagues (2000) conducted an open-label trial where 42 participants with BD I or BD II, mixed or manic episode (aged 8 to 18 years), were randomized to receive treatment with lithium, divalproex sodium, or carbamazepine for six weeks. The results of this study indicated large effect sizes as defined by Cohen (1998) for all three mood stabilizers (1.06 for lithium, 1.63 for divalproex sodium, and 1.00 for carbamazepine). Response rates, as defined by at least a 50% change from baseline YMRS score, were 38% for lithium, 53% for divalproex sodium, and 38% carbamazepine. There was no significant difference in response rates among the three groups; however, the sample size of this study was not adequate to detect such a difference. There were no serious adverse effects with any of the three mood stabilizers in this trial.

Anticonvulsants

Divalproex SodiumDivalproex sodium is one of the most widely studied anticonvulsants in the treatment of PBD. Divalproex has a narrow therapeutic window; the starting dose is 15 mg/kg per day to be administered in two or three divided dosages in children and adolescents. Optimal serum levels for treating mania in adults are between 85 and 110 μg/mL, and the same is thought to be true for the pediatric population (Kowatch et al., 2011). Common adverse events include weight gain, tremor, nausea, diarrhea, cognitive dulling, sedation, fatigue, ataxia, and dizziness. The most severe adverse effects are hepatic failure, thrombocytopenia, pancreatitis, and potential for severe dermatological reactions. Divalproex carries a black box warning by the FDA regarding hepatotoxicity, teratogenicity, and pancreatitis (FDA, 2009a). Divalproex has not been approved by the FDA for treatment of PBD, yet it is used widely based on its effectiveness and efficacy in adults.

When starting divalproex in younger women, the risk of polycystic ovary syndrome should be discussed. The association was first suggested in 1993 in women who were using valproate as an antiepileptic drug, and it was seen as more significant during adolescence (Isojarvi et al., 1993). Since then, this association has been observed in several studies; a study of women with bipolar disorder found this association between valproate and polycystic ovarian disorder in 10% of the subjects, particularly in the younger group (aged thirteen to twenty-five years) (Joffe et al., 2006). This presentation has also been observed in women with epilepsy treated with valproic acid, more frequently within the same age range (Morrell et al., 2008; Talib & Alderman, 2013).

In 2009, Wagner and colleagues conducted an RCT to evaluate the efficacy of monotherapy with extended-release divalproex (maximum dose 35 mg/kg per day; serum levels 80 to 125 μg/mL). In this study, 150 subjects (aged 10 to 17 years) with BD I, manic or mixed episode, were randomized to receive

extended-release divalproex or placebo for 28 days. The results of this RCT were negative; there was no statistical difference between the two groups on the primary outcome as measured by change in mean YMRS score (−8.8 divalproex vs. −7.9 placebo; $p = 0.604$) or on secondary measures. The incidence of adverse effects was similar for both groups, except for weight gain, which was higher in the extended-release divalproex group. The most common adverse events were headache and vomiting (Wagner et al., 2009).

In one of the first reports of divalproex monotherapy for PBD, Pavuluri and colleagues (2005) conducted a six-month open trial to target acute symptoms in 34 subjects (aged 5 to 18 years) diagnosed with BD I, mixed episode, and a baseline YMRS score of more than 20. The primary outcome measures were YMRS and CDRS-R scores. Secondary measures were the Clinical Global Impression Scale for Bipolar Disorder (CGI-BP) and the CGAS. The response rate, as measured by at least a 50% change from baseline YMRS scores and a score of 40 or less on the CDRS-R, was 73.5% and the remission rate was 52.9%. Adverse events ranged from mild to moderate in terms of severity, with the most common being sedation, increased appetite, weight gain, and cognitive dulling (Pavuluri et al., 2005).

Kowatch and colleagues (2007) (unpublished data; presented at 2007 American Academy of Child and Adolescent Psychiatry meeting) enrolled 153 participants (aged 7 to 17 years) with BD I, manic or mixed episode, in an 8-week RCT comparing treatment with lithium, divalproex, or placebo. Response was defined as a Clinical Global Impressions–Improvement (CGI-I) score of 1 ("very much improved)," 2 ("much improved"), or 3 ("minimally improved)" compared to baseline. Results indicated that the response rates were 54% for divalproex, 42% for lithium, and 29% for placebo, with divalproex separating significantly from placebo. Lithium showed a trend toward efficacy but did not separate from placebo. The effect sizes for lithium and divalproex in this study were moderate. The findings from these divalproex trials are mixed, and at this time there is limited information on the effectiveness of monotherapy with divalproex in managing acute manic symptoms in children and adolescents.

Carbamazepine

The suggested starting dose of carbamazepine is 100 mg twice daily in patients aged 6 to 12 years of age and 100 mg three times daily in patients aged 12 years and older. Carbamazepine serum levels between 8 and 11 μg/mL are necessary for seizure control, but the level for therapeutic effect in PBD is unknown. The maximum dose is 1,000 mg/day in children aged 6 to 12 years and 1,200 mg/day in adolescents 13 years and older (Kowatch et al., 2011). The main side effects of carbamazepine include dizziness, drowsiness, vision changes, double vision, gastrointestinal disturbances, loss of appetite, dry mouth, weight gain, and potential for severe dermatological reactions. It is suggested that Asian patients be genetically screened for the human leukocyte antigen allele HLA-B*1502. Carbamazepine is generally not used with patients who test positive for this allelic version of the antigen, which is most common among Asian populations, since it is associated with a higher risk for developing toxic epidermal necrolysis or Stevens-Johnson syndrome. There is a black box warning concerning aplastic anemia and agranulocytosis, which occur rarely (FDA, n.d.).

The empirical evidence for the efficacy and tolerability of carbamazepine in treating PBD is limited. In 2010, Joshi and colleagues conducted a prospective 8-week open-label treatment trial of extended-release carbamazepine monotherapy in 27 children (aged s 6 to 12 years) diagnosed with BD I, BD II, or BD not otherwise specified with significant severity of manic, hypomanic, or mixed symptoms. The mean dose at study endpoint was 788 ± 252 mg/day. A total of 16 children (59%) completed the study. An intent-to-treat analysis showed statistically significant, although modest, improvement in symptoms of mania as measured by change in mean YMRS scores from baseline (−10.1 ± 10.2, $p < 0.001$). The mean YMRS score at study endpoint (21.8 ± 12.2) suggests that mania symptoms did not completely resolve. Additional analyses revealed significant improvements in depression and psychotic symptoms as measured by reduction in baseline CDRS-R and Brief Psychiatric Rating Scale (BPRS) scores respectively. Due to methodological limitations, including lack of a comparison group and small sample size, this study does not provide sufficient evidence for use of extended-release carbamazepine to treat PBD. To date, no RCTs have been conducted to assess the short- or long-term efficacy of using carbamazepine as a pharmacological intervention for PBD.

Oxcarbazepine

Oxcarbazepine is an analogue of carbamazepine with fewer side effects and better pharmacokinetic properties. It can be started at a dose of 8 to 10 mg/kg per day, dosed twice a day. The dose should be increased by 5 mg/kg per day every third day to the recommended maximum based on the child's weight. It does not require blood monitoring and there is less concern about hepatic enzyme induction associated with its use compared to carbamazepine (Goldstein et al., 2012; Kowatch et al., 2011).

Wagner and colleagues (2006) conducted a double-blind RCT where they enrolled 116 subjects (aged s 7 to 18 years) diagnosed with BD I, manic or mixed episode. Participants were randomized to receive either oxcarbazepine with flexible dosing (maximum dose 900 to 2,400 mg/day; mean dose 1,515 mg/day) or placebo for seven weeks. Mean YMRS scores decreased for patients in both groups; however, response rate (defined by at least a 50% reduction in baseline YMRS scores) did not statistically differ between the oxcarbazepine monotherapy (42%) and placebo (26%) groups. The most commonly reported adverse events included dizziness, nausea, somnolence, diplopia, fatigue, and rash, with the incidence of adverse events being higher in the oxcarbazepine group (90%) than in the placebo group (79%).

Lamotrigine

The starting dose for lamotrigine for an adolescent is 25 mg/day for two weeks with gradual increases to 200 to 400 mg/day. If the patient is on divalproex, then the starting dose of lamotrigine is 25 mg every other day for two weeks. For patients younger than 12 years, the dosing of lamotrigine is based on weight and follows guidelines depending on whether the patient is on an enzyme-inducing antiepileptic drug (Kowatch et al., 2011; Micromedex, 2014). Lamotrigine can cause some abdominal symptoms, dizziness, ataxia, headache, tremor, blurred vision, and diplopia and has the potential for severe dermatological reactions. There is a black box warning for Stevens-Johnson syndrome and toxic epidermal necrolysis (FDA, 2013).

There are no RCTs to date that have established the efficacy of lamotrigine to treat PBD. Biederman and colleagues (2010) conducted a prospective open 12-week trial of lamotrigine monotherapy in 39 participants (aged 6 to 17 years) with BD I, BD II, or BD not otherwise specified with manic, hypomanic, or mixed symptoms. The average dose was 160.7 ± 128.3 mg/day for participants under 12 years of age (N = 22) and 219.1 ± 172.2 mg/day in participants aged 12 to 17 years (N = 17). Clinical response was measured as having at least a 30% reduction in baseline YMRS scores or a CGI-I score of 2 or less (i.e., "much improved" or "very much improved"). The results of this trial showed a significant reduction of symptoms, with a response rate of 66% in participants under 12 years of age and 54% in participants greater than 12 years. Lamotrigine was also associated with improvement in depressive, ADHD, and psychotic symptoms. Twenty-five percent of participants discontinued due to adverse side effects. The most common adverse effects in the study were gastrointestinal issues, headaches, cold symptoms, and dermatological complaints. Among participants who discontinued due to an adverse effect, developing a skin rash was the most common reason for dropout. However, none of the skin rashes were life threatening or required hospitalization.

Topiramate

Topiramate is an anticonvulsant, indicated as monotherapy in patients 10 years of age and older with partial-onset or primary generalized tonic-clonic seizures and in adults for the prophylaxis of migraine headache. Topiramate can be started at 25 mg once daily and increased to 100 to 200 mg/day over 3 to 4 weeks. A lower starting dose and a slower rate of increase may decrease some of the negative cognitive effects of this drug (Kowatch et al., 2011).

Data from some open-label studies in adults suggest that topimarate might reduce symptoms of BD (Calabrese et al., 2001; Grunze et al., 2001); however, these findings have not been replicated through RCTs (Powers et al. 2004). Topimarate has been well tolerated in children and adolescents with epilepsy (Levinsohn, 2000), and DelBello and colleagues (2005) started conducting a pilot RCT to test its efficacy and safety as a monotherapy in the treatment of BD I in 56 patients (aged 6 to 17 years). Participants were randomized to receive either topimarate or placebo over a 4-week period. The trial was initially designed to enroll 230 subjects but was discontinued prematurely when a trial in adults with BD failed to demonstrate topimarate's efficacy over placebo

(DelBello et al., 2005; Powers et al., 2004). There was a reduction in mean YMRS scores from baseline in both groups; however, the difference in reduction was not statistically significant between groups. The decrease in sample size due to early termination likely left the study underpowered to be able to detect between-group differences, and therefore the results of this study are inconclusive. The most commonly reported adverse events included nausea, diarrhea, decreased appetite, paresthesia, and somnolence.

Second-Generation Antipsychotics

The SGAs (atypical antipsychotics) combine dopaminergic and serotoninergic properties to provide mood stabilization and treatment of acute symptoms of mania, including psychosis. The following SGAs have received FDA approval for the treatment of PBD (aged 10 to 17 years): aripiprazole (Abilify), quetiapine (Seroquel), risperidone (Risperdal), and olanzapine (Zyprexa; aged 13 to 17 years only) (Correll, 2011). Since 1995, there have been a total of 26 studies evaluating the efficacy of antipsychotic monotherapy for treatment of PBD using various study designs.

Risperidone

The treatment dose range for risperidone is 1 to 6 mg/day, with the most common side effects being fatigue, extrapyramidal side effects (EPS), elevated prolactin levels, weight gain, and elevations in cholesterol levels (Correll, 2011). Risperidone is the first atypical antipsychotic approved by the FDA for the acute treatment of BD I, manic or mixed episode, for children and adolescents aged 10 to 17 years (Correll, 2011).

One of the first RCTs to establish risperidone's efficacy in treating PBD was conducted by Haas and colleagues (2009), who randomized 169 participants (aged s 10 to 17 years) with BD I, manic or mixed episode, for 3 weeks to receive risperidone 0.5 to 2.5 mg/day ($N = 50$), risperidone 3 to 6 mg/day ($N = 61$), or placebo ($N = 58$). The purpose of having two dosing groups was to assess whether higher dose ranges were more effective and/or equally safe and tolerable as compared to lower dose ranges. The primary outcome measure in this study was change in YMRS scores from baseline. The results of this study indicated a statistically significant improvement in YMRS scores in both of the risperidone groups compared to placebo ($p < 0.001$). The clinical response rate (defined as a greater than 50% reduction from baseline in total YMRS scores) was observed to be 59% in the 0.5- to 2.5-mg risperidone group ($p < 0.002$) and 63% in the 3- to 6-mg risperidone group ($p < 0.001$) compared to 26% in the placebo group. Somnolence, headache, and fatigue were the most commonly reported adverse events. Comparison across different measures (YMRS, clinical response, CGI, and BPRS) between the two risperidone groups indicated that risperidone in the higher dosage range is no more efficacious than when administered in the lower dose range to treat PBD in this population. While both risperidone dose ranges were effective, the low-dose group was associated with a lower rate of discontinuation due to adverse events and a lower incidence of EPS-related adverse events. Overall, the lower dose range had a more favorable safety profile, and this was similar to safety data from other risperidone studies to treat BD in adults and children (Haas et al., 2009).

In the first double-blind study of its kind, Pavuluri and colleagues (2010) randomized 66 participants with PBD (aged 8 to 18 years) to receive treatment with divalproex (60 to 120 μg/mL, $N = 33$) versus risperidone (0.5 to 2 mg/day, $N = 33$) over a six-week period. A mixed-effects regression model of YMRS scores by active drug and time found that patients in the risperidone group improved more rapidly than those in the divalproex group. Patients receiving risperidone also had a higher response rate based on more than 50% change in baseline YMRS scores (78.1% for risperidone vs. 45.5% for divalproex, $p < 0.01$), a higher response rate based on more than 50% improvement in CDRS-R scores (65.5% for risperidone vs. 42.4% for divalproex, $p < 0.01$), and higher remissions rates based on a YMRS score of 12 or less and a CDRS-R score of 28 or less (62.5% with risperidone vs. 33.3% with divalproex, $p < 0.05$). Response rates for risperidone were similar to those found in other studies (Biederman et al., 2005). There were no significant differences between groups on safety. However, there was a lower dropout rate in the risperidone group (24%) compared to the divalproex group (48%), the most common reason for dropout in the divalproex group being increased irritability. There was no significant weight gain in this study; however, these results should be interpreted with caution due to the study's small sample size and the frequent documentation of weight gain as a side effect in other risperidone trials. This was the first randomized trial

to establish preliminary evidence that risperidone had a more rapid effect and higher reduction of mania symptoms compared to divalproex in the acute treatment of PBD (Pavuluri et al., 2010).

The results of Pavuluri and colleagues' study (2010) were further extended by another head-to-head RCT conducted by Geller and colleagues (2012) that compared the effect of risperidone, lithium, and divalproex sodium in the acute treatment of BD I, manic or mixed episode. In this study, 279 participants (aged 6 to 15 years) were randomly assigned to receive risperidone (maximum dose 4 to 6 mg), lithium (maximum dose 1.1 to 1.3 mEq/L), or divalproex sodium (maximum dose 111 to 125 μg/mL) for eight weeks. The primary outcome measure was the Clinical Global Impressions for Bipolar Illness Improvement-Mania (CGI-BP-IM) and treatment response was defined as a rating of 1 ("very much improved") or 2 ("much improved") compared to baseline. Patients in the risperidone group had a higher response rate (68.5%) compared to those receiving lithium (35.6%, $p < 0.001$) or divalproex (24%, $p < 0.001$). There were no significant differences in response rates between the lithium and divalproex groups. Consistent with previous studies, the risperidone group had a lower discontinuation rate than the lithium group. Although more efficacious in the acute management of PBD, risperidone was associated with significantly higher weight gain, increase in body mass index (BMI), and increase in prolactin levels compared to treatment with lithium or divalproex.

Quetiapine

The treatment dose range for quetiapine is 150 to 750 mg/day, with the main adverse side effects being sedation, dizziness, gastrointestinal upset, weight gain, dyslipidemia, and dysglycemia (Correll, 2011).

The efficacy and safety of quetiapine monotherapy was investigated by Pathak and colleagues (2013) in a multisite RCT with 284 participants (aged 10 to 17 years) diagnosed with BD I with manic episodes. Participants were randomized to receive quetiapine 400 mg/day ($N = 95$), quetiapine 600 mg/day ($N = 98$), or placebo ($N = 91$) over a period of three weeks. Quetiapine at both doses was associated with significantly greater improvement in total YMRS scores (primary outcome measure) compared to placebo ($p < 0.001$). Participants in both quetiapine treatment arms had significantly greater response rates (64% for quetiapine 400 mg/day, 58% for quetiapine 600 mg/day, 37% for placebo) and remission rates (45% for quetiapine 400 mg/day, 52% for quetiapine 600 mg/day, 23% for placebo). Results indicated statistically significant improvements in both quetiapine groups on other outcome measures, including the CGAS, CGI-BP Severity of Illness, and CGI-BP-Global Improvement scores, compared to placebo. Like risperidone, quetiapine was also associated with a more rapid onset of effect, separating from placebo by as early as day 4. The adverse events reported in this study were broadly consistent with those reported in adult studies of BD and were most commonly somnolence, sedation, dizziness, and headache. The researchers noted that 45% of the sample had comorbid ADHD and 15% of these individuals were also on stimulants; however there were no significant differences in adverse events reported by patients taking other psychotropic medication compared to those taking quetiapine alone (Pathak et al., 2013).

In another head-to-head double-blind RCT, DelBello and colleagues (2006) compared the efficacy and safety of quetiapine versus divalproex among 50 adolescents (aged 12 to 18 years) with BD I, manic or mixed episode. Participants were randomized to 28 days of treatment with either quetiapine (400 to 600 mg/day) or divalproex (serum level 80 to 120 μg/mL). While quetiapine led to more rapid improvement in manic symptoms than divalproex, and both were associated with significant improvement in YMRS scores from baseline, the difference between the groups in YMRS change from baseline was not statistically significant. Secondary outcome measures such as response rate and remission were higher for participants on quetiapine compared to divalproex. The treatment groups did not differ in terms of incidence or severity of adverse events, and rates of completion were the same in both groups. The findings of this study suggest that quetiapine is at least as effective and well tolerated as divalproex in the treatment of acute PBD.

Aripiprazole

The treatment dose range for aripiprazole is 10 to 30 mg, with the main side effects being sedation, stomach discomfort, and EPS (Correll, 2011). There have been two recent positive RCTs that have established the efficacy of aripiprazole as monotherapy for the treatment of PBD.

Findling and colleagues (2009) randomized 296 participants (aged 10 to 17 years) diagnosed with BD I, manic or mixed episode, to receive aripiprazole 10 mg/day, aripiprazole 30 mg/day, or placebo over an acute 4-week treatment period. The study found significantly greater reductions in symptoms of mania in both aripiprazole treatment groups compared to placebo as measured by change from baseline in total YMRS scores. Both aripiprazole dose groups were also superior to placebo on key secondary measures. Remission was defined as YMRS total score of 12 or less and a CGI-BP severity score of 2 or less; significantly higher remission rates were observed in the aripiprazole 10 mg/day (25%) and aripiprazole 30 mg/day (48%) treatment arms compared to placebo (5%). Clinical response (at least 50% reduction from baseline YMRS total score) was observed in 44.8%, 63.6%, and 26.1% of participants in the aripiprazole 10 mg, 30 mg, and placebo groups respectively ($p < 0.01$ for both doses vs. placebo). Aripiprazole did not significantly reduce depressive symptoms in these groups. The most commonly reported adverse events were somnolence and EPS, occurring more frequently in the aripiprazole 30 mg group than the aripiprazole 10 mg group. There was at least one serious adverse event in each treatment group (aripiprazole 10 mg, $N = 5$; aripiprazole 30 mg; $N = 2$; placebo, $N = 5$). In the aripiprazole 10 mg group, the serious adverse events were accidental overdose, grand mal seizure, respiratory arrest, aggression, oppositional behavior, and suicidal ideation. In the aripiprazole 30 mg and placebo groups, all serious adverse events were "exacerbation of bipolar disorder."

In another double-blind placebo-controlled trial conducted by Tramontina and colleagues (2009), 43 participants (aged 8 to 17 years) with comorbid PBD, manic or mixed episode, and ADHD were randomized to receive aripiprazole monotherapy (maximum dose 20 mg/day; $N = 18$) or placebo ($N = 20$) for a 6-week period. The aripiprazole group proved superior to placebo on multiple primary and secondary outcome measures, including reduction in YMRS scores from baseline ($p < 0.02$), Children Mania Rating Scale-Parent Version (CMRS-P) ($p = 0.02$), and CGI-Severity ($p = 0.04$). Findings indicated significantly higher response rates (88.9% vs. 52%, $p = 0.02$) and remission rates (72% vs. 32%, $p = 0.01$) in the aripiprazole group when compared to placebo. There were no significant differences on ADHD or depressive symptoms between groups. Some of the commonly reported adverse events included somnolence, tiredness, increased appetite, headache, and nausea.

Several open-label trials have also supported the efficacy and tolerability of aripiprazole in the treatment of PBD and have been summarized in Table 9.1 (Findling et al., 2008b, 2011; Gibson et al., 2007; Tramontina et al., 2007).

Olanzapine

Olanzapine carries an FDA approval for youths aged 13 to 17 with BD I for mood stabilization and treatment of acute symptoms of mania, including psychosis. The treatment dose range in pediatrics is 5 to 20 mg daily; olanzapine can cause increased appetite, somnolence, sedation, weight gain, dyslipidemia, and dysglycemia (Correll, 2011).

Tohen and colleague (2007) conducted one of the largest double-blind placebo-controlled trials; it enrolled 161 participants (aged 13 to 17 years) with BD I, manic or mixed episode. Participants were randomized to receive olanzapine at a flexible dose (2.5 to 20 mg/day; $N = 107$) or placebo ($N = 54$) for three weeks. Olanzapine was superior to placebo, as indicated by significantly greater reduction in YMRS total scores from baseline among participants in the olanzapine group (–17.65 vs. –9.99, $p \leq 0.001$). Participants receiving olanzapine treatment had significantly higher response and remission rates compared to participants in the placebo arm (response: 48.6% vs. 22.2%, $p = 0.002$; remission: 35.2% vs. 11.1%, $p = 0.001$). Weight gain and increase in BMI were significantly greater in the olanzapine group compared to the placebo group (weight gain: 3.7 kg vs. 0.3 kg, $p < 0.001$; BMI: 1.18 vs. 0.02; $p < 0.001$), as was the frequency of other side effects such as drowsiness and sedation. Furthermore, in the olanzapine group, significant increases were observed in systolic blood pressure ($p = 0.001$), fasting blood glucose ($p = 0.002$), total cholesterol ($p = 0.001$), and prolactin levels ($p < 0.001$). Improved functioning according to the CGAS scores was also observed. This trial established the efficacy of olanzapine as monotherapy during acute treatment of PBD but also highlighted multiple metabolic side effects of significant concern (Tohen et al., 2007).

Ziprasidone

The treatment dose range for ziprasidone is 80 to 160 mg, with the following adverse side effects: sedation,

headaches, and gastrointestinal disturbances. There appears to be less weight gain among patients taking ziprasidone when compared to risperidone and olanzapine. Ziprasidone is contraindicated in patients with a known history of QTc prolongation or arrhythmia (Correll, 2011).

There are limited published data on the efficacy and safety of ziprasidone for the treatment of PBD. In an eight-week, open-label trial, 21 youth (aged 6 to 17 years) with BD I, manic or mixed episode, or *DSM-IV*-defined BD not otherwise specified received ziprasidone monotherapy. Ziprasidone was associated with significant improvement in mean YMRS scores, with a response rate of 57% (CGI-I ≤ 2) (Biederman et al., 2007). DelBello and colleagues (2008) assessed ziprasidone's tolerability in an open-label trial with 63 youth (aged 10 to 17 years) receiving ziprasidone (80 or 160 mg/day in two divided doses) over a three-week fixed-dose period. They concluded that adverse events were more common in the high-dose group than the low-dose group.

In a four-week, double-blind, placebo-controlled trial, 238 participants (aged 10 to 17 years) were randomized to receive ziprasidone or placebo. Target ziprasidone doses ranged from 80 to 160 mg/day for participants weighing more than 45 kg and from 40 to 80 mg/day for participants weighing less than 45 kg. The findings from this RCT have not been published but were presented at the APA's 161st annual meeting and are available on the FDA website (DelBello et al., 2008). The primary efficacy measure was the change in YMRS total scores from baseline. Ziprasidone had a higher response rate for the treatment of mania compared to placebo (62% vs. 35%; $p < 0.001$). Patients receiving ziprasidone 40 to 80 mg/day showed less improvement than the group receiving 80 to 160 mg/day, but it was unclear whether this difference was due to the dose or a weight effect, since the dosing mechanism is related to patient weight. The most frequent side effects reported were dystonia, headache, and sedation. Ziprasidone, however, has not received FDA approval for treatment of PBD due to quality-control issues that occurred with this particular study (FDA, 2009b).

Clozapine

The pediatric treatment dose for clozapine ranges from 50 to 600 mg/day. Common adverse events are sedation, weight gain, increased salivation, seizures, myocarditis, and potentially lethal agranulocytosis (which limits the use of this medication to patients who have not responded to other treatment interventions) (Correll, 2011).

There are currently no RCTs that have established the efficacy and safety of clozapine to treat PBD. Masi and colleagues (2002) conducted a small open trial of clozapine in 10 inpatient adolescents (aged 12 to 17 years) with severe BD I, manic or mixed episode, who had not improved after treatment with SGAs or mood stabilizers. Significant improvement was observed on multiple outcome measures, including CGI-S, CGI-I, YMRS, BPRS, and CGAS, at hospital discharge, which was 15 to 28 days after clozapine treatment had been initiated. Data from open trials such as this one suggest that clozapine may be beneficial as an intervention for treatment-resistant PBD.

Combination Treatment Trials

When youth with PBD do not respond to monotherapy with one of the agents described previously, combination medication treatment is often initiated to help reduce manic or mixed symptoms (Bhangoo et al., 2003). Data from recent combination treatment studies are reviewed below. The majority of these studies are open-label trials with small sample sizes and treatment offered across varying time periods; therefore, results from these studies should be interpreted with caution.

Combined Treatments of Mood Stabilizers and Atypical Antipsychotics

In 2002, DelBello and colleagues investigated the efficacy and tolerability of quetiapine as an adjunctive treatment to divalproex among 30 participants (aged 12 to 18 years) with BD I, manic or mixed episode. All participants received divalproex 20 mg/kg on day 0 and were then randomized to adjunctive treatment with quetiapine (titrated to a maximum dose of 450 mg/day) or placebo for six weeks. Both groups had reduced YMRS scores at the end of the study; however, the divalproex-plus-quetiapine group had significantly greater reduction in YMRS scores from baseline to study endpoint compared to the divalproex-plus-placebo group ($p = 0.03$). Response rates were also significantly higher in the divalproex-plus-quetiapine group (87%) versus the divalproex-plus-placebo group (53%). The most common adverse side effects in both groups

were sedation, headache, nausea, and gastrointestinal irritation, with sedation being significantly more common in the divalproex-plus-quetiapine group compared to the divalproex-plus-placebo one. Subjects in the divalproex-plus-quetiapine group gained more weight than those on divalproex alone (4.2 ± 3.2 kg and 2.5 ± 2.1 kg respectively); however, this difference was not statistically significant. These results indicated that quetiapine in combination with divalproex might be more efficacious in treating manic or mixed symptoms in PBD than divalproex alone.

Pavuluri and colleagues conducted two open-label trials that assessed the efficacy of risperidone in combination with a mood stabilizer for acute treatment of PBD. In the first trial in 2004, 37 subjects (aged 5 to 18 years) with BD I, manic or mixed episode, were sequentially assigned to receive risperidone (3 mg/day) adjunctive to either lithium (0.6 to 1.0 mEq/L) or divalproex (50 to 120 µg/mL) over a 6-month period. Participants in both groups showed significant improvements in YMRS, CGI-S, and CGI-I scores from baseline; however, differences between groups were not statistically significant. The response rate (based on at least 50% change in baseline YMRS scores) was comparable in both groups (82.4% for risperidone plus lithium and 80% for risperidone plus divalproex). There were no significant differences in adverse side effects between groups. In 2006, Pavuluri and colleagues further explored the combination treatment of risperidone and lithium among 38 subjects (aged 4 to 17 years) with preschool-onset BD. All participants first received lithium monotherapy (single dose of 150 or 300 mg/day) for eight weeks. Of the 38 participants, 21 failed to have an adequate response or relapsed after an initial response and were augmented with risperidone (maximum dose 2 mg/day) for up to 11 months. The response rate for the combined medication group (as defined by at least 50% change in baseline YMRS scores) was 85.7%, and 57.1% maintained remission at the end of the 12-month period.

Wozniak and colleagues (2009) conducted two partially concurrent 8-week open-label trials to test the efficacy and safety of olanzapine alone and olanzapine augmented with topimarate in 40 participants (aged 6 to 17 years) diagnosed with BD I or BD II. Participants received either olanzapine monotherapy (N = 17; mean dose 8.6 ± 3.4 mg/day) or the combination of olanzapine (mean dose 9.9 ± 5.2 mg/day) plus topimarate (70.5 ± 30.5 mg/day) (N = 23). Both groups demonstrated statistically significant improvement at study endpoint as measured by change in YMRS and CGI-I scores, but differences between groups were not significant. There was a statistically significant increase in weight from baseline in both groups; however, the olanzapine-only group experienced twice as much weight gain than the olanzapine-plus-topimarate group (5.3 kg vs. 2.5 kg, p = 0.006).

Combined Treatments of Two Mood Stabilizers

Findling and colleagues (2003) examined the combination of lithium (30 mg/kg per day) and divalproex (20 mg/kg per day) in an open-label trial with 90 participants (aged 5 to 17 years) with BD I or BD II, manic or hypomanic episodes for up to 20 weeks. There was significant reduction in manic symptoms, depressive symptoms, and overall functioning at week 8 and at the end of the study as measured by changes in YMRS, CDRS-R, and CGAS scores from baseline. The mean length of treatment in the study was 11.3 weeks. Forty-seven percent of participants met criteria for clinical remission as defined by CDRS-R 40 or less, YMRS 12.5 or less, and CGAS 51 or more for four consecutive weeks.

Findling and colleagues (2006) examined the same combination treatment in another 8-week open-label trial to assess its efficacy in restabilization among 38 patients (aged 5 to 17 years) who had relapsed after monotherapy with either lithium or divalproex. Similar to the previous trial, significant improvements were observed in manic symptoms, depressive symptoms, and overall functioning as measured by changes in YMRS, CDRS-R, and CGAS scores from baseline. At the end of the eight weeks of combination treatment, 89.5% (n = 34) of the participants were successfully restabilized, but four participants required adjunctive antipsychotic treatment to address residual symptoms. While findings of these two open-label trials suggest that the combination of lithium and divalproex may be efficacious in treating mania symptoms in the short term, due to the lack of a comparison monotherapy treatment arm, it cannot yet be concluded that combination treatment is superior to monotherapy with lithium or divalproex.

ACUTE TREATMENT OF BIPOLAR DEPRESSION

Depressive episodes are the most common manifestation of bipolar disorder in youth. In PBD, depressive episodes are characterized by sad mood and irritability along with hopelessness and anhedonia and are associated with increased suicidality (Wozniak et al., 2004). Compared to adults, depressive episodes in PBD are more frequent and longer in duration (Geller et al., 2004) and are commonly undiagnosed in children with BD (Chang, 2009). There is a general lack of controlled studies of pharmacotherapy for bipolar depression in children. This is partially due to the significant concern of suicide risk and exacerbation or induction of mania when using antidepressants to treat bipolar depression (Olfson et al., 2006).

Lithium

Patel and colleagues (2006) conducted an open-label trial where 27 inpatient adolescents (aged 12 to 18) were treated with lithium (30 mg/kg per day, titrated to 1.0 to 1.2 mEq/L) for six weeks. There were significant reductions in the CDRS-R score, which was the primary outcome measure, from baseline to study endpoint. The response rate was 48% (at least 50% reduction in CDRS-S from baseline), and 30% of the participants achieved remission (CDRS-R score 28 or less and CGI-BP 2 or less). The most common adverse side effects in this sample were headaches (74%), nausea or vomiting (67%), stomachache (30%), and abdominal cramps (19%).

Lamotrigine

Chang and colleagues (2006) conducted a small open-label trial of lamotrigine (12 to 25 mg/day) to treat 20 adolescents (aged 12 to 17 years) who were diagnosed with BD I, BD II, or BD not otherwise specified and who were experiencing a depressive episode. Lamotrigine was administered as monotherapy or adjunct to other psychotropic medications such as stimulants, lithium, or antipsychotics. At the end of the study, 84% of participants responded to primary criteria (CGI-I 2 or less), 63% responded to secondary criteria (at least 50% decrease in CDRS-R scores), and 58% attained remission (CDRS-R 28 or less and CGI-S 2 or less). Seven of the 20 participants received lamotrigine as adjunctive medication; however, there were no differences in CDRS-R scores compared to those on lamotrigine monotherapy. There were no serious adverse events in this study, and the adverse side effects reported included headache, fatigue, sweating, nausea, and trouble sleeping. While this study suggests some potential benefit of lamotrigine in the treatment of bipolar depression, it had several methodological limitations, such as the lack of a placebo arm or use of concomitant medications. Controlled trials with larger samples would be needed to establish the efficacy of this drug for use in this patient population.

Quetiapine

The only RCT for bipolar depression in youth was conducted by DelBello and colleagues in 2009. In this RCT, 32 participants (aged 12 to 18 years) with a depressive episode associated with BD I were randomized to treatment with quetiapine (300 to 600 mg/day) versus placebo for eight weeks. There was no statistically significant difference between the two groups on the primary outcome measure (change in CDRS-R scores from baseline), response rate (at least 50% decrease in CDRS-R scores from baseline), or remission rate (CDRS-R 28 or less and CGI-BP-I 2 or less). This study had a very high placebo response rate (67%), which according to the authors could be due to limitations of rating scales and outcome measures used in this study. Findings of this study suggest that quetiapine may not be superior to placebo in improving depressive symptoms among youth with BD and additional research in this area is needed.

Antidepressants

There are limited data on antidepressant treatment for depression within the context of PBD. Biederman and colleagues (2000) did a chart review of 59 patients with PBD and found that when treated with antidepressants, children with bipolar depression improved but they were three times more likely to experience a subsequent manic episode. The use of mood stabilizers was helpful in improving manic symptoms but did not change the course of depression, while selective serotonin reuptake inhibitors (SSRIs) did not improve manic symptoms. In the *Treatment Guidelines for Children and Adolescents with Bipolar*

Disorder, Kowatch and colleagues (2005) discouraged antidepressant monotherapy trials and suggested that SSRIs or bupropion should be considered after mood stabilization.

MAINTENANCE TREATMENT OF PEDIATRIC BIPOLAR DISORDER

PBD is an illness that has a chronic and relapsing course, which often requires long-term treatment (Birmaher et al., 2009). There are very limited data to guide clinical recommendations on maintenance treatment of PBD, with current evidence from three RCTs and a few open-label studies. The medications that have been assessed in these trials for efficacy in maintenance of symptom remission are lithium, divalproex, lamotrigine, and aripiprazole.

Mood Stabilizers

Kafantaris and colleagues (2004) conducted the first placebo-controlled discontinuation trial of lithium among 40 youth (aged 12 to 18 years) with BD I, manic episode who had previously responded to open-label treatment with lithium for up to 4 weeks (Kafantaris et al. 2003). These participants were then randomly assigned to either continue lithium or discontinue and switch to placebo for two weeks. At the end of the 2-week period, both lithium and placebo groups had similar rates of symptom exacerbation as measured by CGI-I scores: 52.6% for lithium and 61.9% for placebo. Despite promising results in the open-label acute treatment phase, lithium was not found to be superior to placebo in sustaining response and remission of symptoms. Researchers suggested that a longer period of treatment with lithium might be required to establish its efficacy for maintenance treatment of PBD.

Findling and colleagues (2005) followed 139 participants (aged 5 to 17 years) with BD I or BD II who had previously been stabilized on combination therapy of lithium and divalproex. Of these 139 participants, 60 met remission criteria for four consecutive weeks and were then randomly assigned to discontinue one of the agents for 76 weeks. The primary outcome measure was time to premature discontinuation for treatment of emerging symptoms of relapse. There was no difference in time to recurrence of symptoms between the lithium (114 ± 57.4 days) and divalproex (112 ± 56 days) monotherapy groups. Divalproex was not found to be superior to lithium monotherapy in the maintenance treatment for youth with PBD who had achieved remission with the combination treatment of lithium and divalproex (Findling et al., 2005).

In 2009, Redden and colleagues examined 226 participants (aged 9 to 17 years) over six months of continuation treatment following acute treatment with extended-release divalproex sodium for BD I, manic or mixed episodes. It was prescribed at 15 mg/kg per day, with a maximum dosage of 35 mg/kg per day. Of the 225 participants enrolled, 109 (44.4%) took divalproex for at least 180 days. The three most common side effects were weight gain (16%), nausea (9%), and increased appetite (8%), and the overall safety profile was comparable to that found in other PBD studies of divalproex. There was a 12.4-point decrease in mean YMRS scores from baseline; however, due to the lack of a placebo-controlled arm, interpretations from these findings are limited.

In another open-label study, Pavuluri and colleagues (2009) examined the effects of maintenance treatment with lamotrigine in 46 patients (aged 8 to 18 years) with BD I, mixed or manic episode or BD II, hypomanic episode. During the first 8-week period, lamotrigine was slowly increased to a therapeutic dose (150 mg in patients weighing 30 kg or less, or 200 mg in those weighing more than 30 kg) in combination with SGAs to stabilize acute symptoms. SGAs were withdrawn over the last two weeks of this acute treatment period, at the end of which patients were receiving lamotrigine alone. Then, remitted patients continued to receive maintenance treatment with lamotrigine monotherapy for a 6-week period. At the end of the 14 weeks, the mania response rate based on the YMRS was 71%, the depression response rate on the CDRS-R was 82%, and the remission rate was 56%. Researchers also found that depressive symptoms continued to decline further with lamotrigine monotherapy in the second 6-week maintenance phase. Of the subjects in remission at the end of the acute 8-week treatment, 23% relapsed by week 14. The most commonly reported adverse side effects included sedation (23.7%), stomachache (19.6%), increased urination (10.9%), and increased appetite (10.9%); three subjects dropped out of the study after developing a benign rash. The findings of this study indicate that lamotrigine appears to be effective in maintaining the response of manic and depressive

symptoms in PBD after acute combination treatment with SGAs. Furthermore, results suggest that SGAs can potentially be withdrawn after reaching a therapeutic dose of lamotrigine without complete relapse of symptoms over a 6-week period.

Second-Generation Antipsychotics

Findling and colleagues (2012) studied the long-term efficacy of aripiprazole in a double-blind placebo-controlled trial with 60 patients (aged 4 to 9 years) diagnosed with BD I or BD not otherwise specified. These participants had previously been part of an acute open trial during which their symptoms were stabilized with aripiprazole for up to 16 weeks (Findling et al., 2011). If they met response criteria for four consecutive weeks, they were then randomly assigned to continued aripiprazole treatment (mean dose 6.4 ± 2.1 mg/day; $N = 30$) or placebo ($N = 30$) for up to 72 weeks. Patients in the aripiprazole group stayed in the study for a significantly longer time (mean weeks 25.93 ± 3.91) compared to those in the placebo group (mean weeks 3 ± 0.57; $p = 0.003$). The time to discontinuation from the study due to a mood event was also significantly longer in the aripiprazole group (mean weeks 25.93 ± 5.81) than in the placebo group (mean weeks 3.10 ± 0.53; $p = 0.005$), with the most common reason for discontinuation being lack of efficacy. There were no significant group differences on symptoms as rated by the YMRS, CDRS-R, CGAS, or CGI-S. Children in the aripiprazole group were more likely to report musculoskeletal and stomach pain and had significantly greater weight gain. The results of this study suggested that aripiprazole may be beneficial in the long-term treatment of children with BD. However, both groups showed a high rate of study dropout (70% for aripiprazole and 90% for placebo), indicating that even though aripiprazole was superior to placebo during maintenance, it was not sufficient to keep youth stable over longer periods of time.

TREATMENT OF COMORBID CONDITIONS

ADHD

ADHD is among the most common comorbidities in PBD, occurring in 30% to 40% of adolescents with PBD (Geller & Luby, 1997). It has been associated with decreased treatment response for acute mania (Consoli et al., 2007). Scheffer and colleagues (2005) conducted a two-stage trial with 42 participants (aged 6 to 17 years) with BD I or BD II. In the first phase, participants received open treatment with divalproex for eight weeks. Participants were eligible to enter the second phase if they had an improvement in manic symptoms based on the YMRS but no improvement in ADHD symptoms based on CGI-I scores ($N = 30$). The second phase consisted of a 4-week double-blind crossover trial of mixed amphetamine salts (MAS; 5 mg twice daily) and placebo (2 weeks in each condition). Participants continued receiving divalproex during the 4-week crossover trial. There were significant improvements in ADHD symptoms in the MAS group, but no differences on change in YMRS scores between groups. The adverse side effects reported included abdominal pain, diarrhea, nausea, and increased appetite, and were not significantly different between the open-label and crossover trials. MAS did not increase mania symptoms in either of the groups. These findings were replicated in a similar 4-week double-blind placebo-controlled crossover trial in 16 youth (aged 5 to 17 years) diagnosed with comorbid PBD and ADHD (Findling et al., 2007). Prior to randomization, patients were being treated with mood stabilizers (lithium, divalproex, or a combination of both). During this crossover study, patients were randomized to 1 week of placebo, 1 week of methylphenidate (MPH) 5 mg twice daily, 1 week of MPH 10 mg twice daily, and 1 week of MPH 15 mg twice daily. At the end of the study, each participant's "best dose week" was determined and compared to placebo on primary and secondary efficacy measures. There were significant differences in ADHD symptoms among patients treated with MPH at any dose versus placebo. There were no group differences for manic or depressive symptoms. This study was underpowered to be able to detect significant differences between the different dose levels of MPH.

Zeni and colleagues (2009) conducted a randomized crossover double-blind controlled trial with 16 youth (aged 8 to 17 years) diagnosed with BD I or BD II comorbid with ADHD. Manic symptoms in these youth had previously responded to treatment with aripiprazole, but they still had clinically significant ADHD symptoms. Participants were randomized to receive aripiprazole and MPH (0.3 mg/kg per day) or aripiprazole and placebo for two weeks each. One of the goals of the study was to determine whether mania symptoms would worsen when adding a stimulant to

antipsychotic treatment in these comorbid cases of PBD and ADHD. The results of this study indicated that there were no significant differences between the MPH and placebo groups on manic or ADHD symptoms as measured by change in YMRS and Swanson, Nolan, and Pelham Scale IV Version (SNAP-IV) scores respectively. There were no significant differences in depressive symptoms as measured by change in clinician-rated CDRS-S scores; however, significant improvement in depressive symptoms was observed based on a secondary self-report measure. There were no significant differences in side effects between the groups, and MPH was no more effective than placebo in improving PBD or ADHD symptoms.

In these three RCTs, manic symptoms were first stabilized with either a mood stabilizer (lithium or divalproex) or an SGA (aripiprazole). The findings were mixed on whether or not stimulants improved ADHD symptoms when added to one of these compounds. However, stimulants did not make manic symptoms worse in any of these trials. RCTs with more rigorous methodology and larger sample sizes are needed to establish the efficacy of stimulants in decreasing ADHD symptoms in youth with PBD. Until more data are obtained, the American Academy of Child and Adolescent Psychiatry treatment guidelines currently recommend that treatment in youth with comorbid PBD and ADHD should be sequential: Bipolar symptoms should be treated first to stabilize mood, and if ADHD symptoms persist, they can be treated with stimulants (Kowatch et al., 2005).

Anxiety

Anxiety disorders are also highly prevalent in youth with PBD, ranging from 37% to 60% depending on bipolar subtype (Axelson et al., 2006; Kowatch et al., 2005). They are associated with severe depressive symptoms, increased risk of mania or hypomania, and lower likelihood of recovery. Currently, no treatment studies have targeted comorbid anxiety in PBD. Treatment guidelines by Kowatch and colleagues (2005) recommend the use of psychosocial interventions that are known to be efficacious in treating anxiety, such as cognitive-behavioral therapy or interpersonal psychotherapy. If medication is needed, it is recommended to first stabilize mood symptoms, particularly mania, before initiating treatment with SSRIs.

Substance Abuse Disorders

The lifetime prevalence of substance abuse disorders in PBD ranges from 6.7% to 9.8% (Axelson et al., 2006). Treatment guidelines recommend that both conditions should be treated simultaneously without delay (Kowatch et al., 2005). This can generally be managed on an outpatient basis, but sometimes an inpatient stay at a hospital or rehabilitation center may be required. Geller and colleagues (1998) conducted the first RCT for lithium in adolescents with BD I, manic or mixed episode, with secondary substance dependence ($N = 25$). In addition to having significant improvements in mood symptoms, participants treated with lithium were less likely to have a positive drug urine test compared to subjects receiving placebo ($p = 0.028$).

SAFETY CONCERNS

Mood Stabilizers

Due to their narrow therapeutic window, lithium, divalproex, and carbamazepine need careful monitoring. The most severe adverse events associated with these medications are seizures, cardiac arrhythmias, coma, and, in extremely rare cases, death (in the case of lithium) (Findling & Pavuluri, 2008; Geller et al., 1998). In the case of divalproex, liver failure and pancreatitis are rare but present a serious concern. For carbamazepine, aplastic anemia, agranulocytosis, and hyponatremia are very serious rare complications. These three mood stabilizers are teratogenic and therefore affect the development of the fetus. It is key to monitor a patient's safety with laboratory assessments and electrocardiograms, and to do a pregnancy test prior to starting lithium, divalproex, or carbamazepine. Lamotrigine can cause a fatal necrotizing rash called Steven-Johnson syndrome and toxic epidermal necrolysis.

Second-Generation Antipsychotics

The most common side effects of SGAs are weight gain and metabolic abnormalities, including diabetes mellitus and hyperlipidemia. Olanzapine and clozapine are associated with the highest amount of weight gain in both adults and children. Other concerning adverse side effects include EPS, prolactin elevation

(primarily for risperidone), intracardiac conduction effects such as QTc prolongation (ziprasidone), and agranulocytosis and seizures (clozapine).

Safety Assessment

Youth should be carefully monitored when receiving pharmacological treatment for PBD with mood stabilizers and/or atypical antipsychotics. Personal and family medical history should be obtained at baseline as well as annually. At each visit, information on lifestyle behaviors, sedation, height, weight, BMI percentile, and BMI *z*-scores should be obtained. BMI can be calculated in kg as follows: weight (kg) / [height (m)]^2 or in pounds as follows: weight (lb) / [height (in)]^2 × 703. BMI *z*-scores, also called BMI standard deviation (s.d.) scores, are measures of relative weight adjusted for the child's age and sex. Given a child's age, sex, BMI, and an appropriate reference standard, a BMI *z*-score (or its equivalent BMI-for-age percentile) can be determined (Correll, 2008; Must & Anderson, 2006). At baseline, during titration, and for every three months thereafter, sexual or reproductive dysfunction should be assessed. Parkinsonism and akathisia should be assessed at these points as well as annually. At baseline, three months after baseline, and annually, tardive dyskinesia, liver function tests, blood pressure, and pulse should be reviewed. Fasting blood glucose and lipids should be obtained at baseline, three months after baseline, and every six months thereafter. Electrolytes, a full blood count, and renal and liver function should be assessed annually; blood count should be monitored more frequently if the patient is taking clozapine. If a patient is taking ziprasidone at the maximum dose, an electrocardiogram should be obtained. If male patients develop gynecomastia or galactorrhea, or female patients develop amenorrhea or oligomenorrhea, prolactin levels should be tested (Correll, 2008).

PSYCHOSOCIAL TREATMENTS FOR PEDIATRIC BIPOLAR DISORDER

The symptoms of PBD are associated with significant psychosocial impairment in multiple domains across a child's development (Weinstein et al., 2013). These include poor academic performance, neurocognitive deficits, poor social and coping skills, and high levels of interpersonal conflict (Geller et al., 2000, 2002; Goldstein et al., 2006; Henin et al., 2007; Kim et al., 2007; Pavuluri et al., 2006b; Rucklidge, 2006; Wilens et al., 2003). Due to the nature and extent of these psychosocial impairments in PBD, experts in the field concur that high-quality, evidence-based psychosocial interventions are needed to improve the course of treatment for this illness (McClellan et al., 2007). Although pharmacotherapy continues to be the first-line treatment for PBD, growing literature suggests that psychosocial interventions are also important to provide family members with a more comprehensive understanding of the illness and appropriate coping strategies. In addition, adverse side effects, poor response to medication, and the inability to address the social, academic, and family factors that affect treatment outcomes through pharmacotherapy also highlight the need for adjunctive psychosocial treatments (McClellan et al., 2007).

This section reviews the evidence base for psychosocial interventions in the treatment of PBD. These interventions are primarily designed to be used as adjunctive treatments with pharmacotherapy and/or TAU. While research has made significant advances in the past decade, data from type 1 studies are limited. This section summarizes data for six types of psychotherapies to treat PBD and includes studies for youth with PBD (BD I, BD II, or BD not otherwise specified) as well as youth at risk of developing PBD.

The psychosocial treatments for PBD with the largest evidence base include Multi-Family Psychoeducational Psychotherapy (MF-PEP), Family-Focused Treatment for Adolescents (FFT-A), and Family-Focused Treatment adapted for youth at risk for bipolar disorder (FFT-HR). The core component of these interventions is providing family psychoeducation and skills building, and each is supported by at least one type 1 trial. Other psychosocial interventions that have shown encouraging treatment gains in preliminary research are supported by type 2 and type 3 studies. These include Individual-Family Psychoeducational Psychotherapy (IF-PEP), Child- and Family-Focused Cognitive-Behavioral Therapy (CFF-CBT), CBT for bipolar disorder in adolescents, Dialectical Behavior Therapy for Adolescents (DBT-A), and Interpersonal and Social Rhythm Therapy for Adolescents (IPSRT-A) (Fristad & MacPherson, 2013).

Multi-Family Psychoeducational Psychotherapy

Fristad and colleagues (2009) have developed and tested both individual and group formats of Psychoeducation-Based Psychotherapy (PEP) for school-aged children. PEP is an adjunctive, manualized intervention that combines psychoeducation with family therapy and CBT techniques. It is designed for children with bipolar or depression-spectrum disorders and their parents and focuses on educating the family on mood disorders; building symptom management skills, including emotion regulation, problem solving, and communication; and increasing support from other families and providers (Fristad, 2006). It was originally developed as an 8-session (90 minutes each) MF-PEP group for children and parents and has subsequently been adapted to a 24-session (50 minutes each) individual-family format (IF-PEP). Parents and children primarily attend sessions separately that run simultaneously during the course of treatment (Weinstein et al., 2013).

Fristad and colleagues (2003) conducted an initial RCT with 35 children (aged 8 to 11 years) with depression and PBD and their families to look at the effects of providing a six-session MF-PEP plus TAU ($N = 18$) compared with a waitlist control condition plus TAU ($N = 17$). At the 6-month follow-up, families who received MF-PEP reported increased perception of support from parents and peers, increased knowledge about mood symptoms, more positive family interactions as reported by the parents, and increased use of appropriate treatment services compared to those in the waitlist control condition. Changes in child mood severity symptoms were not significant after treatment in this study. Fristad and colleagues (2009) then conducted a larger type 1 RCT with 165 children (aged 8 to 12 years) with depression or PBD and their families, where participants were randomized to receive either eight 90-minute MF-PEP sessions plus TAU ($N = 78$) or the waitlist control condition plus TAU ($N = 87$). Participants were assessed at baseline and at 6, 12 and 18 months. Results indicated that MF-PEP was associated with a reduction in mood symptom severity compared to waitlist control over a 1-year follow-up as measured by a combination of the YMRS and CDRS-R scales. MF-PEP participants also demonstrated significant improvement in use of higher-quality mental health services, and this was mediated by parents' beliefs about treatment. As originally designed, this suggests that MF-PEP helped parents become better mental health consumers, and secondary data analyses showed that quality of services used also mediated treatment effects (Mendenhall et al., 2009).

MF-PEP was recently examined in another small open trial to study its implementation in a real-world setting such as a community outpatient clinic (MacPherson et al., 2014). In this trial, MF-PEP was offered to 40 children (aged 8 to 12 years) with depression or PBD and their families at two outpatient clinics, and it was delivered similarly as in the type 1 RCT described above. Preliminary findings indicate that MF-PEP was acceptable, feasible, cost-effective, and sustainable at these clinics. Parents also demonstrated significant improvement in knowledge of mood disorders at the end of treatment. This suggests that such psychosocial interventions for PBD may be transferable and effective in practice settings.

Family-Focused Treatment for Adolescents

FFT is a psychosocial intervention that was originally developed for adults with BD. Miklowitz and colleagues (2004, 2006, 2008) have adapted and evaluated FFT for adolescents with BD in several studies. FFT-A is designed for youth aged 12 to 17 years, and is delivered to youth and their families in 21 50-minute sessions over a 9-month period (Miklowitz et al., 2004). This treatment is based on understanding the central role of the family in managing a young person's PBD symptoms. It consists of four main stages: an *engagement* phase, where the goal is to connect with the patient and family and convey information about the treatment; a *psychoeducational* phase, which educates families on the nature, causes, and management of bipolar disorder (including providing tools for medication adherence and relapse prevention); *communication enhancement training*, where patients and families practice helpful speaking and listening skills; and *problem-solving skills training*, during which patients and families identify problems and generate and implement solutions that are mutually agreed upon (Miklowitz, 2012).

The efficacy of FFT-A as an adjunct treatment to pharmacotherapy for PBD has been established in a two-site type 1 RCT conducted by Miklowitz and colleagues (2008). In this trial, 58 adolescents (aged 12 to 17 years) with BPD and their families were randomized to receive either FFT-A plus pharmacotherapy

(*N* = 30) or enhanced care (three weekly family sessions focused on psychoeducation and relapse prevention) plus pharmacotherapy (*N* = 28). Patients and their families were assessed every three to six months for up to two years. Analyses were by intent to treat, and rates of completion did not differ between the two treatment arms. There were no significant group differences in rates of recovery from the index episode; however, patients receiving FFT-A had significantly shorter times to recovery from depression. The groups did not differ in time to recurrence of mania or depression, although FFT-A patients spent significantly fewer weeks in acute depressive episodes than those receiving enhanced care. FFT-A patients also had significantly greater reduction in depression severity scores and a more favorable trajectory of depressive symptoms over two years. These findings suggest that FFT-A as an adjunct treatment to pharmacotherapy might be effective in stabilizing bipolar depressive symptoms among adolescents, and may need to be supplemented with other interventions for mania symptoms to establish a complete recovery (Miklowitz et al., 2008).

Prior to this RCT, FFT-A was tested in several open trials that would meet criteria for type 3 studies. For example, Miklowitz and colleagues (2004) provided FFT-A in addition to pharmacotherapy to 20 adolescents (aged 13 to 17 years) with PBD. At the 12-month follow-up, they observed improvements in depressive and manic symptoms as reported by adolescents, and improvements in problem behaviors and internalizing and externalizing symptoms as reported by parents. While open trials such as this are not sufficient in and of themselves to establish the intervention's efficacy, they add to the growing body of literature and help inform type 1 studies as described above.

Family-Focused Treatment Adapted for Youth at High Risk for Pediatric Bipolar Disorder

Recently, FFT-A has also been adapted for children and adolescents at high risk for developing PBD (FFT-HR). Its possible efficacy has been established through one type 1 RCT (Miklowitz et al., 2013) and 1 type 3 open trial (Miklowitz et al., 2011). In these studies, youth were considered to be at high risk for developing PBD if they had been diagnosed with major depressive disorder, cyclothymic disorder, or BD not otherwise specified; had active mood symptoms in the past month; and had at least one first-degree relative with BD I or BD II. In the open trial, study clinicians delivered FFT-HR to 13 youth (aged 9 to 16 years) at risk for developing PBD and observed significant improvement in depressive symptoms, hypomanic symptoms and global functioning at the 12-month follow-up (Miklowitz et al., 2011). In the RCT, 40 high-risk youth (aged 9 to 17 years) were randomly assigned to receive either 12 sessions of FFT-HR or family education control (one or two family sessions that incorporated diagnostic feedback, mood monitoring, and symptom management skills) over a 4-month period. Youth and at least one parent were assessed at baseline and 4, 8, and 12 months after randomization. Intent-to-treat analyses demonstrated that youth in the FFT-HR group experienced more rapid recovery from initial mood symptoms, spent more weeks in remission, and had a more favorable trajectory of manic symptoms (as measured by their YMRS scores) over one year than youth in the family education control group. This suggests that FFT-HR may hasten and help sustain recovery from mood symptoms among youth at a high risk for PBD (Miklowitz et al., 2013). The effects of FFT-HR were more pronounced among youth in high-expressed-emotion families than in low-expressed-emotion families. The moderating effects of expressed emotion on patients' responses to FFT have been observed in other RCTs of adolescents and adults with BD (Kim & Miklowitz, 2004; Miklowitz et al., 2009), and therefore findings from this trial provide insight on subgroups of patients who might be more likely to respond to an early intervention such as FFT-HR.

Individual-Family Psychoeducational Psychotherapy

IF-PEP is a single-family adaptation of MF-PEP and has been examined in a small type 2 RCT with 20 children (aged 8 to 11 years) and their families (Fristad, 2006). This intervention consisted of 16 to 24 50-minute sessions alternating between the child and parent, and these sessions covered all the same content as in MF-PEP. IF-PEP also focused on coordination of school mental health services, sibling relationships, and healthy life habits such as good sleep hygiene, exercise, and nutrition. Researchers found that improvement in children's mood symptoms in the IF-PEP-plus-TAU arm was not significant when compared to the

waitlist-control-plus-TAU group; expressed emotion improved significantly more in IF-PEP-plus-TAU families than the waitlist-control-plus-TAU families; and there was no significant improvement in service utilization between the two treatment arms (Fristad, 2006). While this type 2 study offers some support for IF-PEP, additional research is needed to establish IF-PEP as an efficacious psychosocial intervention in the treatment of PBD.

Child- and Family-Focused Cognitive-Behavioral Therapy

CFF-CBT is a family-based adjunctive psychosocial treatment for children aged 7 to 13 years with PBD and their families. It integrates principles of family-focused treatment with those of CBT and interpersonal techniques and is a further adaptation of Miklowitz and Goldstein's FFT-A intervention to address the developmental needs of younger children and their families. Similar to FFT-A, it is based on a vulnerability-stress model, which suggests that environmental agents within the family, such as stressful life events, expressed emotion, coping, and negative communication styles, interact with an individual's genetic and biological predisposition to trigger illness (Pavuluri et al., 2004a). The CFF-CBT model is grounded in the neuroscience literature, specifically around dysfunction in neural systems responsible for processing and modulating emotions in PBD. As such, treatment aims to address impairments in affective circuitry and interpersonal functioning (Weinstein et al., 2013). Typically, CFF-CBT is a 12-session treatment that is delivered weekly over the course of three months (West et al., 2009). The acronym RAINBOW was formed to help parents and children remember the key components of this treatment: *Routine*, *Affect regulation*, *I can do it*, *No negative thoughts and live in the Now*, *Be a good friend and Balanced lifestyle for parents*, *Oh, how can we solve the problem*, *and Ways to get support* (West & Weinstein, 2012).

Findings from an open trial of CFF-CBT plus pharmacotherapy conducted with 34 youth (aged 5 to 17 years) with PBD and their families demonstrated the feasibility and acceptability of this intervention. Youth also experienced significant improvements in attention problems, aggression, mania psychosis, depression, and sleep disturbance and reported increased global functioning after treatment (Pavuluri et al., 2004a). Participation in the maintenance phase after the short-term intensive treatment phase of CFF-CBT was associated with being able to sustain symptom reduction and improvements in functioning over a 3-year period (West et al., 2007).

CFF-CBT has also been adapted to a multiple-family group format and assessed in an open trial where CFF-CBT group treatment was provided to 26 families who had children (aged 6 to 12 years) with PBD. Results indicated that this intervention was feasible and acceptable to families. It was further associated with significant improvement in the child's manic (but not depressive) symptoms and psychosocial functioning. Although not statistically significant, parents also reported increased knowledge and perceived ability to cope with their child's illness (Weinstein et al., 2013; West et al., 2009).

Results from these open CFF-CBT trials are promising, but more type 1 studies are needed to establish CFF-CBT's efficacy to treat PBD. An RCT of CFF-CBT is under way to assess the efficacy of CFF-CBT when compared with TAU in a sample of 60 children (aged 7 to 13 years) with PBD (Weinstein et al., 2012). Preliminary results suggest that CFF-CBT significantly improves symptoms of mania and depression compared to control TAU.

Cognitive-Behavioral Therapy for Bipolar Disorder in Adolescents

A manualized, adjunctive CBT intervention has also been developed for adolescents with PBD. It consists of 12 weekly sessions of acute-phase treatment (which includes sessions with both the child and the parent) followed by 6 to 10 biweekly sessions and biannual booster sessions. This intervention uses a traditional CBT framework with principles from CBT treatment for depressed adolescents, which are retargeted toward the specific needs of adolescents with PBD. Treatment usually involves psychoeducation, medication compliance, mood monitoring, problem solving, identifying and changing negative thinking patterns, sleep regulation, and family communication (Danielson et al., 2004).

Dialectical Behavior Therapy for Adolescents

DBT is an evidence-based intervention that is known to be efficacious in the treatment of adults

with borderline personality disorder (Linehan et al., 2006). Goldstein and colleagues (2007) have adapted this intervention to treat PBD since extreme emotion dysregulation is experienced by youth with PBD, and addressing this emotion dysregulation is a core component of DBT treatment (Birmaher et al., 2006). DBT-A for PBD is delivered in 36 sessions over the course of one year and involves both family skills training and individual psychotherapy for the youth. In a small open trial of DBT plus pharmacotherapy for 10 adolescents (aged 14 to 18 years) with PBD, researchers found that feasibility and acceptability of the intervention were high. Nine out of 10 patients completed treatment, 90% of scheduled sessions were attended, and parent and youth satisfaction rates were high. Adolescents demonstrated significant improvements in suicidality, emotion dysregulation, and depressive symptoms after treatment. There were no significant improvements in mania, interpersonal functioning, or number of medications prescribed (Goldstein et al., 2007).

Interpersonal and Social Rhythm Therapy for Adolescents

IPSRT is an empirically supportive adjunctive treatment for adults with BD (Frank et al., 2005) and has been adapted for youth with PBD (Hlastala and Frank, 2006). The adolescent program, IPSRT-A, comprises 16 to 18 sessions delivered over a period of 20 weeks. Most sessions are with the adolescent alone, with two or three family psychoeducational sessions (Hlastala & Frank, 2006). IPSRT-A differs from other psychosocial interventions for PBD in that it targets a biological diathesis for bipolar disorder—instability in circadian rhythms and neurotransmitter systems involved in regulation and social routines that affect circadian rhythms (Frank, 2005). Based on this, IPSRT focuses on stabilizing social and sleep routines as well as using interpersonal approaches to address psychosocial stressors that increase routine disruption (Hlastala & Frank, 2006). IPSRT has been examined in a small, open trial where 12 adolescents (aged 12 to 18 years) with PBD were treated with IPSRT over a 20-week period. Feasibility and acceptability of IPSRT-A were high; 11 out of 12 participants completed treatment and 97% of the treatment sessions were attended. IPSRT-A participants experienced significant improvements in mania, depression, general psychiatric symptoms, and global functioning. An RCT is under way to establish treatment efficacy (Hlastala et al., 2010).

CONCLUSION AND FUTURE DIRECTIONS

PBD is a severe and disabling condition that has seen higher rates of diagnosis and treatment over the past two decades. Despite the significant shift toward a better conceptualization of PBD, there remains a lack of data from type 1 RCTs to inform treatment recommendations. Much of the evidence for pharmacological and psychosocial treatments for PBD comes from type 2 and type 3 studies, which are limited by small sample sizes, low study completion rates, and lack of control groups and longitudinal data.

Currently, pharmacotherapy remains the first-line treatment for PBD. The two classes of medications currently used to treat PBD are mood stabilizers and SGAs. Of these, the FDA has approved lithium (for youth aged 12 and above), risperidone, aripiprazole, quetiapine (for youth aged 10 and above), and olanzapine (for youth aged 13 and above) for the treatment of PBD. The pharmacological literature on PBD provides empirical support for the efficacy of SGAs in treating acute manic or mixed episodes. However, the tolerability of these medications continues to be a challenge. Data from combination and head-to-head trials comparing SGAs to lithium or divalproex suggest that SGAs may be faster and more effective than mood stabilizers in treating manic symptoms during acute phases of treatment (Geller et al., 2012; Pavuluri et al., 2010). Additional placebo-controlled trials are necessary to support these findings.

At this time, there is limited information on the effectiveness of monotherapy with lithium or divalproex in managing acute manic symptoms. We hope to have additional information or recommendations on the use of lithium during acute treatment once the results from the Collaborative Lithium Trial (Findling et al., 2008a) become available. Data from combination trials suggest that monotherapy might be recommended for youth with mild to moderate PBD symptoms, but patients with more severe symptoms might benefit from combination

pharmacotherapy of an SGA with a mood stabilizer (Pavuluri et al., 2004b).

Treating bipolar depression continues to be a challenge for the pediatric population, with limited support from treatment studies of lithium and lamotrigine. Antidepressant monotherapy is discouraged due to the possibility of inducing mania. The current treatment guidelines recommend stabilizing mood before considering SSRIs to treat depressive symptoms (Kowatch et al., 2005); however, more placebo-controlled trials are needed to develop clear recommendations for treatment of bipolar depression. Similarly, when treating PBD comorbid with other conditions like ADHD, manic symptoms should be stabilized before initiating treatment with stimulants (Kowatch et al., 2005). Finally, there are limited data on continuation or maintenance treatment of PBD. Preliminary findings suggest that mood stabilizers may be more effective in maintenance treatment compared to SGAs, which have been associated with significant metabolic side effects (Correll, 2011; Findling et al., 2005; Pavuluri et al., 2009). More long-term studies are needed to investigate which medications best maintain gains from acute treatment and inhibit or prolong time to relapse.

Over the past decade, considerable progress has also been made in the development and evaluation of psychosocial interventions to treat PBD. Currently, the three psychosocial interventions that are the most thoroughly examined and supported by at least one type 1 RCT are MF-PEP (Fristad et al., 2009), FFT-A (Miklowitz et al., 2008), and FFT-HR (Miklowitz et al., 2013). These interventions focus on family psychoeducation plus skills building and are likely to be the most efficacious as adjunctive treatments to pharmacotherapy for PBD. At the next level, IF-PEP is supported by one type 2 RCT. CFF-CBT and CBT for BD in adolescents are supported by three type 3 studies. DBT-A and IPSRT-A would currently still be considered experimental for the treatment of PBD since they are each supported by only one type 3 open trial. Several RCTs are under way to evaluate the efficacy of these interventions with more rigor.

Although results from the reviewed psychosocial trials are promising, it is important to note some limitations that affect the generalizability and interpretation of the reported findings. First, except for the type 1 RCTs, most samples were small and composed mainly of white males, which makes it challenging to draw broader conclusions about these treatments. Second, all studies included youth with a range of bipolar disorders with varying levels of symptom severity, and in some cases even depressive disorders. This limits our ability to attribute treatment response entirely to the intervention or to determine which of these treatments work best for certain subsets of the PBD population. Another major methodological limitation is the use of waitlist control conditions or other enhanced care conditions in the RCTs instead of a psychological placebo or other active treatment. As a result, one cannot rule out the possibility that significant changes were due to other factors not related to the treatment interventions. Other limitations include all studies being conducted in university-based settings or specialty outpatient clinics, all trials allowing for continuation of TAU or pharmacotherapy without being controlled or reported, and most trials including carefully managed pharmacotherapy by highly trained psychiatrists that might have had a positive effect on treatment outcomes (Fristad & MacPherson, 2013).

Despite these limitations, preliminary findings on pharmacological and psychosocial treatments for youth with PBD are promising and have important clinical implications. More rigorous RCTs are needed with diverse samples that compare these interventions to placebo or other active treatments and clarify whether they are safe and effective in the long term. Additional research should also examine moderators of treatment response, approaches for early intervention, and the effectiveness and implementation of empirically supported treatments in community-based practice settings.

Psychosocial Treatments for Bipolar Disorder

Anjana Muralidharan
David J. Miklowitz
W. Edward Craighead

Although pharmacological interventions remain the primary treatment for bipolar disorder (BD), adjunctive psychosocial interventions have the potential to increase adherence to medication regimens, decrease hospitalizations and relapses, decrease severity of symptoms, improve quality of life, and enhance mechanisms for coping with stress. Four type 1 and 2 studies have established that group psychoeducation, designed to provide information to BD patients about the disorder and its treatment, leads to lower rates of recurrence and greater adherence to medication among remitted BD patients at both short- and long-term follow-up. Type 1 and 2 studies that evaluated cognitive-behavioral therapy (CBT) as an ancillary treatment have found mixed results but generally supportive evidence indicating that the intervention is useful in preventing relapse to depression in remitted patients. Three type 1 studies have shown that family-based intervention, such as Family-Focused Therapy (FFT), may be effectively combined with pharmacotherapy to reduce recurrences and hospitalization rates in adult patients. A type 1 trial with acutely depressed BD patients comparing CBT, FFT, and Interpersonal and Social Rhythm Therapy (IPSRT) to a short-term psychoeducational intervention reported that the three intensive psychotherapy conditions were associated with higher rates of and faster times to recovery. Finally, three type 1 studies have indicated that family psychoeducation and skills training may be effective adjuncts to pharmacotherapy for bipolar spectrum children and adolescents and youths at high risk for BD. Further investigation into mechanisms of treatment efficacy and moderators of clinical outcome will inform continued development and dissemination of effective psychosocial interventions for BD.

INTRODUCTION

Up to 4% of the adult population in the United States experiences BD (Kessler, Berglund, Demler, Jin, & Walters, 2005). For more than 90% of those patients, the disorder is characterized by a recurrent course of mood fluctuation over the lifetime (American Psychiatric Association [APA], 2013). Several studies indicate that approximately half of these patients experience lengthy periods of interepisode residual symptoms despite pharmacotherapy (e.g., Judd et al., 2002; Solomon et al., 2010). BD has been listed as the sixth leading cause of disability among the physical and psychiatric disorders (Murray & Lopez, 1996), and recent epidemiological data indicate that BD continues to be a significant contributor to global disease burden (Whiteford et al., 2013).

BD has a strong impact on patients' work and social functioning. The majority of individuals with BD experience significant work impairment between episodes (Goetz et al., 2007); in a nationally representative U.S. sample, BD was associated with 65.5 lost workdays per patient per year (Kessler et al., 2006). Stable outpatients with BD exhibit social functioning deficits similar to stable outpatients with schizophrenia (Dickerson et al., 2001). The effects of manic episodes on social, occupational, and family functioning can be observed 5 years later (Coryell et al., 1993). The risk of suicide in BD patients is at least 15 times that for the normal population (APA, 2013). Unfortunately, despite recent advances in the treatment of this debilitating disorder, it is estimated that between one fourth and nearly two thirds of BD patients have never sought treatment (Goodwin & Jamison, 2007).

In the recently published fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*-5), bipolar spectrum disorders have been separated from depressive disorders and placed in their own category. This is in acknowledgment of the distinction of this class of disorders from unipolar depression, and its overlap in terms of genetic risk with psychotic spectrum disorders and schizophrenia (APA, 2013). Bipolar spectrum disorders are distinguished from other classes of disorders by the presence of manic or hypomanic symptoms. To meet criteria for bipolar I or II disorder, individuals must exhibit a distinct period of euphoric/elevated mood and/or irritable mood. In *DSM-5*, these mood changes must be accompanied by increased energy and/or goal-directed activity to meet criteria for a manic or hypomanic episode. The majority of individuals with a bipolar illness—although not all—suffer from depressive episodes. Bipolar depression may be distinct from unipolar depression in terms of younger age of onset, greater frequency of episodes, and greater short-term mood variability (Cuellar et al, 2005). Thus, despite overlap of symptoms with other mental illness categories, bipolar spectrum disorders have a number of unique features that warrant specialized, disorder-specific treatment.

A common etiological explanation for BD points to biological dysregulation (with a major genetic component) that is either activated or maintained by psychosocial stressors such as negative family environments or significant life events (e.g., Alloy et al., 2009; Miklowitz & Johnson, 2006). Because of the biological dysregulation associated with BD, pharmacological treatments have become the primary focus of intervention. Although the atypical antipsychotic medications are increasingly treatments of choice for acute manic episodes, lithium carbonate and anticonvulsants such as lamotrigine remain the most effective interventions and figure prominently in the treatment of acute depression and longer-term maintenance treatment (Malhi et al., 2009; Tohen & Vieta, 2009). With one or more of these medications, the majority of patients can now experience some level of mood stabilization with continued use.

Within the context of pharmacological interventions as the primary treatment for BD, psychosocial interventions have been designed to increase adherence to medication regimens, reduce the number of hospitalizations and relapses, decrease severity of symptoms, diminish the impact of stress, and improve patients' quality of life. The major components of a multifaceted psychosocial treatment program could include individual or group psychoeducation (with special attention to medication adherence and symptom management), cognitive training, individual cognitive-behavioral or interpersonal therapy, and family therapy. In this chapter we review the empirical outcome data for each of these treatment components.

PSYCHOEDUCATION

BD patients frequently express resentment at how little information they have received about their disorder or their medications (Goodwin & Jamison, 2007). The primary focus of psychoeducation is provision of information regarding the multifaceted nature of the disorder and its successful treatment. The issue of medication adherence is a particularly salient aspect of the education and treatment of BD. In fact, poor adherence to medication is a highly significant predictor of poor treatment response in BD (Goodwin & Jamison, 2007). Despite the high risk of relapse due to nonadherence, more than half of patients with BD on mood stabilizers or atypical antipsychotics choose to discontinue their medication or do not take it as prescribed (Arvilommi et al., 2013). Therefore, enhancing medication adherence is an important goal of ancillary psychosocial treatments.

Early Psychoeducational Studies

Early attempts to enhance medication adherence in psychiatric patients included brief psychoeducational interventions, tested in type 2 or 3 trials. Interventions including a series of psychoeducational lectures (Seltzer, Roncari, & Garfinkel, 1980) or a brief educational video accompanied by informational handouts (Harvey & Peet, 1991) were found to have favorable short-term effects on knowledge about BD, self-reported medication adherence, and/or plasma lithium levels.

In a type 1 trial that improved on these early efforts by including a more tightly controlled experimental design and a longer period of follow-up, Perry, Tarrier, Morriss, McCarthy, and Limb (1999) compared patients who received medication management with patients who received medication management and a 7- to 12-session individual psychoeducation intervention (n = 69). The psychoeducation consisted of sessions to teach patients to recognize emergent symptoms of BD and to seek appropriate medical/preventive interventions. During an 18-month follow-up period, manic relapses were significantly delayed among bipolar patients in the psychoeducation versus the medication-only group; no differences were found in survival times prior to depressive relapses. Psychoeducation also had a stronger impact on social and occupational functioning than did medication management. There were no differences between the groups in medication adherence.

Group Psychoeducation

A number of studies suggest that group psychoeducation is an effective adjunct to pharmacotherapy for individuals with BD in remission. One type 1 study randomized 84 participants to receive a 12-session group-based psychoeducation intervention or treatment as usual; the psychoeducation group exhibited reduced rates of relapse of any type over the 1-year follow-up period (Castle et al., 2010). Three type 1 and 2 studies show both positive (D'Souza et al., 2010; Eker & Harkin, 2012) and negative (de Barros Pellegrinelli et al., 2012) results. Differences in intervention length, topics covered, and treatment settings may account for these discrepant findings.

Investigators at the Bipolar Disorders Program of Barcelona conducted a rigorous study of a group psychoeducation intervention. This type 1 randomized trial (n = 120 remitted patients with BD; Colom et al., 2003) had an active control condition that matched the experimental group in terms of amount of clinical contact: One group of patients received psychopharmacology and 21 weekly sessions of group psychoeducation, and another received psychopharmacology and 21 unstructured, nondidactic group support sessions. The experimental group psychoeducation focused on illness management (e.g., relapse prevention planning) and decreasing the stigma of mental illness. Patients had been in remission for at least 6 months prior to entering the trial. At the end of 2 years, the rate of relapse was 67% in group psychoeducation and 92% in the unstructured groups. Patients in the experimental group also had higher and more stable lithium levels (Colom et al., 2005). A 5-year follow-up of this study sample indicated that gains from the intervention were maintained. Over the follow-up period, the experimental group reported greater time to recurrence, fewer recurrences, fewer days hospitalized, and less time acutely ill than the control group (Colom et al., 2009).

In an effort to independently replicate Colom and colleagues' (2003) findings, a type 2 study conducted at two outpatient mental health clinics in Italy used their full 21-session intervention. Patients in the psychoeducational groups exhibited decreased rates of hospitalization and fewer days hospitalized than patients in the control group. However, this study did not use an active control intervention (Candini et al., 2013). Thus, independent replication of Colom and colleagues' findings is warranted in a large, type 1 study with an active control condition; one such trial is under way (Morriss et al., 2011).

Overall, group psychoeducation appears to be an effective adjunct to pharmacotherapy for BD patients in remission. Evidence from several type 1 and 2 studies indicates that this intervention is associated with increased medication adherence, increased time to relapse, decreased severity of symptoms, and decreased time spent ill. Group psychoeducation may be particularly helpful in preventing manic relapse, perhaps by improving medication adherence and/or the ability to detect and intervene with prodromal manic symptoms. Questions remain regarding what specific components of group psychoeducation are essential for efficacy. For example, it is unclear whether the intervention must be a specific length or cover certain topic areas in order to be efficacious. Future

studies examining mediators and moderators of outcome, as well as dismantling studies aimed at identifying the "active ingredients" of the intervention, could help to address these questions.

Group Psychoeducation Within Systems of Care Models

Two type 1 studies examined psychoeducation groups embedded within larger systems of care. First, a large-scale randomized controlled trial (RCT) at a health maintenance organization examined group psychoeducation within the context of a multicomponent care-management intervention (Simon et al., 2005). Patients (n = 441) had all been treated within a managed care network within the prior year. They were randomly assigned to pharmacotherapy alone or to a care-management program consisting of pharmacotherapy, telephone-based monitoring, care planning within an interdisciplinary team, and group psychoeducation. The group psychoeducation model focused on individual life goal setting (Bauer & McBride, 1996). Over a 2-year follow-up, patients in the program had lower mania scores and spent less time hypomanic or manic than those who received pharmacotherapy alone (Simon, Ludman, Bauer, Unutzer, & Operskalski, 2006). The intervention did not differentially affect depressive symptoms.

Second, a type I study conducted at 11 Veterans Affairs hospitals across the United States examined group psychoeducation for BD within a collaborative model of chronic care. This model included group psychoeducation, patient monitoring by a nurse care manager, and monitoring of physician adherence to treatment guidelines. Participants (n = 306) were randomized to 3 years in the intervention or usual care. The intervention significantly reduced time spent in affective episodes, especially mania, over the 3 years. Participants in the intervention showed significant improvements on measures of social functioning, quality of life, and treatment satisfaction. The intervention was cost-neutral (Bauer et al., 2006).

COGNITIVE REMEDIATION

Individuals with BD exhibit significant cognitive impairment, both during and between mood episodes (Henin et al., 2009). A novel treatment for BD, cognitive remediation (CR), emphasizes strategies to improve attention, concentration, and memory. CR has also been found to be useful in improving cognitive impairment in schizophrenia spectrum disorders (Wykes et al., 2011). Two type 3 studies and one type 1 study examined CR in samples of patients with BD. In the first study (open trial; n = 18), individuals with BD participated in 14 sessions of individual CR. Subjects exhibited improvements in depressive symptoms and occupational functioning at the end of treatment and at the 3-month follow-up (Deckersbach et al., 2010). In the second type 3 study, 51 patients with unipolar and bipolar depression demonstrated improvements in working memory after 10 weeks of CR (Meusel et al., 2013).

A type 1 study examined an intervention termed "functional remediation," which combined CR with a focus on improving psychosocial functioning through psychoeducation about the nature and impact of cognitive impairment; this intervention was compared to general psychoeducation and treatment as usual in 239 subjects with BD (Torrent et al., 2013). At the end of treatment, functional remediation was associated with greater improvement in global psychosocial functioning compared to treatment as usual; there were no significant differences in psychosocial functioning between the functional remediation and general psychoeducation conditions. Functional remediation did not lead to improved mood symptoms.

The long-term impact of CR on cognition and psychosocial functioning in BD remains to be determined. Given the growing support for the use of CR in psychotic spectrum disorders, additional RCTs in BD appear to be warranted.

INDIVIDUAL PSYCHOTHERAPY INTERVENTIONS

Cognitive-Behavioral Therapy

The past 15 years have seen increased interest in the addition of individual CBT to mood-stabilizing medication regimens for the treatment of BD. The primary assumption of CBT is that mood swings are in part a function of negative thinking patterns (both self-statements and core dysfunctional schemata) that can be alleviated by a combination of behavioral activation and cognitive restructuring

strategies to increase the patient's engagement with the environment.

A large-scale (n = 103) type 1 randomized study (Lam et al., 2003; Lam, Hayward, Watkins, Wright, & Sham, 2005) compared CBT (average of 14 sessions plus 2 booster sessions over 12 months) with pharmacotherapy versus a control group (usual care) with pharmacotherapy. Patients had been in remission for at least 6 months but were considered prone to relapse because they had had at least three episodes in the past 5 years. The results suggested a short-term advantage for CBT: at 1 year, the relapse rate in the CBT condition was 44% and in the control condition it was 75%. Patients in CBT also had higher social functioning and were better able to cope with manic prodromes. In an 18-month follow-up after the initial 1-year study, patients in CBT and usual care did not differ in relapse rates. However, CBT continued to be associated with better self-reported mood and fewer days spent in episodes. A secondary analysis of data from this trial found that BD patients with a hyper-positive sense of self at baseline were more likely to relapse during therapy (Lam et al., 2005).

The largest type 1 CBT trial to date was conducted in the United Kingdom (Scott et al., 2006). Patients (n = 253) were recruited from five different sites in a variety of clinical states. Patients were randomly assigned to CBT plus medications (22 sessions) or treatment as usual and medications. No differences emerged between CBT and treatment as usual on time to recurrence. The authors reported a treatment by prior episodes interaction (CBT was associated with longer survival times prior to recurrences in patients with fewer than 12 prior episodes, whereas treatment as usual was associated with longer survival among patients with 12 or more prior episodes). However, a type 4 study (a "meta-regression" of six RCTs) found no relationship between risk for relapse and number of prior episodes (Lam, Burbeck, Wright, & Pilling, 2009).

An adaptation of CBT, schema-focused CBT, which uses imagery and reliving of early life experiences to target negative cognitive schema, was tested in a type 1 study (Ball et al., 2006). Fifty-two patients with BD on pharmacotherapy were randomized to schema-focused CBT or treatment as usual for 6 months. The schema-focused CBT group had lower levels of depression symptoms and dysfunctional attitudes than the treatment as usual group at the end of treatment. At the 18-month follow-up, the schema-focused CBT group exhibited higher scores on a clinical global impression scale.

A type 2 study investigated whether CBT combined with psychoeducation had a greater impact than psychoeducation alone. Patients with BD in full or partial remission (n = 79) completed 7 sessions of individual psychoeducation; following these sessions, half the sample was randomized to complete a 13-session CBT protocol (Zaretsky et al., 2008). Rates of relapse, hospitalization, and adherence, and levels of manic symptoms, were not different between groups. Participants who received CBT had lower depression scores and dysfunctional attitudes. Data from this study, along with the findings from the study by Ball and colleagues (2006), suggest that CBT may have a particular impact on depression symptoms, and that improvement in dysfunctional negative attitudes may mediate this effect.

All of these studies compared CBT to treatment as usual. More recently, researchers have compared CBT to active control conditions, a more rigorous test of efficacy. For example, Meyer and Hautzinger (2012) compared individual CBT to supportive therapy in a sample of 76 patients with BD in remission. Both interventions included 20 sessions delivered over 9 months. No significant differences in change in depression or mania symptoms between the treatment conditions were found at the end of treatment. Participants were followed for 2 years after treatment and, through the entire 33-month study period, no differences in relapse rates between treatment groups were seen.

Another type 1 study compared CBT to group psychoeducation, randomizing 204 participants with BD who were in remission or minimally symptomatic to receive 6 sessions of group psychoeducation or 20 sessions of individual CBT (Parikh et al., 2012). Despite the greater length of treatment and individualized format of CBT, there were no significant differences between groups in terms of risk for relapse or levels of mania or depression symptoms over 18 months of follow-up. These results suggest that group psychoeducation may be a more cost-effective approach to the psychosocial treatment of BD than individual CBT.

CBT has been rigorously studied in a number of type 1 and 2 trials. Overall, evidence for the efficacy of CBT for BD is mixed. One type 1 study suggests that CBT decreases risk for relapse in the short term (Lam et al., 2005); whether this decreased risk is maintained over long-term follow-up is unclear. Two

studies suggest that the treatment may be particularly impactful in preventing depression in remitted BD patients, potentially through cognitive restructuring of dysfunctional negative attitudes (Ball et al., 2006; Zaretsky et al., 2008). Also, three type 1 studies, including two that employed an active control condition (Meyer & Hautzinger 2012; Parikh et al., 2012; Scott et al., 2006), did not find any significant additive impact of CBT. Further inquiry into the mechanisms of action of CBT treatments or potential moderators of treatment response could help to answer whether and in what circumstances CBT is an effective adjunct to pharmacotherapy for patients with BD.

Interpersonal and Social Rhythm Therapy

Interpersonal Psychotherapy (IPT; Weissman, Markowitz, & Klerman, 2000) is an individual therapy that was originally developed as a treatment for major depressive disorder. Based on modifications of IPT, IPSRT, developed by Frank and her colleagues (Frank, Swartz, & Kupfer, 2000), is an adjunctive individual therapy for BD. IPSRT is based on the social rhythm stability hypothesis (Ehlers, Frank, & Kupfer, 1988). IPSRT has two goals: (a) to help patients to understand and renegotiate the social context associated with mood disorder symptoms and (b) to encourage patients to recognize the impact of interpersonal events on their social and circadian rhythms, and to regularize these rhythms to gain control over their mood cycling. Like other psychosocial therapies, IPSRT includes education about BD and strategies for improving drug adherence (Frank, Kupfer, Ehlers, & Monk, 1994).

The Western Psychiatric Institute at the University of Pittsburgh Medical Center conducted an initial controlled type 1 trial of IPSRT that included lithium and other mood stabilizers (Frank et al., 1997, 2005). Patients were assigned to IPSRT or to a comparison individual therapy, intensive clinical management, which consisted of 20-minute weekly sessions focused on symptom management and medication adherence. Randomization occurred at two time points: (1) initiation of acute stabilization and (2) initiation of maintenance prevention. No differences were found between IPSRT and the intensive clinical management treatment strategies in time to stabilization of the acute episode (Frank et al., 1997). However, patients assigned to IPSRT in the acute phase showed greater stabilization of their daily routines and sleep/wake cycles, and a lower likelihood of recurrence during the maintenance phase. Patients assigned to IPSRT in the acute phase also survived longer without a mood disorder recurrence in the maintenance treatment phase, even if they were not assigned to IPSRT in the maintenance phase (Frank et al., 2005). The presence of a comorbid anxiety disorder moderated this effect; individuals with this comorbid condition had shorter times to recurrence when they were assigned to IPSRT in the acute phase. IPSRT also had a positive impact on vocational functioning (Frank et al., 2008). Future trials of IPSRT would benefit from the use of a control condition that is matched to IPSRT in terms of amount of therapist contact, and/or from comparison to an established intervention such as group psychoeducation.

FAMILY-BASED INTERVENTIONS

BD cycling affects and is affected by the family context (Miklowitz, 2004). Just as the patient needs to understand the disorder and its treatment, the patient's parents, siblings, spouse, and/or other family members need to learn skills to cope with the disorder's impact on interpersonal interactions and relationships.

Current approaches to family treatment are psychoeducational, meaning that the intervention provides patients and their families information about the disorder and training in the coping strategies and interpersonal skills necessary for dealing with the disorder. Psychoeducational family interventions are designed to teach the patient and close relatives (typically spouse or parents) about the symptoms, course, and treatment of BD, emphasizing strategies for relapse prevention. Psychoeducational family interventions are most successful when accompanied by pharmacotherapy (typically mood-stabilizing medications, with or without adjunctive agents).

Family Environment and Bipolar Disorder

The nature and extent of stress in the family environment predict the course of BD. Much of the literature examining family environment in BD uses a construct termed expressed emotion (EE; Miklowitz, 2007). High EE, characterized by criticism and hostility from or emotional overinvolvement (intrusiveness)

in a caregiver or family member, predicts a poorer course of illness in a number of psychiatric disorders, including schizophrenia, depression, eating disorders, and BD (Hooley, 2007). Specifically, individuals with BD who return to high-EE families following hospitalization have a two to three times greater risk of relapse in the ensuing 9 months than patients who return to low-EE families (Barrowclough & Hooley, 2003; Miklowitz, 2004). EE appears to contribute to a poorer course of illness in BD beyond its correlation with genetic loading or symptom severity (Miklowitz, 2004). Thus, the family environment plays a strong prognostic role in mood disorders (see also the meta-analysis by Butzlaff & Hooley, 1998).

On the positive side, BD patients with high levels of social and emotional support from friends and families recover more quickly from a bipolar episode than patients with low levels of such support (Johnson, Winett, Meyer, Greenhouse, & Miller, 1999). Thus, family interventions that maximize the protective effects of the family context are potentially powerful adjuncts to pharmacotherapy in relapse prevention.

The Cornell University and Brown University Studies

Several investigations have examined whether family interventions, as adjunctive to pharmacotherapy, lead to improved outcomes in BD. To this end, a group at the Cornell University Medical College developed and tested an inpatient family intervention for families of hospitalized psychiatric (including BD) patients, focused on helping participants cope with the hospitalization and make plans for a positive adjustment after discharge. The intervention was associated with better symptomatic and global functioning at the 6- and 18-month follow-ups (Clarkin et al., 1990).

Clarkin, Carpenter, Hull, Wilner, and Glick (1998) later conducted a type 2 study specifically for BD: a marital intervention focused on psychoeducation about the disorder and improving spousal communication, as an adjunct to standard medications. When compared to standard medications only, the marital intervention did not yield significant improvements in mood symptoms or time to recurrence over the 11-month treatment period; however, it was associated with greater improvements in global functioning and higher levels of medication adherence over the treatment period.

In a type 1 trial, Miller, Solomon, Ryan, and Keitner (2004) at Brown University Medical Center assigned 92 bipolar patients who were either manic or depressed to one of three treatment conditions: (a) standard treatment, consisting of medication plus active clinical management by a psychiatrist; (b) standard treatment plus family therapy (six to eight sessions over 4 months of treatment, and follow-up "booster sessions"); and (c) standard treatment plus multifamily groups, in which four to six families met together in 1½-hour sessions over 6 weeks, followed by "reunion meetings" over the next 6 months. The family treatments were oriented toward education about the disorder and problem solving. Results indicated that the two family-treated groups did not differ from the standard care group in time to recovery or number recovered. Family intervention did not hasten the stabilization that would be expected from pharmacotherapy alone. However, family impairment was a significant moderator of outcomes in this trial: For families with high levels of impairment, the addition of family intervention (therapy or psychoeducation) resulted in significantly fewer depressive episodes and decreased time spent depressed (Miller et al., 2008).

A secondary analysis of these data examined the 53 patients who recovered from their index mood episode during the study to investigate the potential effect of treatment on risk for recurrence. Treatment groups did not differ on rates of recurrence, time to recurrence, or time to hospitalization over the 28-month follow-up period. However, participants in the adjunctive multifamily groups required significantly fewer hospitalizations than the other two groups (Solomon et al., 2008).

Family-Focused Treatment

Miklowitz and Goldstein (1990, 1997) developed a 9-month FFT program for bipolar adults who had been recently hospitalized or were being treated on an outpatient basis for a recent acute episode. FFT is delivered in 21 sessions titrated over 9 months (12 weekly, 6 biweekly, and 3 monthly). The model is similar to Falloon, Boyd, and McGill's (1984) behavioral family management for schizophrenic disorders, but it is adapted to the needs of BD patients and their families.

The treatment model comprises three modules. In the first module, psychoeducation, patients and

relatives are given information about how to cope with BD. This includes didactic material about the symptoms, diagnosis, causes, and prognosis of the disorder; vulnerability and stress interactions; and risk and protective factors. It also includes a relapse prevention drill in which participants identify the patient's prodromal signs of mania or depression and the family develops plans for how to intervene should these appear (e.g., arranging an emergency medical visit or hospitalization). Later modules of FFT (communication enhancement training and problem-solving skills training) involve teaching the patients and family members the skills for dealing with disorder-related conflicts; this is accomplished by role playing and behavioral rehearsal assignments. A type 3 pilot study (Miklowitz & Goldstein, 1990) compared 9 BD patients and their families to 23 historical controls who did not receive FFT; relapse rates over 9 months were 11% (1/9) in FFT versus 61% (14/23) in the historical controls.

Miklowitz, George, Richards, Simoneau, and Suddath (2003a) at the University of Colorado reported the results of a type 1 clinical trial of FFT. Bipolar I patients (n = 101) were randomized to FFT (9 months, 21 sessions) or a brief psychoeducation comparison condition called crisis management, consisting of two sessions of family education followed by 9 months of crisis intervention, delivered on an as-needed basis. All patients received standard pharmacotherapy from community psychiatrists. Survival analyses indicated that patients in FFT and pharmacotherapy had higher 2-year survival rates without relapsing (52%) and longer survival times during the 2-year study than patients in the crisis management plus pharmacotherapy group (17%). Patients in FFT stabilized more completely over 2 years in terms of depressive symptoms and, to a lesser but still significant extent, manic symptoms. Moreover, patients in FFT had higher rates of medication adherence over the 2-year study. Improvements in medication adherence mediated the effects of FFT on manic, but not depressive, symptoms.

Within the Colorado trial, Simoneau, Miklowitz, Richards, Saleem, and George (1999) examined whether FFT leads to improvements in the quality of family communication and problem-solving skills. They coded videotapes and transcripts of problem-solving interactions from a subset of families assessed before and after the 9-month FFT or CM protocols (n = 44). No differential effects were found for treatments in reducing the frequency of negative communication behaviors (i.e., criticisms, disagreements, negative nonverbal behaviors) among patients and family members. Within the FFT group, however, positive communication behaviors among patients and relatives increased from the pretreatment to the posttreatment period. When the family was not treated (the crisis management condition), positive communication decreased slightly over the pretreatment to the posttreatment period. Moreover, treatment-associated increases in positive interactional behaviors (particularly patients' nonverbal behaviors) predicted greater improvement over the study year in patients' mood disorder—notably depressive—symptoms. Thus, FFT may achieve its effects in part through increasing the protective influences of the family environment.

In addition to the Colorado trial, FFT was tested in conjunction with IPSRT in an open trial with a historical comparison group (Miklowitz et al., 2003b). Patients (n = 30) who received an average of 30 individual IPSRT and family psychoeducational sessions (with parents or spouses) had longer survival times prior to depressive relapse and greater stabilization of depressive symptoms over 1 year than patients (n = 70) who received pharmacotherapy, two sessions of family psychoeducation, and crisis intervention as needed.

The Colorado study compared FFT to a brief psychoeducational comparison group that was not matched on amount of therapist attention. In a subsequent randomized type 1 trial, Rea and colleagues (2003) at the University of California, Los Angeles, compared 9 months of clinic-based FFT to an individually focused therapy. BD patients began the study during a hospitalized manic episode (n = 53) and were maintained on mood-stabilizing medications. Patients in individually focused therapy received regular sessions of education, support, and problem solving, with a duration and pacing of sessions that was identical to FFT (21 weekly, biweekly, and monthly sessions). Patients in the FFT group had longer delays prior to relapse, but only when the full 2- to 3-year study period was considered. Patients who received FFT also had a lower risk of rehospitalization (12%) than patients in individual therapy (60%) during a 1- to 2-year posttreatment interval. No group differences were observed in the first year, suggesting that for some patients and families, the effects of FFT may not be "absorbed" until the full course of treatment is

complete. Of particular significance for health care cost containment is that patients in FFT were less likely to be hospitalized when they did relapse than were the individually treated patients. Thus, FFT appears to have assisted patients and families in avoiding a hospitalization when a relapse occurred.

Caregiver Psychoeducation

Three studies have examined the efficacy of "caregiver only" psychoeducational groups. A type 3 study (van Gent & Zwart, 1991) examined the effects of educating the partners of BD patients. Subjects were 26 manic bipolar patients and their partners: 14 partners attended psychoeducation sessions without their patient-partners being present, and the partners of the 12 remaining patients served as controls. After the intervention and at a 6-month follow-up, partners who attended psychoeducational sessions demonstrated a greater knowledge of the disorder, medications, social support, and coping strategies. However, patients' medication adherence did not change over the 12-month follow-up, compared with the preintervention values or the control group values.

A type 1 controlled trial randomized caregivers for 113 euthymic medicated BD patients to receive 12 group psychoeducation sessions or no intervention. Caregivers in the psychoeducational groups received information about BD and training in coping skills. Patients were assessed monthly during the treatment period and over a 12-month follow-up; those with caregivers in the psychoeducation group exhibited decreased risk for any mood recurrence. When manic and depressive episodes were analyzed separately, patients with caregivers in the psychoeducation group exhibited greater time to manic recurrence and decreased risk for manic recurrence; this was not the case for depressive recurrences (Reinares et al., 2008). A post hoc analysis of these data found that the positive effects of the intervention on time to recurrence only held true for recently diagnosed individuals and not others (Reinares et al., 2010).

A type 2 study examined an adaptation of FFT designed to promote healthy behaviors and self-care in caregivers of patients with BD: Family-Focused Treatment-Health Promoting Intervention (FFT-HPI: Perlick et al., 2010). FFT-HPI is a 12-session individual intervention that includes skills training to help caregivers better manage distress related to caregiving and engage in health-promoting behaviors. Forty-six primary caregivers for individuals with BD were randomized to FFT-HPI or an 8- to 12-session health education intervention delivered by videotape. Compared to the control group, FFT-HPI was associated with greater decreases in patient depression at the end of treatment; this relationship was mediated by decreases in caregiver depression.

Summary of Findings on Family-Based Interventions

In summary, three type 1 studies support the efficacy of family-based intervention for the treatment of BD patients stabilizing from an acute episode, including one trial that used a control condition that matched the experimental condition in terms of amount of clinician contact. One type 1 study supports the efficacy of caregiver psychoeducation in the treatment of euthymic BD patients. Family-based interventions appear to decrease rates of hospitalization, decrease risk for relapse, and increase time to relapse in treated patients. Future trials of family-based interventions would benefit from comparison to a strong control condition with sessions of equal number and duration as the intervention being tested. Family-based interventions such as FFT should also be compared to other evidence-based interventions, such as group psychoeducation, to more rigorously test the unique impact of family involvement.

THE SYSTEMATIC TREATMENT ENHANCEMENT PROGRAM FOR BIPOLAR DISORDER

To examine the efficacy of adjunctive psychosocial intervention in combination with mood stabilizers, a large multisite type 1 trial was conducted as part of the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD; Miklowitz et al., 2007). Currently depressed patients with BD ($n = 293$) all received mood-stabilizing medications; they were then randomized to receive a standard antidepressant agent or a placebo. Patients were further randomized to one of four psychosocial intervention conditions: a 3-session psychoeducational intervention or 30 sessions of one of three intensive psychotherapies (FFT, CBT, or IPSRT). Patients

assigned to any intensive psychotherapy had higher rates of recovery (64.4% vs. 51.5%) at the end of the study year and recovered 110 days faster on average. Also, patients in intensive psychotherapy were more likely to be clinically well in a given month over the course of the study (Miklowitz et al., 2007). Psychotherapy appears to be an essential component of the treatment of bipolar depression.

Importantly, patients randomized to adjunctive antidepressants were not significantly different from patients randomized to adjunctive placebo in terms of speed of recovery from depression (Sachs et al., 2007). When clinicians treat bipolar depressed patients with mood-stabilizing medication, adding an intensive therapy may be associated with more rapid recovery than adding an antidepressant (Miklowitz et al., 2007). There were no significant differences among the intensive psychotherapies; thus, it may be that common factors across these interventions contribute to improved clinical outcomes. Potential common factors include therapeutic alliance with a mental health professional, identification of prodromal symptoms, mood management and relapse prevention strategies, focus on medication compliance, and interpersonal and family relationship repair.

Investigators have examined potential moderators of response to psychotherapy using data from STEP-BD. In one naturalistic study of acutely depressed BD patients (n = 248; not the RCT sample), patients who were more severely depressed and functionally impaired benefited most from intensive adjunctive psychotherapy, whereas patients who were less severely ill and impaired benefited most from less frequent contacts (i.e., maintenance check-ins; Miklowitz et al., 2006b). Another study (n = 269) found that within the RCT sample, intensive psychotherapy was more effective for individuals with a lifetime comorbid anxiety disorder; this was a small to medium effect (Deckersbach et al., 2013). This finding contrasts with data from a previous study, which found that comorbid anxiety was a negative moderator of outcomes in a type 1 trial of IPSRT (Frank et al., 2005).

Overall, it is still unclear whether there is a subset of acutely depressed patients with BD for whom psychotherapy would be particularly effective. It is possible that when depression symptoms are particularly severe, or when there is a concrete target for psychotherapy (e.g., anxiety), intensive psychotherapy is indicated for individuals with BD. However, these findings are preliminary and require replication.

TREATMENTS UNDER DEVELOPMENT

Novel psychotherapeutic treatments for BD continue to be developed and tested. These newer treatments aim to ameliorate symptoms associated with the disorder with greater specificity. One such treatment is an adaptation of CBT for insomnia for a BD population; it is called CBTI-BP and involves eight individual psychotherapy sessions that target sleep disturbance. An RCT tested CBTI-BP against a psychoeducational intervention in a group of 58 bipolar patients; the experimental group exhibited greater improvement in sleep and mood symptoms and reduced impairment compared to the control group at the end of treatment and at the 6-month follow-up (Harvey et al., 2013).

Another adaptation of CBT, Mindfulness-Based Cognitive Therapy (MBCT), was originally developed for treatment-refractory unipolar depression (Teasdale et al., 2000). This intervention, which can be delivered in individual or group formats, supplements traditional CBT with training in mindfulness meditation skills. MBCT for BD has been tested in three small type 3 studies, with promising results in terms of feasibility (Weber et al., 2010) and symptom management (Miklowitz et al., 2009a; Deckersbach et al., 2012). An additional study examined individuals with BD within a larger RCT of MBCT for mood disorder patients in remission with a history of suicidal ideation or behavior. Compared to the waitlist control group, subjects with BD (n = 17) in the MBCT group exhibited greater decreases in depressive and anxiety symptoms (Williams et al., 2008).

A number of other open trials provide preliminary data on the feasibility and efficacy of novel psychotherapeutic interventions for BD, including IPSRT monotherapy for unmedicated individuals with bipolar II disorder (Swartz et al., 2009), CBT for the rapid-cycling subtype of BD (Reilly-Harrington et al., 2007), behavioral activation for bipolar depression (Weinstock, Melvin, & Miller, 2013), and a psychoeducation intervention with a focus on regulating responses to goal attainment and reward (Johnson & Fulford, 2009). Continued development and rigorous testing of these innovative psychotherapeutic

interventions may augment the arsenal of effective psychosocial interventions for BD.

INTERNET-BASED APPROACHES

A number of studies have begun to examine the feasibility of use of the Internet as a viable method of delivery of psychoeducation and self-help for BD. One type 1 trial tested a novel Web-based psychoeducation intervention titled "Beating Bipolar." This intervention consisted of eight online modules that provided information on the diagnosis, causes, treatment, and management of BD. The modules featured video-based delivery of information and interactive exercises. Participants were given the opportunity to interact with others, including a study psychiatrist, in an online discussion forum. Fifty participants with BD were randomized to the "Beating Bipolar" intervention or to treatment as usual; the intervention was delivered over a 4-month period. The trial demonstrated positive results in terms of feasibility and participant engagement in the online intervention; however, at the 6-month follow-up, there were no differences between groups on the main outcome measure (overall quality of life) or any of the secondary outcome measures (Smith et al., 2011).

Another type 1 trial examined the efficacy of an eight-session noninteractive, didactic, Web-based audiovisual program that included psychoeducational information about BD as well as personal testimonies and advice from peers and experts. This intervention (n = 139) was compared to an enhanced condition (n = 134), in which participants also received peer support and coaching via e-mail, and a control condition (n = 134), which consisted only of facts about BD delivered via online text. No significant differences were found between groups on mood symptoms or stigmatization (Proudfoot et al., 2012). Thus, while some evidence suggests that online interventions for BD are feasible and engaging, there is no evidence to suggest that these interventions are efficacious, although further studies are under way (Barnes et al., 2011 Todd et al., 2012).

INTERVENTIONS FOR BIPOLAR SPECTRUM CHILDREN AND ADOLESCENTS

There has been growing interest in psychosocial interventions for pediatric-onset BD (see Fristad & MacPherson, 2013, for a more in-depth review). The early-onset form of the disorder is characterized by chronicity of symptoms, rapid cycling, a preponderance of mixed episodes, slow recoveries from acute episodes, and significant psychosocial impairment (Pavuluri, Birmaher, & Naylor, 2005). It may be particularly important to intervene with child- and adolescent-onset BD because the human brain is most malleable at these ages (Giedd, 2004; Spear, 2000). The modification of dysfunctional neurological pathways—via psychosocial interventions, psychopharmacology, or both—may reduce the severity, frequency, and life disruptions of future manic and/or depressive episodes.

Multifamily Psychoeducational Psychotherapy (MF-PEP), a manualized intervention that provides psychoeducation and cognitive and behavioral skills training in a multifamily group format, has been developed and tested for school-aged children with bipolar spectrum disorders. One type 1 study randomized 165 participants (children aged 8 to 11 with mood disorder diagnoses) to eight sessions of MF-PEP or a waitlist control. Children in the MF-PEP group exhibited greater decreases in mania and depression symptoms at the end of treatment and at the 1-year follow-up, and these gains were maintained at the 18-month follow-up (Fristad et al., 2009). Outcome data from two type 2 studies and one open trial (Fristad et al., 2002, 2003) provide additional support for this intervention, including an individual family version (Fristad, 2006) and preliminary data from an implementation trial in a community mental health setting (Macpherson et al., 2013).

FFT has been adapted for bipolar spectrum adolescents (FFT-A); like FFT for adults, the intervention includes psychoeducation sessions about the illness, communication, and problem-solving skills training. FFT-A has been tested in one open trial and one type 1 study. In the type 3 open trial, Miklowitz and colleagues (Miklowitz, Biuckians, & Richards, 2006a) examined a 21-session version of FFT involving 20 bipolar teens (mean age 15 years). All patients received pharmacotherapy and entered FFT following an acute period of illness. Over 2 years, significant improvements were observed in observer-rated depression scores (Cohen's d = 0.87), mania scores (d = 1.19), total mood symptom scores (d = 1.05), and parent-rated Child Behavior Checklist total problem behavior scores (d = 0.99).

In a type 1 RCT of 58 adolescents with BD, participants were randomized to pharmacotherapy plus a three-session psychoeducation intervention, or pharmacotherapy plus FFT-A (Miklowitz et al., 2008). The FFT-A group exhibited faster recovery from baseline depressive symptoms, less time in states of depression, less severe depressive symptoms over time, and more time in remission than patients in the briefer treatment group. One moderator of outcome was high EE: FFT-A was particularly effective in decreasing mood symptoms in adolescents with high-EE families (Miklowitz et al., 2009b).

FFT has also been adapted for children and adolescents at high risk for BD (FFT-HR); these youths have a mood disorder diagnosis (typically major depressive disorder or bipolar not otherwise specified), have exhibited mood symptoms in the past month, and have a first-degree relative with a BD diagnosis. In an open trial of this intervention, 13 families received FFT-HR. High-risk children and adolescents in the trial exhibited improved global functioning and decreased symptoms of depression and hypomania at the 1-year follow-up (Miklowitz et al., 2011).

In a type 1 study of FFT-HR, 40 high-risk children and adolescents were randomized to either FFT-HR or a one- or two-session family psychoeducation control group (Miklowitz et al., 2013). All participants were receiving as-needed pharmacotherapy and had access to crisis intervention sessions during the study. Children and adolescents in the FFT-HR group exhibited faster times to recovery, fewer weeks in symptomatic states, and a more favorable trajectory of hypomanic symptoms than youths in the control condition. High EE was a moderator of treatment outcome (i.e., high-EE families benefitted most from FFT-HR).

Several open trials have provided preliminary data to support the feasibility and efficacy of novel psychotherapeutic treatments for bipolar spectrum children and adolescents. One such intervention is called Child and Family Focused Cognitive Behavior Therapy (CFF-CBT). This family-based 12-session intervention consists of psychoeducation, cognitive-behavioral therapy, and skills training in communication, emotion regulation, and problem solving. In an open trial of CFF-CBT with an individual family format ($n = 34$), bipolar children aged 5 to 17 exhibited reductions in mania, aggression, psychosis, depression, and global functioning scores from pretreatment to posttreatment (Pavuluri et al., 2004); these gains were maintained over a 3-year follow-up (West et al., 2007). Another open trial ($n = 26$, bipolar children aged 6 to 12) tested CFF-CBT in a multiple family format; children exhibited significant improvement in manic symptoms and psychosocial functioning. More rigorous trials of this intervention appear warranted.

Small open trials have also suggested the feasibility of three other psychosocial interventions for bipolar spectrum adolescents: dialectical behavior therapy (with family skills training, individual therapy, and coaching calls as needed; Goldstein et al., 2007), individual CBT with limited family involvement (Feeny et al., 2006), and a version of IPSRT adapted for adolescents (IPSRT-A; Hlastala et al, 2010).

In summary, family interventions are promising adjuncts to pharmacotherapy in stabilizing the course of early-onset BD. The interventions with the strongest empirical support (MF-PEP, FFT-A, and FFT-HR) each include heavy family involvement, as well as psychoeducation and skills training components; these may be the key ingredients necessary for successful psychosocial intervention. Data from two type 1 studies indicate that high-EE families in particular may benefit from this type of intervention. However, precise mechanisms of action (modification of expressed emotion, family interactional behavior, medication adherence, ability to recognize and cope with prodromal symptoms, knowledge of the illness, or social support) and, in turn, whether such improvements map differently onto changes in manic or depressive symptoms remain to be clarified in future trials.

CONCLUSIONS

There are now substantially more randomized trials of psychosocial treatments for BD than in prior editions of this volume. Those studies that have been completed suggest an advantage for patients receiving psychosocial intervention and medication in the domains of time to recurrence, symptom stabilization, and medication compliance. Some evidence also indicates that psychosocial interventions exert positive effects on social, vocational, and global functioning. There remains a pressing need for more controlled research regarding specific psychosocial interventions as adjunctive treatments for this serious disorder. In future studies, it will be important to

compare disorder-specific psychosocial interventions to control conditions that are matched in terms of therapist contact and attention. Of particular importance will be effectiveness studies to examine uptake, feasibility, and outcomes of evidence-based practices in "real-world" (and potentially resource-poor) clinical settings; outcomes from such studies can provide information about which interventions are most amenable to dissemination.

Although they differ in terms of underlying theory, conceptualization, and specific foci, the psychosocial interventions for BD presented here have several components in common. In terms of length of treatment, they ranged from 12 to 30 sessions; the average number of sessions attended across trials was approximately 13 to 15 (Scott & Colom, 2008). Psychoeducation was an important component of each of the interventions, and clinicians worked collaboratively with patients and/or their families to create a shared conceptualization of the illness as it affected the patient. These interventions also shared an emphasis on building skills to manage the illness and helping the patient/family generalize these skills to their daily lives (Miklowitz & Scott, 2009).

Research has begun to shed light on which psychosocial interventions may be most appropriate for various phases of illness in BD. Group psychoeducation has been tested in bipolar patients in remission and is effective in improving medication adherence and preventing manic relapse at both short- and long-term follow-up. Also in remitted patients, caregiver psychoeducation may be useful in delaying recurrence, CBT may be useful in improving dysfunctional negative attitudes and preventing depression, and CR may be useful in improving psychosocial functioning. FFT and IPSRT, on the other hand, have been tested as adjuncts to pharmacotherapy in BD patients who are stabilizing from acute manic or depressive episodes, with promising results. For acutely depressed BD patients on mood stabilizers or atypical antipsychotics, intensive psychotherapies such as FFT, IPSRT, and CBT may be more appropriate treatments for depressive symptoms than adding an antidepressant to the medication regimen. Taken together, these results begin to form a picture of appropriate psychosocial intervention across illness phases for individuals with BD. Replication of these findings, particularly in effectiveness trials, is necessary to continue to hone guidelines for psychosocial intervention.

Despite this growing evidence base, the key components or "active ingredients" necessary for successful psychosocial treatment of BD remain unclear. Potential mediators of treatment outcomes include increased medication adherence, increased self-monitoring and detection of prodromal symptoms, cognitive restructuring, stabilization of sleep/wake cycles, and improved family communication. Future studies with a priori hypotheses regarding potential treatment mediators are necessary. Rigorous identification of mechanisms of change can inform the development of more cost-effective, efficient, and targeted interventions, which are essential to broad-based dissemination.

In addition to further study of potential treatment mediators, continued investigation of treatment moderators is also required. Despite attempts to examine predictors of treatment outcome, it is still unclear whether there are subtypes of patients with BD who benefit the most from specific psychosocial interventions. Moderator analyses from a few studies indicate that psychosocial intervention is more effective for individuals earlier in their course of illness, but evidence for this is mixed. There is some evidence that the efficacy of family interventions is moderated by the family's level of EE or other indicators of family conflict or impairment. The role of comorbid anxiety in the psychosocial treatment of BD is unclear, as conflicting evidence exists regarding its relationship to treatment outcome; this is a topic worthy of further investigation. Overall, consistent patient and family characteristics that predict positive outcomes from various forms of individual, family, or group therapy still need to be identified. Because investigations of mediators and moderators require large sample sizes, meta-analytic methods that combine data from many different trials may be useful in this regard.

Finally, the application of psychosocial interventions during the earliest phases of the disorder (e.g., cases in which the onset has occurred in childhood or adolescence, or in which genetically at-risk children are in subsyndromal, preonset phases) has received more attention since the appearance of previous editions of this volume. Evidence indicates that family psychoeducation and skill building may be important adjuncts to pharmacotherapy in the treatment of bipolar spectrum disorders in children and adolescents. Early intervention may change the long-term trajectory of the illness, which in turn should result in better functional outcomes, lower rates of suicide,

and lower personal and societal costs; however, the long-term impact of early intervention remains to be seen. We do not know, for example, whether early psychosocial intervention reduces the risk of developing BD in high-risk children. Longitudinal follow-up studies of cohorts currently being treated may eventually shed light on this issue.

Thus, next steps include independent replication of efficacious findings, increased specificity in terms of mechanisms of change and moderators of outcome, and implementation considerations such as cost-effectiveness and disseminability. Type 1 clinical trials of specific, manualized treatments, with rigorous control conditions, documentation of treatment integrity, and careful assessment of specific and relevant domains of outcome (e.g., symptoms, social-occupational functioning, medication adherence, sleep/wake cycle regularity, cognitive styles, and family functioning) are essential. The successful investigation of these questions may broaden prevailing views of the treatment of BD beyond purely pharmacological approaches to integrative models that provide more powerful protection against recurrences of the disorder.

Pharmacological Treatments for Unipolar Depression

Stefania Prendes-Alvarez
Alan F. Schatzberg
Charles B. Nemeroff

The treatment of unipolar major depression with antidepressant medication is well established on the basis of scores of randomized placebo-controlled trials involving hundreds of thousands of patients. Tricyclic antidepressants (TCAs) were the first to be studied extensively, and meta-analyses of randomized, placebo-controlled trials show them to be consistently and significantly more efficacious than placebo. Because of a narrow safety margin and a significant drug-induced adverse side effect profile, TCAs have now been replaced as the first-line treatment of depression by selective serotonin reuptake inhibitors (SSRIs: fluoxetine, sertraline, paroxetine, citalopram, and escitalopram), serotonin norepinephrine reuptake inhibitors (SNRIs: venlafaxine, duloxetine, and levomilnacipran), as well as other compounds, including, for example, bupropion and mirtazapine. Each of these agents has been shown to be superior to a placebo and as effective as comparator TCAs or SSRIs in controlled trials. Clinical trials consistently show them to be better tolerated than TCAs, and they clearly have a wider margin of safety. However, controversy continues over whether TCAs are more effective than SSRIs for the treatment of the most severely ill depressed patients. Monoamine oxidase inhibitors (MAOIs), while also more effective than placebo, have generally been reserved for treatment-refractory patients; however, a recently released transdermally delivered selegiline may be used in less refractory patients. It is now generally recognized that patients with recurrent major depression benefit from continued antidepressant treatment, and there is evidence that antidepressants of all classes are effective for the long-term management of recurrent major depression. Additionally, combination and augmentation therapy practices are gaining in popularity for patients who are partial responders and nonresponders to monotherapy. An important issue in evaluating the antidepressant literature is to distinguish between response rated as a reduction in the level of symptoms on a rating scale and response rated as true remission from illness.

INTRODUCTION

Major depressive disorder is a chronic syndrome associated with high mortality (secondary to suicide and increased rates for heart disease, stroke, and other serious diseases), and it is one of the most common medical disorders affecting adults in the world today. In the United States, the lifetime prevalence of major depression is 16.7% for adults (Kessler et al., 2005). The average age of onset is 32 years, and women are 70% more likely to develop depression than men (Kessler et al., 2003). Neither the core requisite

symptoms for the diagnosis of a major depressive episode nor the required duration of at least 2 weeks has changed from the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*) to *DSM-5*.

In this chapter we discuss the main issues surrounding the treatment of major depressive disorder, such as suicidality and goals of treatment, as well as provide the most up-to-date information about all treatment options approved by the U.S. Food & Drug Administration (FDA). Drugs are categorized by their known mechanisms of action and discussed as such.

The efficacy of antidepressant medications has been well established in a myriad of controlled clinical trials, and in general the response of patients with unipolar depression is comparable to the success rates of treatment of major medical disorders such as coronary artery disease (by angioplasty), hypertension, and diabetes. Antidepressants are actually one of the most commonly prescribed classes of medications in the United States. Meta-analyses of the vast database of double-blind, placebo-controlled clinical trials have revealed a highly statistically significant effect of all of the currently available antidepressants approved by the FDA for the management of acute unipolar depression. No other mental illness has received this much scrutiny. Because the FDA approval process usually involves comparison to both a placebo and an already approved antidepressant, such as a TCA, large numbers of patients, literally thousands, have been involved in these trials. While some meta-analyses suggest that the efficacy of antidepressants for major depression is overstated and limited to severe depression, a recent reanalysis of trials concluded that antidepressants are indeed efficacious and baseline severity is not significantly related to degree of treatment advantage over placebo (Gibbons et al., 2012).

The monoamine hypothesis of depression states that monoamines, such as serotonin, norepinephrine (NE), and dopamine (DA), may be relatively deficient in the central nervous system (CNS) of depressed patients. Although this hypothesis has not proven accurate in describing the pathophysiology of depression, the majority of the antidepressants currently available in the United States act in one way or another to increase these monoamine levels in the brain, and they are usually classified by their purported neurochemical mechanism of action (Table 11.1). Not only have all of the listed antidepressants been demonstrated to be effective in treating major depression, but no single antidepressant has ever been conclusively demonstrated to be more effective than any other antidepressant (Nemeroff, 1994). A recent study investigated this further and found that observed mood and cognitive symptoms improved more with escitalopram, an SSRI, than with nortriptyline, a TCA. However, neurovegetative symptoms improved more with nortriptyline than with escitalopram (Uher et al., 2009). Thus, physicians must consider the clinical presentation of their patients when deciding which medication to prescribe. There is also some controversy (see below) regarding whether antidepressants that interact with more than one monoamine receptor system, such as venlafaxine, duloxetine, mirtazapine, and TCAs, might be more effective than the others, particularly for severe or treatment-refractory depression.

TABLE 11.1 Tricyclic and Tetracyclic Agents: Pharmacological Effects

	Reuptake Blockade		*Receptor Blockade*		
Drug	*NE*	*5-HT*	*ACh*	H_1	α_1
Imipramine	+	+	++	+	++
Desipramine	+++	0	+	0	+
Amitriptyline	±	++	++++	++++	+++
Nortriptyline	++	±	++	+	+
Doxepin	++	+	++	+++	++
Trimipramine	+	0	++	+++	++
Protriptyline	++	0	+++	+	+
Clomipramine	+	+++	++	+	++
Maprotiline	++	0	+	++	+
Amoxapine	++	0	0	±	++

Note: Based on Potter, Manji, and Rudorfer (1998). Reprinted with permission.

NE = norepinephrine; 5HT = serotonin; ACh = acetylcholine; H_1 = histamine-1; α_1 = alpha-1; + = mild effect; ++++ = marked effect.

One important issue to discuss in this chapter is, of course, the definition of response in an antidepressant drug trial. A 50% decline in a dimensional measure of depression severity, such as the Hamilton Depression Rating Scale (HAM-D) or the Montgomery-Asberg Depression Rating Scale (MADRS), is the generally accepted definition of a responder. However, many patients with severe depression (HAM-D scores, for example, greater than 28) can exhibit a 50%

improvement in depression severity and therefore are defined as responders but have considerable residual depressive symptoms (e.g., a HAM-D score of 13). Thus, patients included as responders may, in fact, be partial responders and clearly not euthymic. More stringent definitions of response (i.e., remission) include HAM-D scores of less than 7 or some other measure of euthymia. Additionally, while response was once the goal of depression treatment, this has shifted in recent years to remission and recovery without relapse and recurrence. Remission is defined as the removal of essentially all symptoms; recovery is when this is sustained for longer than 6 months (Stahl, 2013). If depression returns before or during remission, it is called relapse; if it returns after a patient has recovered, it is termed recurrence (Stahl, 2013). These are critical concepts to understand when reviewing the literature on treatments for unipolar depression, and we must understand that leaving patients with residual symptoms predisposes them to a full relapse of depression within a much shorter time than if remission were achieved. A brief questionnaire was distributed to 535 patients being treated for major depressive disorder and they were asked to rate the importance of 16 statements in determining whether their depression was in remission. The three items that were most frequently judged to be important were (1) the presence of features of positive mental health (optimism, self-confidence); (2) return to one's usual, normal self; and (3) return to usual level of functioning (Zimmerman et al., 2006). Indeed, there is increasing awareness that symptom severity and functional outcomes in the treatment of major psychiatric disorders are often not tightly correlated (Bowie, Reichenberg, Patterson, Heaton, & Harvey, 2006), suggesting the importance of real-world function in assessing recovery.

A somewhat poorly understood issue regarding the treatment of unipolar depression is the response of depressed patients to placebo, which can occur at surprisingly high rates in clinical trials comparing a placebo and an antidepressant. This is no trivial issue because, as previously mentioned, novel antidepressants must be shown to be statistically superior to placebo and usually as efficacious as an already approved antidepressant in order to receive FDA approval. This subject has previously been discussed in considerable detail (Schatzberg & Kraemer, 2000), but the primary point to be made to the reader who is not familiar with clinical psychopharmacology trials in depression is that placebo treatment is *not* identical to no treatment. Patients enrolled in clinical trials spend considerable periods of time with the staff (research nurses, research assistants) as well as with the trial physicians. This is equally true for patients in the intervention and the placebo arm. The quantity of time spent by patients in clinical trials (often several hours each week) far exceeds the time spent by a patient treated by a mental health professional in a "standard" fee-for-service setting or managed-care setting. This contact between the patient and the research team clearly has effects on the patient's clinical state. Alternative approaches to evaluating the meaningfulness of clinical effects have been reviewed in detail elsewhere (Kraemer & Kupfer, 2006; Schatzberg & Kraemer, 2000). Another suggested explanation of this placebo response phenomenon is the idea that some subjects in clinical trials may really be "symptomatic volunteers" who are less ill and less complicated than "real" patients (Stahl, 2013). Perhaps this explains why a recent meta-analysis concluded that the magnitude of benefit of antidepressant medication compared with placebo increases with severity of depression symptoms, and for patients with very severe depression the benefit of medications over placebo is substantial (Fournier et al., 2010).

Another issue that has received considerable attention is the rapidity of response to antidepressants. It is generally acknowledged that antidepressants require 3 to 5 weeks before their therapeutic response is clinically evident, likely due to their effects on receptor regulation and/or gene expression. Specifically, the amount of neurotransmitter available in the synaptic cleft changes relatively rapidly when an antidepressant is administered, but both the clinical effects and changes in receptor sensitivity are delayed. This temporal correlation of clinical effects with changes in receptor sensitivity has given rise to the neurotransmitter receptor hypothesis, which states that depression is caused by upregulation of certain receptors and thus antidepressant efficacy is related to downregulation of receptors (Stahl, 2013). This downregulation occurs as a result of the increased extracellular concentrations of neurotransmitters in the CNS that is the primary mechanism of action of many antidepressant drugs. There is also evidence that the delay in therapeutic effects of antidepressants may be secondary to changes in gene transcription.

This is a very complex issue, and space constraints preclude a comprehensive discussion of this

controversial topic. Another hypothesized mechanism underlying antidepressant response is increased neurogenesis in the hippocampus, an effect that parallels the time course of clinical response. However, it is important to note that the so-called lag time in antidepressant drug response in clinical trials is, of course, a mean of patients who respond relatively quickly, patients who respond after a few weeks, and patients who are nonresponders. In addition, the definition of response, as described above, obviously has a major impact here; few patients show complete euthymia after 1 week. It used to be thought that if patients do not respond to antidepressants after 4 to 6 weeks, they should be treated for an additional 4 to 6 weeks. However, several studies (Boyer & Feighner, 1994; Nierenberg et al., 1995) have revealed that if the patient has not responded to paroxetine by 3 weeks of treatment or fluoxetine by 4 weeks of treatment, there is little likelihood that additional treatment, at that dose, will be successful. Dose escalation has also not proven to be effective, and this is discussed in greater detail below. Pipamperone, an antipsychotic drug, administered at low doses, acting primarily as a $5HT_2$ receptor antagonist, in combination with citalopram was reported to accelerate the antidepressant effects compared with citalopram plus placebo (Wade et al., 2011), but a second study did not confirm these findings.

Unfortunately, a generation of studies attempting to identify biological markers that predict treatment response to one or another antidepressant failed to provide valid predictors of either response or nonresponse to any antidepressant drug class. However, pharmacogenetics and brain imaging offer considerable potential for predicting response (Murphy, Kremer, Rodrigues, & Schatzberg, 2003a, 2003b; Murphy, Hollander, Rodrigues, Kremer, & Schatzberg, 2004). For example, the short form of the serotonin transporter promoter may predict poor response to an SSRI or intolerance to such therapy (Murphy et al., 2004). Functionally, the use of positron emission tomography (PET) to label neurotransmitter transporters and receptors in vivo may provide for the first time the ability to determine whether a given patient shows, for example, a deficit in serotonin transporter binding, which might predict response to SSRIs.

Other critical areas that the reader might wish to consider are issues of age, gender, and comorbid medical disorders. For many years, there was a widespread belief among clinicians that antidepressants are effective for children and adolescents, but few controlled studies had demonstrated such efficacy (see DeVane & Sallee, 1996, and Fisher & Fisher, 1996, for a review). Now, evidence for the efficacy of fluoxetine (Emslie et al., 1997), paroxetine (Keller et al., 2001), and citalopram (Wagner et al., 2004) in children and adolescents is available. There are many failed reports of efficacy of various classes of antidepressants in the elderly (Roose & Schatzberg, 2005; Schatzberg & Roose, 2006). This group tends to manifest high placebo response rates, although here too there are several positive trials with second-generation agents. The exclusion of women of childbearing potential from clinical trials because of fears of potential teratogenic effects of antidepressants has resulted in an embarrassing lack of knowledge of pharmacokinetics and clinical efficacy in the population that has the highest prevalence rate of unipolar depression. Further studies with a focus on antidepressant–gonadal–steroid interactions are advisable.

Of paramount importance is the documentation of antidepressant efficacy and tolerability in patients with comorbid medical disorders. Prevalence rates of unipolar depression in patients with medical disorders such as cancer, diabetes, myocardial infarction, cardiovascular disease (CVD), Parkinson's disease, multiple sclerosis, stroke, and Alzheimer's disease are remarkably high (25% to 50%), and for many years relatively few controlled treatment trials had been conducted in these populations (see Boswell, Anfinson, & Nemeroff, 1997, for a review). Depression in patients with CVD is associated with an increased risk of morbidity and mortality, and treatment of depression has been hypothesized to reduce cardiac mortality. A recent search of the PubMed and PsychINFO databases provided considerable evidence from randomized controlled clinical trials that SSRIs are safe in the treatment of major depression in patients with CVD (Mavrides & Nemeroff, 2013). Additionally, a recent systematic review and meta-analysis of randomized controlled efficacy trials of antidepressants in patients with depression and chronic medical disorders demonstrated that SSRIs and TCAs are efficacious and safe (Taylor et al., 2011). In this study, SSRIs were shown to improve quality of life over TCAs, an important finding to consider when deciding what to prescribe. Additional studies in this area are vitally important to conduct because of the increasing evidence that depression is associated with an increased risk of morbidity and death following events such as a myocardial infarction or stroke.

Since the majority of patients with medical disorders are prescribed a variety of other medications, it is also of paramount importance to prescribe antidepressant medications that are safe and, in particular, have no drug–drug interactions with other prescribed medications. This is not a trivial issue because most antidepressants are bound to plasma proteins and therefore can displace other commonly prescribed drugs, such as coumadin, from their protein-binding sites. In a case like coumadin, this would result in increasing plasma drug concentration, thereby increasing bleeding times, with potentially adverse consequences. Moreover, some antidepressants inhibit the activity of certain hepatic cytochrome P_{450} isoenzymes, which are responsible for metabolizing a wide variety of other commonly prescribed medications. Such drug–drug interactions, if not acknowledged, could lead to increases in plasma concentrations of drugs. These data have been comprehensively reviewed (DeVane, 1994; Ereshefsky, 1996; Nemeroff, DeVane, & Pollack, 1996). Of note, however, is that for nontricyclic agents, slow drug metabolism seems to be a less pressing and potentially less dangerous issue (Murphy et al., 2003b).

Yet another area of crucial importance is maintenance/continuation treatment of depression and assessment of its efficacy compared with placebo treatment. This is particularly important considering the shift in treatment goal from response to remission and recovery. For many years, it was generally recommended that, after a single episode of depression, patients should be treated for 6 months. If a patient has suffered more than one episode of depression, if the first episode was particularly severe (e.g., with a serious suicide attempt) or particularly difficult to treat, or if the patient has a very strong family history, long-term treatment should be considered. All of the reported studies that have evaluated treatment with antidepressants for 1 year or longer compared with a placebo have found highly significant beneficial effects of antidepressant treatment. Such studies have included TCAs, SSRIs, venlafaxine, and so forth. For instance, in patients with type 2 diabetes mellitus who had recovered from major depression, maintenance therapy with sertraline prolongs the depression-free interval (57 days to 226 days) (Lustman et al., 2006). Sustained remission needs to be the goal for these patients because it is also associated with improvements in HgA1c levels (Lustman et al., 2006) Data on maintenance therapy have been reviewed extensively (Blacker, 1996; Hirschfeld & Schatzberg, 1994; Kornstein et al., 2006; Perahia et al., 2009; Thase & Sullivan, 1995). One seminal study in this area is the PREVENT Study (Prevention of Recurrent Episodes of Depression with Venlafaxine for Two Years). Patients with recurrent unipolar depression were initially randomized to venlafaxine extended-release (ER) or fluoxetine for 10 weeks of acute treatment. Responders then received 6 months of continuation treatment with the drug they were initially randomized to receive. Continued responders were subsequently enrolled in two 12-month maintenance periods. Results showed that those who were successfully treated with venlafaxine ER during the acute and continuation phases were significantly less likely to experience recurrence with continued venlafaxine ER than with placebo in both maintenance phases (Keller et al., 2007; Kocsis et al., 2007). These data point toward the need to view unipolar depression as a chronic condition that benefits from long-term treatment. More about maintenance treatment will be discussed below for different classes of antidepressants.

A point should be made about the use of more than one medication to treat depression. For many years, the prevailing opinion in psychiatry had been that monotherapy for depression is highly desirable and, conversely, that polypharmacy is to be avoided. This is certainly not the case in other branches of medicine, in which treatment with two or three drugs is virtually the rule. Failure of a single agent to provide adequate control of hypertension, diabetes, or a neoplasm invariably leads to the use of two or three pharmacological agents. If the goal is to return the patient to complete euthymia, combination therapy with more than one psychotropic agent, as well as combination psychopharmacology and psychotherapy, may be necessary. Indeed, some combinations—for example, addition of antipsychotics—may rapidly convert nonresponders to responders (Shelton et al., 2001). Blier and colleagues recently reported that combination therapy from treatment initiation with mirtazapine plus fluoxetine, mirtazapine plus venlafaxine, and mirtazapine plus bupropion is just as well tolerated and more clinically effective than fluoxetine alone (Blier et al., 2009). In contrast, however, Rush and colleagues compared two antidepressant medication combinations with SSRI monotherapy, and neither combination outperformed monotherapy (Rush et al., 2011). Please refer to the chapter section titled

"Combination and Augmentation Therapy" for further information.

More than 35,000 individuals die in the United States by suicide every year. In 2003, an FDA advisory warned that antidepressants may be associated with an increased risk of suicidal thoughts and behaviors in adolescents, and in 2006 they recommended that the black box warning be extended to include young adults. This has brought about much attention to the topic and has recently been reviewed (Ryan & Nemeroff, 2014). Meta-analyses of trials in adults have found no overall increase in risk. Instead, increases in prescriptions for SSRIs and new-generation non-SSRIs are associated with lower suicide rates (Gibbons, Hur, Bhaumik, & Mann, 2005). This may reflect the efficacy of these antidepressants, increased adherence, and a better quality of mental health care. Additionally, a reanalysis of the randomized, placebo-controlled studies of fluoxetine and venlafaxine showed that these two drugs actually decreased suicidal thoughts and behavior for adult and geriatric patients (Gibbons, Brown, Hur, Davis, & Mann, 2012). This protective effect is most likely mediated by decreases in depressive symptoms with treatment. It must be noted, though, that while current antidepressant use has not been associated with completed suicide and death, it has been associated with an increased risk of attempted suicide (Tiihonen et al., 2006). The low therapeutic index and risk of fatality after overdose of some antidepressants is discussed below.

Before discussing the different antidepressant classes below, we will summarize the results from the largest and longest effectiveness study ever conducted to evaluate depression treatment—the STAR*D (Sequenced Treatment Alternatives to Relieve Depression). The treatments used in the study include citalopram, sertraline, bupropion, venlafaxine, mirtazapine, nortriptyline, tranylcypromine, lithium, thyroid hormone (triiodothyronine, T3), buspirone, and cognitive-behavioral therapy (CBT). The study design consisted of four levels, each with a different treatment or medication combination. The primary goal of each level was to determine whether the treatment used could optimally treat the patient's depression—and if not, whether the next levels could treat it. Important to keep in mind is that the STAR*D outcome measure was remission. In level 1, approximately one third of participants reached remission in an average of 7 weeks. About 25% of participants became symptom-free in the level 2 switch group, 12% to 20% in level 3, and 7% to 10% in level 4. Overall, these results show that patients with depression who are difficult to treat can indeed get well after trying several treatment strategies, but the odds of remission decrease with every additional treatment strategy needed (Fava et al., 2006; McGrath et al., 2006; Rush et al., 2006).

TRICYCLIC ANTIDEPRESSANTS

TCAs were for many years the mainstay of treatment for major depression. They are so named because of their chemical three-ringed structure. They were introduced into the United States in the 1960s after the discovery that they had antidepressant properties when they failed as antipsychotic drugs. In this country, seven TCAs are approved for treatment of major depression, and one additional compound—clomipramine—is approved for obsessive-compulsive disorder (OCD) but is viewed throughout the world as an efficacious antidepressant as well. Two other compounds (maprotiline and amoxapine) have four-ringed structures and are variants of the tricyclic class.

The TCAs as a class are potent inhibitors of the reuptake of NE into presynaptic neurons; they exert fewer effects on serotonin reuptake, although this is dose-dependent (see Table 11.1). The one major exception is clomipramine, which is a potent serotonin reuptake blocker with a demethylated metabolite that is a potent NE reuptake blocker. Additionally, some TCAs are antagonists at serotonin receptors ($5HT_{2A}$ and $5HT_{2C}$) (Stahl, 2013). NE reuptake blocking effects probably account for some patients' becoming activated (increased anxiety or agitation) on these agents. Generally, such effects are dose-related and can be minimized by conservative dosing and gradual dose increases. TCAs are documented antianxiety agents after chronic dosing.

There is vast literature demonstrating efficacy of the TCAs (Potter, Manji, & Rudorfer, 1998). In the United States, some of the original randomized clinical trials (RCTs) in psychiatry included imipramine or amitriptyline and showed these agents to be effective in what we now term *major depression*. Efficacy of the TCAs has been revisited in SSRI comparator trials, and the TCAs still appear to be more effective than a placebo and to be of comparable efficacy to the

SSRIs. However, SSRIs have an advantage over TCAs in terms of tolerability. Janicak, Davis, Preskorn, and Ayd (1993) performed meta-analyses of the TCA RCT literature and reported these antidepressants to be overwhelmingly more effective than a placebo. For example, 50 studies that had compared imipramine with a placebo reported an aggregate response rate to the TCA of 68%, compared with a 40% response rate to the placebo, a difference significant at the $p < 10^{-40}$ level. Intention-to-treat response rates for placebo-controlled studies of imipramine in outpatients were 51% for imipramine and 30% for placebo (Nelson, 2013).

The efficacy of TCAs appears to vary in different subtypes of depression. Some investigators have argued that the TCAs are more effective than SSRIs in the treatment of more severely depressed or melancholic inpatients in that they are more likely to induce remission within 4 to 6 weeks. In a study by the Danish University Antidepressant Group (1990), clomipramine produced significantly higher rates of remission than did paroxetine (an SSRI). In another report on inpatients by this group (Danish University Antidepressant Group, 1986), clomipramine was also significantly more effective than citalopram (another SSRI). Roose, Glassman, Attia, and Woodring (1994) reported that nortriptyline was more effective than fluoxetine (yet another SSRI) in hospitalized cardiac patients with melancholia. Other studies have found that TCAs and SSRIs have comparable efficacy, although the perception of superior efficacy persists among some investigators.

Monotherapy with TCAs is less effective in major depression with psychotic features (delusional depression) or in those with so-called atypical features. In the former, TCA monotherapy has been found to be effective in only 35% of patients, in contrast to a 65% response rate in their nondelusional counterparts, a difference that is highly statistically significant (Chan et al., 1987). In delusional depressives, TCAs in combination with antipsychotics have been reported to be significantly more effective than TCAs alone (Schatzberg & Rothschild, 1992). For such patients, clinical practice now calls for combining TCAs or other antidepressants with antipsychotic agents. The presence of atypical features (hypersomnia, hyperphagia, prominent anxiety, reverse diurnal mood variation) predicts poorer responses to imipramine than to MAOIs according to some RCTs (see below).

The TCAs all have some affinity for muscarinic cholinergic receptors as antagonists (see Table 11.1) and therefore can cause dry mouth, blurred vision, constipation, urinary hesitancy, memory disturbance, and tachycardia. Agents within the class vary in the degree to which they produce these side effects, with the so-called secondary tricyclics, which represent demethylated metabolites of parent tertiary TCAs, exerting less anticholinergic effects than their parents. Examples are nortriptyline (the metabolite of amitriptyline) and desipramine (the metabolite of imipramine). The TCAs are also antihistaminic, with amitriptyline and doxepin being most potent at this site (see Table 11.1) and being most likely to produce sedation and weight gain. These agents also block α_1-adrenergic receptors and produce orthostatic hypotension. Here, too, these side effects are mainly dose-related and can be minimized by using lower doses of drugs, particularly when initiating treatment. Some patients may, however, not be able to tolerate even the most minimal doses of these agents.

Because of their α_1-adrenergic and anticholinergic effects, and because they weakly block voltage-sensitive sodium channels in the heart and brain, the TCAs are potentially cardiotoxic in overdose and have relatively narrow safety margins (low therapeutic index).

Generally, clinicians initiating treatment with a TCA begin at low doses (e.g., 50 mg of amitriptyline, imipramine, or desipramine or 25 mg of nortriptyline) to avoid side effects as much as possible and to maximize adherence. Over 7 to 10 days, doses are increased gradually to 150 mg/day of amitriptyline, imipramine, or desipramine or to 75 mg/day of nortriptyline. After 2 weeks of these doses, further gradual dosage increments can be undertaken to achieve the maximum recommended doses. Therapeutic dosage ranges are summarized in Table 11.2. Plasma concentrations of the TCAs can also help guide optimal dosing; this is especially important with the TCA nortriptyline.

Maintenance therapy with the TCAs has been the focus of two major studies. In one, Prien and colleagues (1984) reported relatively low efficacy for maintenance imipramine therapy; however, in that study patients were often maintained at relatively low doses, which reflected the common practice of the day. In another study by Frank and colleagues (1990), imipramine was clearly demonstrated to be more effective than placebo in 3-year maintenance

TABLE 11.2 Typical Therapeutic Dosage Ranges of Tricyclic and Tetracyclic Antidepressant Drugs (Adult Patients)

Drug		
Generic Name	*Trade Name*[*]	*Therapeutic Dose Range (mg/day)*
Imipramine	Tofranil	150–300
Desipramine	Norpramin	150–300
Amitriptyline	Elavil	150–300
Nortriptyline	Pamelor, Aventyl	50–150
Doxepin	Sinequan	150–300
Trimipramine	Surmontil	150–200
Clomipramine	Anafranil	75–200
Maprotiline	Ludiomil	75–200
Amoxapine	Asendin	200–400
Protriptyline	Vivactil	5–60

[*]Original trade names—all are now generic.

therapy of recurrent unipolar depression (20% recurrence on imipramine vs. approximately 90% on the placebo). This study maintained patients at the doses to which they had responded. Moreover, lower-dose versus full-dose maintenance strategies were tested in a subset of subjects (Frank et al., 1993), and full doses were significantly more effective than half doses (30% vs. 70% recurrence, respectively). Thus, maintenance therapy with TCAs appears to require continuing patients on the doses effective during acute treatment, and this should be standard practice.

In conclusion, the TCAs are extremely effective for the treatment of depression, but their multiple actions lead to undesirable adverse effects that make it unlikely that there will be a resurgence of interest in this class, except in patients who have failed to respond to other antidepressants.

MONOAMINE OXIDASE INHIBITORS

The development of the MAOIs is one of the most interesting chapters in the history of psychopharmacology. When tuberculosis was ravaging civilizations and patients infected with the tubercular bacillus were admitted to sanitariums for long-term care, new antitubercular drugs were tested for efficacy in these settings. One such antitubercular drug, iproniazid, was noted to produce mood elevation in many patients. This led to the development of the three MAOIs still approved for depression in the United States: phenelzine, tranylcypromine, and isocarboxazid. These are all irreversible (enzyme activity returns only after new enzyme is synthesized about 2 to 3 weeks after the drug has been discontinued), nonselective (i.e., inhibit both A and B isoforms) MAOIs and, compared with newer antidepressants (see below), have a less favorable side-effect profile.

The MAOIs are believed to produce their therapeutic effects by preventing the degradation of monoamines, particularly serotonin (5-HT), NE, and DA. The enzyme monoamine oxidase exists in two forms, A and B. MAO A metabolizes NE, 5-HT, and DA in the brain and important aminergic compounds (e.g., tyramine) in the gut. MAO A inhibition in the gut necessitates patients being placed on dietary restrictions (see below). MAO B metabolizes DA, tyramine, and phenylethylamine. Inhibition of MAO B alone is not an effective antidepressant action; inhibition of MAO A activity in the brain appears to be key for achieving antidepressant response.

All of the available MAOIs have been shown to be effective in the treatment of unipolar depression and, in particular, atypical depression characterized by hypersomnia and hyperphagia (Krishnan, 2004). Table 11.3 lists the currently available MAOIs and their usual dose ranges. In addition to unipolar depression, MAOIs also appear effective, like SSRIs and certain TCAs, in the treatment of panic disorder. They are also effective in the treatment of bipolar depression. One disadvantage of oral MAOIs include the necessity of dosing multiple times per day, which is associated with considerably poorer compliance

TABLE 11.3 Monoamine Oxidase Inhibitors

Drug		
Generic Name	*Trade Name*	*Dose Range (mg/day)*
Phenelzine	Nardil	45–90
Tranylcypromine	Parnate	10–30
Isocarboxizid	Marplan	10–30
Selegiline[*]	Emsam[*]	6–12[*]

[*]Transdermal delivery.

when compared with once-a-day dosing. Additionally, misinformation about diet and drug interactions acts as a barrier to using MAOIs, so it is prudent to address these two issues in this chapter.

Tyramine, in the presence of MAO A and B inhibition, accumulates and displaces NE from vesicles, and this increased availability of NE can elevate blood pressure. For this reason, patients taking MAOIs are advised to follow a diet low in tyramine. There is a common myth, though, that patients taking MAOIs must avoid all cheeses, as well as beer and wine. In reality, only aged cheeses and tap and nonpasteurized beers need to be avoided. With regard to wine, many wines are actually quite low in tyramine. A patient who ingests more tyramine than suggested can subsequently experience a hypertensive crisis, also known as the "cheese reaction," which is characterized by severe hypertension and possible medical sequelae including stroke. Symptoms of this syndrome include severe headache, flushing, palpitations, and nausea. For a complete discussion of food restrictions necessary for patients taking an MAOI, the reader is referred to the National Institutes of Health Clinical Center Drug-Nutrient Interaction Task Force (http://www.cc.nih.gov/ccc/patient_education/drug_nutrient/maoi1.pdf)

Recently, a transdermal formulation of selegiline has been approved in the United States for treating major depression. At low doses, oral selegiline is an MAO B inhibitor, and at these doses, it does not require dietary restrictions. We have already noted, though, that isolated MAO B inhibition does not have antidepressant properties. When delivered transdermally, selegiline appears to exert MAO A and B inhibition in the brain but does not inhibit MAO A in gut. This obviates the need for dietary restrictions, particularly at the lowest dose (i.e., 6 mg/day). A double-blind, placebo-controlled, dose-titration trial of the selegiline transdermal system (STS) for the treatment of major depressive disorder provided evidence of short-term efficacy, safety, and tolerability in the dose range of 12 mg/day (Feiger et al., 2006). In another study, patients receiving STS had significantly fewer relapses, and when they did relapse, the time to relapse was significantly longer compared with placebo (Amsterdam & Bodkin, 2006). At doses greater than 12 mg/day it is possible that a patient could experience a hypertensive reaction if tyramine is ingested or a sympathomimetic amine is taken, and therefore diet and drug restrictions that apply to nonselective MAOIs should be imposed. There is also the possibility of local skin reactions at the site of selegiline patch placement.

There are two general types of dangerous drug interaction with MAOIs: (1) sympathomimetics that can raise blood pressure and (2) medications that inhibit serotonin reuptake and can cause a potentially fatal serotonin syndrome. In the first category, patients should avoid taking decongestants, stimulants, and antidepressants with NE reuptake inhibition, many of which are available without prescription. General and local anesthetics that contain epinephrine should also be avoided because they can cause changes in blood pressure. In the second category, physicians should avoid prescribing antidepressants (SSRIs, SNRIs, and clomipramine) and certain opiates (e.g., meperidine, tramadol, methadone, and fentanyl). One must also obtain a thorough history of substance use from the patient because some drugs of abuse (e.g., Ecstasy, cocaine, methamphetamine) can adversely interact with MAOIs.

In addition to the drug–drug and drug–food interactions noted above, MAOIs have a number of other untoward side effects, including orthostatic hypotension, sexual dysfunction, weight gain, dizziness, insomnia, tachycardia, palpitations, and edema.

Lastly, the issues of switching patients to and from MAOIs should be addressed. When trying to switch a patient on a serotonin reuptake inhibitor to an MAOI, one must wait at least five half-lives after discontinuing the serotonergic drug before starting the MAOI. If trying to switch in the other direction, one must wait at least 14 days after discontinuing the MAOI. These recommendations should be followed to avoid the risk of serotonin syndrome. Switching between MAOIs also requires a waiting period.

The MAOIs have not been generally considered first-line treatments for depression because of their unfavorable side-effect profile, dietary restrictions, need for dosing multiple times per day, and the general unavailability of platelet MAO activity measurements. They did appear to be more effective than the TCAs and perhaps the SSRIs for patients with so-called atypical depression characterized by leaden limb paralysis, lack of reactivity, hypersomnia, and so forth. Although reversible MAOIs with a more favorable side-effect profile have been developed (e.g., moclobemide), they are not available for clinical use in the United States.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Since their introduction in 1988, the SSRIs have become first-line treatments (Rush & the Depression Guideline Panel of the Agency for Health Care Policy and Research, 1994) for most patients with major depression (Table 11.4). The first of these agents was fluoxetine, and since then five others have been released in the U.S. market: sertraline, paroxetine, fluvoxamine, citalopram, and escitalopram. Of these, fluvoxamine is approved for use in the United States only for OCD, although it is used as an antidepressant in many other countries. In this chapter, we focus on the SSRIs approved for major depression in the United States. All of these have the same mechanism of action: They inhibit the reuptake of serotonin (also known as inhibition of the serotonin transporter). They have virtually no effect to date on blocking NE reuptake (except paroxetine at high doses), and they also do not interfere with various ligands binding to muscarinic cholinergic, α_1-adrenergic, or histamine H_1 receptors. Thus, they produce little if any dry mouth, constipation, or urinary hesitancy (anticholinergic effects), orthostatic hypotension (α_1-adrenergic blockade), or sedation and weight gain (H_1 blockade).

The efficacy of the SSRIs has been clearly demonstrated in numerous RCTs, and these data have been reviewed elsewhere (Nemeroff, 1994). Published data are most extensive for fluoxetine, sertraline, and paroxetine, with these drugs having been studied in several thousand patients. In the RCTs published before the release of fluoxetine that formed the basis of the FDA submission, fluoxetine was significantly more effective than placebo in four placebo-controlled studies and was generally comparable to TCAs in six comparison trials (Schatzberg, 1995a). Additionally, significantly fewer patients on fluoxetine discontinued treatment because of adverse events (Bech et al., 2000). Fluoxetine was also reported in the early trials to be "activating," likely because of its $5HT_{2C}$ antagonist properties. Some clinicians and investigators therefore advised against using it in depressed patients with prominent anxiety. Analyses of the comparative clinical trials have subsequently revealed that the drug is as effective in anxious depressives as it is in major depressives without anxiety (Schatzberg, 1995b; Tollefson, Holman, & Sayler, 1994). Some patients may, however, require starting at a lower dose (e.g., 10 mg/day of fluoxetine). The potential "activating" property has also led some to believe that it should be strongly considered for patients with reduced positive affect, hypersomnia, psychomotor retardation, and fatigue. Significant SSRI efficacy in purely anxious patients (e.g., panic disorder) has been revealed in RCTs as well. Thus, the SSRIs (including fluoxetine) appear effective in both depressed and anxious patients or in those who demonstrate mixed symptoms. Subsequent to the FDA submission, thousands of papers have appeared in the archival literature that continue to show significantly greater efficacy for fluoxetine over placebo in patients of all age groups with major depression. Two RCTs of fluoxetine in children and adolescents with major depression have found the drug to be significantly more effective than placebo in that age group as well (Emslie et al., 1997). Additionally, fluoxetine is the only SSRI approved for the treatment of bulimia.

There has been an ongoing debate regarding whether the SSRIs, particularly fluoxetine, are as effective as the TCAs and more recently the dual uptake blockers (discussed below) in the treatment of patients with severe depression. These data have been reviewed in detail elsewhere (Anderson, 1998; Schatzberg, 1996; Thase, Entsuah, & Rudolph, 2001). Although there are occasional reports in the literature that an SSRI was less effective in these subjects, the overall data from RCTs does not bear out this conclusion. In one study, we compared desipramine and fluoxetine in a group of moderately to severely depressed patients (Bowden et al., 1993). The two drugs were of comparable efficacy, but fluoxetine had

TABLE 11.4 Typical Antidepressant Therapeutic Dosage Ranges of Selective Serotonin Reuptake Inhibitors (Adult Patients)

Drug		
Generic Name	*Trade Name*	*Therapeutic Dose Range (mg/day)*
Fluoxetine	Prozac	20–80
Paroxetine	Paxil	20–50
Paroxetine	Paxil CR	25–75
Sertraline	Zoloft	50–200
Citalopram	Celexa	20–40
Fluvoxamine	Fluvoxamine	100–300
Escitalopram	Lexapro	10–20

a far more benign side-effect profile. In a small-scale study of more severely depressed inpatients, Clerc, Ruimy, and Verdeau-Palles (1994) reported that venlafaxine (a dual 5-HT/NE uptake blocker) was significantly more effective at 4 to 6 weeks than fluoxetine. Subsequently, Thase, Entsuah, and Rudolph (2001) reported on a pooled analysis of eight studies comparing venlafaxine with SSRIs and reported a significantly greater response with venlafaxine. Further analyses that included a larger pool of studies pointed to the superiority of venlafaxine over fluoxetine but not over other SSRIs, particularly paroxetine (Nemeroff et al., 2003). Most recently, though, the GENPOD RCT tested the hypothesis that individuals with more severe depression would benefit more from noradrenaline reuptake inhibitors than SSRIs, but this did not end up being the case (Wiles et al., 2012). Thus, the debate is likely to continue for some time, although to date the data overall do not support the impression of lesser efficacy of SSRIs compared to SNRIs for severe depression.

All SSRIs have been reported to be significantly more effective than placebo in preventing relapse or recurrence for up to 1 year of treatment. For example, of patients treated with fluoxetine for 1 year, 26% experienced a relapse or recurrence, in contrast to 57% on placebo (Montgomery et al., 1988). Similarly, 14% of patients treated with paroxetine relapsed or recurred versus 30% on placebo (Montgomery & Dunbar, 1993). The sertraline relapse rate over 44 weeks of continuation treatment was 13%, in contrast to 46% for placebo (Doogan & Caillard, 1992). Similarly, citalopram was significantly more effective than placebo in preventing relapse (Montgomery, Rasmussen, & Tanghoj, 1993). There are similar data for the newer SSRIs. These data are all remarkably similar and point to the efficacy of the SSRIs during continuation and maintenance treatment. Of note is that in these longer-term studies, no new side effects of the SSRIs emerged. Thus, the relative safety of this class of agents appears to be maintained after long-term treatment.

A systematic review and meta-analysis of RCTs of SSRIs versus placebo found that treatment with SSRIs is associated with symptomatic improvement (50% reduction in HAM-D score) by the end of the first week of use (Taylor et al., 2006). Dose escalation is often applied to patients who do not respond to a standard dose of an SSRI (estimated to be between 50% and 60% of patients). A systematic literature search on this practice showed that dose escalation before 4 weeks of treatment at a standard dose appeared to be ineffective (Ruhe et al., 2006). The explanation for this finding is that the occupancy of the serotonin transporter often does not increase following dose escalation. Therefore, dose escalation of SSRIs should not be recommended in treatment guidelines based on these studies. Whether some patients who are rapid metabolizers achieve suboptimal plasma levels of SSRIs and inadequate serotonin transporter blockade and would therefore benefit from dose escalation remains an unresolved area. The practice of combining other medications with an SSRI is discussed below in the section "Combination and Augmentation Therapy." SSRIs are also effective in the treatment of bipolar depression and less likely to cause a switch into mania than either TCAs or MAOIs (Nemeroff et al., 2001).

Paroxetine is a unique SSRI because it has mild anticholinergic actions and weak NE transporter inhibitory properties. These additional properties potentially explain why paroxetine has been noted to be sedating in some patients, and why it is preferred by many clinicians for patients with symptoms of anxiety. Efficacy studies of paroxetine have also been reviewed in detail by our group and others (DeBattista & Schatzberg, 1995; Herr & Nemeroff, 2004). Paroxetine was significantly more effective than placebo in 8 of 11 comparison studies in major depression. Paroxetine was comparable in efficacy to the TCAs in all but five studies, which found either the TCA or paroxetine to be more effective. Overall, dropout rates due to adverse events were lower in patients on paroxetine compared to TCAs. An early inpatient study in Denmark reported greater efficacy with clomipramine than paroxetine, and this study has been cited in the debate on SSRI efficacy in more severely depressed patients. However, this study used a relatively low dose of paroxetine (30 mg/day). Paroxetine also exists in a controlled-release form (Paxil CR) that is better tolerated by some patients.

The SSRI sertraline is unique because in addition to serotonin reuptake inhibition, at higher doses it is a DA transporter inhibitor and also binds to sigma-1 receptors. Sertraline efficacy data have been reviewed in detail by Janicak and colleagues (1993), Mendels (1995), and Shim and Yonkers (2004). Sertraline has been reported to be more effective than placebo in two large-scale clinical trials ($N = 545$) and to be of comparable efficacy to standard TCAs in two studies

(N = 320). Sertraline has also been reported to be effective in the treatment of postpartum depression (Stowe, Casarella, Landry, & Nemeroff, 1995). A systematic review and meta-analysis found that sertraline is statistically significantly superior to fluoxetine and other SSRIs as a class (Cipriani et al., 2008).

Citalopram was introduced into the U.S. market in 1998; it comprises two enantiomers (R and S). The R enantiomer has mild antihistaminic properties and is the reasons for higher-dose restrictions due to the potential for QTc prolongation. A recent FDA warning cautioned that citalopram doses exceeding 40 mg/day could cause abnormal heart rhythms, including torsades de pointes, but a large cohort study examining over 600,000 patients treated with citalopram found no elevated risk of ventricular arrhythmia compared to patients treated with sertraline (Zivin et al., 2013). In 2002, escitalopram (the S enantiomer of citalopram) was introduced. The enantiomer appears to be at least as effective as the parent compound, with potentially fewer side effects. Escitalopram is superior to citalopram in the treatment of patients with severe depression (MADRS score of 30 or more) (Llorca et al., 2005). Some have argued that alterations in the basic pharmacology, including greater effects on transporter and reuptake sites and fewer P_{450} effects, result in stronger efficacy and better tolerability for the S enantiomer, although this is still a subject of debate. Escitalopram was found to be significantly more effective than paroxetine for long-term treatment of severely depressed patients (MADRS score of 30 or more) (Boulenger et al., 2006). In this trial, patients were randomized to 24 weeks of double-blind treatment with fixed doses of either 20 mg of escitalopram (n = 232) or 40 mg of paroxetine (n = 227), and the MADRS was used to measure symptoms (Boulenger et al., 2006). This finding was also replicated by Kasper and colleagues (2009), and taken together they suggest that one should strongly consider long-term treatment with the SSRI escitalopram for severely depressed patients.

The side effects associated with increased serotonin availability and commonly seen with the SSRIs include nausea, diarrhea, insomnia, nervousness, headache, and sexual dysfunction. The first four of these are commonly dose-dependent, so that more conservative dosing frequently prevents their occurrence. Sexual dysfunction and headache are less clearly dose-related and can be observed even at low doses. The initial trials failed to report high rates of sexual dysfunction (e.g., delayed ejaculation in men and anorgasmia in women) with SSRI therapy—only 4% in an early fluoxetine trial, for example—because patients were not specifically queried about such side effects. These have become apparent with wider long-term use. It is probable that many depressed patients were not aware of or bothered by sexual dysfunction in the initial weeks of treatment but do become troubled by this side effect over time as they resume their normal activities. Currently, estimates are that at least 30% to 40% of patients on SSRIs experience adverse sexual side effects. A meta-analysis was performed to investigate the frequency of side effects induced by fluoxetine or alternative antidepressants. Fluoxetine was found to have more activating and gastrointestinal adverse effects that often required additional pharmacotherapy (Brambilla et al., 2005). It is also generally believed that SSRIs increase the risk of abnormal bleeding by blocking the uptake of serotonin into platelets, and epidemiological studies have shown that SSRI use is associated with a twofold increase in upper gastrointestinal bleeding (Andrade et al., 2010). Precautions should especially be taken with high-risk patients, particularly those with a history of gastrointestinal bleeding and those treated with nonsteroidal anti-inflammatory drugs (NSAIDs).

Because SSRIs have limited anticholinergic and noradrenergic effects, they are not cardiotoxic and are safe in overdoses. This represented a major step forward in treatment over the TCAs, which have a narrow safety margin (discussed above in the TCA section).

The SSRIs can be co-administered with the TCAs, but this needs to be done cautiously because, as a class, SSRIs generally inhibit P_{450} isoenzymes in the liver that metabolize TCAs, resulting in higher TCA blood levels and increased side effects (DeVane, 1994; Nemeroff et al., 1996). Citalopram has little effect on the activity of the cytochrome P_{450} isoenzyme. The co-prescription of SSRIs with MAOIs is generally contraindicated because of a risk of the serotonergic syndrome, characterized by myoclonic jerks, hyperpyrexia, and coma. One must also take care when switching patients from MAOIs to SSRIs (and vice versa), as previously discussed in the MAOI section.

All the SSRIs, with the exception of fluoxetine, that are marketed as antidepressants have half-lives of approximately 24 hours and can be given in a

once-a-day dose. The long half-life of fluoxetine (3 to 5 days) and its active metabolite norfluoxetine (7 to 14 days) suggests that the drug can be administered one or two times a week. Indeed, once-weekly fluoxetine has been FDA approved for the treatment of depression. Such dosing is not possible for paroxetine, citalopram, or sertraline.

Therapeutic antidepressant dosage ranges for the SSRIs are summarized in Table 11.4. The standard starting dose for fluoxetine, paroxetine, and citalopram is 20 mg/day; for sertraline, it is 50 mg/day. For most patients, 20 mg/day of fluoxetine is the therapeutic dose, with 40 mg/day the next most common dose. Some patients require higher doses (e.g., 60 to 80 mg/day), whereas others derive benefit from 10 mg/day. In double-blind studies, 20 mg/day and 40 mg/day appeared to be the most effective doses, but a 5-mg/day dose also was more effective than a placebo. (For review of dosage issues, see Schatzberg, 1995a.) Paroxetine is generally effective at doses of 20 to 30 mg/day, with a maximum recommended dose in major depression of 50 mg/day. The usual starting dose is 20 mg/day. Sertraline may be effective at 50 mg/day, but many studies report average doses of 100 to 150 mg/day. The starting dose is typically 50 mg/day and the recommended maximum dose is 200 mg/day. For citalopram, the recommended starting dose is 20 mg/day, aiming for therapeutic doses of approximately 40 mg/day; for the S enantiomer, escitalopram, the starting dose is 10 mg/day, with the recommended daily dose being 10 to 20 mg/day. There is evidence that patients who do not respond to 20 mg of escitalopram may respond to 30 or 40 mg. Paroxetine CR is dosed up to 75 mg/day. In elderly patients or for those with prominent anxiety or agitation, the recommended starting doses for SSRIs are 50% lower. To date, there are no available data that correlate antidepressant responses to SSRI plasma levels.

The abrupt cessation of an SSRI may result in a discontinuation syndrome that can mimic serious illness and can be distressing and uncomfortable to the individual. Potential symptoms of this syndrome include but are not limited to insomnia, nausea, vomiting, dizziness, headache, chills, fatigue, and myalgias. These symptoms appear within 24 to 72 hours after discontinuing an SSRI and can be alleviated by reintroducing the medication. In one RCT, fluoxetine-treated patients experienced fewer discontinuation symptoms than sertraline-treated and paroxetine-treated patients (Rosenbaum, Fava, Hoog, Ascroft, & Krebs, 1998).

SEROTONIN PARTIAL AGONIST/REUPTAKE INHIBITOR

Vilazodone was FDA approved for the treatment of depression in 2011. It is unique because in addition to acting as an SSRI, it is also a partial agonist at the $5HT_{1A}$ serotonin receptor. Human neuroimaging studies suggest that vilazodone is dosed so that about 50% of both serotonin transporters and $5HT_{1A}$ receptors are occupied (Stahl 2013). Two randomized, double-blind, placebo-controlled trials with vilazodone demonstrated its efficacy for the treatment of major depressive disorder in adults. Improvement was noted after 1 week, and it was well tolerated at a dose of 40 mg/day (Khan et al., 2011; Rickels et al., 2009). Vilazodone should be initiated at 10 mg/day and titrated to 40 mg over 2 weeks (10 mg for 7 days, then 20 mg for 7 days, and then 40 mg/day). To date, no advantage of vilazodone in terms of efficacy or tolerability in comparison with SSRIs has been demonstrated (Stahl, 2013).

SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS

SNRIs combine the robust serotonin reuptake inhibition of the SSRIs with various degrees of inhibition of the NE transporter. Because there is evidence that both NE and 5-HT are involved in the pathophysiology of depression and, moreover, because of evidence that both NE and 5-HT reuptake blockade is associated with therapeutic efficacy in depression, an uptake blocker of both monoamines was considered of interest, especially if such a drug lacked the adverse side-effect profile of the TCAs. Additionally, the inhibition of NE transporters in the prefrontal cortex increases the availability of DA in this area of the brain because DA presynaptic terminals in the prefrontal cortex lack DA transporters. The DA released in this region is not inactivated until it is degraded by the enzyme catechol-*O*-methyl-transferase or until it is taken up by the NE transporter (Stahl, 2013). When SNRIs inhibit NE transporters, DA levels in the prefrontal cortex increase. Currently there are four SNRIs approved for major depressive disorder in

the United States: venlafaxine, desvenlafaxine, duloxetine, and levomilnacipran, the latter approved in July 2013. Milnacipran is currently approved in the United States for the treatment of fibromyalgia but not depression.

Venlafaxine produces different degrees of inhibition of serotonin and NE reuptake depending on dose. Its serotonergic actions are present at low doses, while its noradrenergic actions are progressively enhanced as the dose increases (Stahl, 2013). Unlike TCAs, venlafaxine produces no orthostatic hypotension, dry mouth, constipation, blurry vision, or sedation. Its side-effect profile is exactly what one would predict from its postulated mechanism of action, namely the combination of the SSRIs' side effects (nausea, headache, sexual dysfunction, and insomnia) and the NE reuptake blockers' side effects (hypertension, tachycardia, and sweating). The original preparation was associated with considerable nausea, but this has been partly obviated with the introduction of an ER formulation. The starting dose is 75 mg/day, and although this is an effective dose in some patients, most require doses of up to 225 mg/day or even higher (Table 11.5). Another major advantage of venlafaxine is its lack of inhibition of any of the cytochrome P_{450} hepatic isoenzymes responsible for drug–drug interactions with certain of the SSRIs (see the introductory section of this chapter). This allows for the combination of venlafaxine with other medications in nonresponsive patients. Venlafaxine is proconvulsant in overdose and thus should not be prescribed to a patient at risk for seizures (Whyte, Dawson, & Buckley, 2003). Additionally, compared to TCAs, venlafaxine overdose is more likely to cause serotonin toxicity but less likely to cause coma (Whyte et al., 2003). It is also more lethal in overdose than SSRIs, as described in the British Behavioral Health Science database (Whyte et al., 2003).

TABLE 11.5 Atypical Antidepressants

Drug		
Generic Name	*Trade Name*	*Dose Range (mg/day)*
Trazodone	Desyrel	300–600
Nefazodone*	Serzone*	400–600
Bupropion	WellbutrinXL**	150–300**
Venlafaxine	Effexor	75–300
Venlafaxine ER	Effexor XR	75–225
Mirtazapine	Remeron	30–45
Duloxetine	Cymbalta	60–120
Levomilnacipran	Fetzima	40–120

*Serzone trade named product not currently available. Generic nefazodone is available.

**Also available as Wellbutrin and Wellbutrin SR with upper dose limitations of 450 mg and 400 mg/day, respectively.

Venlafaxine has a short half-life, so it attains steady-state plasma levels very rapidly compared with other antidepressants. This has led to the question of whether venlafaxine is superior to SSRIs in attaining remission rates in patients. Indeed, data from eight comparable randomized, double-blind studies showed that remission rates were significantly higher with venlafaxine (45%) than with an SSRI (35%) (Thase, Entsuah, & Rudolph, 2001). The difference between venlafaxine and the SSRIs was significant at week 2, whereas the difference between the SSRIs and the placebo did not reach significance until week 4 (Thase et al., 2001).

Venlafaxine may be more effective than the SSRIs in severe depression (frequently defined as the melancholic subtype or the endogenous subtype) as well as in hospitalized depressed patients. Two early double-blind controlled studies evaluated the efficacy of venlafaxine for severe depression. In one (Guelfi, White, Hackett, Guichoux, & Magni, 1995), venlafaxine was shown to be effective for severe depression compared with placebo; most impressive was the lack of any effect of the placebo in this population. In a second study (Clerc et al., 1994), fluoxetine and venlafaxine were compared in depressed inpatients; both drugs were effective, but venlafaxine was more effective than fluoxetine, and its antidepressant effect had a more rapid onset of action. Another interesting finding from the EPIC 014 Study (Nemeroff & Thase, 2007) was that venlafaxine is superior to placebo on most outcome measures, whereas the differences between fluoxetine and placebo are not as consistent. Nemeroff and colleagues (2008) reviewed 34 studies and reported that venlafaxine appears to be statistically superior to SSRIs as a class in major depression, but only to fluoxetine individually. Sertraline and venlafaxine ER have comparable effects on quality of life and efficacy in treatment, but sertraline has a reduced risk of blood pressure increase (Shelton et al., 2006; Sir et al., 2005).

Additionally, venlafaxine ER is more effective than fluoxetine and paroxetine for sustaining remission of depressive symptoms (Shelton, Entsuah, Padmanabhan, & Vinall, 2005), and as previously discussed in the introduction, venlafaxine ER is efficacious and safe as maintenance therapy for patients with recurrent unipolar depression.

Venlafaxine is a substrate for cytochrome P_{450} 2D6, which converts it to the active metabolite desvenlafaxine. Desvenlafaxine is a more potent NE transporter inhibitor than a serotonin transporter inhibitor as compared to venlafaxine (Stahl, 2013). Desvenlafaxine was recently FDA approved for the treatment of depression. It is superior to placebo in the short-term treatment of depression (DeMartinis, Yeung, Entsuah, & Manley, 2007); and, similar to venlafaxine, desvenlafaxine at the recommended dose of 50 mg/day is effective in relapse prevention of depression (Rickels et al., 2010; Rosenthal, Boyer, Vialet, Hwang, & Tourian, 2013). The safety and tolerability of desvenlafaxine have been proven to be consistent with those of the SNRI class (Clayton, Kornstein, Rosas, Guico-Pabia, & Tourian, 2009). To date, there is no evidence that desvenlafaxine is more effective or better tolerated than its parent compound, venlafaxine.

Duloxetine is similar in structure to fluoxetine but, unlike the latter, it blocks both NE and serotonin reuptake (the serotonin reuptake inhibition being slightly more potent). The drug, which was introduced in the United States in 2004, is approved for major depression, as well as for diabetic neuropathic pain, generalized anxiety disorder, fibromyalgia, and chronic musculoskeletal pain. It is now widely appreciated that painful physical symptoms are frequently associated with depression. As a dual uptake inhibitor, duloxetine appears to enhance the filtering of pain signals and to decrease the chronic physical pain often seen in depression. Its side-effect profile is similar to those of SSRIs, with nausea being perhaps the most common adverse event, occurring in as many as 40% of subjects started at 60 mg/day. There are data suggesting that starting duloxetine at 20 mg in the morning for 1 week with or without food, or starting it at 60 mg in the morning with food can improve the initial tolerability of the medication (Whitmyer et al., 2007).

Duloxetine has been reported to be significantly more effective than placebo at 60 mg/day (Detke, Lu, Goldstein, McNamara, & Demitrack, 2002; Goldstein, Mallinckrodt, Lu, & Demitrack, 2002), and its efficacy does not differ significantly in male and female patients (Kornstein, Wohlreich, Mallinckrodt, Watkin, & Stewart, 2006). Duloxetine 60 mg/day is as effective as 120 mg/day dose in treating severe depressive symptoms in hospitalized patients (Brecht et al., 2011). Patients who do not obtain remission (HAM-D-17 score of more than 7) after 6 weeks of duloxetine 60 mg/day can obtain symptom improvement if they continue on the drug, but there is no difference in improvement between those kept on a 60-mg/day dose and those whose dosage is increased to 120 mg/day (Kornstein et al., 2008). Duloxetine has also been shown to be effective in preventing relapse during maintenance/continuation treatment and in providing better global well-being and quality of life when compared to placebo (Perahia et al., 2006, 2009). Duloxetine has been compared to escitalopram in two studies, both of which showed similar efficacy between the drugs (Khan et al., 2007; Pigott et al., 2007). Escitalopram does have an advantage over duloxetine, though, in improving sleep and in tolerability measures (Pigott et al., 2007). In two studies sponsored by the manufacturer of duloxetine, Eli Lilly, venlafaxine was superior in efficacy to duloxetine (www.lillytrials.com).

Levomilnacipran was approved by the FDA for the treatment of major depressive disorder in July 2013. On the basis of in vitro studies, it is the SNRI with the greatest effect on the NE transporter (Auclair et al., 2013). A phase 3 trial showed that levomilnacipran sustained-release (SR) provides significant improvement in depressive symptoms and functioning compared to placebo (Asnis, Bose, Gommoll, Chen, & Greenberg, 2013). The dosage range of this drug is 40 to 120 mg/day. Patients should be instructed to take 20 mg for the first 2 days and then increase the dose to 40 mg. The daily dose can be increased in increments of 40 mg/day at intervals of 2 or more days, never exceeding 120 mg/day.

NOREPINEPHRINE-DOPAMINE REUPTAKE INHIBITORS

Bupropion differs from many of the other antidepressants discussed because it does not have substantial serotonergic activity. Its exact mechanism of action remains obscure. It is a very weak inhibitor of both DA and NE uptake (Eshleman et al., 1999).

Like the other antidepressants, the efficacy of bupropion in the treatment of major depression is

comparable to that of TCA and fluoxetine. Bupropion was introduced in immediate-release form with three-times-daily dosing, but this was associated with an increased incidence of seizures in patients with a history of bulimia or head injury. A twice-a-day formulation (bupropion SR) reduced the frequency of seizures at peak plasma drug levels and enhanced adherence. Actually, the once-a-day dosing formulation (bupropion XL) has a risk of seizures no greater than that observed with other antidepressants.

Bupropion has certain advantages over TCAs, including a lack of orthostatic hypertension, few cardiovascular effects, and no anticholinergic effects. Bupropion produces no sedation or cognitive impairment and, most important, in contrast to the SSRIs it produces no sexual dysfunction. It has similar HAM-D-17 remission rates to that of escitalopram (Clayton et al., 2006). There is no statistically detectable difference in the onset of antidepressant effect between bupropion and the SSRIs (Papakostas et al., 2007). Thus, bupropion is a reasonable first-line choice and a particularly useful antidepressant for patients who cannot tolerate the serotonergic side effects of SSRIs or for those who do not respond to SSRIs. In contrast to the TCAs, which are well known to produce weight gain, treatment with bupropion is either weight-neutral or results in weight loss in many patients.

Bupropion appears to be especially useful in targeting the symptoms of "reduced positive affect" (loss of interest, pleasure, energy) (Jefferson et al., 2006). Because of its activating/stimulating property, bupropion is rarely prescribed by physicians when a patient has comorbid anxiety disorder or symptoms of CNS activation (Zimmerman et al., 2005). However, there are considerable data indicating that it is just as effective as SSRIs in treating patients with depression and prominent anxiety symptoms. It is prescribed more than other antidepressants when the desire to avoid side effects, especially sexual dysfunction and weight gain, is the priority (Zimmerman et al., 2005). Lastly, bupropion SR, sertraline, and venlafaxine ER are all equally reasonable second-step choices for patients with depression who have failed to respond to treatment with an SSRI (Rush et al., 2006).

SEROTONIN ANTAGONIST/REUPTAKE INHIBITORS

Trazodone and nefazodone fall into this category of antidepressants because they block serotonin 2A and 2C receptors, as well as weakly inhibit the reuptake of serotonin. Due to this unique dual mechanism, what happens when trazodone raises serotonin levels is different from what happens when SSRIs and SNRIs increase them. Specifically, the blocking action of these drugs on the 2A and 2C receptors results primarily in stimulation of the serotonin 1A receptors only and likely explains why the drugs are not associated with sexual dysfunction or insomnia/anxiety (Stahl, 2013).

Trazodone is an interesting drug because it acts differently at different doses. At low doses, it causes sedation and is an effective treatment of insomnia. Because insomnia is one of the most frequent residual symptoms of depression during treatment with an SSRI, sedative-hypnotics are often necessary for patients with a major depressive episode (Stahl, 2013). Therefore, the sedating property of trazodone may be one important mechanism whereby trazodone can augment the efficacy of other antidepressants. The antidepressant properties of trazodone are not observed until higher doses are prescribed. Additionally, trazodone has a short half-life of 3 to 9 hours, requiring multiple daily doses. Trazodone is usually initiated at a dosage of 100 to 150 mg/day and is increased to a dosage of 400 to 600 mg/day to obtain optimal antidepressant effects. Although these doses can be administered once per day, usually at bedtime, they are often administered in divided doses, particularly when the dosage exceeds 300 mg/day.

Several RCTs have revealed that trazodone is as effective as TCAs and fluoxetine in the treatment of major depression (Schatzberg, 1987), although many clinicians have the impression that it is not as effective in moderate to severe depression.

Nefazodone is not commonly used because of the very rare emergence of severe hepatotoxicity and a need for liver transplantation, seen in 1/250,000 exposures. This resulted in the manufacturer ceasing production, although a generic form is still available. Nefazodone is an inhibitor of the cytochrome P_{450}-3A4 isoenzyme. If prescribed, caution should be used if combining it with benzodiazepines such as alprazolam, triazolam, or midazolam because they are also metabolized by the same enzyme. When they are co-administered with nefazodone, marked elevation of plasma concentrations can occur. Similar drug–drug interactions can occur when nefazodone is co-prescribed with protease inhibitors used in the treatment of HIV/AIDS.

The major side effect of this class of drug is sedation, but as previously mentioned, they can be used in combination with SSRIs and SNRIs to treat persistent insomnia. These drugs have fewer anticholinergic side effects than TCAs, but a primary drawback, particularly in the elderly, is orthostatic hypotension, thought to be due to α_1-adrenergic receptor blockade. Another potentially serious adverse side effect of trazodone particularly is the fact that a small percentage of men develop priapism after trazodone use; in a small percentage of those individuals, surgical intervention is necessary. Trazodone has also been associated with arrhythmias in patients with preexisting cardiac disease.

ADRENERGIC RECEPTOR ALPHA-2 ANTAGONISM

Alpha-2 adrenergic antagonism is another way to enhance the release of NE and serotonin and theoretically exert an antidepressant effect. Currently, there is no selective α_2 antagonist available for use as an antidepressant, but mirtazapine has prominent α_2 antagonist properties. In addition to its α_2 antagonism action, it is also a $5HT_{2A}$, $5HT_{2C}$, and $5HT_3$ receptor and an H_1 receptor antagonist. Its major advantages include a single daily dose, the lack of sexual dysfunction, safety in overdose, and sedating properties; the latter is particularly helpful in depressed patients with profound insomnia, as often seen in elderly patients. Its major side effects include marked daytime somnolence, to which patients eventually become tolerant, as well as increased appetite, weight gain, and dizziness. Of 2,796 patients in clinical trials, 2 developed agranulocytosis and 1 developed severe neutropenia. Wide-scale use after release has not revealed an increased risk of this reaction. The drug has become commonly used in geriatric patients, where sedation is a potential benefit and in whom weight gain is less common (Schatzberg, Kremer, & Rodrigues, 2002). Its efficacy has been reported to be faster and slightly greater than that of the SSRIs and SNRIs in several studies (Benkert, Szegedi, & Kohnen, 2000; Benkert et al., 2006; Schatzberg et al., 2001). Actually, a recent meta-analysis of 15 controlled trials reported that mirtazapine-treated patients had a 74% higher likelihood of achieving remission during the first 2 weeks of therapy compared to patients treated with SSRIs (Thase et al., 2010). Additionally, mirtazapine has been shown to be effective in SSRI nonresponders (Thase, Kremer, & Rodrigues, 2001).

SEROTONIN MODULATING AGENTS

Vortioxetine is a multimodal antidepressant that was just approved by the FDA for the treatment of major depressive disorder. It is a serotonin $5HT_3$, $5HT_7$, and $5HT_{1D}$ receptor antagonist; a serotonin $5HT_{1B}$ receptor partial agonist; a serotonin $5HT_{1A}$ receptor agonist; and an inhibitor of the serotonin transporter (Alvarez, Perez, Dragheim, Loft, & Artigas, 2012). In one study, patients with a MADRS total score of at least 30 were randomized to receive (1) 5 or 10 mg of vortioxetine; (2) placebo; or (3) 225 mg of venlafaxine XR (Alvarez et al., 2012). Vortioxetine was superior to placebo at week 6 in change from baseline MADRS total score (Alvarez et al., 2012). It was not superior to venlafaxine, however. A more recent study of vortioxetine 5 mg versus placebo found no statistically significant difference between the two groups in change from baseline in HAM-D at the end of 6 weeks (Jain, Mahableshwarkar, Jacobsen, Chen, & Thase, 2013). Additional positive trials have now been realized.

SELECTIVE NOREPINEPHRINE REUPTAKE INHIBITORS

The first truly SNRI marketed in Europe and other countries is reboxetine; the first in the United States is atomoxetine. Reboxetine is approved for the treatment of major depressive disorder in Europe, but not in the United States. In an RCT with reboxetine 4 mg twice daily and citalopram 20 mg daily, reboxetine did not confer any advantage over citalopram in Beck Depression Inventory total scores after 6 weeks of treatment (Wiles et al., 2012). Atomoxetine is currently approved only for the treatment of attention-deficit/hyperactivity disorder (ADHD) in the United States.

MELATONIN AGONIST

There is growing evidence that depression is associated with altered circadian rhythm of patients, causing a phase delay in their sleep/wake cycle (Stahl, 2013). This can have a negative effect on many organ systems and in particular on melatonin secretion.

Agomelatine is an agonist at melatonin 1 and 2 receptor subtypes and is approved as an antidepressant in many countries outside of the United States. By stimulating melatonin receptors, this drug appears to resynchronize circadian rhythms, reverse the phase delay of depression, and exert an antidepressant effect (Stahl, 2013). Additionally, agomelatine is an antagonist at serotonin $5HT_{2C}$ receptors, which is believed to contribute to its antidepressant effects. A recent meta-analysis of all acute treatment studies reported a modest mean difference from placebo of approximately 1.5 points on the HAM-D (Koesters et al., 2013). This same meta-analysis, though, reported that data extracted from three relapse prevention studies failed to show significant effects of agomelatine over placebo. Since the negative trials of agomelatine have not been published, a clinically important difference between agomelatine and placebo may be unlikely.

COMBINATION AND AUGMENTATION THERAPY

Frequently, patients exhibit only partial or no response to antidepressant monotherapy. These patients with treatment-resistant depression (commonly defined as treatment failure on two antidepressants) often benefit from combination or augmentation therapy. Combination therapy is the practice of prescribing two antidepressants from different classes; augmentation therapy is the addition of a pharmacological agent that is not itself an antidepressant but increases the efficacy of antidepressants. There is a vast literature on these two treatment strategies, and some of the major findings are described here.

There is evidence suggesting that antidepressant combinations (mirtazapine plus fluoxetine, mirtazapine plus venlafaxine, mirtazapine plus bupropion) from treatment initiation may double the likelihood of remission (HAM-D score of less than 7) compared with fluoxetine monotherapy (Blier et al., 2009). These drug combinations are believed to work because they modulate all three monoamines (serotonin, DA, and NE). The combination of citalopram with sustained-release bupropion has also appeared useful in clinical settings (Trivedi et al., 2006). It must be noted, though, that another clinical trial demonstrated no benefit of combination antidepressant therapy over monotherapy in patients with chronic and/or recurrent major depressive disorder (Rush et al., 2011). In this study, patients received escitalopram plus placebo, sustained-release bupropion plus escitalopram, or extended-release venlafaxine plus mirtazapine. There was no significant difference in remission rates among the treatment groups at 12 weeks.

Multiple agents have been investigated for augmentation use in treatment-refractory depression. Adjunctive S-adenosyl methionine (SAMe) and L-methylfolate have both been reported to be effective and well tolerated in patients who are nonresponders to SSRIs (Papakostas et al., 2010, 2012). Lithium has been studied as both an augmenting agent and an accelerating agent. There is firm evidence that it is effective when used as an augmentation agent, but it does not accelerate response to antidepressants (Crossley & Bauer, 2007). Lithium and T3 augmentation were compared in the STAR-D trial, and although their remission rates did not differ significantly, the lower side-effect burden of T3 suggests that it might have a slight advantage over lithium (Nierenberg et al., 2006). Other studies have reached conflicting conclusions about whether T3 augmentation is a promising treatment strategy in SSRI-resistant depression (Iosifescu et al., 2005; Garlow, Dunlop, Ninan, & Nemeroff, 2012). Creatine augmentation of SSRI treatment may be a promising therapeutic approach that has shown efficacy in women and should be further investigated (Lyoo et al., 2012).

Atypical antipsychotics, such as olanzapine, risperidone, quetiapine, and aripiprazole, have been studied extensively as augmentation agents and have clear efficacy in this regard (Papakostas et al., 2005; Rapaport et al., 2006; Simon & Nemeroff, 2005; Thase et al., 2007). Indeed, data from 10 clinical trials of adjunctive treatment with an atypical antipsychotic agent revealed that the patients randomized to adjunctive treatment were more likely to experience remission when compared to placebo (Papakostas, Shelton, Smith. & Fava, 2007). Data from a pilot study also showed that risperidone is beneficial as an augmenting treatment for patients who develop high-risk suicidal ideation during a depressive episode (Reeves et al., 2008). Further larger-scale investigation is warranted. Recently, oral scopolamine was administered as an augmentation agent and was found to be safe and effective, showing higher rates of response and remission than placebo (Khajavi et al., 2012). Other agents, such as pindolol and atomoxetine, have been

studied but have not demonstrated any clear benefit (Geretsegger et al., 2008; Michelson et al., 2007). The role of omega-3 fatty acids is another strategy that has produced mixed results and requires further study.

UNDER INVESTIGATION

Amitifadine is a serotonin, NE, and DA reuptake inhibitor that is most potent at the serotonin transporter. In one study with 63 patients, 6 weeks of treatment significantly improved MADRS total score versus placebo (Richelson, 2013).

An interesting development in recent years has been the observation that an intravenous infusion of a subanesthetic dose of ketamine, a glutamate *N*-methyl-D-aspartate (NMDA) receptor antagonist, can exert an immediate antidepressant effect and reduce suicidal thoughts in patients with treatment-resistant depression. A preliminary study of 14 depressed patients with suicidal ideation in the emergency department showed improvement in MADRS scores following a single intravenous bolus of ketamine (Larkin & Beautrais, 2011). A more recent study randomly assigned patients with treatment-resistant depression to a single intravenous infusion of ketamine or midazolam and measured the change in depression severity 24 hours after drug administration with the MADRS (Murrough et al., 2013). Patients in the ketamine group had greater improvement in the MADRS score than the midazolam group. Further studies are needed to better understand the role that ketamine and related compounds may play in the treatment of major depression and to gain more information on response duration and safety.

HOW TO CHOOSE AN ANTIDEPRESSANT

Currently, there is little evidence for superiority of one treatment option over another. An increasingly popular approach to selecting an antidepressant is basing the decision on the patient's specific symptoms (e.g., decreased interest, problems concentrating, insomnia). Using this approach, a patient's specific individual symptoms of depression are matched with the brain circuits that hypothetically mediate them and a treatment with the appropriate neuropharmacological mechanism is chosen. Although of considerable heuristic value, the data obtained thus far have not, with few exceptions such as atypical depression, supported this approach.

There is one general treatment principle that is agreed upon, and this is when to switch a medication versus when to augment it. A new medication should be prescribed when the first treatment is not tolerated because of side effects of if the patient shows absolutely no response after an appropriate trial at an adequate dose. In contrast, antidepressant monotherapy should be augmented with a second antidepressant or augmenting agent if the patient exhibits a partial response.

DISCUSSION

For all antidepressants available in the United States, efficacy has been clearly demonstrated in double-blind, placebo-controlled RCTs. The differences among these classes of agents revolve primarily around their side effects and safety. The first-generation TCAs and MAOIs are less well tolerated and are more dangerous in overdose than are the newer agents. For this reason alone, the SSRIs and other newer agents represent an incremental advance in the treatment of major depression. Moreover, the TCAs are largely noradrenergic in their reuptake blocking effects, exerting less effects on serotonin reuptake (with clomipramine a notable exception). The difference in monoamine reuptake blockade most likely accounts for the broad range of efficacy for the SSRIs (e.g., panic, OCD, bulimia, premenstrual syndrome) as well as for their salutary effects in milder forms of depression, such as dysthymia.

Although the various classes enjoy efficacy for major depression, a number of issues about their relative efficacy for specific subgroups or subtypes of depression remain in debate. For example, as indicated earlier, some argue that the TCAs are more efficacious and are more likely to induce remission in melancholic depressives than the SSRIs. Another issue is whether the MAOIs (and perhaps the SSRIs) are more effective in atypical depressives than are the TCAs. These areas require further RCTs.

The relatively high placebo response rates in outpatient studies are of concern because both known and investigational antidepressants have failed to separate from placebo. Research and clinical experience suggest more severely ill patients exhibit a

lower placebo response rate, but they also show poorer response to active drug. Thus, including more severely ill patients to address this issue is not a perfect solution. As indicated in the introduction, we need to clarify what placebo treatment in a study actually represents. Certainly, the supportive hand-holding and patient contact that occur in clinical trials do not really reflect a no-treatment condition but instead constitute potentially powerful interventions. Novel study designs are urgently needed to test drug efficacy.

Although many issues remain regarding the range of efficacy for antidepressants, these drugs are certainly effective in patients with major depression, and their use has had a tremendous impact on the lives of many depressed patients.

DISCLOSURES

Dr. Nemeroff currently has research grants from the National Institutes of Health (NIH) and consults to Xhale, Takeda, SK Pharma, Shire, Roche, Lilly, Allergan, Mitsubishi Tanabe Pharma Development America, Taisho Pharmaceutical Inc., and Lundbeck. He is a stockholder of CeNeRx BioPharma, PharmaNeuroBoost, Revaax Pharma, and Xhale and has other financial interests with CeNeRx BioPharma and PharmaNeuroBoost. He is on multiple advisory boards: American Foundation for Suicide Prevention (AFSP), CeNeRx BioPharma (2012), National Alliance for Research on Schizophrenia and Depression (NARSAD), Xhale, PharmaNeuroBoost (2012), Anxiety Disorders Association of America (ADAA), and Skyland Trail. He is on the following Board of Directors: AFSP, NovaDel (2011), Skyland Trail, Gratitude America, and ADAA. He has income sources or equity of $10,000 or more in PharmaNeuroBoost, CeNeRx BioPharma, NovaDel Pharma, Reevax Pharma, American Psychiatric Publishing, and Xhale. He currently has patents for method and devices for transdermal delivery of lithium (US 6,375,990B1) and method of assessing antidepressant drug therapy via transport inhibition of monoamine neurotransmitters by ex vivo assay (US 7,148,027B2). Lastly, he has various honoraria and royalties.

Dr. Schatzberg currently consults to Bay City Capital, CeNeRx, Cervel, Eli Lilly, Genentech, Gilead, Lundbeck, Takeda, McKinsey, Merck, MSI, Neuronetics, PharmaNeuroBoost, and Xhale. He has equity in Amnestix, BrainCells, Cervel, Corcept (co-founder), Delpor, Forest, Merck, Neurocrine, Pfizer, Titan, and Xhale. Lastly, he is Named Inventor on pharmacogenetic and antiglucocorticoid use patents on prediction of antidepressant response.

Dr. Prendes-Alvarez has no disclosures.

Treatments for Pediatric Depression

Carolina Biernacki
Prerna Martin
Pablo H. Goldberg
Moira A. Rynn

Practice guidelines recommend psychosocial interventions for mild or brief cases of pediatric depression. In moderate to severe cases, medication treatment is recommended, with or without cognitive-behavioral therapy (CBT). Currently, fluoxetine and escitalopram are the only antidepressants approved by the U.S. Food & Drug Administration (FDA) for acute pediatric depression. Among psychosocial interventions, CBT and Interpersonal Psychotherapy for Adolescents (IPT-A) have the largest evidence base for treatment of depressed youth. Combination treatment with CBT and antidepressant medication is superior to treatment with either modality alone. In youths with treatment-resistant depression, a switch in antidepressant is more likely to yield a positive response when medication is used with CBT. Antidepressant use in youths should remain judicious as higher rates of adverse events have been demonstrated, and data from adult medication trials cannot be systematically extrapolated to the pediatric population. Further studies are needed to continue assessing alternative medication and psychosocial treatments as well as factors predictive of treatment response.

BACKGROUND

Major depressive disorder (MDD) is one of the more common psychiatric disorders of adulthood, known to affect primarily one's mood and motivation. However, the symptoms that define depression result in a wide range of dysfunction, causing significant morbidity, including the possibility of leading to suicide. Children and adolescents diagnosed with MDD present similarly to adults, with some differences that have been attributed to their physical, emotional, cognitive, and social developmental stage (Birmaher et al., 1996; Lewinsohn et al., 2003; Yorbik et al., 2004). Depressed school-aged children tend to present with "typical" depressive symptoms and display fewer "masked" symptoms such as sleep or appetite disturbance (Luby et al., 2003). Irritability, behavioral manifestations, and somatic symptoms are more commonly seen in children and adolescents than in adults, whereas melancholic symptoms, delusions, and suicide attempts are less common in children than in teens and adults (Birmaher et al., 2007). The presence of psychotic symptoms in depressed youths has also been associated with an increased risk of bipolar disorder later in life, which is not the case in adults with psychotic depression (Strober & Carlson, 1982).

Epidemiology and Risk

Epidemiological data show that approximately 8% of children and adolescents experience depression

worldwide (Eapen & Črnčec, 2012), with an increasing risk of diagnosis with age. By the time youths reach 18 years of age, 11% of them are affected (Merikangas et al., 2010), with a 2:1 female: male ratio above the age of 15 years (Hankin et al., 1998). Recurrence of depression is common, with a rate of 50% in one's lifetime and up to 70% within 5 years of the initial episode (Kessler et al., 2001; Kovacs et al., 1984). In fact, according to the World Health Organization, the leading cause of disability among Americans between the ages of 15 and 44 years is MDD (Mathers et al., 2008). In children and adolescents, the burden of illness manifests itself with severe impairment in at least one major domain such as home, school or work, family relationships, and social life (SAMHSA, 2012) and leads to an increased risk of early pregnancy, legal problems, substance abuse, and suicide (Sakolsky & Birmaher, 2012). An inverse relationship between chronicity and response has been established, making early diagnosis and treatment more likely to lead to improved outcomes (Bridge et al., 2007; Rey & Birmaher, 2009). It is therefore crucial for early diagnosis and systematic treatment to become the rule rather than the exception, with the hope of preventing future morbidity and mortality.

Current vulnerability models focus on the interplay between genes and environment; however, such models are challenging to study, and results have been difficult to reproduce (Brzustowicz & Freedman, 2011). Biological risk has nevertheless been well established. Monozygotic twin concordance rates vary between 40% and 60% (Todd & Botteron, 2001), while first-degree relatives show a two- to four-fold increase in depression, both from parents to children and vice versa (Weissman et al., 2005). Actual biological mechanisms are less clear, although pubertal hormonal changes have been implicated, particularly in girls (Angold et al., 1999). Broader factors pertaining to one's ability to self-regulate emotions seem to be at play, with an increased risk of depression in children who experience less positive affectivity, less mood repair, and impaired functioning in the hypothalamic-pituitary-adrenal (HPA) axis and cerebral and vagal systems (Kovacs & Lopez-Duran, 2010). Environmental factors have been shown to be at least as important as genetic predisposition, with poverty, stressful life events, maltreatment by caregivers or peers, parental mental illness, and low family cohesion increasing the likelihood of depression (Gilman et al., 2003; Jaffee et al., 2002). In addition, cognitive vulnerabilities in children and adolescents can lead to depression (Kendall et al., 1990). Overall, it appears that youths with a higher genetic vulnerability, as represented by relatively higher negative affectivity, may require only a small environmental insult to develop depression. Youths with less genetic predisposition would likely develop the disorder only in the context of a major environmental stressor (Brzustowicz & Freedman, 2011).

Diagnostic Criteria

The diagnostic criteria in the various iterations of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) have not distinguished between MDD in adults and its manifestation in children and adolescents (American Psychiatric Association [APA], 2013). The criteria remain mostly the same in today's *DSM-5* and continue to be used for children and adolescents. They consist of depressed mood and/or loss of interest or pleasure in life activities for at least 2 weeks, along with five or more of the following symptoms causing significant impairment in functioning: (1) depressed mood for most of the day nearly everyday—mood can be irritable in children/adolescents, (2) diminished interest or pleasure in usual activities, (3) significant weight loss or gain that is unintentional, (4) insomnia or increased sleep, (5) agitation or psychomotor retardation, (6) fatigue or low energy, (7) feelings of worthlessness or guilt, (8) difficulty concentrating or indecisiveness, and (9) recurrent thoughts of death or suicide. Two specifiers ("with anxious distress" and "with mixed features") have been added to the diagnosis, while the bereavement exclusion has been removed (APA, 2013). A new diagnosis of premenstrual dysphoric disorder, which was previously mentioned in the appendix of the *DSM-IV*, has also been included in the depressive disorders category. When discussing treatment of depressive disorders or "depression" in youths, one would previously be referring to MDD and dysthymic disorder (DD). However, *DSM-5* has brought about interesting and important changes in this category, establishing a new diagnosis of disruptive mood dysregulation disorder (DMDD) in children and adolescents. The presence of persistent, severe, and pervasive symptoms differentiates these children and adolescents from merely temperamental youths or those diagnosed with oppositional defiant

disorder (ODD) (APA, 2013). The diagnostic criteria do include an age range between 6 and 18 years old outside of which a diagnosis of DMDD cannot be made, and initial symptoms must be present prior to age 10. The criteria further require chronic and severe temper outbursts, verbal aggression, or emotional storms that are disproportionate to the situation and occur at least three times a week over a period of 12 months; persistent irritability that does not remit between episodes or when stressors go away; irritability that is observed in two out of three settings (home, school, with peers) and is severe in at least one of them; no prior diagnosis of mania or euphoric mood for more than 1 day; and no other disorder (psychiatric, medical, or neurological) that could result in or better account for such behavior (APA, 2013).

Extensive research has shown that children exhibiting symptoms now ascribed to DMDD are at risk of developing MDD or generalized anxiety disorder (GAD) later in life (APA, 2013). These children were previously being diagnosed with bipolar disorder (BD), suggesting a more worrisome prognosis and possibly misguiding their treatment. Although the new diagnosis of DMDD hopes to address the overdiagnosis of BD and warrants more appropriate treatment for these youths, there are little to no research data providing DMDD-specific treatment guidelines, leaving us to abide by the guidelines set forth for MDD. A further change brought about by the *DSM-5* is the inclusion of DD and chronic MDD in a "persistent depressive disorder" category, as scientific research could not distinguish between the two diagnoses in a meaningful way (APA, 2013). The duration criteria for children remain unchanged at 1 year (vs. 2 years for adults), with an early-onset specifier to be given if a diagnosis is made prior to the age of 21. There is similarly very little research aimed at the pharmacological treatment of dysthymia or persistent depressive disorder in children and adolescents. We will therefore include all three diagnoses—MDD, DMDD, and persistent depressive disorder—when discussing treatment for "depression" in youths. The diagnosis itself is usually made by clinical interviews with the parent(s) and child separately. Collateral information from school staff can be useful if available, and contextual factors should be explored (e.g., peer relationships, family stressors). Comorbid conditions should be assessed for, since the presence of additional diagnoses will influence treatment approaches. Various rating scales can also be used to assess the initial severity of symptoms and monitor improvement or worsening of symptoms during treatment. These scales include the clinician-rated Children's Depression Rating Scale-Revised (CDRS-R), Clinical Global Impression-Improvement (CGI-I), Hamilton Depression Rating Scale (HAM-D), and Quick Inventory of Depressive Symptomatology-Clinician Rated (QIDS-C_{16}), as well as self-reports like the Beck Depression Inventory (BDI), Children's Depression Inventory (CDI), Mood and Feelings Questionnaire (MFQ), Patient Health Questionnaire (PHQ-9), Quick Inventory of Depressive Symptomatology-Self Report (QIDS-SR_{16}), and Reynolds' Adolescent Depression Scale—2nd Edition (RADS-2) (Choe et al., 2012).

PRACTICE GUIDELINES AND TREATMENT RECOMMENDATIONS

In light of the robust placebo response seen across pediatric depression medication trials (Cohen et al., 2008), practice guidelines recommend that antidepressant treatment be reserved for patients with moderate to severe depression (Birmaher et al., 2007; Bridge et al., 2007, 2009; Curry et al., 2006). Supportive treatment and education are recommended as first-line treatment for youths with uncomplicated, brief, or mild depression, as symptoms can be reduced in as little as 1 to 4 weeks (Birmaher et al., 2007; Cheung et al., 2007; Hughes et al., 2007). If symptoms do not respond, a trial of psychotherapy, medication management, or both can be initiated. For children and adolescents with depressive symptoms that are chronic or recurrent, that are moderate or severe, or that occur in the presence of agitation, psychosis, suicidality, or considerable functional impairment, a trial of a specific type of psychotherapy and/or antidepressant medication is recommended (Birmaher et al., 2007). Current psychotherapy modalities with the strongest evidence base for depressed children and adolescents are CBT and Interpersonal Psychotherapy (IPT). These, along with other modalities, will be discussed in the psychosocial treatment section of this chapter. Psychotherapy can be initiated before trying medication, or medication can be started first as it can begin to alleviate symptoms more quickly and help youth become more amenable to psychotherapeutic treatment. If neither modality produces a response on its own, they should

both be implemented simultaneously (Birmaher et al., 2007).

Once the need for a medication trial is established, treatment proceeds in the usual sequence recommended for adults, which consists of the acute phase, the continuation phase, and the maintenance phase. The goal of the acute phase is remission or maximal response of symptoms. As will be discussed in a later section, most antidepressant trials for pediatric depression have only examined the acute phase of treatment spanning 8 to 12 weeks, and they have shown mostly modest efficacy. The continuation phase, which aims to consolidate the acute phase as well as relapse prevention, should last at least 6 months (Birmaher et al., 2007). In fact, the follow-up treatment phase for acute treatment trials such as the Treatment of Adolescent Depression Study (TADS; TADS Team, 2007) and the Treatment of Resistant Depression in Adolescents Study (TORDIA; Brent et al., 2008) showed further improvement in response rates when subjects received continuation treatment with medication and/or CBT (Emslie et al., 2010; TADS Team, 2007). Maintenance treatment has yet to be studied thoroughly in children and adolescents, but naturalistic follow-up of adolescents after completion of acute and continuation phases has revealed further improvement in symptoms (Curry et al., 2011; Kennard et al., 2009; Vitiello et al., 2011). The goal of the maintenance phase is to prevent recurrence of depression for at least 12 months following recovery from an acute episode. Current pediatric guidelines recommend maintenance treatment for at least 1 year in patients who have had two depressive episodes or one severe episode, as well as in patients with chronic or recurrent depression (Birmaher et al., 2007). For patients with longstanding DD with superimposed MDD, lifetime maintenance should be considered (Birmaher et al., 2007). Other factors warranting maintenance treatment include comorbidity, severe functional impairment, marked suicidality, psychosis, family psychopathology, and significant psychosocial stressors (Birmaher et al., 2007).

PHARMACOLOGICAL TREATMENT FOR DEPRESSION IN CHILDREN AND ADOLESCENTS

In its nascent stages, child and adolescent psychiatry was forced to extrapolate from scientific data obtained from treatment research completed in the adult population. However, as the field advanced, it became clear that such extrapolations are not always correct or even safe. Tricyclic antidepressants (TCAs) are a good example, as their efficacy in adults has been proven consistently, yet they do not appear to be helpful in the treatment of depression in children, with only marginal evidence of efficacy in adolescents (Hazell & Mirzaie., 2013). There are currently only two antidepressants approved by the FDA for treatment of MDD in children and adolescents—fluoxetine for youths aged 8 to 18 years old and escitalopram for those aged 12 to 17 years old. Nevertheless, over the years there have been multiple antidepressant trials completed in the pediatric population, and the present literature will be reviewed to serve as a guide to evidence-based pharmacological treatment. These trials have been summarized in Table 12.1.

Selective Serotonin Reuptake Inhibitors

Fluoxetine

Fluoxetine is one of the best-known and most commonly prescribed antidepressants for adults. It was the first and remains the only selective serotonin reuptake inhibitor (SSRI) approved to treat depression in children as young as 8 years. The current recommended dosage range for children and adolescents with MDD is 10 to 20 mg daily, although dosages up to 40 mg were studied in one positive trial (March et al., 2004). The first double-blind placebo-controlled trial examining its effect in youths aged 13 to 18 years included only 40 participants, and it failed to show any statistical difference between the fluoxetine and placebo treatment groups (Simeon et al., 1990). The trial did include follow-up data after a mean interval of 24 months following study termination. Two thirds of participants and their parents from both the fluoxetine and placebo arms were interviewed to assess symptomatic improvement, but once again fluoxetine treatment failed to differentiate from placebo (Simeon et al., 1990). Two subsequent randomized controlled trials (RCTs) led to fluoxetine's FDA approval for depression in youths. Both studies looked at acute-phase treatment, with 96 patients randomized in the first study and 219 in the second (Emslie et al., 1997, 2002b). The first trial found clinically significant improvement with fluoxetine treatment

TABLE 12.1 Summary of Pharmacological Trials for Treatment of Depression in Children and Adolescents

Type of Pharmacological Treatment	*Citation*	*Design/Duration*	*Class Type*	*Sample Size (N)*	*Age Range*	*Results/Primary Outcome Measure*
Fluoxetine	Simeon et al., 1990	RCT 6 weeks	2	40	13–18	Fluoxetine = Placebo HAM-D
Fluoxetine	Emslie et al., 1997	RCT 8 weeks	1	96	7–17	Fluoxetine > Placebo CDRS-R, CGI ≤ 2
Fluoxetine	Waslick et al., 1999	Open label 8 weeks	3	19	8–18	↓ Symptoms of DD and MDD K-SADS, HAM-D, BDI, CGAS, CGI
Fluoxetine	Emslie et al., 2002	RCT 9 weeks	1	219	8–18	Fluoxetine > Placebo CDRS-R (≥30%)
Fluoxetine	March et al., 2004 (TADS)	RCT 12 weeks	1	439	12–17	Fluoxetine + CBT > Fluoxetine > CBT > Placebo ↓ CDRS-R, CGI-I
Fluoxetine	Emslie et al., 2004	RCT 32 weeks Maintenance	2	40	8–18	Fluoxetine > Placebo ↓ Relapse (CDRS-R > 40 w/2 week clinical deterioration)
Fluoxetine	Emslie et al., 2008	RCT 6 months Maintenance	1	102	7–18	Fluoxetine > Placebo ↓ Relapse (CDRS-R > 40 w/ & w/out 2 week clinical deterioration)
Escitalopram	Wagner et al., 2006	RCT 8 weeks	1	264	6–17	Escitalopram > Placebo for 12-17yo subpopulation ↓ CDRS-R
Escitalopram	Emslie et al., 2009	RCT 8 weeks	1	312	12–17	Escitalopram > Placebo ↓ CDRS-R
Sertraline	Wagner et al., 2003	RCT 10 weeks	1	376	6–17	Sertraline > Placebo ↓ CDRS-R
Sertraline	Rynn et al., 2006	Open label 24 weeks Maintenance	2	226	6–18	Sertraline = Placebo ↓ CDRS-R
Sertraline	Cheung et al., 2008	Open label 52 weeks Maintenance	3	22	13–19	Sertraline = Placebo HAM-D; recurrence/relapse determined clinically
Paroxetine, Imipramine	Keller et al., 2001	RCT 8 weeks	1	275	12–18	Paroxetine > Placebo HAM-D ≤ 8 or ↓ HAM-D ≥ 50%
Paroxetine, Clomipramine	Braconnier et al., 2003	RCT 8 weeks	1	125	12–20	Paroxetine = Clomipramine CGI, MADR-S
Paroxetine	Berard et al., 2006	RCT 12 weeks	1	286	13–18	Paroxetine = Placebo ↓ MADR-S ≥ 50%
Paroxetine	Emslie et al., 2006	RCT 8 weeks	1	206	7–17	Paroxetine = Placebo ↓ CDRS-R
Citalopram	Wagner et al., 2004	RCT 8 weeks	1	174	7–17	Citalopram > Placebo CDRS-R ≤ 28

(continued)

TABLE 12.1 (continued)

Type of Pharmacological Treatment	*Citation*	*Design/Duration*	*Class Type*	*Sample Size (N)*	*Age Range*	*Results/Primary Outcome Measure*
Citalopram	Shirazi et al., 2005	Open label 6 weeks	3	30	8–17	↓ HAM-D & CGAS > 50%
Citalopram	Von Knorring et al., 2006	RCT 12 weeks	1	244	13–18	Citalopram > Placebo w/ out psychotherapy K-SADS-P ≤ 2 (depr/anh) ↓ MADR-S ≥ 50%
Fluvoxamine	Sepehrmanesh et al., 2008	Open label 8 weeks	3	18	6–18	CDI, GAF and CGI-I
Venlafaxine	Mandoki et al., 1997	RCT 6 weeks	2	33	8–18	Venlafaxine = Placebo CDI, CBCL, HAM-D, CDRS
Venlafaxine ER	Emslie et al., 2007	RCT 8 weeks	1	367	7–17	Venlafaxine ER = Placebo ↓ CDRS-R
Duloxetine	Prakash, 2012	2 Open-label trials 8 weeks	3	776	7–17	Duloxetine > Placebo in trial II ↓ HAM-D
Duloxetine	Emslie et al., 2014	RCT 36 weeks	1	463	7–17	Duloxetine = Placebo ↓ CDRS-R
Duloxetine	Atkinson et al., 2014	RCT 36 weeks	1	337	7–17	Duloxetine = Placebo ↓ CDRS-R

Bupropion SR	Glod et al., 2003	Open label 8 weeks	3	11	12–17	SIGH-SAD CGI-I
Nefazodone	Findling et al., 2000	Open label 6 weeks	2	28	7–17	↓ Depressive symptoms
Nefazodone	Rynn et al., 2002	RCT 8 weeks	1	195	7–17	Nefazodone = Placebo ↓ CDRS-R
Mirtazapine	Unpublished data, Organon Inc.	RCT 8 weeks	2	126	7–17	Mirtazapine = Placebo ↓ CDRS-R
Mirtazapine	Unpublished data, Organon Inc.	RCT 8 weeks	2	124	7–17	Mirtazapine = Placebo ↓ CDRS-R
Omega-3 FA	Nemets et al., 2006	RCT—pilot 16 weeks	2	28	6–12	Omega-3 FA > Placebo ↓ CDRS >50%

RCT = randomized controlled trial; HAM-D = Hamilton Depression Rating Scale; CDRS-R = Children's Depression Rating Scale, Revised; K-SADS-P = Kiddie-Schedule for Affective Disorders and Schizophrenia-resent episode version; BDI = Beck Depression Inventory; CGAS = Children's Global Assessment Scale; CGI = Clinical Global Impression; CGI-I = Clinical Global Impression-Improvement; TADS = Treatment of Adolescent Depression Study; MADR-S = Montgomery-Asberg Depression Rating Scale; GAF = Global Assessment of Functioning; CDI = Children's Depression Inventory ; CBCL = Child Behavior Checklist; ADHD = Attention Deficit Hyperactivity Disorder; SIGH-SAD = Structured Interview Guide for the Hamilton Depression Rating Scale, Seasonal Affective Disorders.

based on CDRS-R and CGI measures, yet only 31% of fluoxetine participants attained remission as defined by a CDRS-R score of 28 or less compared to 23% of participants treated with placebo. Fluoxetine treatment was also superior to placebo in the second trial as measured by improvement in CDRS-R only, but remission rates for fluoxetine did separate from placebo with 41% versus 20% respectively. Emslie and colleagues (1998) also conducted a naturalistic follow-up of participants in their first fluoxetine study and found that approximately 40% of subjects had a recurrence of depression within 12 months, with 55% of those experiencing it within the first 6 months.

TADS ($N = 359$) randomized children aged 12 to 17 to receive fluoxetine treatment alone, CBT alone, or a combination of the two active treatments, versus placebo (March et al., 2004). In the fluoxetine-only arm, 60.6% were considered responders based on the primary outcome measures (CDRS-R total score and CGI-I improvement of "much" or "very much"). Although fluoxetine outperformed both placebo and CBT alone, the highest response rate obtained was 71.0% with the combination of fluoxetine and CBT. These findings first brought to light the benefits of combined treatment. TADS was the longest depression study in duration at 12 weeks. A treatment follow-up phase at 18 and 36 weeks showed continued improvement in all three arms of treatment (March et al., 2007). Fluoxetine treatment alone reached a response rate of 81% at week 36.

In terms of tolerability, commonly reported nonpsychiatric side effects in TADS included headache, gastrointestinal problems, sedation, and insomnia, thereby making fluoxetine quite easily tolerated by most children and adolescents. In regards to psychiatric side effects, fluoxetine treatment alone showed a statistically significant elevated risk of psychiatric adverse events, while the risk with combined fluoxetine and CBT treatment was intermediate between that of fluoxetine alone and CBT alone. Only two events—worsening depression with fluoxetine, and mania with placebo—met the adverse-event reporting criteria set forth by TADS, and all adverse events in the trial responded to treatment modification or discontinuation (March et al., 2004). Safety was specifically assessed for by looking at suicidality (Suicidal Ideation Questionnaire-Junior [SIQ-JR]) and harm-related adverse events. Although high-risk suicidality was an exclusion criterion, 29% of participants did report some suicidal ideation, which improved across all groups during the course of treatment. However, only the combination of CBT and fluoxetine proved to be statistically superior to placebo in decreasing suicidal ideation; fluoxetine alone did not. Seven participants did attempt suicide, but six of them already met SIQ-JR criteria for clinically significant suicidal ideation at baseline.

Currently, fluoxetine remains the oldest and most studied antidepressant to be approved for acute treatment of children and adolescents experiencing depression. It has reliable safety data and efficacy results supported by multiple type 1 and type 2 studies. In addition, two maintenance trials were conducted using fluoxetine. The first study ($N = 40$) showed fluoxetine to be superior to placebo in preventing relapse (defined as a CDRS-R score of more than 40 with 2-week clinical deterioration) when continued for 32 weeks following remission during acute treatment (Emslie et al., 2004). The second trial ($N = 102$), which followed youths for 6 months after initial response during open-label treatment, similarly demonstrated fluoxetine's superiority to placebo in preventing relapse and in increasing time to relapse in depressed youths (Emslie et al., 2008). Fluoxetine was also used in an open-label trial for treatment of dysthymic disorder, showing promise as an effective and safe treatment in the pediatric population (Waslick et al., 1999).

Escitalopram

Escitalopram is the second antidepressant approved for treatment of MDD in adolescents aged 12 to 17 years old. The usual dosage ranges from 10 to 20 mg/day. The first randomized placebo-controlled trial conducted with escitalopram in depressed children aged 6 to 17 years old ($N = 268$) showed no significant difference in improvement defined by the CDRS-R scores between the escitalopram group and the placebo group (Wagner et al., 2006). However, a post hoc analysis of the data showed a statistically significant difference across measures for the adolescent subpopulation aged 12 to 17 years old, as demonstrated by Clinical Global Impression–Severity (CGI-S), CGI-I, Children's Global Assessment Scale (CGAS), and CDRS-R scores at week 8. The second randomized placebo-controlled trial included 155 adolescents and found a statistically significant improvement in the escitalopram group compared to

the placebo group, with highest statistical difference at 4 weeks based on improvement in the CDRS-R score from baseline (primary outcome measure) (Emslie et al., 2009). Statistically significant improvement was also observable on CGI-I and CGI-S measures but not CGAS scores. Both studies were able to demonstrate statistical significance despite robust placebo responses (Emslie et al., 2009; Wagner et al., 2006), which had previously been noted in other pediatric antidepressant trials (Emslie et al., 2004; Wagner et al., 2004). Escitalopram was generally well tolerated in both trials, with side effects ranging from headache to influenza-like symptoms. Suicidality was not assessed systematically in the first study, but two suicide-related events were noted in the placebo group and one was noted in the escitalopram group. None of them was considered to be a serious adverse event (Wagner et al., 2006). In the second trial, suicidality was assessed using the clinician-rated Modified Columbia Suicide Severity Rating Scale (MC-SSRS) and the patient-rated SIQ-JR scale, while adverse events were categorized according to their relation to self-harm (Emslie et al., 2009). Both suicidal ideation and suicidal events were observed at a similar incidence in both the medication and placebo groups, with no indication of increased risk with medication treatment.

This second escitalopram trial did replicate the results obtained from post hoc analysis of the adolescent subpopulation in the first randomized placebo-controlled trial, which led to FDA approval. However, certain concerns with regards to generalizability remain, such as the lack of comorbid diagnoses in the trials, as well as the relative severity of depression of participants compared to those encountered in clinical practice. While FDA approved, escitalopram still lacks the strength of evidence that is available for fluoxetine.

Sertraline

Although not FDA approved for use in pediatric MDD, sertraline is FDA approved for obsessive-compulsive disorder (OCD) in children as young as 6 years. Typical pediatric dosage ranges from 25 to 200 mg/day. Three small open-label studies initially looked at sertraline treatment for adolescent MDD and showed promising results (Ambrosini et al., 1999; McConville et al., 1996; Nixon et al., 2001). These were followed by two multicenter randomized double-blind placebo-controlled trials that were conducted using sertraline in youths 6 to 17 years old (Wagner et al., 2003). Participants (N = 376) were assigned to 10 weeks of sertraline or placebo. Patients were selected to have at least a moderate severity of illness, but previous suicide attempters and high-risk subjects were excluded. Data from both trials were included in a prospectively defined combined analysis, with results at the primary endpoint showing statistically significant improvement in the sertraline arm when measured as improvement in CDRS-R scores. Secondary measures also showed statistical differences as early as 1 week into treatment. At study endpoint, 69% of sertraline patients met CDRS-R response criteria as opposed to 59% of placebo patients (Wagner et al., 2003). Sertraline was well tolerated overall despite a 9% discontinuation rate due to adverse events occurring mostly in children. Common side effects that were noted in at least 5% of sertraline participants and occurred twice as often when compared to placebo included agitation, diarrhea, anorexia, and vomiting. Suicide attempts occurred at the same rate in both medication and placebo groups (two in each arm), although the study was powered to look only at efficacy. Two subsequent open-label trials using sertraline for maintenance treatment have suggested some potential benefit, which merits further investigation (Cheung et al., 2008; Rynn et al., 2006).

Paroxetine

The usual adult dosage of paroxetine ranges up to 50 mg/day. Paroxetine is known to cause withdrawal upon abrupt discontinuation due to its short half-life, which can be quite a disadvantage in pediatric populations, where adherence can be inconsistent. Paroxetine has been investigated in three randomized placebo-controlled trials, only one of which yielded positive results (Berard et al., 2006; Emslie et al., 2006; Keller et al., 2001). The single positive study (Keller et al., 2001) looked at 275 youths who were assigned to an 8-week course of paroxetine, imipramine, or placebo in a 1:1:1 ratio. At endpoint, paroxetine did separate from placebo with statistical significance, with 63.3% of subjects attaining a HAM-D score of 8 or less (primary outcome measure) compared to 46% in the placebo group. These response rates rose to 76.1% and

57.6% respectively in patients who completed the full 8 weeks of treatment. Positive results were also observed in several secondary outcome measures. In terms of tolerance, common side effects were mostly benign, with only somnolence occurring at a significantly higher rate than in the placebo group. However, study withdrawal due to adverse events was the most common reason for discontinuation in the paroxetine group, with a rate of 9.7% compared to 6.9% in the placebo group. Suicidality was not assessed systematically, although psychiatric events were noted in the serious adverse event category. In the paroxetine group, there were two cases of worsening depression and five cases of "emotional lability" for which suicidal ideation or gestures were given as examples but without further details. There were two cases of conduct problems or hostility and one case of euphoria or expansive mood. These were ultimately not attributed to medication treatment. In the placebo group, one patient showed worsening of depression and another emotional lability. The latter was attributed to treatment with placebo, resulting in the patient's withdrawal from the study. Two subsequent randomized double-blind placebo controlled trials failed to show that paroxetine is more efficacious than placebo (Berard et al., 2006; Emslie et al., 2006). Another randomized trial comparing paroxetine to clomipramine showed no difference in efficacy between the two (Braconnier et al., 2003). Based upon these mixed and limited results from type 1 studies, paroxetine is generally not recommended for the treatment of pediatric depression.

Citalopram

The usual citalopram dosage in pediatric trials ranges from 10 to 40 mg/day, as the FDA has warned against doses exceeding 40 mg/day due to the risk of QT prolongation. There have been two randomized double-blind placebo-controlled trials (type 1 studies) looking at citalopram for treatment of pediatric MDD. The first trial followed 174 children aged 7 to 17 years; they were assigned to citalopram treatment or placebo for 8 weeks (Wagner et al., 2004). Compared to subjects taking placebo, those treated with citalopram showed a statistically significant improvement in CDRS-R scores as early as week 1, which persisted until endpoint. Additionally, 36% of patients in the citalopram arm met response criteria (CDRS-R score of 28 or less) compared to 24% in the placebo arm, a difference that also attained statistical significance. The most common adverse events were rhinitis, nausea, and abdominal pain in both the citalopram and placebo arms. Discontinuation rates due to adverse events were also very similar in both groups (5.6% for citalopram and 5.9% for placebo). Suicidality was not assessed systematically but none was reported, and the two cases of aggravated depression occurred in the placebo arm. Although a small citalopram pilot study assessing for efficacy and safety has shown a 16.7% switch to mania (Shirazi & Alaghband-Rad, 2005), no instance of conversion to mania was noted in this study. A second randomized placebo-controlled trial was conducted with citalopram in 244 adolescents aged 13 to 18 years over the course of 12 weeks (Von Knorring et al., 2006). Citalopram did not differentiate from placebo on either primary or secondary outcome measures. However, the study did allow for concurrent psychotherapy, which two thirds of participants were receiving. In patients who did not receive psychotherapy, citalopram treatment resulted in a higher response rate of 41% on the Schedule for Affective Disorders and Schizophrenia for school-aged children—Present episode version (Kiddie-SADS-P) compared to 25% for placebo. Citalopram also separated statistically from placebo in terms of improvement in Montgomery-Asberg Depression Rating Scale (MADR-S) scores. Response rates (defined as a 50% reduction in MADR-S score) in adolescents not receiving psychotherapy were 52% for citalopram and 45% for placebo, while remission rates were 22% and 19%, respectively. Most subjects tolerated the medication, with headache, nausea, and somnolence reported as the most common adverse side effects. Eighteen serious adverse events were reported with citalopram and 16 with placebo, with psychiatric hospitalization being the most common one. Fourteen patients in the medication arm reported treatment-emergent suicidality versus five patients in the placebo arm. However, a history of suicidality was common in this sample, with nearly one third of patients having previously attempted suicide.

Fluvoxamine

Although FDA approved for treatment of pediatric OCD for youth aged 9 years and up at a maximal dose

of 200 mg/day, fluvoxamine has not been the subject of any RCTs for treatment of depression in children or adolescents, and it is generally not used for such purposes. One open-label trial with 18 participants showed statistically significant improvement on CDI, Global Assessment of Functioning (GAF), and CGI-I measures, with no safety concerns (Sepehrmanesh et al., 2008).

Non–Selective Serotonin Reuptake Inhibitors

Venlafaxine (Extended-Release)

Typical adult dosages of venlafaxine range up to 225 mg/day. Dose-dependent increase in blood pressure warrants regular monitoring, and a shorter half-life puts patients at risk for discontinuation syndrome. The first study assessing the efficacy of venlafaxine in child and adolescent depression was a small randomized double-blind placebo-controlled trial, which recruited 40 youths between the ages of 8 and 18 years, assigning them to treatment with venlafaxine and psychotherapy versus placebo and psychotherapy (Mandoki et al., 1997). No difference was found between the two treatment arms. Two subsequent multicenter randomized trials (type 1 studies) were conducted with a total of 367 subjects aged 7 to 17 years receiving either venlafaxine extended-release (ER) (37.5 to 225 mg/day) or placebo. Initial results showed no statistically significant difference between the two treatment groups on any of the measures used. However, age-subgroup analysis demonstrated a significant difference in adolescents 12 to 17 years old, as shown by CDRS-R scores and several secondary outcome measures. CDRS-R responder rates in the adolescents were significant at 71% for venlafaxine ER, but the placebo response rate was considerable at 55%. Despite statistical significance, however, clinical significance was questionable in these trials due to the modest effect size of 0.28. Serious adverse events were reported at a rate of 7% (12 subjects) in the venlafaxine group versus 2% (3 subjects) in the placebo group; they included suicidal ideation, hostility, manic reaction, suicide attempt, overdose, agitation, and hallucinations, but no suicides (Emslie et al., 2007). These data were later included in the FDA meta-analysis of suicide-related events in pediatric patients from antidepressant treatment trials, demonstrating the highest risk estimates for suicide-related behaviors among the trials included (Hammad, 2004). Venlafaxine should therefore be used with caution and should be avoided as a first-line treatment for depression in the pediatric population as its risks may outweigh its questionable efficacy.

Duloxetine

The recommended adult dosage for duloxetine is usually 60 mg/day, with a maximal dosage of 120 mg/day. Three case reports have shown efficacious treatment with duloxetine in depressed female pediatric patients with comorbid pain (Desarkar et al., 2006; Meighen, 2007). One open-label study assessed the safety and pharmacokinetics of duloxetine in patients 7 to 17 years old with MDD (Prakash et al., 2012). It concluded that the medication is well tolerated and safe for use in children and adolescents, with dosing guidelines similar to adults. Two additional efficacy and safety studies of duloxetine in the treatment of childhood and adolescent depression were most recently published. They were both placebo-controlled but also used fluoxetine (20 to 40 mg/day) as an active control, and consisted of a 10-week acute-treatment phase followed by a 26-week extension-treatment phase. One of the studies used flexible dosing (60 to 120 mg/day) while the other used fixed dosing (30 mg or 60 mg), but both yielded inconclusive results as neither duloxetine nor the active control separated from placebo based on the mean change in total CDRS-R score (Atkinson et al., 2014; Emslie et al., 2014).

Bupropion

Bupropion is an antidepressant that is used in adults but is also prescribed off-label for attention-deficit/hyperactivity disorder (ADHD) in youths, with dosages ranging up to 450 mg/day administered in three divided doses. It is contraindicated in patients with eating disorders as it is more likely to cause seizures in this population. Once again, data are limited on the use of bupropion in depressed youths, with no double-blind RCTs available. One open study followed 24 adolescents (11 to 16 years old) with depression and comorbid ADHD during 8 weeks of treatment with bupropion flexibly titrated up to 3 mg/kg BID; it showed response rates of 88% for depressive symptoms, 63% for symptoms of ADHD, and

58% for both diagnoses (Daviss et al., 2001). Another open trial of 11 adolescents treated with 300 to 400 mg of bupropion sustained-release daily for 8 weeks showed a marked response with a significant decrease in scores on the Structured Interview Guide for the Hamilton Depression Rating Scale—Seasonal Affective Disorder Version (SIGH-SAD) (Glod et al., 2003).

Mirtazapine

The recommended mirtazapine dosage for adults is between 15 and 45 mg QHS, and its major side effects include sedation and weight gain. Two unpublished multicenter randomized placebo-controlled trials were conducted using mirtazapine in depressed youths, with a total of 259 subjects aged 7 to 17 years (unpublished data on file with Organon Inc., Cheung et al., 2006). There was no statistical difference between the mirtazapine and placebo arms in CDRS-R total scores in either study.

Nefazodone

Nefazodone is notable for causing hepatotoxicity that can be fatal or so severe as to require a liver transplant. It has been taken off the market is some countries such as Sweden, but it remains available in the United States with the addition of a black box warning. The FDA currently estimates that about one case of liver failure is reported per 250,000 to 300,000 patients who have taken the medication for at least a year. Typical adult dosing for depression is 150 mg to 300 mg BID. An open-label trial was initially conducted with nefazodone, evaluating pharmacokinetics in 28 depressed youths ages 7 to 17 years (Findling et al., 2000). Results showed reduction in depressive symptoms after 6 weeks of treatment. A double-blind randomized placebo-controlled trial followed, looking at 195 adolescents treated with 300 to 400 mg of nefazodone daily for 8 weeks, but it did not show a statistical difference between the two groups on the primary outcome measure, the CDRS-R score (Emslie et al., 2002a). It did, however, show statistical significance on the secondary outcome measure, the HAM-D score. To be noted, the study also mentioned a second unpublished trial showing no significant distinction between nefazodone treatment and placebo in a depressed pediatric population.

Tricyclic Antidepressants and Monoamine Oxidase Inhibitors

Although quite efficacious in adults, TCAs have been consistently shown to be ineffective for depressed children, with only marginal evidence for possible use in adolescents (Hazell et al., 1995, 2002). Their lack of efficacy and adverse side-effect profile, as well as potential lethality in overdose, do not make this class of medications a treatment option for pediatric depression. Monoamine oxidase inhibitors (MAOIs) have not been investigated significantly in youths and carry the particular disadvantage of requiring a tyramine-free diet. The selegiline patch differs from other MAOIs by its selectivity for MAO B, as it bypasses hepatic first-pass metabolism and avoids inhibition of MAO A in the liver and gastrointestinal tract (Lee & Chen, 2007). As a result, it does not require any dietary restrictions in doses up to 6 mg/24 hours, and it has recently been evaluated in a double-blind placebo-controlled trial in youths. It was determined to be safe and well tolerated, but a paper presented at the 2011 meeting of the American Academy of Child and Adolescent Psychiatry (AACAP) did not show any statistical difference in terms of improvement of depressive symptoms in adolescents treated with the selegiline transdermal system compared to placebo (DelBello et al., 2011).

Omega-3 Fatty Acids

Used widely as supplements to improve cardiovascular health, and believed to reduce nonspecific inflammation, omega-3 fatty acids have also been investigated in the treatment of adult depression and other psychiatric disorders. Studies in children include treatment for ADHD, bipolar disorder, and autism. One open pilot study looking at 28 children aged 6 to 12 years showed significant improvement in depressive symptoms with omega-3 fatty acids in comparison to placebo (Nemets et al., 2006).

COMORBIDITY

Psychiatric comorbidity is quite common, with 40% to 90% of depressed youths carrying a comorbid diagnosis, most frequently an anxiety disorder, ADHD, or substance abuse disorder (Birmaher et al., 2007; Lewinsohn et al., 1998, 2003). Comorbidity of MDD

with dysthymia has shown the highest correlation with a poor prognosis as well as poor response to treatment with SSRIs (Emslie et al., 1998; Kratochvil et al., 2009). Comorbid ADHD has been associated with moderation of treatment response in TADS (Curry et al., 2006), as well as lower response rates to treatment with paroxetine, imipramine, and even placebo (Birmaher et al., 2000). Response rates among patients without ADHD were 71% for paroxetine, 64% for imipramine, and 59% for placebo, whereas rates for patients with ADHD were 25% for paroxetine, 31% for imipramine, and 13% for placebo (Keller et al., 2001). Substance use disorders tend to be more common in adolescents with treatment-resistant depression, predicting poor treatment response in the TORDIA study (Emslie et al., 2010). There have been very few trials looking at the optimal sequence of treatment in patients with psychiatric comorbidities, which leaves clinicians with little to no guidance (Hughes et al., 2007; Rey & Birmaher, 2009). Nevertheless, usual practice involves determining which disorder is causing the most distress and the greatest impairment in functioning, and treating it first (Birmaher et al., 2007). One must also keep in mind that the treatment of one co-occurring psychiatric condition can also be useful in treating the other. In the case of comorbid depressive and substance abuse disorders, both conditions need to be treated simultaneously as they worsen each other's prognosis, and their co-occurrence itself has been shown to be a risk factor for completed suicide (Goldstein, 2009).

TREATMENT-RESISTANT DEPRESSION

Before proceeding with the management for treatment-resistant depression, it is important to establish nonresponse and address any underlying factors that may be contributing to failure of treatment. Most commonly, such factors include nonadherence to treatment, inaccurate diagnosis, untreated comorbidity (psychiatric and/or medical), insufficient length of treatment, and inadequate medication dosage (Birmaher et al., 2007). The initial management strategy consists of optimizing a patient's ongoing treatment in terms of dosage and duration (Birmaher et al., 2007; Hughes et al., 2007). However, if the child or adolescent is showing no response at all or is experiencing intolerable side effects with the current antidepressant, a different antidepressant should be tried. The TORDIA study is the only RCT looking at pharmacological strategies in SSRI-resistant adolescent depression (Brent et al., 2008). Three hundred thirty-four participants (aged 12 to 18 years) with MDD who had not responded to one adequate SSRI trial were randomized to one of four treatment options for 12 weeks: switch to another SSRI (fluoxetine, paroxetine, or citalopram) with or without CBT, or switch to venlafaxine with or without CBT. Results showed that patients who were switched to another antidepressant showed a 40.5% response rate, regardless of the antidepressant class. Medication monotherapy, however, was inferior to switching to a different antidepressant with the addition of CBT, which led to a response rate of 54.8%. Although venlafaxine appeared to be as efficacious as the alternate SSRIs, it was less well tolerated. Another strategy for management of treatment-resistant depression is augmentation, which is usually considered when a partial response is already being observed. A post hoc analysis of the TORDIA study demonstrated higher remission rates with the addition of a mood stabilizer (atypical antipsychotic, lithium, divalproex, or topiramate) to an SSRI (Emslie et al., 2010). Fifty percent of those patients showed remission compared to 17% for patients who did not receive a mood stabilizer. Recommendations for augmentation strategies as well as class switching generally follow adult evidence, as very few data are available for use in children and adolescents (Hughes et al., 2007; Rey & Birmaher, 2009).

SUICIDALITY AND THE BLACK BOX WARNING

In October 2004, the FDA issued a black box warning for all antidepressants, addressing concerns of increased suicidal thinking and behavior in children and adolescents in the acute phase of antidepressant treatment. A meta-analysis was conducted with data from 24 trials for a pooled total of 4,582 subjects (Hammad et al., 2006). There were 16 studies looking at MDD, 4 at OCD, 2 at GAD, 1 at ADHD, and one at social anxiety. Results indicated an overall risk ratio of 1.95 for all antidepressants across indications and a lower risk of 1.66 for SSRIs in depression trials. A second meta-analysis (Bridge et al., 2007), which included three additional trials (both published and unpublished), showed a pooled absolute rate of 3%

for suicidal ideation or suicide attempt in patients with MDD treated with antidepressants, compared to 2% for patients with the same diagnosis and treated with placebo. As depression itself may lead to suicidal ideation and suicide attempts, it is important to weigh the risk of treatment with the actual risk of suicide—occurring most often in youths with unipolar or bipolar depression (Bridge et al., 2006)—and proceed with frequent symptom-specific monitoring. Moreover, a study by Lu and colleagues (2014) has been interpreted as indicating that the warning about the emergence of suicidal ideation in patients taking antidepressant medication may have had the paradoxical effect of increasing the rate of suicide attempts. They reported that the safety warnings, which received widespread media coverage, were associated with both a reduction in the rate of antidepressant prescribing and an increase in suicide attempts in young adults.

ACTIVATION AND CONVERSION TO MANIA

Activation, which consists of increased activity, irritability, insomnia, and disinhibition presenting in the first few weeks of treatment (Goodman et al., 2007; Safer & Zito, 2006), is thought to occur more commonly in children than in adolescents and adults (Safer, 2011) and has also been suggested as a precursor to antidepressant-related suicidality (Goodman et al., 2007). It is therefore recommended to start antidepressants in children at a low dose, titrating upward slowly and cautiously. Conversion to mania as a result of antidepressant treatment is also of significant concern, although rates have been low across RCTs conducted in youths. Patients should be assessed for risk factors for BD such as family history of BD, very-early-onset depression, psychosis, or previous manic switch, and should be monitored accordingly (Choe et al., 2012).

PSYCHOSOCIAL TREATMENTS FOR DEPRESSION IN CHILDREN AND ADOLESCENTS

Due to the high prevalence and chronicity of pediatric depression if left untreated, it is important to understand the available and effective psychosocial treatments in addition to the pharmacological options (Lewinsohn & Clarke, 1999; Weersing & Brent, 2006). Far too often, depressed youth do not receive effective treatment despite its availability (Lewinsohn & Clarke, 1999), which in turn can lead to long-term functional and social impairment (Mufson et al., 2004b). The psychosocial treatments for pediatric depression with the largest evidence base include CBT and IPT-A (Stark et al., 2012). Additionally, recently developed approaches are showing encouraging treatment gains in preliminary research. Such interventions include Attachment-Based Family Therapy (ABFT) and Parent–Child Interaction Therapy (PCIT) for younger pediatric populations, and some support is emerging for psychodynamic therapies (Diamond et al., 2002; Luby et al., 2012; Trowell et al., 2007).

To provide a comprehensive yet content-specific review, we only include and examine studies that used an RCT design with the primary purpose of reducing depressive symptoms. For example, this review excludes prevention studies that targeted youth who were not presenting with depressive symptoms. Although the results of other studies warrant consideration for the potential to reduce rates of afflicted children and adolescents, such a discussion is beyond the scope of the present chapter.

Cognitive-Behavioral Therapy

CBT has been extensively researched as a psychosocial intervention of choice for depression in children and adolescents, with RCTs that offer promising outcomes (Compton et al., 2004). These studies demonstrated that CBT may be more effective than other psychosocial interventions such as family therapy, supportive counseling, and relaxation training (Brent et al., 1997; Wood et al., 1996). Traditional CBT for depression uses skills training toward recognizing and restructuring negative patterns of thought that will ultimately stimulate changes in behaviors (Beck, 2011; Kaslow & Thompson, 1998). Often, CBT for children and adolescents incorporates additional sessions to include parents and other family members to support the child and his or her treatment (Compton et al., 2004). Other basic techniques used in these interventions include (TADS Team, 2000):

1. Mood monitoring
2. Cognitive restructuring

3. Behavioral activation, pleasant activity scheduling, and goal-setting strategies
4. Relaxation and stress management
5. Social skills and conflict-resolution training
6. Training in general problem-solving skills

Numerous research studies involving RCTs have evaluated the effectiveness and efficacy of individual CBT for depressed children and adolescents. These studies, and meta-analyses of these studies, suggest that CBT offers significant symptom improvement and treatment gains compared to waitlist conditions and treatment-as-usual groups (Compton et al., 2004; Klein et al., 2007). In a type 2 RCT, 53 adolescents with MDD received five to eight sessions of individual CBT treatment or relaxation training, Wood and colleagues concluded that CBT resulted in significantly greater improvement on various measures of mood, depressive symptoms, and overall functioning (Wood et al., 1996). In another type 2 RCT, Brent and colleagues (1997) randomized 107 adolescents with MDD to receive 12 to 16 sessions of individual CBT, family therapy, or supportive therapy. Findings indicated that adolescents in the CBT treatment arm had lower rates of depression diagnoses at the end of treatment. In both these studies, individual CBT was superior to other interventions at the end of treatment; however, these differences between groups did not persist at the 6-month (Wood et al., 1996) and 2-year follow-up assessments (Brent et al., 1997) respectively.

The efficacy of group CBT has also been well established in the treatment of depression in children and adolescents (David-Ferdon & Kaslow, 2008). Clarke and colleagues (1999) conducted a type 1 RCT in which 123 adolescents with MDD or dysthymia were randomly assigned to 8 weeks of group CBT, group CBT with a separate parent group, or waitlist control. Patients in both the group CBT treatment arms had higher depression recovery rates (64.9% and 68.8%) compared to those in the waitlist control group (48.1%). Outcomes in the two CBT treatment arms did not significantly differ from each other. For children, group CBT is currently the most efficacious psychosocial intervention to treat depression, with support from multiple type 2 studies (Asarnow et al., 2002; Stark et al., 1987, 1991). More generally, reviews of rigorous treatment outcome studies conclude that adolescent-only group CBT, child-only group CBT, and child group CBT plus a parent component have sufficient empirical support for the treatment of depression, with stronger support than that of CBT delivered individually (David-Ferdon & Kaslow, 2008).

An emerging area of research supports the use of computerized versions of CBT for depressed children and adolescents (Richardson et al., 2010). The findings of two type 2 RCTs, one with male participants and one with females, suggest that computerized CBT interventions situated as part of high-school curriculums offer some benefits in reducing depressive symptoms (O'Kearney et al., 2006, 2009). The participants in these studies presented with depressive symptoms but did not meet criteria for a depressive disorder. In the first of those studies, 78 male adolescents with depressive symptoms were randomized to the Internet-based CBT program (five modules) or a usual curriculum of developmental activities (O'Kearney et al., 2006). At the end of the treatment period, adolescents who had completed three or more modules of the CBT program had improvements in depressive symptoms, attributional patterns, and self-esteem, but only the effect for self-esteem was sustained at 16 weeks after treatment (O'Kearney et al., 2006). The same Internet program, employed with adolescent females, demonstrated more rapid improvements of depressive symptoms in the group receiving the CBT Internet program, with effect sizes of these differences reaching statistical significance from the posttreatment point to 20 weeks after that (O'Kearney et al., 2009). Both studies found that completion rates of the Internet program were problematic, with the most depressed individuals tending to complete fewer modules (O'Kearney et al., 2009), suggesting the need for additional treatment development.

More recently, a pilot double-blind type 2 RCT compared another self-help computerized CBT program called "The Journey" (cCBT) with a control attention placebo program with brief psychoeducational content (CPE) among 34 adolescents (aged 13 to 18 years) in a school setting (Stasiak et al., 2014). Participants were referred by school counselors and were eligible to participate if they scored 30 or more on the CDRS-R or 76 or more on RADS-2, indicating a possible depressive disorder or risk for major depressive symptoms, respectively. Unlike the two previous studies, completion rates were much higher at 94%, with 89% of them liking the program enough to recommend it to others, indicating both feasibility and acceptability of cCBT in this setting. This increase

in completion rates over previous studies (O'Kearney et al., 2006, 2009) is hypothesized to be due to the perceived attractiveness of cCBT's interface, ease of use, and appropriate language and difficulty level to meet adolescents' needs. Additionally, preliminary efficacy was shown by significantly greater improvement in CDRS-R scores and problem-solving skills for adolescents treated with cCBT compared to the CPE program (Stasiak et al., 2014).

Until recently, most of the research that supported the efficacy of CBT to treat pediatric depression compared CBT to other psychosocial interventions, waitlist controls, or treatment as usual. Very few pediatric depression studies have looked at combination treatments of CBT and medication or compared them to each other. As discussed earlier in this chapter, TADS is one of the most compelling type 1 studies to document the efficacy of combined CBT and fluoxetine treatment as superior to CBT alone, fluoxetine alone, and placebo for adolescents with MDD. Adolescents assigned to the treatment arms that offered CBT in this study received 15 50- to 60-minute sessions over 12 weeks. These sessions involved the techniques mentioned earlier and integrated parent and family sessions as needed. CBT significantly enhanced treatment with fluoxetine, leading to the highest response rate of 71.0% among all treatments (March et al., 2004). The combination of CBT and fluoxetine was also superior to CBT alone and placebo with respect to probability of remission, quality of life, and multiple measures of acceptability, tolerability, and safety. Patients receiving fluoxetine alone were twice as likely as those receiving the combination treatment to experience a suicidal event, suggesting that CBT may have had a protective effect against suicidality among patients receiving combination treatment. Findings from the longitudinal analyses of TADS suggest that the long-term response rates (at weeks 18 and 36) for treatment with CBT alone are comparable to those for combined treatment and treatment with fluoxetine alone (TADS Team, 2007). Another type 1 study that demonstrated the increased efficacy of combined treatment was the TORDIA RCT, where adolescents with MDD who had failed to respond to an adequate SSRI trial were randomized to switch to another medication with or without CBT for 12 weeks. Results indicated that switching to a combination of CBT with another medication led to significantly higher response rates than switching to another medication without CBT (54.8%; Brent et al., 2008). This study highlighted combination treatment as an effective intervention for adolescents with chronic treatment-resistant depression.

In various studies examining CBT, research suggests that certain cognitive styles are associated with better treatment outcomes. Adolescents and children with lower levels of hopelessness, less negative thinking, and fewer distortions in their thought processes generally experience greater improvement with treatment (Becker et al., 2008). Additionally, individuals at higher levels of functioning and those who were diagnosed with depression at younger ages tended to evidence greater improvements after individual CBT treatment (Jayson et al., 1998).

Interpersonal Psychotherapy for Adolescents

IPT-A is a brief, structured, manualized intervention targeting specific relational problem areas to reduce depressive symptoms and improve social functioning (Moreau et al., 1991; Mufson et al., 2004b). The problem areas or developmental issues addressed over the course of treatment include grief, role disputes, role transitions, and interpersonal deficits (Mufson et al., 2004b). Through IPT-A, the youth learns strategies to cope with these challenges, especially in regard to overcoming interpersonal obstacles with friends and family members (Mufson et al., 2004b). IPT-A was adapted by Moreau and colleagues (1991) from the original IPT manual designed for depressed adults (Klerman et al., 1984). It typically consists of 12 individual sessions, 30 to 60 minutes each, conducted over a 12- to 16-week period. The techniques most commonly used include psychoeducation, communication analysis, encouragement of affect expression, role playing, and interpersonal problem solving (Moreau et al., 1991). IPT-A has been modified for use with depressed adolescents in the following ways: shorter treatment duration, parental involvement, and a more narrowly defined assignment of the "sick role" (e.g., helping the adolescent to understand his or her depression as an illness rather than a personal shortcoming) in order to encourage the patient to participate in activities as normally as possible (Brunstein-Klomek et al., 2007).

There have been a number of research studies evaluating the efficacy of IPT-A to treat adolescent depression. Through RCTs, situated within hospital and school-based clinics, researchers found that

IPT-A reduced depressive symptoms and improved global and social functioning in depressed adolescents (Mufson et al., 1999, 2004a, 2004c; Rosselló & Bernal, 1999). One of the first type 1 RCTs of IPT-A compared the 12-week intervention to routine clinical monitoring, consisting of monthly or biweekly supportive therapy, for 48 participants with MDD referred to a hospital clinic (Mufson et al., 1999). After treatment, significantly more adolescents in the IPT-A group (75%) met depression recovery criteria on the HAM-D than control patients (46%). IPT-A participants also reported greater improvement in overall social functioning in friendships, dating relationships and interpersonal problem solving. In a subsequent type 2 RCT within school-based clinics, 63 adolescents who met criteria for a depressive disorder were randomized to receive 16 weeks of IPT-A or treatment as usual, which most closely resembled supportive counseling (Mufson et al., 2004c). Treatment outcomes were similar to those of the initial hospital clinic trial: Adolescents in the IPT-A group showed improvements in self-reported and clinician-reported depressive symptoms and overall social and psychological functioning. This study was one of the first to assess the effectiveness of delivering an evidence-based intervention for depressed adolescents by school-based clinicians in a community setting (Mufson et al., 2004c). In both these studies, the samples were predominantly female and Hispanic and of low socioeconomic status, limiting generalizability to other adolescent populations.

In 2004, Mufson and colleagues adapted individual IPT-A to be delivered in a group format (IPT-AG). This format provides an immediate forum for adolescents to be able to practice new interpersonal interactions and is also more cost-effective and feasible for implementation in school-based clinics and other community mental health settings. Data from type 2 and type 3 studies suggest IPT-AG's feasibility, acceptability, and preliminary benefits in reducing depression symptoms (Mufson, 2004, Mufson et al., 2004d; Rosselló et al., 2008), with further research under way.

As expected, interpersonal functioning has been indicated as a moderator of treatment outcome among adolescents. In particular, conflict in patients' relationships with their mothers and friends prior to receiving treatment predicted greater symptom relief for adolescents receiving IPT-A compared to those in the control condition, although problems in family functioning also slowed the pace of those symptom improvements (Gunlicks-Stoessel et al., 2010). The authors also found that less favorable treatment outcomes were predicted by adolescents' perception of their own dysfunction (Gunlicks-Stoessel et al., 2010). The increased age of patients, greater severity of depression, presence of comorbid disorders, and elevated levels of cortisol during interpersonal conflict tasks have also been shown to moderate the effects of treatment using IPT-A (Gunlicks-Stoessel et al., 2013; Mufson et al., 2004b; Young et al., 2006).

Other Psychotherapy Approaches

Attachment-Based Family Therapy

Based on structural and multidimensional family therapy, ABFT is a manualized treatment drawing from contextual therapy, emotion-focused therapy, and attachment theory (Diamond et al., 2002). Developers of ABFT suggest that a family-based treatment is particularly important for children and adolescents as factors within parent–child relationships are related to an individual's development of depression and maintenance of symptoms (Diamond et al., 2002). Stemming from this assertion, ABFT is based on the assumption that poor attachment, high conflict, and criticism in parent–child relationships can result in serious negative consequences when combined with inadequate affective attunement (Diamond et al., 2002). Additionally, ABFT came about as a result of the expectation that these problematic attachments can be improved as parents learn how to be better caregivers and adolescents rebuild better trust and communication. Resulting gains in these areas of functioning reduce adolescents' symptoms of depression while preventing possible relapse (Diamond et al., 2002).

ABFT is organized around five treatment tasks:

1. *Rational Reframe Task*: Refocuses the intervention on improving relationships within the family rather than "fixing" the patient and assigning blame
2. *Adolescent Alliance-Building Task*: Emphasizes the importance of building a therapist–adolescent bond and identifying specific and stressful intrafamily conflicts for eventual discussion with parents

3. *Parent Alliance-Building Task*: Encourages parents to examine their personal stressors and explore their own attachment experiences
4. *Attachment Task*: Adolescent communicates with parents about previously concealed emotions and conflicts in the parent–child relationship.
5. *Competence-Promoting Task*: Parents focus on supporting the adolescent's success in relationships and connections outside the family as conflict decreases within.

In a type 2 study conducted in 2002, Diamond and colleagues compared treatment outcomes of adolescents with MDD receiving ABFT to a waitlist control group. Researchers found that participants treated with ABFT for 12 weeks demonstrated greater reductions in depression diagnoses and severity of depressive symptoms, including hopelessness and suicidality, along with improvements in attachment relationships with mothers (Diamond et al., 2002). Recent research also indicates that ABFT offered relief from depressive symptoms more rapidly than enhanced usual care in a small type 2 RCT for adolescents with suicidal ideation (Diamond et al., 2010).

Psychodynamic and Supportive Therapies

Traditionally, there have been fewer research studies suggesting empirical support of psychodynamic therapies to treat childhood and adolescent depression (Trowell et al., 2007). Recently, however, researchers at three international sites conducted a type 2 RCT, assigning 72 children (aged 9 to 15) diagnosed with MDD to receive short-term individual psychodynamic therapy focused on interpersonal relationships and attachments or family therapy (Trowell et al., 2007). Analysis at the end of treatment and at follow-up indicated that there were no significant differences between the two treatment groups but that the majority of participants evidenced improvement in symptoms and functioning (Trowell et al., 2007).

Parent-Child Interaction Therapy Emotional Development

No treatments have been empirically validated for use with depressed children between the ages of 3 and 6 years. Therefore, Lenze and colleagues (2011) created an Emotional Development (ED) module, which was integrated into PCIT, to adapt the treatment for use with depressed children. In its original format, PCIT is primarily used for families with a child displaying oppositional defiant and disruptive behaviors and involves real-time parent coaching during interactions with the child (McNeil & Hembree-Kigin, 2010). The additional ED module addresses emotion development impairments identified in preschool-onset depression. Luby and colleagues (2012) further investigated the efficacy and feasibility of PCIT-ED in a type 2 pilot RCT comparing the treatment to psychoeducation. The findings suggest that PCIT-ED significantly improved executive functioning and increased recognition of emotion, although there were no differences between the treatment conditions on depressive symptoms or functional impairment (Luby et al., 2012).

CONCLUSION AND FUTURE DIRECTIONS

Depression is a common and impairing condition that accounts for a substantial proportion of disability and mortality among children and adolescents. This chapter reviews the evidence base for pharmacological and psychosocial interventions to treat pediatric depression. Multiple type 1 and type 2 RCTs have demonstrated the efficacy of the following treatments. The two antidepressant medications that are FDA approved for treatment of MDD in children and adolescents are fluoxetine (for patients aged 8 to 18 years) and escitalopram (for patients aged 12 to 17 years), and both are well tolerated among pediatric patients (Birmaher et al., 2007; Emslie et al., 2002, 2009; TADS, 2004). Fluoxetine remains the oldest and most studied antidepressant to be approved for acute treatment of pediatric depression. Two psychosocial interventions have been shown to be the most efficacious for treating pediatric depression: CBT and IPT-A. CBT has demonstrated efficacy as an individual treatment for adolescents (Brent et al., 1997; Compton et al., 2004; TADS, 2004; Wood et al., 1996) and as a group treatment for both children and adolescents with depression (Asarnow et al., 2002; David-Ferdon & Kaslow, 2008; Clarke et al., 1999; Stark et al., 1987, 1991). IPT-A has demonstrated efficacy as an individual treatment for adolescents with depression (Mufson et al., 1999, 2004b).

TADS was a pivotal type 1 study that established the efficacy of combined treatment with CBT and fluoxetine as superior to either treatment alone for adolescents with MDD (March et al., 2004). The TORDIA RCT further established that adolescents with chronic, treatment-resistant depression were more likely to respond to a combination treatment of CBT and a switch in antidepressant medication than to a switch in medication alone (Brent et al., 2008). Overall, psychosocial interventions are recommended as first-line treatments for adolescents with brief or mild depression. In children and adolescents with moderate to severe depression, treatment with medication alone or in combination with CBT is most effective. Adding CBT to medication may enhance the safety of medication (TADS Team, 2007).

Despite a significant number of RCTs (type 1 and 2 studies) carried out thus far, evidence-based pharmacological recommendations remain limited in the treatment of depressive disorders in children and adolescents. Medications that have consistently shown response in adults have not demonstrated similar efficacy in youths (Ryan, 2003), and adverse effects have proved to be more concerning in the pediatric population (Bridge et al., 2007). It has therefore become quite clear that treating depression in children and adolescents is not merely an extension of adult protocols. Very few medications are currently FDA approved, leaving physicians with narrow treatment strategies and families with few pharmacological options to choose from. As SSRI trials continue to show inconsistent results, non-SSRIs should be investigated further, most importantly in studies sufficiently powered to determine efficacy and safety. Long-term maintenance and prevention studies, also assessing long-term safety, are also crucial to forge ahead with a comprehensive long-term treatment/prevention model. Factors currently known to affect treatment response include severity of illness, age of onset, duration, comorbidity, family history, and environmental stressors. However, more specific predictors of response and remission should be explored in pharmacological studies in order to directly improve prognosis. Biological markers also warrant further investigation to help elucidate vulnerability as well as guide treatment beyond a simple trial-and-error model.

The aforementioned benefits of psychosocial treatments for childhood and adolescent depression suggest that these interventions remain an important and viable option as alternatives and/or additions to medication treatment. With empirically supported versions of new and more traditional interventions emerging and generating promising research, psychotherapy continues to merit consideration to help children and adolescents with depression. Future research should continue to investigate the implications of the consistent observation that the differential response rates between evidence-based treatments and their control counterparts fail to maintain statistical significance beyond the end of treatment. To this end, analysis of the functional components offering the greatest symptom alleviation for depressed pediatric populations appears to be a worthy examination.

Psychosocial Treatments for Major Depressive Disorder

W. Edward Craighead
Benjamin N. Johnson
Sean Carey
Boadie W. Dunlop

Behavior therapy (BT), cognitive-behavior therapy (CBT), and interpersonal psychotherapy (IPT) have each been shown by at least two type 1 or type 2 randomized controlled trials (RCTs), as well as by numerous meta-analytic reports of the literature, to be effective psychosocial interventions for patients meeting criteria for major depressive disorder (MDD). All three psychosocial treatments have yielded substantial reductions in scores on the two major depression rating scales (the Beck Depression Inventory [BDI] and the Hamilton Rating Scale for Depression [HRSD]), significant decreases in the percentage of patients meeting the criteria for MDD at the end of treatment, and substantial maintenance of effects well after treatment has ended. The data for outcomes of psychosocial and pharmacological interventions for MDD episodes suggest that the two treatment modes are equally efficacious. Meta-analyses lend support for the superior effectiveness of combined psychosocial and pharmacological treatments with chronic depression. Recently published data suggest that psychosocial interventions may also be as effective as antidepressant medications for some patients with more severe forms of depression. Current research efforts are examining methods to better match individuals to the specific form of treatment most likely to prove beneficial.

INTRODUCTION

MDD is one of the most commonly diagnosed psychiatric disorders among adults, with U.S. lifetime prevalence rates of approximately 17%, with rates of 20% to 25% for women and 9% to 12% for men; point prevalence rates are approximately 6% and 3% for women and men, respectively (Ferrari et al., 2013; Kessler et al., 2005).

Prevalence rates and gender differences are relatively constant across the adult lifespan. In addition, the diagnosis of MDD has increased over the past 30 years (Fergusson, Horwood, Ridder, & Beautrais, 2005; Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993; Weissman et al., 1996); this suggests that the lifetime prevalence will be higher for current younger cohorts (for an alternative view, see Baxter et al., 2014). The age of first episode of MDD has been decreasing (Burke, Burke, Regier, & Rae, 1990; Lewinsohn, Clarke, Seeley, & Rohde, 1994), so that the peak years for first onset are at present between 15 and 29 years of age (Burke et al., 1990; Fergusson et al., 2005; Hankin et al., 1998). The earlier onset of a first depressive episode has been linked to more

chronic MDD (Mondimore et al., 2007). Regardless of age of onset, 75% of patients with MDD will experience multiple depressive episodes (Hughes & Cohen, 2009). Thus, MDD is a major health problem for which it is important to have efficacious treatments and ultimately to personalize treatment by matching interventions to empirically derived subtypes of depression.

Depression engenders not only extraordinary personal and family suffering but also significant societal burdens, such as role impairment and an increased use of social and medical services (Johnson, Weissman, & Klerman, 1992; Merikangas et al., 2007). Furthermore, there are enormous financial costs for treatment and for lost productivity due to absenteeism from work (Greenberg, Stiglin, Finkelstein, & Berndt, 1993; Wells et al., 1989). MDD costs an estimated $36 billion each year in the United States, including an annual $11.7 billion in lost productivity (Kessler et al., 2006). MDD is among the top three major causes of societal and economic disease burden across the globe (Ferrari et al., 2013; Mathers & Loncar, 2006; World Health Organization, 2008). The sequelae following the first episode of MDD are substantial. The probability of subsequent episodes is significantly increased, so that most now consider MDD a recurrent or chronic disease. For example, a recent study found that approximately 73% of teens who experienced a first episode before age 18 had a recurrence within the next 12 years (Pettit, Hartley, Lewinsohn, Seeley, & Klein, 2013).

To receive a diagnosis of MDD a person must experience marked distress or a decrease in level of functioning. In addition, the 2 weeks before examination must be characterized by the almost daily occurrence of a dysphoric mood (sad, empty, or hopeless) or a loss of interest or pleasure in almost all activities (American Psychiatric Association [APA], 2013). The individual must also experience at least four (only three if both dysphoric mood and anhedonia are present) of the following seven symptoms (with the second through sixth occurring nearly every day):

1. Significant weight loss (while not trying to lose weight), significant weight gain, or a change in appetite
2. Insomnia or hypersomnia
3. Psychomotor agitation or retardation
4. Fatigue or loss of energy
5. Feelings of worthlessness or excessive or inappropriate guilt
6. Decreased concentration or indecisiveness
7. Recurrent thoughts of death or suicidal ideation, plan, or attempt

Substantial advances have been made over the past three decades in the treatment of depression. Treatments of choice now include a number of psychosocial interventions—BT (including behavioral marital therapy [BMT]), CBT, and IPT—in addition to the somatic interventions reviewed in a separate chapter. This chapter reviews the evidence regarding the efficacy of these specific psychosocial treatments (including their combinations with somatic treatments), discusses the possible mechanisms of change in these therapies, and addresses issues regarding the appropriate use of psychosocial treatments. This review includes only those studies that obtained information for diagnosis via a structured interview such as the Structured Clinical Interview for *DSM* (SCID; First, Spitzer, Gibbon, & Williams, 1995; Spitzer, Williams, Gibbon, & First, 1992) and employed a formal, defined diagnostic system such as the Research Diagnostic Criteria (Spitzer, Endicott, & Robins, 1978) or the *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* (*DSM*-5; APA, 2013). Further, to be included, an investigation must also have employed cutoff scores on standard depression severity measures, such as clinical rating scales or self-report measures, as a criterion for admission to the study. Thus, by virtue of the severity, frequency, and duration of their observed symptoms, the participants in these studies are comparable in severity to patients who might typically seek and receive outpatient treatment by mental health professionals for MDD. Studies reported herein do not include depressed patients with psychotic features, patients who are imminently suicidal, or depressed inpatients. Within the context of this book, the included efficacy studies would all be considered type 1 studies. Based on the preceding criteria, only BT, CBT, and IPT have been studied in at least two comparative type 1 outcome trials for outpatients between the ages of 18 and 65 years and, therefore, have been included in this review.

BEHAVIOR THERAPY

Description

Lewinsohn developed the first behavioral treatment program of significance by building on previous behavioral formulations of depression (Ferster, 1973; Skinner, 1953; see Lewinsohn & Gotlib, 1995, for a summary of Lewinsohn's contributions and Cuijpers, 1998, for a meta-analysis of Lewinsohn's BT for depression). Although numerous flavors of BT have been developed for treatment of MDD, they all assume that MDD is related to a decrease of behaviors that produce positive reinforcement. As such, behavior therapies for depression have focused largely on monitoring and increasing positive daily activities, improving social and communication skills, increasing adaptive behaviors such as positive and negative assertion, increasing contingent positive reinforcement for adaptive behaviors, and decreasing negative life experiences (Craske, 2010).

Empirical Evidence

In an RCT, Lewinsohn and his group demonstrated that, relative to various control groups, BT increased pleasant experiences and reduced aversive experiences, and these changes resulted in concomitant decreases in depression severity (see Lewinsohn & Gotlib, 1995). Lewinsohn's work was extended by Bellack, Hersen, and Himmelhoch (1981, 1983) and Hersen, Bellack, Himmelhoch, and Thase (1984), who demonstrated that BT was as effective as the antidepressant amitriptyline in reducing depression over a 12-week treatment period; these effects were maintained over a 6-month follow-up period with six to eight booster sessions.

Extending the behavioral model, Rehm developed self-control therapy (1977) and found it to be superior to nonspecific psychosocial treatments and no-treatment controls (Rehm, 1990). It has not, however, been compared with standard antidepressant medication treatment. The apparently essential ingredient (and perhaps the most important contribution) of this self-control therapy is the self-monitoring of thoughts and behaviors (Rehm, 1990), a component that is included in most other empirically supported psychosocial depression treatment protocols that will be discussed in this chapter.

Following upon Rehm's (1977) suggestions, McLean and Hakstian (1979) added problem-solving and self-control procedures to a BT protocol, and they conducted a 10-week clinical trial comparing this expanded BT intervention to relaxation therapy, insight-oriented psychotherapy, and amitriptyline. The BT program was equal or superior to the other treatment conditions. These results were maintained at a 27-month follow-up (McLean & Hakstian, 1990).

Subsequently, there was a hiatus in studies of BT for MDD because, in the development of the Treatment of Depression Collaborative Research Program (TDCRP; Elkin et al., 1989), Beck and his colleagues integrated BT with cognitive therapy (Beck, 1976) and produced CBT for depression (Beck, Rush, Shaw, & Emery, 1979). Thus, there was minimal BT research for nearly 20 years.

Based in part on the earlier BT work and outcomes, Jacobson and his colleagues (1996) developed a contemporary behavioral activation treatment protocol (see Dimidjian, Barrera, Martell, Muñoz, & Lewinsohn, 2011). These investigators, led by Jacobson, tested the hypothesized theory of mechanisms of change in CBT for depression by comparing the full CBT treatment protocol to its component parts: (1) "behavioral activation" and (2) CBT comprising "behavioral activation plus modification of automatic dysfunctional thoughts." The behavioral activation treatment included techniques such as monitoring daily activities, assessment of pleasure and mastery of activities, assignment of increasingly difficult activities, imaging of behaviors to be performed, discussion of specific problems and identification of behavioral solutions to those problems, and interventions to ameliorate social skills deficits. The primary finding of this study (Jacobson et al., 1996) was that behavioral activation, modification of automatic thoughts, and the full CBT intervention were equally effective, both immediately after the 20-session treatment trial and at the 6-month follow-up. Furthermore, behavioral activation performed equally well over a 2-year follow-up period, with patients across the three treatments having equivalent rates of relapse, time to relapse, and number of well weeks (Gortner, Gollan, Dobson, & Jacobson, 1998).

In a follow-up replication study of Jacobson's CBT component analysis, Dimidjian and colleagues (2006) compared a somewhat modified model of behavioral activation, CBT, the antidepressant paroxetine, and pill placebo in a 16-week MDD treatment

trial. In addition to the behavioral activation techniques employed in Jacobson and colleagues' trial, the expanded model emphasized the importance of avoidance and withdrawal, particularly from interpersonal situations and daily routines. The model also stressed shifting attention from ruminative thinking toward direct experience. Dimidjian and colleagues randomly assigned 241 individuals to the four treatment conditions. Contrary to a primary hypothesis, the investigators found that, among the more severely depressed patients, behavioral activation and paroxetine were comparably effective treatments, while each treatment significantly outperformed CBT. Furthermore, a significantly greater percentage of participants randomized to expanded behavioral activation reached remission when compared with individuals in either the paroxetine or the CBT condition. However, in a later analysis of 2-year follow-up data from this study, CBT was found to be superior to both behavioral activation and paroxetine in the prevention of relapse; behavioral activation and paroxetine were equally effective (Dobson et al., 2008). As Dimidjian and colleagues note, these findings challenge treatment recommendations that stated that moderate to severe depression necessitates medication. Behavioral activation interventions expanded to include an emphasis on avoidance behaviors and the function of rumination may provide an equally efficacious treatment alternative for moderately to severely depressed patients who prefer not to take antidepressant medications.

Since Dimidjian and colleagues' 2006 replication study, preliminary clinical trials have been conducted using behavioral activation in a variety of patients with MDD. Specifically, studies using small samples have suggested that it may be efficacious in patients with comorbid MDD and posttraumatic stress disorder (Mulick & Naugle, 2010) and in patients with MDD characterized by atypical features (e.g., extreme fatigue, hypersomnia; see Weinstock, Munroe, & Miller, 2011).

Given the high prevalence of MDD in individuals with medical concerns, behavioral activation has been evaluated in individuals with comorbid MDD and obesity. Pagoto and colleagues (2008) found a decrease in symptoms of depression as well as significant weight loss after 12 weeks of behavioral activation. There is some evidence that it may be effectively modified for culturally specific groups, for example Latinas (Kanter, Santiago-Rivera, Rusch, Busch, & West, 2010). Behavioral activation continues to be adapted to non–mental-health settings, such as for use in primary care (Uebelacker, Weisberg, Haggarty, & Miller, 2009) or via computer delivery (Spates, Kalata, Ozeki, Stanton, & Peters, 2013). Further research on adaptations of behavioral activation, including virtual delivery, may allow for easier dissemination and implementation of this evidence-based treatment for depression. Evidence from this body of research suggests that behavioral activation may be broadly effective for many variations in the presentation of MDD.

Cognitive-Behavioral Analysis System of Psychotherapy (CBASP; McCullough, 2000)[1] is a form of BT that has been blended with aspects of problem-solving therapy, particularly as applied to interpersonal situations. CBASP focuses on the consequences of a patient's behavior and the use of social problem solving to address interpersonal difficulties. Keller and colleagues (2000) randomly assigned 681 adults with chronic major depression to 12 weeks of acute treatment with CBASP, the antidepressant nefazodone, or the combination of CBASP and nefazodone. Remitters and responders to acute-phase treatment subsequently entered a 16-week continuation treatment phase. Chronic depression was defined as (a) MDD of at least 2 years' duration; (b) current MDD superimposed on a preexisting dysthymic disorder; or (c) recurrent MDD (with incomplete remission between episodes and a total duration of continuous illness of at least 2 years). The overall rate of response was equivalent in the CBASP and nefazodone groups, although patients receiving nefazodone had a more rapid reduction in depression during the first 4 weeks of treatment. Immediately following treatment, the combination of CBASP and nefazodone was superior to either treatment alone (i.e., monotherapy), and this benefit of combination treatment was sustained through the 16-week continuation phase (Kocsis et al., 2003). A greater proportion of participants who received CBASP and nefazodone, compared with the monotherapy conditions, maintained full or partial remission status through the continuation phase. Findings from the same multiphase investigation suggest that CBASP may also be an effective maintenance treatment to prevent the recurrence of major depression (Klein et al., 2004).

A follow-up (Nemeroff et al., 2003) to the study by Keller and colleagues (2000) has provided interesting results regarding the relative contributions of psychotherapy and pharmacotherapy among depressed

patients who experienced an early-life traumatic event (e.g., sexual abuse, loss of a parent). Nemeroff and colleagues reanalyzed data for the 681 patients in the CBASP depression treatment study. These analyses indicated that among those chronically depressed patients who had experienced early childhood trauma, psychotherapy (CBASP) was superior to nefazodone alone for the outcome of remission. However, this interaction was only significant when depression severity data from the first week of treatment were used and not in analyses of change from baseline (see correction, Nemeroff et al., 2005). Further, the combination of the antidepressant with CBASP resulted in only minimally greater efficacy than CBASP alone. A small pilot study by Schramm and colleagues (2011) followed on the study by Nemeroff and colleagues (2003) by stratifying randomization to CBASP and IPT by childhood trauma severity, thus limiting the confounding effects of differential levels of childhood abuse among treatment conditions. This study found no difference after 16 weeks between CBASP and IPT on change scores on the clinician-rated HRSD (Warren, 1996), but there was a significantly higher likelihood to remit with CBASP when rated on the self-reported BDI (Beck, Steer, & Brown, 1996).

The preceding studies regarding early life trauma and depression need replication with more adequately powered studies in which patients are randomly assigned based on early life abuse. At this point, there is a suggestion that an individual, disorder-specific psychotherapy may be the best initial treatment option for depressed patients who have experienced early-life trauma. It is also important that future studies investigate what the underlying neurobiological pathways of effective CBASP are and how they compare to the mechanisms of change in CBT for major depression (see Heim, Shugart, Craighead, & Nemeroff, 2010).

CBASP has also been recently compared to brief supportive psychotherapy (BSP), IPT, and various antidepressant medications for chronic depression. Kocsis and colleagues (2009) conducted a 12-week augmentation trial testing the additive effects of either CBASP or BSP along with an adaptable pharmacotherapy regimen for individuals with chronic depression nonresponsive or only partially responsive to an initial medication trial. However, in contrast to the previous encouraging findings regarding CBASP, the authors found that neither CBASP nor BSP in combination with antidepressant medication based on an ideographic algorithm significantly enhanced response compared to adjustment of antidepressant treatment alone. Swan and colleagues (2014) have found preliminary data in the United Kingdom supporting the usefulness of CBASP for chronic depression. Findings from these studies suggest that CBASP is likely a valid treatment option for chronic depression.

Behavioral Marital Therapy

Another development in behavioral approaches to the treatment of depression has been the use of behavioral marital therapy (BMT) with individuals who are concurrently experiencing MDD and marital distress. Both O'Leary and colleagues and Jacobson and colleagues demonstrated that standard BMT (Beach, Sandeen, & O' Leary, 1990) was equal to individual CBT for alleviating depression among individuals with both MDD and marital discord (Jacobson, Dobson, Fruzetti, Schmaling, & Salusky, 1991; O'Leary & Beach, 1990). BMT was found to have the added advantage of being superior to individual CBT in reducing marital discord, a finding that argues for the use of BMT with depressed patients who are also experiencing marital discord. Although none of the preceding studies used adequate follow-up procedures to test prophylactic effects of BMT versus individual CBT following successful treatment, a recent study by Bodenmann and colleagues (2008) examined the effects of Coping-Oriented Couples Therapy (a version of BMT), CBT, and IPT on relapse rates in the depressed partner in a marriage dyad. Results showed the lowest relapse rates for the Coping-Oriented Couples Therapy group 1.5 years after the 20-week treatment phase (28.6%, compared to CBT: 42.9% and IPT: 62.5%); however, because there were only 20 participants in each treatment group, this difference did not reach significance. Given that "marital disputes" is the most frequently discussed topic among depressed patients in maintenance therapy (Weissman & Klerman, 1973) and that marital friction is an enduring problem among formerly depressed patients even when they are asymptomatic (Bothwell & Weissman, 1977), it is understandable that successful BMT may reduce the rate of relapse among successfully treated MDD patients in discordant marriages. Unfortunately, BMT has not been evaluated with adequate numbers of severely depressed patients in

discordant marriages to know whether these findings will be applicable to such patients or whether the presence of severe depression will necessitate alternative or adjunctive treatments.

Conclusion

Consistent findings support the efficacy of BT for depression. For several years the findings for BT were overshadowed by outcome studies that focused on CBT and IPT as psychosocial interventions for MDD. However, given the applicability of BT to depressed patients of all age groups and the relative efficacy, efficiency, and endurance of behavioral interventions, as well as the recent results for behavioral activation, CBASP, and BMT, it seems that this was an unwarranted and premature redirection of research efforts. From a historical perspective, it appears to have been due primarily to the sociology of science and the exclusion of BT from the well-publicized and influential TDCRP study (Elkin, Parloff, Hadley, & Autry, 1985) rather than to the relative scientific merit and empirical outcomes of the then-available comparative treatment studies. The past decade has seen an increase in research confirming the efficacy of BT for depression, chronic depression, and depression with various comorbidities. Several recent meta-analyses corroborate this conclusion (Cuijpers, Andersson, Donker, & van Straten, 2011a; Cuijpers et al. 2011b; Cuijpers, van Straten, Andersson, & van Oppen, 2008a; Cuijpers, van Straten, & Warmerdam, 2007; Cuijpers, van Straten, Warmerdam, & Andersson, 2009; van Straten, Geraedts, Leeuw, Andersson, & Cuijpers, 2010), indicating a promising trend in the domain of behavior therapy for MDD.

COGNITIVE BEHAVIOR THERAPY

Description

The most extensively evaluated psychosocial treatment for MDD is Beck's cognitive behavior therapy (CBT) (Beck, Rush, Shaw, & Emery, 1979), alternatively referred to simply as cognitive therapy. CBT is a short-term (16 to 20 sessions over a period of 12 to 16 weeks), directive therapy designed to change the depressed patient's negative view of the self, world, and future. The therapy begins with the presentation of the rationale, which is designed to inform the client of the therapy model and the process of therapeutic change. Subsequent early CBT sessions consist of the implementation of strategies designed to increase behavioral activities. The purpose of such an increase is to allow the monitoring of behaviors and their associated thoughts and feelings; CBT models do not posit behavioral changes to be directly responsible for the desired changes in depression. At about the third week, expanded self-monitoring techniques are introduced to demonstrate the relationship between thoughts and feelings; patients are subsequently taught to evaluate their thoughts for logical errors that include arbitrary inference, selective abstraction, overgeneralization, magnification and minimalization, personalization, and dichotomous thinking (Beck, 1976). About the middle of therapy (around session 8 or 9), the concept of schema, or beliefs underlying negative and positive thoughts, is introduced, and therapy begins to focus on changing those negative schemas that are posited to have been activated, thus precipitating the MDD. Toward the end of therapy (sessions 14 through 16), the focus shifts to termination and the use of cognitive strategies to prevent relapse or a future recurrence of depression.

Empirical Evidence

A number of studies have compared the effectiveness of CBT with several tricyclic antidepressant medications (Elkin et al., 1989; Hollon et al., 1992; Rush, Beck, Kovacs, & Hollon, 1977; Simons, Murphy, Levine, & Wetzel, 1986).[2] With the possible exception of the National Institute of Mental Health's TDCRP study (Elkin et al., 1989), the essential finding in all these studies was that CBT and tricyclic antidepressant medication were equally effective in alleviating MDD among outpatients[3] (Tables 13.1 and 13.2). CBT was also as effective as a monoamine oxidase inhibitor (phenelzine), and more effective than pill placebo, in the treatment of atypical depression (Jarrett et al., 1999). This equal efficacy was also obtained when study physicians were free to prescribe the antidepressant of their choice (and free to switch medications during the treatment trial), provided they prescribed at or above established therapeutic doses (Blackburn & Moore, 1997). Recent meta-analyses continue to show that CBT and antidepressant medications are comparable in treating nonpsychotic

MDD (e.g., Cuijpers et al., 2013). Furthermore, the combination of pharmacotherapy and psychotherapy showed only a small additive benefit when medicine was added to CBT (Craighead & Dunlop, 2014; Cuijpers et al., 2009).

Typically, 30% to 35% of patients with MDD remit and an additional 30% to 35% show response to a course of CBT, thereby no longer meeting criteria for MDD at the end of treatment. Typically, pre–post changes range from the high 20s to single digits for BDI scores and changes from the high teens/low 20s to single digits for HRSD scores (see Tables 13.1 and 13.2). Furthermore, among the samples studied, CBT appeared to confer some enduring prophylactic effects inasmuch as only 20% to 30% of successfully treated patients relapsed during the first year following treatment. Indeed, 16 weeks of CBT produced a 1-year follow-up success rate that equaled or slightly exceeded that achieved by a full year of antidepressant medication treatment (Dobson et al, 2008; Evans et al., 1992). When added to care as usual (including continuing pharmacotherapy) for MDD patients in remission, CBT significantly reduced the chances of relapse or recurrence. Among patients with five or more episodes in the preceding 2 years, the relapse rate in the CBT condition was 46%, compared with 72% in the care-as-usual condition (Bockting et al., 2005). CBT's maintenance effects are clearly superior to short-term (16 weeks) antidepressant treatment. (Sixteen weeks is not the recommended treatment period, but it is, unfortunately, longer than the actual average length of completed medication treatment in clinical practice; Bull et al., 2002; Nemeroff, 2003; Olfson, Marcus, Tedeschi, & Wan, 2006).

Because the TDCRP study (Elkin et al., 1989) has received so much attention, including its significant role in the development of guidelines (not standards) for treatment of outpatients with MDD (Agency for Health Care Policy and Research [AHCPR], 1993; APA, 2010), it is worthy of special note. This study included 250 outpatients who were randomly assigned to one of four 16-week treatment conditions: CBT, IPT, imipramine hydrochloride plus clinical management (IMP-CM), or pill placebo plus clinical management (PLA-CM). The "CM" component of IMP-CM and the PLA-CM conditions included 20 minutes per week talking with an experienced psychiatrist; CM's additive effects simply are not known.

The results of the TDCRP for those patients who completed treatment generally supported the equality of the three presumed active treatments in ameliorating depression at the end of treatment as measured by a HRSD score of 6 or less (CBT, 51%, IPT, 55%, and IMP-CM, 57%); however, only IPT and IMP-CM produced significantly greater reductions in depression than PLA-CM (29%) over the course of treatment, and only then for a few of the outcome measures (Elkin et al., 1989). Even these acute treatment effects were not maintained at the 18-month follow-up: Because the percentages of patients remaining nondepressed and not receiving treatment for depression were quite low (CBT 30%, IPT 26%, IMP-CM 19%, and PLA-CM 20%), none of the active treatments was superior to the PLA-CM condition at the 18-month follow-up (Shea et al., 1992a). These follow-up outcomes indicate that all treatments in this study had considerably weaker effects than had typically been reported in other long-term follow-up studies of these same psychotherapies. Of course, as Klein (1996) has noted, such short-term treatment (16 weeks) with antidepressant medication would not be expected to produce sustained effectiveness.

Based on the original report of the TDCRP data, it has been noted (Hollon, Shelton, & Loosen, 1991), and sustained by reanalyses of the original data tape (Jacobson & Hollon, 1996a), that the lack of unequivocal findings (coupled with the uniqueness of some of the exploratory findings) ensures that any interpretation of the TDCRP data is likely to be controversial. One of the major problems described in the original report of the TDCRP was "consistently significant treatment-by-site interactions for the more severely depressed and functionally impaired patients" (Elkin, Gibbons, Shea, & Shaw, 1989, p. 980). Even though this conclusion has been somewhat attenuated with the use of more sophisticated reanalysis of the data (Elkin et al., 1995, 1996), the general pattern for a treatment-by-site-by-severity interaction is still acknowledged, and the authors conclude: "In regard to the general efficacy of CBT in the treatment of severely depressed (and functionally impaired) outpatients . . . we believe . . . that the answer is not yet in" (Elkin et al., 1996, p. 101).

In their reanalysis of the TDCRP data, Jacobson and Hollon (1996a) underscored the importance of this site-by-treatment-by-severity interaction. They presented data illustrating that at one site CBT did as well as IMP-CM and better than PLA-CM with severely depressed patients (probably not coincidentally, this was also the site at which CBT was rated as

having been conducted at the highest level; see Elkin et al., 1996). At a second site, the data favored either IPT or IMP-CM over both CBT and PLA-CM, with the last two groups not significantly different from one another. At the third site, there were not enough subjects to warrant a comparison. In fact, it is ironic that so much has been made of the findings among the severely depressed patients, since even across three sites there were 15 or fewer severely depressed patients per condition, and "severity" was not taken into account in the random assignment procedure except for the minimal cutoff criterion of 14 on the HRSD.

The essential point regarding the TDCRP is that the findings regarding the appropriateness of CBT alone for severely depressed patients remain inconclusive. Finally, although little has been made of it, there was also a treatment by marital status confound (compounded by differential treatment effects for single and married patients), making interpretation of the data even more difficult (see Jarrett, Eaves, Grannemann, & Rush, 1991; Sotsky et al., 1991).

The TDCRP results played a major role in stimulating work by DeRubeis and colleagues (2005), who conducted a placebo-controlled trial comparing the efficacy of CBT and the antidepressant paroxetine (with lithium or desipramine augmentation, if necessary) for adults with moderate to severe depression. A total of 240 individuals were randomly assigned to a 16-week trial of antidepressant medication, 16 weeks of CBT, or 8 weeks of pill placebo. At 8 weeks, participants in the antidepressant condition displayed significant improvement compared with the pill placebo condition; there was a nonsignificant trend of greater improvement due to CBT compared with pill placebo. At 16 weeks, which marked the end of acute treatment, 40% of the CBT condition and 46% of the medication condition were in remission. When one adds responders (defined as a score of 12 or less on a modified version of the HDRS), 58% of patients treated with CBT and 58% of patients treated with medication met response criteria. Due to a significant site-by-treatment interaction, the findings indicate that with more experienced therapists CBT is as effective as antidepressant medications in treating moderate to severe major depression.

In the associated continuation study of DeRubeis and colleagues (2005), Hollon and colleagues (2005) examined the efficacy of CBT and antidepressant treatment in preventing depressive relapse among the 104 responders of the CBT/antidepressant study. Participants who responded to the antidepressant during the initial 16-week trial were randomly assigned to continuation antidepressant treatment or withdrawal onto pill placebo. Participants who responded to CBT during the acute phase of treatment were asked to refrain from enrolling in additional treatment for depression during the yearlong continuation phase. These participants were allowed up to three booster sessions, at least 1 month apart, during the continuation period. In this investigation, acute treatment with CBT significantly reduced the risk for relapse by 70% compared with the placebo withdrawal group. There was a nonsignificant trend for continuation medication reducing the risk for relapse by approximately 50%. Participants who completed CBT were no more likely to relapse during the 12-month continuation phase than were participants who continued antidepressant treatment, even though the continuation CBT was limited to up to three booster sessions. Overall, these findings indicate substantial, enduring effects of CBT that rival continued pharmacological treatment for severely depressed patients.

CBT can also affect treatment gains for some patients who fail to respond to psychopharmacology. In the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial, Thase and colleagues (2007) studied CBT and several medication alternatives as second-step treatments for patients whose depression failed to remit with initial treatment with citalopram. Patients either switched entirely to the new treatment or received it as an augmentation to citalopram. About 30% of patients who received CBT, either alone or in combination with citalopram, experienced MDD remission, similar to the remission rate among the medication-treated patients.

Recently, strides have been made in employing CBT through virtual means, such as the Internet. Johansson and Anderson (2012) compared a modified form of computer-based CBT, tailored to individual patients according to a treatment plan prepared by a CBT therapist, with standardized virtual CBT and an online discussion group control condition. The authors found, in a sample of 121 outpatients, that the three treatment modalities led to similar significant decreases in depressive symptoms, but that the tailored treatment showed greater effect for those patients with higher baseline depression severity and increased comorbidity.

Continuing CBT after the end of acute treatment can help maintain treatment gains and prevent relapse or recurrence. A meta-analysis of four maintenance studies found that continuation CBT reduced the chance of relapse or recurrence 21% over nonactive control conditions (Vittengl, Clark, Dunn, & Jarrett, 2007). The comparison between relapse and recurrence rates in continuation CBT versus active treatments achieved trend-level significance ($p < 0.06$), and patients who had received continuation CBT had a 12% lower risk of relapse or recurrence than patients receiving other active treatments.

Treatments involving adapted CBT principles also show efficacy in preventing recurrence of MDD. Sheets and colleagues developed a 12-week recurrence prevention program integrating CBT and IPT and taught it in a group setting to young adults who had previously experienced MDD (Sheets, Duncan, Bjornsson, Craighead, & Craighead, 2014). During a 2-year follow up, participants completing the program showed a 50% decline in their risk of recurrence compared to participants receiving assessment only.

Another line of investigation includes studies that have provided a full course of slightly varying forms of CBT following successful treatment of MDD with another type of intervention (e.g., medications). For example, Fava, Grandi, Zielezny, Rafanelli, and Canestrari (1996) compared their form of CBT, "well being therapy," with CM following a course of successful antidepressant medication treatment (although patients were responders and not remitters and still had residual symptoms of depression). All patients were withdrawn from antidepressants prior to the maintenance phase. As has been typical of short-term antidepressant treatment, the 4-year relapse rate following termination of medications was 70%. In contrast, the relapse rate was 35% for the participants who received the additional 10 sessions of this intervention. The difference had dissipated by the 6-year follow-up (75% CM vs. 50% CBT) and was no longer statistically significant (Fava, Rafanelli, Grandi, Canestrari, & Morphy, 1998).

Paykel and colleagues (1999) evaluated patients who had responded to acute treatment with antidepressants but still had residual symptoms. In contrast to the study by Fava and colleagues (1996), all patients were maintained on therapeutic antidepressant doses during the maintenance phase. Patients were randomized to receive either 20 weeks of CBT or CM with antidepressant medication. At the end of the 20-week maintenance treatment phase, relatively few participants had achieved full remission, but those who received CBT were at a significant advantage (25% remission vs. 13% in CM). Furthermore, across the entire study period (maintenance phase and 1-year follow-up), the combination of continued antidepressant medication with maintenance CBT resulted in a lower rate of relapse (29%) than did continued CM with an antidepressant (47%).

A few recent studies have evaluated Mindfulness-Based Cognitive Therapy (MBCT) for the prevention of relapse/recurrence of MDD after discontinuation of antidepressants. MBCT is an eight-session group intervention based on the combination of a mindfulness-based stress reduction program (Kabat-Zinn, 1990) and components of CBT for depression. Teasdale maintained that the critical variables to change in CBT are styles of "thinking about thinking" rather than the content of irrational thinking. Thus, MBCT, while targeting thought processes, helps participants become more aware of and relate differently to their cognitive experiences (Segal, Williams, & Teasdale, 2002). In this sense, MBCT is an extension of Rehm's (1977) emphasis on self-monitoring of thoughts and behaviors in his self-control therapy. A meta-analysis of six RCTs evaluating MBCT for the prevention of relapse or recurrence of MDD found that patients with three or more previous depressive episodes had a 34% lower chance of relapse/recurrence than patients in placebo or treatment-as-usual conditions. Two of the six studies compared MBCT to maintenance antidepressant treatment and found MBCT to be at least as effective (Piet & Hougaard, 2011).

Conclusion

Given the substantial number of studies supporting the efficacy of CBT with patients diagnosed with MDD, it is concluded that CBT is a viable treatment of choice for patients with MDD.[4] Data to date indicate that CBT confers resistance to relapse of MDD whether it is presented as the primary treatment or given as a supplement following successful treatment via some other intervention. MBCT seems especially effective in preventing recurrence among patients with greater numbers of lifetime depressive episodes. Given the widely varying outcomes across studies and the apparent differential competence with which the therapy was delivered across sites in two multisite

studies, it is particularly important that therapists delivering CBT be well trained before they undertake the therapy with patients and that their competence in delivering the therapy be evaluated throughout the intervention phase of any clinical trial of CBT.

INTERPERSONAL PSYCHOTHERAPY

Description

Interpersonal Psychotherpay (IPT) was originally developed as a time-limited (12 to 16 weeks), weekly intervention for unipolar, nonpsychotic MDD (Klerman, Weissman, Rounsaville, & Chevron, 1984). The IPT model derived in large part from Sullivan's interpersonal theory (1953) and the psychobiological theory of Meyer (1957), with its emphasis on the reciprocal relationship between biological and psychosocial facets of psychopathology. Although the IPT model "makes no assumptions about the causes of depression" (Klerman & Weissman, 1993, p. 6), it does suggest that the patient's interpersonal relations may play a significant role in both the onset and the maintenance of MDD. Accordingly, IPT focuses on the identification and amelioration of the patient's difficulties in interpersonal functioning associated with the current MDD. The primary problem areas targeted include unresolved grief, interpersonal disputes, role transitions, and interpersonal deficits (e.g., social isolation).

Empirical Evidence

As shown in Tables 13.1 and 13.2, there have been five reported RCTs of IPT for the acute treatment of MDD in middle-aged adults and one RCT with responders to pharmacotherapy treatment for depression. Three of these studies included long-term follow-up assessments designed to evaluate the prophylactic effects of acute IPT treatment. In addition, there have been two separate controlled studies of "maintenance" IPT following remission of the MDD and one type 1 study of ethnic minority women receiving IPT.

The first RCT of IPT for the acute treatment of MDD was conducted by the treatment's originators, Weissman and Klerman and their colleagues (DiMascio et al., 1979; Weissman et al., 1979). They randomly assigned 81 patients to treatment with 16 weeks of IPT, amitriptyline, combined IPT and amitriptyline, or a "nonscheduled" (i.e., therapy on request, up to one session per month) supportive psychotherapy control. All three treatments were superior to the nonscheduled control condition, and the combination of IPT and amitriptyline trended toward being more effective than either condition alone.

The second (and most frequently cited) RCT of IPT is the previously summarized NIMH multisite clinical trial, the TDCRP study (Elkin et al., 1989). As noted, the study's principal significant finding concerned the clinical rating of depression as measured by the HRSD. All groups began with a pretreatment mean of about 19 and, using the criterion of a posttest HRSD score of 6 or less, both IPT (55%) and IMP-CM (57%) had a significantly greater proportion of patients who achieved the recovery criterion than was observed in the PLA-CM condition (29%). In a secondary data analysis (Elkin et al., 1995), IPT and IMP-CM were also found to be of comparable efficacy among the subset of patients who were severely depressed (defined as a pretreatment HDRS score of 20 or greater). However, as previously highlighted, the presence in this investigation of either a strong trend or a significant treatment-by-site-by-severity interaction (depending on the analysis) precludes the drawing of definitive conclusions from this finding (Elkin et al., 1996; Jacobson & Hollon, 1996b).

A third RCT compared IPT to CM in the treatment of 124 severely depressed inpatients receiving sertraline as a first-line treatment or amitriptyline if patients had a history of nonresponse to sertraline (Schramm et al., 2007). A modified form of IPT was used and included an increased number of sessions, several sessions of group IPT, and incorporation of family members into several psychoeducational sessions. Compared to CM there was a greater decrease in depressive symptoms after 5 weeks of treatment with IPT. Similarly, more IPT patients than CM patients experienced remission (49% and 34%, respectively). In contrast to the preceding studies, Lespérance and colleagues (2007) found no added benefit of IPT over CM in an RCT of 284 outpatients with comorbid MDD and coronary artery disease. Participants were randomized to one of four groups: IPT plus CM and citalopram, IPT plus CM and placebo, CM only and citalopram, or CM only and placebo. After 12 weeks of treatment, citalopram outperformed placebo in reducing depression symptoms, as measured by the Beck Depression Inventory—Second

Edition (BDI-II; Beck, Steer, & Brown, 1996) and the HRSD. Contrary to expectations, IPT showed no advantage over CM and placebo in decreasing depressive symptoms. Furthermore, CM was superior to IPT for patients who reported low baseline levels of social support and daily functioning, a finding the authors attributed to difficulties for these patients in dealing simultaneously with interpersonal problems and heart concerns, required of IPT, in comparison to regular medical management, which entails fewer demands. However, the implication that CM is superior to IPT may not be generalizable to the wider population of individuals with MDD because participants in this study were concurrently diagnosed with coronary artery disease.

Frank and colleagues (2011) recently compared IPT to escitalopram in the treatment of depressed adult outpatients seeking treatment at two major medical centers, in Pittsburgh, Pennsylvania, and Pisa, Italy. A total of 318 patients who met *DSM-IV* criteria for MDD and who scored at least 15 on the HRSD were randomized to receive either IPT or escitalopram for a minimum of 12 weeks and up to 32 weeks or until remission was reached (defined as a HRSD score of 7 or less for 3 consecutive weeks). Any patient who did not respond (defined as at least a 50% decrease in HRSD score from baseline) after 3 weeks of treatment or did not experience remission by week 12 received a combination of IPT and escitalopram for the remainder of the study. Although IPT monotherapy significantly reduced depressive symptoms after 12 weeks (67.1% of the patients in Pisa and 26.6% in Pittsburgh achieved remission), there was no significant difference between treatment conditions in the number of patients experiencing remission.

An RCT by Reynolds and colleagues (2010) examined the usefulness of IPT in depressed older adults who had partially responded (defined as HRSD scores between 11 and 14) to 6 weeks of escitalopram treatment. After the initial acute treatment phase, participants were randomized to receive 16 weeks of adjunctive IPT or to continue with escitalopram alone. The addition of IPT did not increase the likelihood of remittance, with roughly 50% of both the IPT and non-IPT groups experiencing remission. There was also no difference between the groups in the rate of symptomatic improvement.

After the completion of treatment, patients in the previously cited studies by Weissman and colleagues (1979), TDCRP (Elkin et al., 1989), and Schramm and colleagues (2007) were evaluated longitudinally for several months in a naturalistic follow-up design as a means of examining possible prophylactic effects achieved with the acute therapeutic interventions. In the first study, no prophylactic effect was associated with IPT versus amitriptyline based on a 12-month follow-up (Weissman, Klerman, Prusoff, Sholomskas, & Padian, 1981); however, the authors reported significantly greater adaptive social functioning among IPT patients. The TDCRP study also found no relative prophylactic effects for IPT. Among patients who recovered during acute treatment, the percentages of patients who remained well during the 18 months of follow-up were as follows: IPT (26%), CBT (30%), IMP-CM (19%), and PLA-CM (20%; Shea et al., 1992a). Primarily because of the small number of subjects and corresponding lack of statistical power, there were no statistically significant differences among the groups. Similarly, there were no differences at follow-up; none of the treatments was superior even to PLA-CM. Finally, Schramm and colleagues (2007) found at the 3-month follow-up that significantly fewer patients in the IPT-plus-antidepressant group had relapsed than in the CM-plus-antidepressant group (3% and 25%, respectively), although this difference was no longer significant 12 months after treatment. Between baseline and the 5-year follow-up, the patients in the IPT condition showed a somewhat greater decrease in HRSD-rated depressive symptoms than the CM group, although the difference between these groups at 5 years was not significant (Zobel et al., 2011). Finally, significantly more patients who had received IPT showed sustained remission at 5 years compared to those in the CM group (28% and 11%, respectively).

The IPT protocol has also been used as an ongoing maintenance therapy following recovery from an MDD. Klerman, DiMascio, Weissman, Prusoff, and Paykel (1974) found nearly equivalent prophylactic benefits when patients received either weekly maintenance IPT or amitriptyline over an 8-month follow-up period, with relapse rates of only 17% and 12%, respectively. Among a group of chronic and treatment-resistant depressed patients, Frank and her colleagues (1990) reported a significant decrease in relapse probability associated with monthly IPT maintenance sessions over a 36-month follow-up period. For this sample, however, there was a substantially larger prophylactic benefit associated with maintenance imipramine, with a 36-month relapse

rate of only 18% in the imipramine group compared with 46% in the IPT group. In a later study, Frank and colleagues (2007) examined differences in recurrence between women who experienced remission from recurrent depression randomized to weekly, biweekly, and monthly IPT maintenance sessions. Although the authors found no difference in relapse rates based on the frequency of maintenance visits, women who had experienced remission from IPT monotherapy were less likely to relapse during the 2-year maintenance phase than those who received combined IPT and selective serotonin reuptake inhibitor (SSRI) treatment during the acute treatment phase (26% and 50%, respectively).

Reynolds and colleagues (2006) examined the likelihood of recurrence of MDD during a 2-year maintenance period in patients who experienced partial or full remission from depression. Patients had received both paroxetine and weekly to biweekly psychotherapy treatment for 16 weeks during the acute treatment phase. During the maintenance period, patients were randomized to receive paroxetine or placebo and IPT or CM. Results indicated that the likelihood of remission did not differ between patients receiving paroxetine and IPT (37%) and those receiving paroxetine and CM (35%) (Reynolds et al., 2006). Some debate has surrounded the validity of this study's conclusions due to initial differences in depression severity between these groups (see Bajbouj & Danker-Hopfe, 2006; Dew, Houck, & Reynolds, 2006; Edwards, 2006). Additionally, there was no difference between IPT and CM in improvements in health-related quality of life across treatment (Dombrovski et al., 2007).

Finally, one type 1 study has shown support for IPT for ethnic minority women with depression. Toth and colleagues (2013) randomized ethnically diverse, low-socioeconomic-status mothers into two 14-week treatment groups: an IPT group and an "enhanced community standard" group (these patients received treatment as usual, psychoeducation about MDD, and access to medication and other support services). Growth mixture modeling revealed differences in the trajectories of depressive symptoms from baseline through 8 months of follow-up, with patients in the IPT group showing significant decreases when compared with the enhanced community standard group.

IPT has been used to address a number of different clinical problems, including comorbidities with depression (Markowitz, 2013). IPT has also been adapted for use with adolescents (sometimes called IPT-A), and initial results are encouraging (Mufson et al., 2004).

Conclusion

The data regarding IPT as a treatment alone and in combination with antidepressants for MDD are favorable. Although there are mixed results for the efficacy of IPT as a maintenance therapy, several recent meta-analyses have concluded that IPT appears to be an efficacious intervention for the acute treatment of MDD (Barth et al., 2013; Cuijpers et al., 2009, 2010, 2011a, 2011b, 2011c; Cuijpers, van Straten, Warmerdam, & Andersson, 2008b; van Straten et al., 2010).

PATIENT MODERATORS OF TREATMENT RESPONSE

Although each of the empirically supported interventions reviewed herein (BT, CBT, IPT) has been shown to be efficacious for depressed individuals, treatment response is highly variable from patient to patient, and a growing body of evidence documents the existence of patient characteristics that moderate treatment response. Following is a brief summary of relevant findings.

The amelioration of dysfunctional cognitive phenomena is the sine qua non of CBT. Accordingly, one might expect the subset of depressed patients with high pretreatment levels of dysfunctional, depressotypic cognitions to be especially likely to benefit from CBT. But the very opposite appears to be the case; that is, patients who score *low* on pretreatment measures of depressotypic cognition tend to experience the most favorable responses to CBT (Hamilton & Dobson, 2002; Rector, Bagby, Segal, Joffe, & Levitt, 2000; Rude & Rehm, 1991; Simons, Gordon, Monroe, & Thase, 1995). Furthermore, MDD patients who report low levels of depressotypic cognitions appear to respond preferentially to CBT in comparison with either IPT or pill placebo (Sotsky et al., 1991), a finding consistent with the hypothesis that effective therapies capitalize on patients' preexisting strengths rather than compensate for their presenting weaknesses (Cronbach & Snow, 1977). Other patient characteristics associated with favorable outcomes in CBT include absence of chronic

depression (Hamilton & Dobson, 2002; Howland, 1991), low social relationship dysfunction (Sotsky et al., 1991), high learned resourcefulness (Simons, Lustman, Wetzel, & Murphy, 1985; see also Burns, Rude, Simons, Bates, & Thase, 1994), experience of intact marriage (i.e., nonsingle/nondivorced marital status; Jarrett et al., 1991; Sotsky et al., 1991), absence of co-occurring social phobia (DeRubeis et al., 2005), and increased number of significant pretreatment life events (Fournier et al., 2009).

Several studies of physiological and neural activity have also found predictors of CBT effectiveness, including decreased pupillary response (indicative of emotional stability and executive control; Siegle et al., 2011), low activity in the subgenual cingulate cortex in response to emotional stimuli (Siegle, Ghinassi, & Thase, 2007), high activity in the amygdala in response to similar stimuli (Siegle et al., 2012), left-hemispheric verbal processing advantage (Bruder et al, 1997), efficiency in emotional processing (Ritchey, Dolcos, Eddington, Strauman, & Cabeza, 2011; Siegle et al., 2012), normal REM latency during sleep EEG (Simons et al., 1995), and baseline hypoactivity in the anterior insula (McGrath et al., 2013)—a region responsible for emotional awareness and decision making as well as cognitive control (see Craighead & Dunlop, 2014). CBT has also been shown to be especially efficacious with highly ruminative patients (Jones, Siegle, & Thase, 2008), which may relate to excessive frontocortical activity in some forms of depression (Goldapple et al., 2004).

Although personality disorder comorbidity has frequently been observed to predict poor response to various antidepressant interventions (Ilardi & Craighead, 1994/1995; Shea, Widiger & Klein, 1992b), there does not appear to be a robust association between personality pathology and unfavorable outcome in CBT (Hardy et al., 1995; Kuyken, Kurzer, DeRubeis, Beck, & Brown, 2001; Shea et al., 1990; Simons & Thase, 1990; although see Fournier et al., 2008, for opposing evidence). In fact, in the TDCRP study, comorbid personality pathology was predictive of poor treatment response in every treatment modality except CBT (Shea et al., 1990). If replicated, this finding would suggest CBT is a treatment of choice (alone or in combination with antidepressants) for the large subset of MDD patients with comorbid personality disorders. Intriguingly in this respect, with preliminary data, CBASP (McCullough, 2000) has been found to be superior to antidepressant medication (nefazodone) in the treatment of depressed patients with a history of childhood trauma (Nemeroff et al., 2003)—itself a potential developmental precursor of personality pathology.

In keeping with the aforementioned capitalization hypothesis (Cronbach & Snow, 1977), the TDCRP study found that patients with particularly low levels of social dysfunction responded more favorably to IPT than to other treatment interventions (Sotsky et al., 1991). Among variables linked to an unfavorable IPT response are higher pretreatment depression severity (Hollon et al., 2005), trait neuroticism (Frank, Kupfer, Jacob, & Jarrett, 1987), cognitive dysfunction (Blatt, Quinlan, Pilkonis, & Shea, 1995; Sotsky et al., 1991), a lifetime history of panic-agoraphobic spectrum symptoms (Frank et al., 2000., 2011), childhood trauma severity (Zobel et al., 2011), symptoms of dementia (Carreira et al., 2008), persistent insomnia (Dombrovski et al., 2008), a fearful attachment style (Constantino et al., 2013), and lack of need for medical assurance, psychomotor retardation, and psychotic features (Frank et al., 2011). Especially high relapse-proneness following a favorable acute response to IPT has been observed among elderly (older than 70) depressed patients (Reynolds et al., 1999). Comorbid personality disorders may also be associated with less effective IPT (Pilkonis & Frank, 1988; Shea et al., 1990). Joyce and colleagues (2007), for example, found that personality pathology, specifically avoidant and schizoid symptoms, predicted poorer response to IPT treatment than to CBT treatment. Some more recent evidence, however, suggests that personality pathology may not relate to remission in IPT (Levenson et al., 2010). Furthermore, differences exist between dimensional and categorical measures of personality disorders such that the former, but not the latter, are associated with longer time to remission in IPT (Levenson, Wallace, Fournier, Rucci, & Frank, 2012), a finding perhaps explained by the increase in power associated with analyses using dimensional symptom measures (see Joyce et al., 2007). Supplementary analyses in the study by Levenson and colleagues (2012) revealed that the association between personality pathology and less effective IPT was driven by symptoms of borderline personality disorder alone.

Although sorely needed, there has been little research on patient characteristics that moderate treatment response to BT for MDD. Two studies have looked at predictors of change in CBASP. Maddux

and colleagues (2009) found that personality disorder diagnoses did not differentially predict success of CBASP versus nefazodone treatment for chronic depression. Arnow and colleagues (2013) suggest that a positive therapeutic alliance early in treatment predicts better response to CBASP, even more than its association with brief supportive therapy. In another relevant investigation, patients who endorsed "existential" reasons for their depression (i.e., attributed the depression to their feeling that life was meaningless) were found to respond less favorably to BT than to CBT (Addis & Jacobson, 1996). Conversely, however, evidence from an RCT suggested that BT may be superior to CBT overall in the treatment of more severely depressed patients (Dimidjian et al., 2006). Finally, the effectiveness of behavioral activation was not moderated by comorbid personality disorders, and this lack of moderation was also shown in a comparison sertraline group (Moradveisi, Huibers, Renner, Arasteh, & Arntz, 2013).

CONCLUSIONS AND FUTURE RESEARCH DIRECTIONS

Although additional research regarding the impact of psychosocial interventions for MDD is still needed, adequate published data exist to permit the conclusion that three forms of psychotherapy—BT, CBT, and IPT—are efficacious first-line interventions for depressed outpatients. This conclusion is consistent with major meta-analytic reports of psychosocial treatments for MDD (Cuijpers et al., 2008a, 2014; Dobson, 1989; Nietzel, Russell, Hemmings, & Gretter, 1987; Robinson, Berman, & Neimeyer, 1990). Recent meta-analyses indicate that for more chronic cases of MDD, a combination of psychotherapy and antidepressant medication treatment may outperform either type of monotherapy (von Wolff, Hölzel, Westphal, Härter, & Kriston, 2012), but otherwise there are no consistent and robust overall differences between antidepressant medications and psychotherapies alone in the treatment of MDD.

Additionally, recent research indicates that BT and CBT interventions may be as effective as antidepressant medications in the treatment of some severely depressed outpatients, excluding those with psychotic symptoms and those who are imminently suicidal. Initial reports on this topic are mixed (e.g., Elkin et al., 1995; Hollon et al., 1992; Schulberg, Pilkonis, & Houck, 1998). The two large, placebo-controlled investigations (DeRubeis et al., 2005; Dimidjian et al., 2006) previously reviewed provide preliminary evidence that psychosocial interventions alone can be as efficacious as antidepressant medications in treating moderately to severely depressed patients.

Despite the established efficacy of the reviewed psychotherapeutic interventions, it now seems clear that about only one third of MDD patients in clinical research studies will experience remission with the first treatment they receive, whether it be a pharmacological or a psychosocial intervention, and an additional one third of MDD patients will show a response that falls short of remission. Unfortunately, a very high percentage of these responders (as vs. remitters) will suffer a relapse or recurrence of MDD in a fairly short period of time (Craighead & Dunlop, 2014). Except for the fairly consistent finding that patients with MDD and comorbid personality or anxiety disorders (see Fava et al., 2008; Smits, Minhajuddin, Thase, & Jarrett, 2012) tend to fare somewhat differentially with various treatments but relatively poorly in all treatments (especially during post-treatment follow-up periods), there is a dearth of research reliably identifying salient clinical and demographic features that characterize the two thirds of patients whose depression is refractory to their first psychosocial treatment. Furthermore, we know very little about whether this subset of initially refractory patients may respond favorably to a second treatment, although reported crossover studies suggest that many individuals who fail to respond to one antidepressant will experience some treatment gains when switched to a different medication (see Nemeroff & Schatzberg, 1998) or CBT (Thase et al., 2007). Recent research has revealed promise in identifying neurobiological markers that predict a differential response to psychotherapy (McGrath et al., 2013; Siegle et al., 2012), but at present there are still few empirical data to guide clinicians in tailoring psychosocial interventions to individuals with MDD.

Treatment outcome research with long-term follow-up has increasingly pointed to high recurrence rates and to the need for continued intervention beyond acute treatment (Mueller et al., 1999). Some (e.g., Andrews, 2001) have even gone so far as to argue that MDD needs to be managed like a chronic disease. Numerous clinical research efforts are under way to improve the sustainability of acute treatment gains. These approaches include a tapered

schedule of psychotherapeutic "booster sessions" in the months following acute treatment (e.g., Frank et al., 1990; Jarrett et al., 1998; Jarrett, Minhajuddin, Gershenfeld, Friedman, & Thase, 2013) and prophylactic programs for recovered patients designed specifically to prevent the recurrence of the disorder (Fava, Rafanelli, Grandi, Canestrari, & Morphy, 1998; Sheets et al., 2013). Programs directed toward preventing an initial episode of depression among "at risk" youths have also shown promising results after up to a year of follow-up (Arnarson & Craighead, 2009, 2011; Beardslee et al., 2013; Garber et al., 2009).

It is now widely believed that psychotherapy treatments and antidepressants for depression affect the brain through different mechanisms (Craighead & Dunlop, 2014; DeRubeis et al., 2005). Psychotherapy, with the possible exception of behavioral activation, is proposed to work on cortical networks to decrease excessive negative emotion-related activity in limbic regions, while psychopharmacological treatments act in part to modify neurotransmitter activity in the limbic system in order to affect cortical regions (see Ochsner et al., 2009). Although research is elaborating on this simple "top-down" versus "bottom-up" model of depression treatment, few studies have used neuroimaging to assess differential changes across treatment modalities (e.g., Brody et al., 2001; Goldapple et al., 2004; Kennedy et al., 2007; Siegle et al., 2012).

As research moves forward, it will be increasingly important to address the question raised by Paul (1969) and determine which patients will most benefit from which treatment or combination of treatments. Identifying genetic, inflammation, and neural biomarkers and their interactions with clinical predictors of treatment outcomes will help increase treatment remission rates and optimize the provision of mental health services. Neuroimaging, including positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), currently leads in this direction, although researchers are also exploring other methods (Kemp, Gordon, Rush, & Williams, 2008). Recent neuroimaging studies show some promise in identifying neurobiological markers that predict a differential response to psychotherapy (McGrath et al., 2013; Siegle et al., 2012) For example, McGrath and colleagues (2013) found that pretreatment levels of resting-state activity in the anterior insula as measured by PET differentially predicted individual patient outcomes to antidepressant medications or psychotherapy. This study, and most studies identifying biomarkers of treatment response, used post hoc analyses to identify neural factors predicting outcome. It is extremely timely and important that we identify psychosocial and neurobiological markers that differentially predict alternative treatment outcomes; this will require prospective studies using the hypothesized predictive factors to stratify the treatment assignments in clinical research trials.

NOTES

1. Although it might be argued that CBASP is a form of CBT, we have included this study in the BT section. Although there is some focus on cognitive factors associated with depression, this focus is in service of helping the person achieve a behavioral goal; the primary emphasis of treatment is on problem solving and change of interpersonal behavior. "This approach draws on many behavioral, cognitive, and interpersonal techniques used in other forms of psychotherapy. It teaches patients to focus on the consequences of their behavior and to use a social problem-solving algorithm to address interpersonal difficulties. It is more structured and directive than interpersonal psychotherapy and differs from cognitive therapy by focusing primarily on interpersonal interactions (including those with therapists). In this type of psychotherapy, patients learn how their cognitive and behavioral patterns produce and perpetuate their interpersonal problems and learn how to remedy maladaptive patterns of interpersonal behavior" (Keller et al., 2000, p. 1463).

2. Additional comparative outcome trials of CBT have been conducted in other countries with different diagnostic systems; the most notable of these studies are those by Blackburn, Bishop, Glen, Whalley, and Christie (1981); Blackburn, Eunson, and Bishop (1986); and Teasdale, Fennell, Hibbert, and Amies (1984).

3. MDD patients who have psychotic features or are imminently suicidal have been excluded from all these evaluation studies comparing the effectiveness of antidepressant medications and psychosocial treatments.

4. Although space limitations preclude discussion, two topics warrant brief mention: treatment of the elderly and treatment in inpatient settings. Several studies by Thompson and colleagues (Thompson & Gallagher, 1984; Thompson, Gallagher, & Breckenridge, 1987) and one by Steuer and colleagues (1984) have demonstrated that CBT is as effective as antidepressant medication for the treatment of depression among the elderly. Thompson and colleagues (1987) also found that short-term psychodynamic psychotherapy was as effective as CBT and antidepressant medications for depression

among the elderly. There is modest evidence that the presence of Axis II personality disorders predicts poor outcome among these patients (Thompson, Gallagher, & Czirr, 1988). In a study of IPT (a shortened version), Sloane, Staples, and Schneider (1985) compared the efficacy of 6 weeks of treatment with either IPT or nortriptyline in a small sample ($N = 43$) of elderly depressed patients. By the end of treatment, there was a nonsignificant trend for a superior response to IPT; however, this trend was largely due to patients' poor tolerance of medication side effects, and a corresponding high rate of attrition, in the nortriptyline group. Although this study is frequently cited to support the relative effectiveness of IPT, the absence of details on dependent measures and data analytic techniques severely limits the contribution of this investigation.

There are several systematic studies of CBT with MDD inpatients. In a stringent test of the intervention, Thase and his colleagues (e.g., Thase, 1994; Thase, Bowler, & Harden, 1991) treated unmedicated MDD inpatients for up to 4 weeks with daily CBT. Although a large percentage of these patients responded well to CBT, the outcome was poorer for those inpatients whose HRSD scale scores were 25 or higher or who had hypercortisolemia. The other studies (Bowers, 1990; Miller, Norman, Keitner, Bishop, & Dow, 1989) have combined CBT with antidepressant medications, and this combination seems to reduce relapse among such patients if booster sessions of CBT are maintained following hospital discharge.

Psychological Treatments for Panic Disorders, Phobias, and Social and Generalized Anxiety Disorders

David H. Barlow
Laren R. Conklin
Kate H. Bentley

A substantial number of type 1 studies to date have established the efficacy of cognitive-behavioral treatment (CBT) for persons with panic disorder (PD) with or without the presence of agoraphobia; these treatments include some combination of cognitive elements, exposure to interoceptive sensations similar to physiological panic sensations, in vivo exposure, and breathing retraining. Recently, several large effectiveness trials (type 1) have also established successful dissemination of CBT for PD. In addition, a substantial number of excellent studies, largely type 1, have established the clinical efficacy of situational in vivo exposure for patients with moderate to severe agoraphobia. The treatment of choice for specific phobias is also exposure-based procedures, particularly in vivo exposure; this consensus reflects a large number of type 1 studies of these procedures with patients with specific phobias. The most common treatment approaches for social anxiety disorder (SAD) include social skills training (SST), relaxation techniques, exposure-based methods, and multicomponent CBT, with the latter, as well as exposure-based procedures, attaining the highest level of treatment efficacy in type 1 studies. In early controlled trials, most studies comparing different treatment conditions for patients with generalized anxiety disorder (GAD) did not observe differential improvement rates, while reporting that active treatments were superior to nondirective approaches and uniformly superior to no treatment. Recently, however, studies have suggested that CBT is the most successful form of treatment for GAD. Specifically, newer variants of CBT that target intolerance of uncertainty or metacognitive beliefs about worry are showing promising levels of efficacy and superiority to alternative treatment. Finally, transdiagnostic treatments are gaining support for their efficacy across multiple anxiety disorders and increasing the ease with which manualized CBT approaches may be disseminated in the future.

INTRODUCTION

The development of evidence-based psychological treatments has been, perhaps, most evident in the appearance of effective new treatments for anxiety disorders, particularly during the past two decades. Prior to 1970, anxiety disorders were a highly prevalent but ill-defined group of problems subsumed under the general headings of "anxiety neuroses" or "phobic neuroses." Treatment of neurosis was most often carried out in the context of long-term psychotherapy, with little or no evidence available on the efficacy

of this approach (Barlow, 1988; Hayes, Barlow, & Nelson-Gray, 1999). During the late 1960s and into the 1970s, clinical trials began to establish the efficacy of exposure-based treatments for phobic disorders, specifically agoraphobia and specific phobias.

The successful delineation of specific anxiety disorders with the appearance of the third edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-III)* in 1980 (American Psychiatric Association [APA], 1980) led to the development of more structured and targeted psychological and drug treatments. From the period 1985 through 1995, effective and evidence-based psychological treatments were developed for PD with no more than mild agoraphobia, GAD, and SAD, as well as posttraumatic stress disorder (Barlow, 1996; Barlow & Lehman, 1996). As our knowledge of the psychopathology and pathophysiology of these conditions deepened, substantial improvements were made in these treatments, including those for certain varieties of specific phobia. From 1995 through 2005, additional evidence accumulated on the efficacy and effectiveness of these procedures, particularly from major clinical trials, including those evaluating the separate and combined effects of these approaches and pharmacological treatments. Since 2005, we have begun to make greater strides in identifying effective treatments for GAD that demonstrate superiority to other active treatment conditions—an area of research that had previously lagged behind controlled trials for other anxiety disorders. In addition, researchers have continued to refine our understanding of the efficacy of psychotherapy and medications in combination, alternative treatment modalities such as virtual reality therapy, and transdiagnostic treatments. In this chapter, we systematically review the current status of the evidence regarding efficacious, evidence-based treatments for agoraphobia, PD, specific phobia, SAD, and GAD. This review is followed by a section describing promising transdiagnostic treatments and a brief concluding section on future directions in treatment development and research for the anxiety disorders contained within this chapter.

Empirical studies are evaluated according to a template created by the American Psychological Association to guide the development of practice guidelines (APA, 2002; American Psychological Association Task Force on Psychological Intervention Guidelines, 1995). This template evaluates studies along two axes, one that examines the treatment's efficacy (internal validity) and a second that examines the clinical utility (effectiveness or external validity) of the treatment under consideration. This template is depicted in Table 14.1. The studies held to the most rigorous research standards are classified as type 1 studies, whereas those that fall short of this standard of excellence are classified as type 2 studies. Research studies conducted with more substantial methodological limitations are classified as type 3 through type 6 studies. When available, we will also include the clinical guidelines established by the United Kingdom's National Institute for Health and Care Excellence (NICE), a government agency working within the National Health Service, which uses a rigorous process to identify and consolidate available evidence to set quality standards of care for treatment providers working in the National Health Service.

PANIC DISORDER AND AGORAPHOBIA

Although panic attacks have been discussed in the literature over the centuries (e.g., Freud, 1895/1961), they were largely ignored by the diagnostic system until the past few decades. In fact, the diagnoses of PD and of agoraphobia with panic attacks were not included in the diagnostic system until the publication of the *DSM-III* in 1980 (APA, 1980). In the *DSM-IV* (APA, 1994) and *DSM-IV* text revision (*DSM-IV-TR*; APA, 2000), diagnoses directly related to panic included the related diagnoses of PD without agoraphobia, PD with agoraphobia, and agoraphobia without history of PD. In the fifth and most recent version of this diagnostic system (*DSM-5*; APA, 2013), agoraphobia is considered a disorder in its own right in that it can occur independently of panic attacks, although these attacks frequently accompany agoraphobia and seem to result in the development of agoraphobia in most cases. The *DSM-5* also includes panic attacks as a specifier applicable to any disorder, thereby acknowledging the ubiquity of panic attacks across a variety of conditions (Craske et al., 2010).

Individuals diagnosed with PD report experiencing recurrent unexpected panic attacks that consist of physical symptoms such as racing heart, shortness of breath, dizziness, sweating, and trembling or shaking. Moreover, they experience continued anxiety focused on experiencing future panic attacks and worry about consequences of the panic attacks or changes in their behavior due to the panic attacks. It is the additional

TABLE 14.1 Overview of Template for Constructing Psychological Intervention Guidelines

Efficacy (Internal Validity)	*Clinical Utility or Effectiveness (External Validity)*
1. Better than alternative therapy 2. Better than nonspecific therapy (RCTs) 3. Better than no therapy (RCTs) 4. Quantified clinical observations 5. Strongly positive clinical consensus 6. Mixed clinical consensus 7. Strongly negative clinical consensus 8. Contradictory evidence *Note:* Confidence in treatment efficacy is based on both (a) the absolute and relative efficacy of the treatment and (b) the quality of the studies on which the judgment is made, as well as their replicability. Confidence in efficacy increases from item 8 (lowest) to item 1 (highest).	1. Feasibility a. Patient acceptability (cost, pain, duration, side effects, etc.) b. Patient choice in face of relatively equal efficacy c. Probability of compliance d. Ease of disseminability (e.g., number of practitioners with competence, requirements for training, opportunities for training, need for costly technologies or additional support personnel) 2. Generalizability a. Patient characteristics: cultural background issues, gender issues, developmental issues, other relevant patient characteristics b. Therapist characteristics c. Issues of robustness when applied in practice settings with different time frames and the like d. Contextual factors regarding setting in which treatment is delivered 3. Costs and benefits a. Costs of delivering intervention to individual and society b. Costs of withholding effective intervention from individual and society *Note:* Confidence in clinical utility as reflected on these dimensions should be based on systematic and objective methods and strategies for assessing these characteristics of treatment as they are applied in actual practice. In some cases, randomized clinical trials will exist. More often, data will be in the form of quantified clinical observations (clinical replication series) or other strategies such as health economic calculations.

RCT = randomized clinical trial.

anxiety about the attacks, combined with catastrophic cognitions in the face of panic, that distinguish individuals with PD from nonclinical panickers (Craske & Barlow, 2014). Individuals diagnosed with agoraphobia avoid situations for which escape or finding help would be difficult in the event of developing panic-like or other incapacitating, embarrassing symptoms (e.g., vomiting, disorientation, loss of bowel control). Types of avoided situations could include public transportation, crowded shopping malls, restaurants, or movie theaters. Of note, individuals are diagnosed with agoraphobia alone when they experience agoraphobic avoidance due to anxiety focused on specific somatic symptoms, some of which may be defining symptoms of a panic attack yet have never met criteria for a full, unexpected panic attack. Clinically, patients presenting with agoraphobia only may be treated with protocols intended for patients with PD, and they will usually benefit from such treatment (Craske & Barlow, 2014).

Reports on the prevalence of isolated panic attacks, PD, and agoraphobia vary somewhat across ages. The National Comorbidity Survey Replication (NCS-R), which was conducted in the United States and used the *DSM-IV* criteria, cited lifetime prevalence rates among adults for isolated panic attacks at 28.3% and for PD at 4.7% (Kessler et al., 2006). This same report noted the lifetime prevalence of panic attacks with agoraphobia at 0.8% and PD with agoraphobia at 1.1% among adults. Both PD and agoraphobia have been estimated to have lower lifetime prevalence among older (ages 65+) than younger adults (Kessler et al., 2012), which may be explained by a true decrease in prevalence among older adults,

underreporting due to forgetting among older adults, or sample selection bias (e.g., exclusion of elderly with high morbidity and early mortality).

Finally, it seems that many more women than men experience these disorders. One meta-analysis found that fully three fourths of the participants in research studies on the treatment of the PDs are women (Gould, Otto, & Pollack, 1995), and the NCS-R found the lifetime prevalences of PD and agoraphobia among women to be significantly greater than those for men (7.0% and 3.2% vs. 3.3% and 2.0%, respectively; Kessler et al., 2012). The most common explanation for this marked sex difference in prevalence involves differences in the socialization of men and women (Wolitzky-Taylor et al., 2010). In most cultures around the world, it is more acceptable for women to report fear and to avoid various situations due to it than men, who are expected to minimize their fears and overcome avoidant tendencies regardless of the cost, and often turn to alcohol to self-medicate their anxiety and panic (Barlow, 1988, 2002).

Most individuals with PD can clearly recall life stressors that occurred around the time they experienced the onset of their panic attacks. One study noted that 72% of patients with PD reported life stress existing when their panic attacks began (Craske, Miller, Rotunda, & Barlow, 1990). Moreover, patients with PD often experience other Axis I disorders concurrent with their PD (e.g., Brown, Campbell, Lehman, Grisham, & Mancill, 2001a; Roy-Byrne, Craske, & Stein, 2006). Specifically, results from one study indicated that 60% of patients presenting with PD also met criteria for an additional anxiety and/or mood disorder; further, when presence of a disorder is examined over the lifetime, this rate increased to 77% (Brown et al., 2001a). A recent meta-analysis of 125 empirical papers found that up to 47% of patients with PD (with or without agoraphobia) are also diagnosed with a personality disorder, most commonly avoidant, dependent, or obsessive-compulsive personality disorder (Friborg, Martinussen, Kaiser, Overgard, & Rosenvinge, 2013).

Our own model of etiology, referred to as the "triple vulnerabilities model" (Barlow, 2002; Barlow, Ellard, Sauer-Zavala, Bullis, & Carl, 2014a), posits a nonspecific biological predisposition to experience stress or emotionality and possibly a separate heritability for a low threshold to experience panic attacks (the first vulnerability). Specifically, this generalized biological predisposition, combined with early development of a sense of uncontrollability over potentially threatening life events (a generalized psychological predisposition, the second vulnerability), creates a diathesis. The later experience of life stress then triggers an unexpected panic attack, and in those with first and second vulnerabilities (the diathesis), and a specific learned psychological vulnerability to focus anxiety on "dangerous" somatic symptoms (the third vulnerability), anxiety becomes focused on the next possible panic attack, and PD subsequently develops. Agoraphobia may then follow as a complication of PD in a large proportion of these individuals, mostly women (Barlow, 1988, 2000, 2002; Barlow, Chorpita, & Turovsky, 1996). Empirical investigations conducted in large samples of individuals with PD have supported the existence of such a triple vulnerabilities model (e.g., Bentley et al., 2013; White, Brown, Somers, & Barlow, 2006).

In this section, we first review the development and evaluation of early treatments for agoraphobia and then provide a description of the development and evaluation of psychological treatments targeting PD. More cost-effective treatments are reviewed, as well as translational research (effectiveness studies). Finally, combination treatments are discussed, as well as future directions in treatment development and assessment for these disorders.

TREATMENT OF AGORAPHOBIA (SITUATIONAL IN VIVO EXPOSURE)

There has been a longstanding controversy regarding the nature of the relationship between PD and agoraphobia (Barlow, 2000). As we have noted, the *DSM-III* considered agoraphobia to be a separate phobic disorder (APA, 1980); with the publication of the *DSM-III-R* (APA, 1987), however, agoraphobia was viewed as diagnostically secondary to PD. This change was primarily the result of findings that suggested that, in clinical samples, agoraphobia typically developed as a result of the experience of panic attacks or limited symptoms attacks (Craske & Barlow, 1988; Turner, Williams, Beidel, & Mezzich, 1986). The next two iterations of the *DSM* (*DSM-IV* and *DSM-IV-TR*) included PD with and without agoraphobia, as well as agoraphobia without phobic disorder. The inclusion of agoraphobia without phobic disorder spurred much debate about whether this syndrome actually

exists (Barlow, 2000); however, accumulating evidence indicates that agoraphobia can exist independently of PD, panic attacks, or panic-like features (Wittchen, Gloster, Beesdo-Baum, Fava, & Craske, 2010). Studies also show that agoraphobia in the absence of panic-like features is associated with levels of impairment and disability equal to PD without agoraphobia, and that key differences between agoraphobia and PD in incidence and response to treatment exist (Wittchen et al., 2010). Given that from 1987 until 2013 agoraphobia was only diagnosed within the context of PD or panic-like features, the development of treatments specifically designed to address agoraphobia occurred primarily in the 1960s and 1970s. However, acknowledgment of PD and agoraphobia as distinct, albeit highly comorbid, conditions in the *DSM-5* suggests that we may witness increased focus on the development and testing of treatments to target agoraphobia in its own right.

One initial treatment for agoraphobia was systematic desensitization. This procedure involved imaginal exposure to feared situations coupled with muscle relaxation. Systematic desensitization was originally used because it was believed that actual exposure to feared situations (situational in vivo exposure) might be too intense and would have deleterious effects. Studies conducted to examine the efficacy of systematic desensitization consistently found this approach to be largely ineffective (Gelder & Marks, 1966; Marks, 1971). During this same era, researchers began to treat patients with agoraphobia successfully by conducting graded situational in vivo exposure exercises (Agras, Leitenberg, & Barlow, 1968). In this procedure, patients under the supervision of a clinician were expected to engage in exposure practices by which they systematically ventured away from places they considered "safe" and into the situations they had been avoiding.

During the next several years, situational in vivo exposure continued to be evaluated and was found to be more effective than no treatment or attentional control procedures (Barlow, 1988, 2002; Jansson & Öst, 1982; Mavissakalian & Barlow, 1981). Situational in vivo exposure treatment routinely begins with the patient creating a hierarchy of feared situations or activities that have been consistently avoided (e.g., driving out of a safety zone, shopping in a crowded mall alone, seeing a movie in a theater). Patients are then encouraged to repeatedly enter and remain in these feared situations, using therapeutic coping procedures learned during sessions. Although patients with more severe agoraphobia may require the presence of their therapist during initial exposures, most patients are able to conduct these exercises either alone or with a friend or family member who acts as a supportive coach (Barlow, 1988, 2002).

Throughout the past few decades, researchers have examined the clinical efficacy of situational in vivo exposure using the highest methodological standards. Nearly all these studies fall into the top two categories of the internal validity axis (Axis 1) of the APA template; moreover, the majority also can be characterized as type 1 studies according to the classification system of this volume. These studies have consistently shown the efficacy of situational in vivo exposure; the current consensus is that situational in vivo exposure is an effective treatment for agoraphobia whether or not a PD diagnosis is present (Craske & Barlow, 2014).

Several reviews and meta-analyses conducted primarily in the 1980s found that 60% to 75% of patients who completed situational in vivo exposure treatments show evidence of clinical improvement (Barlow, 1988, 2002; Jacobson, Wilson, & Tupper, 1988; Jansson & Öst, 1982; Munby & Johnston, 1980; Trull, Nietzel, & Main, 1988). Yet while relatively few of these patients were completely symptom-free at the conclusion of their exposure treatment, the clinical gains that were achieved were maintained at long-term follow-up. For example, Jansson, Jerremalm, and Öst (1986) reported maintenance of gains and some continued improvement at a 15-month follow-up. Burns, Thorpe, and Cavallaro (1986) also noted continuation of gains up to 8 years following treatment, albeit punctuated by brief setbacks. More recently, Fava and colleagues (2001) published long-term follow-up data from 132 patients treated with an exposure-based treatment for agoraphobia. This study is classified as type 2 due to the lack of a comparison group. Treatment was delivered in 12 biweekly 30-minute sessions over 6 months; the follow-up period ranged from 2 to 14 years across patients, with a median of 8 years. Findings showed that 23% of patients experienced a relapse at some time during follow-up. Survival analysis also indicated that 93% of patients remained in remission for at least 2 years after treatment, 82% after 5 years, 79% after 7 years, and 62% after 10 years. These results were consistent with a similar long-term follow-up study

of 90 patients previously conducted by the same research group (Fava, Zielezny, Savron, & Grandi, 1995). Additional results from Fava and colleagues (2001) indicated that residual agoraphobia and having a comorbid personality disorder were associated with poorer outcome; additionally, pretreatment depressed mood and the use of psychotropic drugs were identified as significant predictors of relapse.

Results from another type 2 study also support the efficacy of exposure treatment in individuals with agoraphobia. In a study by Peter and colleagues (2008), 42 female patients with agoraphobia were followed for 3 to 9 years (mean of 6 years) after receiving a course of in vivo exposure treatment delivered in individual or group format. Treatment consisted of five 4-hour exposure sessions (four therapist-aided and one self-conducted), as well as exposure homework. Following treatment, 40% of patients were classified as in complete remission at follow-up and 35% met criteria for mild to moderate agoraphobia. Over the follow-up period, approximately two-thirds of patients maintained their posttreatment status, whereas 21% experienced improved agoraphobic symptoms and 14% experienced a worsening of agoraphobic symptoms.

Strategies to Improve the Effectiveness of Exposure-Based Procedures

Researchers have tried a number of strategies to improve the effectiveness of situational, in vivo, exposure-based treatments (Meuret, Wolitzky-Taylor, Twohig, & Craske, 2012). For example, a number of studies attempted to determine whether adding relaxation training to situational in vivo exposure would improve the clinical efficacy of the situational in vivo exposure. In most of these studies, the combined treatments were no more effective than situational in vivo exposure alone (Michelson, Mavissakalian, & Marchione, 1988; Öst, Hellström, & Westling, 1989; Öst, Jerremalm, & Jansson, 1984). Additionally, controlled studies examining the effectiveness of situational in vivo exposure and breathing retraining have found the combined treatment to be no more effective than situational in vivo exposure alone and that it may actually detract from optimal treatment outcomes (Bonn, Readhead, & Timmons, 1984; Craske, Rowe, Lewin, & Noriega-Dimitri, 1997; De Ruiter, Rijdken, Garssen, & Kraaimaat, 1989; Schmidt et al., 2000). When considering the use of these added elements, one must consider the potential for that element to act as a "safety aid," reducing actual exposure to the anxiety-provoking elements of the stimulus.

Researchers have attempted to improve the efficacy of situational in vivo exposure by adding cognitive therapy components such as paradoxical intention or Beck and Emery's (1985) cognitive therapy. Apart from two notable exceptions (Michelson, Marchione, & Greenwald, 1989; Murphy et al., 1998), the current consensus is that combining cognitive elements with exposure generally does not result in added benefit over exposure alone for the treatment of agoraphobia (Craske & Barlow, 2014). Researchers have also manipulated the pace of situational in vivo exposure treatment to identify the approach with maximum therapeutic gains; specifically, massed and intensive exposure sessions have been compared with spaced and graduated exposure sessions (Barlow, 1988, 2002). Generally, studies have not found important differences between graduated, spaced situational in vivo exposures and intensive, massed situational in vivo exposures conducted throughout 4 to 10 days, during which individuals were expected to experience feared situations for several hours each day (Craske & Barlow, 2014; Feigenbaum, 1988). Another important component to consider when seeking to maximize the efficacy of exposure is how to optimize learning during exposure trials. Early perspectives suggested that habituation of fear responding within exposure trials was necessary for long-term corrective learning over repeated exposure sessions (e.g., Foa & McNally, 1996); however, recent research suggests that learning does not necessarily require habituation during individual trials or even between sessions (e.g., Craske et al., 2008; Craske, Liao, Brown, & Vervliet, 2012). The current consensus is that fear toleration, which may involve maintaining high levels of fear and anxiety during exposure trials, rather than fear reduction (i.e., waiting for declines in fear levels) is a primary goal of exposure therapy for PD and other related conditions (e.g., Deacon et al., 2013). Other research emphasizes preventing or removing safety behaviors or signals (e.g., medication, drink, trusted person), providing stimulus variability (e.g., varying intensity levels, durations, settings), and including retrieval cues (e.g., wristbands) as other variables to consider during exposure trials (e.g., Helbig-Lang & Petermann, 2010; Mystkowski, Craske, Echiverri, & Labus, 2006; Rowe & Craske, 1998).

Researchers have also focused their attention during treatment on the interpersonal support systems of persons with agoraphobia as a means of further improving treatment outcome. Because agoraphobia, at its more severe levels, produces a great deal of dependency, researchers theorized that the incorporation of spouses or partners in treatment might facilitate the treatment process. Barlow, O'Brien, and Last (1984) compared exposure treatment with and without spousal involvement in sessions and found that spousal involvement significantly improved treatment effectiveness for a number of women with agoraphobia (with spouses, 86% were treatment responders; without, 43%). Additionally, Arnow, Taylor, Agras, and Telch (1985) examined the effectiveness of communication skills training with spouses or partners by adding it to a situational in vivo exposure protocol. The combined communication skills training and situational in vivo exposure treatment showed greater clinical improvement at both the posttreatment and the 8-month follow-up assessment. Of note, Vos and colleagues (2012) found that treatment focused on interpersonal relationships was less effective than a combination of exposure and cognitive therapy. Collectively, studies support the value of including significant others in treatment of agoraphobia; however, targeting interpersonal contexts without other core components (namely, exposure) may be insufficient.

Briefer Cost-Effective Modifications to Exposure-Based Procedures

Researchers have also studied the effectiveness of more self-directed treatment protocols for agoraphobic avoidance. These studies explore questions raised on the second axis of the APA template mentioned above by examining the clinical utility or external validity of treatments that are typically computer-aided or administered via a workbook or manual (Ghosh & Marks, 1987; Holden, O'Brien, Barlow, Stetson, & Infantino, 1983; Marks, Kenwright, McDonough, Whittaker, & Mataix-Cols, 2004; Schneider, Mataix-Cols, Marks, & Bachofen, 2005; Swinson, Fergus, Cox, & Wickwire, 1995). The results from these studies, along with others (e.g., Andrews, Cuijpers, Craske, McEvoy, & Titov, 2010; Kenwright, Liness, & Marks, 2001; Marks et al., 2003), suggest that delegating traditional therapeutic components (particularly exposure instruction) to self-directed programs, whether administered by computer or telephone, is an efficient, cost-effective method for delivering evidence-based treatment for agoraphobia, unless the patients are too severely phobic, in which case the presence of a therapist seems necessary (Holden et al., 1983).

Another avenue that holds promise for translating traditional exposure-based procedures into more cost-effective treatment is virtual reality (for a review, see Powers & Emmelkamp, 2008). During virtual reality exposure (VRE), artificially created stimuli replace reality within the context of a computerized world. Published studies testing the effectiveness of VRE treatments for agoraphobia have begun to appear in the literature. Although most lack adequately sized samples and control conditions, several recent investigations employing more rigorous methodology are worth noting. In a study by Botella and colleagues (2007), 37 patients (82.9% with agoraphobia) were randomly assigned to VRE, in vivo exposure, or a waitlist condition. Both treatment programs consisted of nine weekly sessions that included psychoeducation, cognitive restructuring, and breathing retraining, exposure with either VRE or in vivo, and relapse prevention. The VRE program included several scenarios simulating a variety of agoraphobic situations and induced bodily sensations similar to those experienced during panic attacks. At posttreatment, there were no significant differences between VRE and in vivo conditions on any outcome variables (including agoraphobic avoidance), and both active conditions significantly outperformed the waitlist at the 12-month follow-up.

One potential weakness of the study by Botella and colleagues (2007) was that both VRE and in vivo exposure contained elements of cognitive therapy and breathing retraining; thus, it was impossible to adequately assess the role of VRE alone. To address this limitation, Malbos, Rapee, and Kavakli (2011) randomly assigned 10 patients with agoraphobia to receive VRE only and VRE combined with elements of cognitive therapy in order to examine the isolated effects of VRE. They found no significant differences between groups on any of the 10 outcome measures at posttreatment. Finally, a recent study conducted by Meyerbroeker and colleagues (2013) examined the effects of four CBT sessions followed by six sessions of VRE, six sessions of in vivo exposure, or a waitlist control condition. Their sample consisted of 55 patients

who met criteria for agoraphobia and PD. Both active conditions resulted in significantly greater improvements than the control, and there were no significant differences between VRE and in vivo exposure on primary outcome measures targeting agoraphobia avoidance and cognitions. Taken together, although initial studies using VRE to treat agoraphobia are promising, further trials using larger samples and a variety of settings are needed to confirm the efficacy of this novel tool.

TREATMENT OF PANIC

Psychological treatments focusing on the unexpected and uncued panic attacks experienced by individuals with PD were developed relatively recently. The majority of these involve CBT (for reviews see Gould et al., 1995; McHugh, Smits, & Otto, 2009; Sánchez-Meca, Rosa-Alcázar, Marín-Martínez, & Gómez-Conesa, 2010), and they share many commonalities. They focus on education about the nature of anxiety and panic, cognitive therapy, and some form of exposure and coping skills acquisition. Of note, the NICE quality standards designate CBT as an evidence-based psychological treatment for PD (NICE, 2011). Some of the more widely used CBT approaches are reviewed here. The studies reviewed in this discussion are categorized as type 1 research unless otherwise noted.

Panic Control Treatment

In the mid-1980s, Craske and Barlow (2007a) developed a psychological treatment protocol for panic attacks now known as *panic control treatment* (PCT). This treatment focuses on exposing the patient to interoceptive sensations similar to physiological panic sensations. PCT also includes a cognitive restructuring component directed at correcting misconceptions about anxiety and panic and evaluating "automatic" cognitions, particularly the overestimations of threat and danger associated with panic attacks. Finally, breathing retraining is incorporated into PCT to correct the tendency of some panic patients to hyperventilate and to provide a meditational calming exercise that can be effectively used by a subset of patients. More recent versions of the treatment discourage the use of breathing retraining because, as discussed earlier in the chapter, there is a possibility for these skills to be misused as a way to avoid the full experience of anxiety. In fact, there is research to show that CBT with breathing retraining is associated with poorer outcomes during follow-up than CBT without breathing retraining (Schmidt et al., 2000).

PCT has been extensively applied throughout the past two decades, with good results (Craske & Barlow, 2014), and has been designated an evidence-based treatment by the Substance Abuse and Mental Health Services Administration (SAMHSA) of the U.S. Department of Health and Human Services through its National Registry of Evidence-Based Programs and Practices program (SAMHSA, 2013). In the first controlled study of PCT (Barlow, Craske, Cerny, & Klosko, 1989), three treatment conditions (PCT alone, relaxation alone, and PCT combined with relaxation) were compared with a waitlist control condition. The relaxation component consisted of progressive muscle relaxation training along with instructions to apply this relaxation when in anxiety-provoking situations. At posttreatment, all three treatment conditions proved to be more effective than the waitlist control condition. Of the patients, 60% in the relaxation condition and 87% in the PCT-alone condition and the PCT-plus-relaxation condition achieved panic-free status by the conclusion of the 15-week treatment. Two years after acute treatment, 81% of the patients in the PCT-alone condition were panic-free compared with only 43% of the patients in the PCT-plus-relaxation condition and 36% of the patients in the relaxation-alone condition (Craske, Brown, & Barlow, 1991). Craske and colleagues suggested that the patients in the PCT-plus-relaxation condition were not able to show evidence of greater therapeutic gains due to the abbreviated nature of PCT in this condition compared to the PCT-alone condition.

Recent years have witnessed several larger-scale trials aimed to rigorously evaluate PCT. In one large multisite study that compared single and combined effects of CBT and imipramine for patients with PD with no more than limited agoraphobia, patients were randomly assigned to receive 3 months of imipramine only, CBT only (PCT), placebo only, PCT plus imipramine, or PCT plus placebo (Barlow, Gorman, Shear, & Woods, 2000). They were then seen monthly in a maintenance condition for 6 additional months (except for nonresponders to the

drug-only condition) and followed for 6 months after treatment discontinuation. The results indicated that all the treatment groups were significantly superior to placebo after the acute and maintenance phases, with some evidence that among those who responded, imipramine alone produced a better quality of response (e.g., less depression). However, PCT plus imipramine was generally not superior to PCT plus placebo immediately following treatment, although there was some advantage for the combined treatment after 6 months of maintenance. But 6 months after treatment termination, significantly more patients in the imipramine-alone group or the PCT-plus-imipramine group relapsed compared with groups receiving PCT without imipramine (PCT alone and PCT plus placebo). This study suggests that PCT produces a more durable response than medication.

One criticism of the majority of research examining the efficacy of PCT is that most treatment trials target participants displaying minimal to moderate levels of agoraphobia, and little is known about the effect of PCT on panic patients with more severe levels of agoraphobia. In an attempt to better target agoraphobia within the context of panic treatment, Craske, DeCola, Sachs, and Pontillo (2003) examined whether PCT with an additional in vivo exposure component would be more effective in treating patients with PD with agoraphobia than traditional PCT alone. Results indicated that the two treatment conditions were equally efficacious, suggesting the additional component added no benefits above and beyond the relatively robust treatment outcome effect of PCT alone. Further, a large-scale trial by Aaronson and colleagues in 2008 ($N = 381$) included participants with moderate to severe agoraphobia to examine whether response rates during PCT differ among these patients. Findings showed that response rates did not differ across individuals with and without agoraphobia and were similar to those in the prior study by Barlow and colleagues (2000) that excluded patients with moderate or severe agoraphobia.

The fourth edition of a comprehensive PCT treatment manual for PD for adults titled *Mastery of Your Anxiety and Panic* (*MAP-4*; Craske & Barlow, 2007a) presents clinicians with a step-by-step guide to conducting the various aspects of PCT therapy. A PCT manual adapted for adolescents (*MAP-A*; Pincus, Ehrenreich, & Mattis, 2008) is also available.

Cognitive Therapy

Both PCT and other forms of CBT, as well as more traditional cognitive therapies, include nearly identical components. Cognitive therapies, naturally, place a greater focus on cognitive components, while PCT emphasizes interoceptive and in vivo exposure procedures. In a controlled trial of cognitive therapy for panic, Beck, Sokol, Clark, Berchick, and Wright (1992) compared the efficacy of 12 weeks of cognitive therapy with 8 weeks of brief supportive therapy. After 8 weeks of treatment, 71% of the patients who received cognitive therapy were panic-free as compared with 25% of the patients who received supportive therapy. Moreover, at posttreatment, 94% of the patients in the cognitive therapy condition were panic-free, and at the 1-year follow-up assessment, 87% of these patients continued to be panic-free. While cognitive therapy has superior performance when compared to brief supportive therapy, other research suggests the strength of its effects is comparable to interoceptive exposure (Arntz, 2002). However, cognitive therapy and interoceptive exposure appear to use different change processes. To this end, Arntz identified the reduction of idiosyncratic beliefs to be an active mechanism of change in cognitive therapy but not interoceptive exposure. In a similar vein, an interesting study by Meuret and colleagues (2010) showed that during a 4-week cognitive training targeting panic-related cognitions, significant changes in symptoms were mediated by changes in symptom appraisal, whereas during respiratory training (but not cognitive training), changes in respiration mediated panic symptom severity.

Clark and his colleagues also developed a psychological treatment for PD consisting of a unique variation of cognitive therapy (Clark, 1989; Salkovskis & Clark, 1991). This treatment attempts to change patients' appraisals of bodily sensations like PCT; however, Clark's approach places a greater emphasis on the cognitive therapy component of the protocol. Results from a variety of controlled studies conducted in different countries have shown that this cognitive therapy program is superior to control conditions, including other active treatments such as supportive therapy, applied relaxation, and imipramine (for a review see Clark, 1999). For example, Clark and colleagues (1994) conducted a randomized controlled trial (RCT) comparing the effectiveness of three active treatments (cognitive therapy, applied relaxation, and

imipramine) to a waitlist control condition. Patients in the active treatment conditions met weekly with a clinician for 3 months and then monthly for 3 months. Posttreatment results showed that all three active treatments were significantly more effective than the waitlist control condition. In fact, the cognitive therapy treatment was superior to the waitlist control condition on all panic and anxiety treatment outcome measures; the applied relaxation condition and the imipramine treatment condition were superior to the waitlist control condition on just over half and fewer than half of the treatment outcome measures, respectively. Moreover, a 9-month follow-up after the discontinuation of treatment showed that the patients in the cognitive therapy condition largely maintained their treatment gains. Of the patients who received cognitive therapy, 85% remained panic-free, while 60% of the patients who received imipramine and 47% of the patients who were treated with applied relaxation were panic-free.

Alternative and Adjunctive Treatments

Although several novel alternative treatments have been evaluated, most recent studies have focused on integrating adjunctive strategies into basic CBT interventions. In 1994, Shear, Pilkonis, Cloitre, and Leon developed a novel treatment approach called *emotion-focused therapy* that focuses on interpersonal triggers for panic attacks rather than interoceptive cues (for a review see Shear & Weiner, 1997). Attrition was high in this first study, but preliminary results were promising. In a further evaluation by Shear, Houck, Greeno, and Masters (2001), patients were randomly assigned to emotion-focused therapy, CBT, imipramine, or placebo. Treatment included approximately 3 months of weekly visits and six monthly maintenance sessions. This study found that emotion-focused therapy was less effective than either CBT or imipramine for symptoms of PD. In addition, results for emotion-focused therapy at postacute and postmaintenance follow-up were similar to placebo. At follow-up, patients receiving emotion-focused therapy fared better than those receiving placebo but less well than those treated with CBT or imipramine.

Panic-Focused Psychodynamic Psychotherapy (PFPP; Milrod et al., 1997), a psychodynamic treatment specifically targeting PD, has been evaluated in two empirical investigations to date. PFPP involves three phases that aim to target acute panic symptoms, panic vulnerability, and treatment termination; it addresses how psychodynamic conflicts and transference, as well as interpersonal relationships, interact to render individuals more vulnerable to experiencing panic. In 2007, following a type 2 pilot study of PFPP ($N = 16$; Milrod et al., 2001), Milrod and colleagues compared PFPP with applied relaxation in its first type 1 trial. Participants ($N = 49$) with PD were randomly assigned to receive 24 twice-weekly sessions of either PFPP or applied relaxation; those in the PFPP condition evidenced significantly greater reductions in panic symptom severity and were more likely to respond at treatment termination. Although further research is needed, these data indicate that psychodynamic approaches may be useful in the treatment of panic.

Turning to adjunctive strategies, recent years have also shown increasing interest in integrating mindfulness- and acceptance-based therapies into the treatment of PD. For example, Kim and colleagues (2009) randomly assigned 63 patients with PD (or GAD) to receive Mindfulness-Based Cognitive Therapy (MBCT; a training program including a combination of mindfulness techniques, cognitive approaches, psychoeducation, and homework) or an anxiety disorder education program for 8 weeks. Both interventions were applied as an adjuvant to ongoing pharmacotherapy. Results indicated that the MBCT group demonstrated significantly more improvement than the education group on all general anxiety and depression scale scores at the posttreatment assessment. Kim and colleagues (2010) sought to extend these findings by conducting another type 2 study with 23 PD patients that included a panic-specific scale. After the 8-week MBCT program (administered as an adjunct to ongoing pharmacotherapy), panic symptom severity, phobic symptoms, anxiety sensitivity, general anxiety, and depressive symptoms were all significantly improved.

In a similar vein, extending approaches that emphasize acceptance (e.g., Acceptance and Commitment Therapy [ACT]; Hayes, Strosahl, & Wilson, 2011) to the treatment of panic has also been subjected to recent empirical investigation. Meuret and colleagues (2012) examined the feasibility and efficacy of four sessions of ACT, which emphasized assuming an open, nonjudgmental stance to thoughts, feelings, and sensations that arise in a given moment, followed by six sessions of more traditional

exposure procedures in a type 2 trial of 11 patients diagnosed with PD. Treatment was associated with clinically significant improvements in panic symptom severity, reductions in avoidant behavior, and willingness to allow inner experiences to occur, suggesting that the use of ACT to facilitate exposure to feared stimuli may be efficacious. Although these initial findings provide support for the contribution of mindfulness- and acceptance-based strategies to the treatment of panic, rigorous type 1 trials are necessary to determine the efficacy of these procedures.

There is also increasing evidence to suggest that aerobic exercise may lead to reductions in anxiety and mood disorders in general (for reviews see Salmon, 2001, and Stathopoulou, Powers, Berry, Smits, & Otto, 2006). Studies have specifically shown that aerobic exercise reduces anxiety sensitivity, a known precursor of panic attacks and PD (e.g., Broman-Fulks, Berman, Rabian, & Webster, 2004; Broman-Fulks & Storey, 2008). For example, in one study, participants were randomly assigned to a 2-week exercise intervention, a 2-week exercise-plus-cognitive-restructuring intervention, or a waitlist control (Smits, Berry, Rosenfield, Powers, Behar, & Otto, 2008). Results showed that both exercise conditions resulted in clinically significant reductions in anxiety sensitivity compared to the waitlist. Aerobic exercise may serve as a more intense form of interoceptive exposure and thus may decrease anxiety associated with bodily sensations similar to the mechanism associated with the interoceptive component of PCT; research that directly compares aerobic exercise with traditional interoceptive exposure is needed. Although newer research suggests some advantage for traditional CBT compared to exercise alone due to greater reductions in some symptoms, such as anxiety focused on bodily sensations (Hovland et al., 2013), the fact that exercise can be easily disseminated across many populations suggests that it is still a practical, useful intervention to consider in the treatment of PD.

As we have noted, there are accumulating data to suggest that breathing retraining is often misused as a means for distracting or otherwise avoiding physical symptoms (e.g., Meuret, Wilhelm, Ritz, & Roth, 2003; Schmidt et al., 2000). While current consensus in the field is that breathing retraining may be useful when it does not serve as a form of avoidance or safety behavior (Craske & Barlow, 2014), recent years have witnessed the development of a related, yet distinct, biofeedback treatment modality—capnometry-assisted respiratory training (CART; Meuret, Wilhelm, & Roth, 2004). CART aims to change breathing dysregulation in individuals with PD. During a 4-week training, patients are taught how to use feedback from a portable capnometer about their PCO_2 (partial pressure of carbon dioxide) levels to raise subnormal levels of PCO_2, thereby better controlling their dysfunctional respiratory patterns and symptoms associated with hyperventilation that are related to panic (e.g., dizziness, shortness of breath; Meuret, Rosenfield, Seidel, Bhaskara, & Hofmann, 2010). This intervention represents a divergence from traditional breathing retraining as it relies on biofeedback and direct manipulation of respiratory physiology (Meuret et al., 2003). Several preliminary studies to date have examined the efficacy of CART (Meuret et al., 2008, 2010). In one controlled trial, PD patients were randomized to receive 4 weeks of CART (n = 21) or cognitive therapy (n = 20; Meuret et al., 2010). Reductions in panic symptom severity and panic-related cognitions, as well as increases in perceived control, were significant and comparable across the two conditions. Further, corrections in hypocapnic levels were only observed in the CART condition, which supports the notion that CART operates through a pathway distinct from other procedures. Although initial results are promising, future studies must evaluate the degree to which CART augments well-established procedures such as exposure therapy in the treatment of PD and that any observed results are specific and causally related to biofeedback.

Finally, some recent trials have examined whether the addition of memory-enhancing medications and cognitive rehabilitation to CBT may contribute to outcomes and perhaps shorten treatment. For example, Otto and colleagues have explored the use of D-cycloserine (DCS), a partial *N*-methyl-D-aspartate (NMDA) agonist, in augmenting brief CBT for panic. DCS has been identified as an augmentation agent that facilitates the extinction of learned fear in laboratory animals and enhances the effects of traditional therapy for anxiety and related disorders (for reviews see Bontempo, Panza, & Bloch, 2012; Hofmann, Wu, & Boettcher, 2013; Norberg, Krystal, & Tolin, 2008). One randomized, double-blind, placebo-controlled augmentation trial compared brief (five-session) CBT augmented with either DCS or pill placebo (Otto et al., 2010). Results indicated large effects for DCS augmentation on PD symptoms and global severity of disorder at posttreatment and 1-month follow-up time

points; however, the between-group difference in clinically significant change was not statistically significant at follow-up. Of note, over half of participants in the CBT-plus-placebo condition met criteria for clinically significant change at follow-up; these findings underscore the effectiveness of five-session CBT without an active memory-enhancing agent. A similar study conducted by Siegmund and colleagues (2011) indicated that although DCS did not improve outcomes for patients with agoraphobia and PD, this mechanism did accelerate symptom reduction during 11 sessions of CBT in severely ill patients. Future research in this realm, such as an ongoing multisite, large-scale trial conducted by Otto and colleagues, may further elucidate the augmenting role of DCS in the treatment of PD.

Briefer Cost-Effective Treatments

Several studies have explored the effectiveness of CBT for PD when it is administered in a more cost-effective manner, such as with limited therapist contact or other self-directed modalities including Internet delivery (e.g., Cote, Gauthier, Laberge, Cormier, & Plamondon, 1994; Newman, Erickson, Przeworski, & Dzus, 2003). These studies address the questions raised on the second axis of the APA template, or the clinical utility or external validity of these treatments.

For instance, Cote and colleagues (1994) conducted a study in which patients were randomly assigned to receive CBT with either a standard amount of therapist contact (weekly hour-long sessions) or reduced therapist contact (twice-monthly hour-long sessions with twice-monthly 10-minute telephone contacts). Results of this study demonstrated that both treatment modalities were equally effective; more than 73% of the patients in both groups were both panic-free and clinically improved at the 6-month follow-up assessment. Other research has produced mixed findings; for example, a study by Sharp and colleagues (2000) showed that patients receiving standard therapist contact evidenced a stronger and more comprehensive treatment response than those receiving minimum therapist contact or self-directed manualized therapy.

Multiple studies have investigated the effectiveness of bibliotherapy, or self-directed treatment using a manual, in the treatment of PD (e.g., Lidren et al., 1994). In fact, the NICE clinical guidelines include bibliotherapy based on CBT principles as a treatment recommendation for individuals with PD (NICE, 2011). In one randomized trial, Febbraro and colleagues (1999) found some additional benefit of bibliotherapy that also included phone contact. This study compared the effectiveness of bibliotherapy alone, bibliotherapy plus phone contact, or phone contact alone. Among the 30 patients who completed the study, individuals in both bibliotherapy conditions showed significant reductions in panic-related cognitions and anxiety focused on panic at posttreatment; however, only individuals in the bibliotherapy-plus-phone-contact group exhibited significant reductions in panic symptoms and avoidance. More recently, Nordin and colleagues (2010) addressed concerns that therapist support is necessary in successful treatment of PD with bibliotherapy by showing that patients receiving unassisted bibliotherapy ($n = 20$) for 10 weeks (with a scheduled follow-up interview) evidenced significantly greater improvements on all outcome measures at posttreatment and a 3-month follow-up than those on a waitlist ($n = 19$). Questions remain about the severity of disorder in this sample.

Recent years have also witnessed other attempts to increase the cost-effectiveness of CBT, such as shortening the traditional treatment duration, which is typically 12 to 15 weeks (for a review, see Otto et al., 2012). This often involves more intense sessions that occur over a shorter time period. Deacon and Abramowitz (2006) examined the effectiveness of a brief (2-day), intensive CBT for PD. They found that 6 out of 10 patients were panic-free after treatment and continued to report nonclinical levels of panic symptomatology at the 1-month follow-up. In a similar vein, Bohni and colleagues (2009) observed comparable panic outcomes between 3 weeks of massed group CBT (daily 4-hour sessions in week 1, two 2-hour sessions in week 2, and one 2-hour session in week 3) and standard, spaced group CBT (13 consecutive, weekly 2-hour sessions) at posttreatment, 3-, 6-, and 18-month follow-ups.

Roberge and colleagues (2008) recently conducted a cost-effectiveness study of CBT for PD with agoraphobia where they compared standard PCT (14 individual sessions), group PCT (14 group sessions), and brief PCT (7 individual sessions at 2- to 3-week intervals). All treatment conditions were shown to significantly reduce symptoms, maintain gains, and

reduce rates of relapse as compared to a waitlist control (Marchand, Roberge, Primiano, & Germain, 2009). Cost-effectiveness analyses showed that both brief and group PCT conditions incurred lower direct and indirect treatment costs than standard PCT. These findings suggest that both group and brief formats are cost-effective alternatives to standard CBT for PD.

Clark and colleagues (1999) investigated the effectiveness of brief cognitive therapy for PD. Forty-three PD patients were randomly assigned to either standard cognitive therapy consisting of up to 12 1-hour sessions in the first 3 months or brief cognitive therapy, where patients attended five sessions in addition to using between-session self-study modules. Both treatments produced significantly better results than a waitlist control group. Taken together, findings suggest that brief interventions for PD that incorporate cognitive or exposure elements (or some combination) are promising alternatives to longer, traditional approaches.

With the advance of technology, researchers have also attempted to use the popularity of the Internet to increase both treatment dissemination and time- and cost-effectiveness (for reviews see Andrews et al., 2010; Richards, Klein, & Carlbring, 2003). Carlbring, Ekselius, and Andersson (2003) randomized 22 patients with PD to receive one of two Internet-based self-help programs (applied relaxation or CBT) plus minimal therapist contact via e-mail. Both conditions resulted in medium to large effects on PD symptoms, anxiety, depression, and quality of life, with no significant differences between groups. Hedman and colleagues (2013) also found Internet-based CBT to be effective in the context of routine psychiatric care for patients with PD. Further, Klein, Richards, and Austin (2006) randomly assigned 55 patients with PD to Internet-based CBT with therapist e-mail contact, therapist-assisted CBT manual with therapist telephone contact, or information control. They found that both CBT treatment groups were effective in reducing panic symptomatology, panic-related cognition, and negative affect. Interestingly, the Internet treatment was found to be more effective than the CBT manual/telephone contact on all outcome measures.

In yet another study, Ruwaard and colleagues (2010) randomly assigned 58 community-based participants with chronic panic-related symptoms to receive either Web-based therapist-assisted CBT or a waitlist. Participants who received Internet-delivered CBT evidenced significantly greater improvements on primary panic-related and general psychopathology outcomes at posttreatment. At a 3-year follow-up, these effects were more pronounced. In another study by Bergström and colleagues (2010), findings indicated that patients who received Internet-delivered CBT (n = 53) or group-administered CBT (n = 60) for PD in a psychiatric care setting evidenced similar reductions in severity of panic symptoms; these effects were maintained at the 6-month follow-up. Other analyses showed that the Web-based treatment had superior cost-effectiveness ratios compared to the group treatment at both posttreatment and follow-up. Carlbring and colleagues (2005) also found that Internet-based CBT self-help treatment (with minimal therapist contact) was comparable to in-person CBT of the same 10-week duration. Collectively, these studies suggest that the Internet may be a practical, cost-effective, and efficacious way of delivering CBT (or its components) for PD. However, more randomized controlled studies are needed to examine whether Internet-based treatments are effective in treating PD associated with severe levels of agoraphobia and diagnostic comorbidity.

Current Status

Table 14.2 summarizes the results of selected influential studies evaluating psychological treatment for PD through 2013. Nearly all these studies are classified as type 1; the studies by Öst, Westling, and Hellström (1993), Aaronson and colleagues (2008), Meuret and colleagues (2008), and Meuret and colleagues (2012) fall into the type 2 category due to an absence of comparison groups. Most studies demonstrate the effectiveness of PCT or similar CBT approaches for patients with PD with or without agoraphobia (compared with either no treatment or credible psychotherapeutic alternatives).

Translational Research (Effectiveness Studies)

Several large type 1 effectiveness studies have now appeared evaluating the clinical utility of CBT procedures delivered under naturalistic conditions in primary care settings (e.g., Rollman et al., 2005). For example, Addis and colleagues (2004) compared the efficacy of PCT to treatment as usual in a managed

care setting. This study was unique at the time in that few studies had attempted to examine the efficacy of PCT in traditional treatment settings rather than laboratory settings. In this study, 80 patients diagnosed with PD with or without agoraphobia were randomly assigned either to PCT delivered by a recently trained PCT therapist or to treatment as usual. In this case, treatment as usual involved whatever treatment orientation the therapist felt was appropriate for each individual client. Using a number of treatment outcome variables, the researchers found that although both groups showed a significant decrease in panic symptomatology from pretreatment to posttreatment, among the treatment completers, an average of 49% of those in the PCT group and 18.8% of those receiving treatment as usual achieved significant change from pretreatment to posttreatment. Follow-up data at 1 and 2 years after acute treatment with the same sample (using intent-to-treat analyses) indicated no significant differences between those who received PCT versus treatment as usual (Addis et al., 2006). However, when completer status was added as a moderator, those receiving PCT showed significantly lower levels of panic severity and phobic avoidance and a greater likelihood of achieving and maintaining clinically significant change. In a more recent study, Roy-Byrne and colleagues (2005) identified and treated 232 primary care patients meeting criteria for PD across six primary care clinics that were ethnically and socioeconomically diverse. Patients were randomized to receive 12 weeks of either treatment as usual or CBT that consisted of six sessions of PCT modified for the primary care setting. Up to six follow-up telephone contacts were permitted during the subsequent 9 months. Patients also received a copy of a manual modified for primary care patients, *Mastery of Your Anxiety and Panic: Workbook for Primary Care Settings* (Craske & Barlow, 2007b). PCT was delivered by mid-level behavioral health specialists with little or no CBT experience prior to training for this study. Both groups were also offered pharmacotherapy provided by the primary care physician, with guidance from a psychiatrist, with no differences in the use of drugs across the groups and only about 9% of individuals taking advantage of this option. Nevertheless, PCT resulted in sustained and gradually increasing improvement relative to treatment as usual on PD symptomatology, overall mental health functioning, and disability scales.

With the same sample, Craske and colleagues (2006) conducted a hybrid efficacy-effectiveness trial to examine effects of the intensity of CBT in this primary care setting. CBT intensity was operationalized as number of sessions, follow-up phone calls, and number of cognitive-behavioral coping and exposure strategies. Study therapists were the same midlevel behavioral health specialists with minimal or no CBT experience who were trained to deliver a six-session protocol over a 3-month period (plus six brief follow-up phone calls over the next 9 months). Results demonstrated that CBT intensity was associated with lower anxiety sensitivity at 3 and 12 months; further, the number of booster phone calls was associated with lower levels of anxiety sensitivity and depression, and less phobic avoidance, at 12 months. These data emphasize the importance of dose (and in particular phone contacts) when CBT is implemented in primary care settings.

There is also research to indicate that the intensity of training in CBT for PD makes a difference. Grey and colleagues (2008) compared outcomes from primary care therapists before and after receiving training in CBT. The first set of patients received up to 12 sessions of treatment as usual ($N = 12$). Therapists then underwent a 3-day training workshop in cognitive therapy for PD, followed by 8 months in which they treated PD patients with CBT with ongoing supervision. They then participated in another 1-day workshop and another 8-month period of treating patients with CBT while receiving regular supervision. Participants from the post-CBT-training period ($N = 24$) who received CBT achieved significantly greater improvements on all measures of PD and agoraphobia measures at posttreatment and 6-month follow-up compared to participants receiving treatment as usual. These findings suggest that, with adequate training and supervision, cognitive therapy can be disseminated in primary care settings and can significantly improve panic symptoms.

One study suggests that PFPP can be effectively translated into routine clinical care settings. Beutel and colleagues (2013) randomized 54 patients with PD to receive 24 50-minute sessions of either PFPP or CBT. The CBT intervention was delivered in the same number of therapist hours as PFPP, but sessions varied in length; homework was included. Clinicians were community psychodynamic psychotherapists who attended a training course in PFPP and certified CBT therapists. Patients who had failed to respond to previous pharmacological or psychological treatments were included in the study. Findings showed no significant differences between conditions at posttreatment or follow-up, with both treatments resulting in strong effect sizes.

Psychological Treatments in Combination with Pharmacotherapy

Results from a recent large-scale meta-analysis suggest that, overall, CBT is more effective than first-line pharmacological agents for the treatment of PD (Roshanaei-Moghaddam et al., 2011). However, research on the effectiveness of combined psychological and pharmacological treatment is more mixed. Prior to Barlow and colleagues (2000; discussed above), research in this area focused primarily on combining pharmacotherapy with exposure-based treatments for patients with moderate to severe levels of agoraphobia. Studies that compared the effectiveness of tricyclic antidepressants and exposure-based procedures with exposure alone have, for the most part, shown evidence of superior posttreatment results for the combined treatment (Mavissakalian, 1996; Telch, Agras, Taylor, Roth, & Gallen, 1985). However, these results generally were not maintained at follow-up assessments due to the high incidence of relapse experienced by patients in the combined treatment condition after imipramine had been discontinued (e.g., Mavissakalian & Michelson, 1986). The clinical trial by Barlow and colleagues (2000) of PD with no more than mild agoraphobia showed equivalence of monotherapies, no marked advantage of combining treatments, and more durability of CBT.

Recent meta-analyses in this area continue to show a similar pattern of findings. One meta-analysis of 124 studies testing psychological treatment and/or pharmacotherapy for PD determined that the combination of CBT elements and pharmacotherapy was slightly more effective than CBT alone at posttreatment; however, no significant differences were observed at follow-up (Mitte, 2005). The potential long-term negative effects of a combination approach, such as medication use reducing the motivation to practice CBT skills, impairing extinction learning, or contributing to context-dependent learning (for a review, see Otto, McHugh, & Kantak, 2010), may help explain these findings. In a similar vein, another

meta-analysis determined that the combination of antidepressant pharmacotherapy and psychotherapy (largely CBT) was slightly more effective than antidepressants or psychotherapy alone during the acute treatment phase (Furukawa, Watanabe, & Churchill, 2006). During follow-up, however, the combined approach was similarly effective to psychotherapy but more effective than pharmacotherapy.

Along these lines, Raffa and colleagues (2008) investigated why PCT was less effective in offsetting relapse for individuals receiving active drug compared to placebo, which was contrary to expectations based on previous comparisons during the trial by Barlow and colleagues (2000). One hypothesis was that participants had correctly deduced treatment assignments; thus, those taking imipramine believed they were no longer taking an active drug following discontinuation, which accounted for the increased risk of relapse. However, analyses indicated that the study blind remained intact and thus did not support this hypothesis. The researchers suggest other potential reasons for discrepancies in relapse rates, including attribution of change, state-dependent learning, and return of physical symptoms after discontinuation of the active drug. Overall, there is a need to continue studying effective maintenance strategies for PD, in particular the most effective ways to combine medications with CBT to offset potential relapse (Otto, Smits, & Reese, 2006).

With regard to the cost-effectiveness of combined approaches, a comprehensive analysis of psychosocial, pharmacological, and combined treatments for PD indicated that evidence-based monotherapies produced superior cost-efficacy compared to combined treatments (McHugh al., 2007). Of note, CBT was also determined to be the most durable and cost-effective monotherapy. Another recent study indicated that CBT is more cost-effective than either selective serotonin reuptake inhibitors (SSRIs) alone or the combination of CBT plus SSRI for PD (van Apeldoorn, Stant, van Hout, Mersch, & den Boer, 2014). Thus, it would seem that CBT alone may be a more cost-effective treatment,

Combining CBT with benzodiazepines is generally not recommended based on reports that high-potency benzodiazepines may interfere with and detract from CBT treatment gains (Brown & Barlow, 1995; Otto, Pollack, & Sabatino, 1996). Indeed, NICE quality standards state that benzodiazepines should not be prescribed for the treatment of PD and refer to SSRIs and tricyclic antidepressants as the only evidence-based pharmacological interventions for long-term management of PD (NICE, 2011).

Sequential Strategies and Long-Term Maintenance

Psychological treatments, including modifications of PCT, have been used to help patients discontinue benzodiazepines. Researchers have found that a slow taper of alprazolam in conjunction with 10 to 12 weeks of PCT is significantly more successful at helping patients discontinue alprazolam fully than a slow taper alone (Otto et al., 1993) or a slow taper with routine supportive medical management (Spiegel, Bruce, Gregg, & Nuzzarello, 1994). More recently, Otto and colleagues (2010) randomly assigned 47 patients with PD seeking taper from benzodiazepines to receive PCT (targeting benzodiazepine discontinuation), taper alone, or taper plus relaxation. Results indicated that adjunctive CBT provided significant, large additive benefits above taper alone and taper plus relaxation at a 6-month follow-up. These studies suggest that an innovative combination treatment in which high-potency benzodiazepines are administered initially to those who need immediate relief or otherwise desire medication treatment, followed by psychological treatment such as PCT, may be quite effective for patients with PD. It is possible that the future of combined treatment lies in these sequential strategies as opposed to simultaneous administration of drug and psychological treatment.

Along these lines, clinical investigators have also examined the effectiveness of psychological treatments for patients who were previous nonresponders to pharmacological treatment. For example, Pollack and colleagues (1994) found that 12 weeks of group CBT improved global functioning and panic attack frequency of patients who had shown evidence of an incomplete response to previous pharmacotherapy. Data from one RCT suggest that the combined approach of CBT and antidepressants may be an effective next-step strategy for individuals who do not respond to initial pharmacotherapy (Simon et al., 2009). Taken together, these results (and those from a type 2 trial by Heldt et al., 2006) suggest that there might be a select group of patients with PD who may not benefit from medication treatment but then are able to show evidence of improvement when effective psychological treatments are administered. There

is also some evidence that reversing the sequence for those who initially do less well than expected with CBT by subsequently administering an effective pharmacological treatment produces similar results (e.g., Kampman, Keijsers, Hoogdiun, & Hendriks, 2002; Payne et al., 2013), but additional research is necessary. We know that even those individuals doing well at follow-ups of a year or more with CBT often experience setbacks or other exacerbations of symptoms that occasionally progress to a full relapse (e.g., Burns et al., 1986; Furukawa et al., 2006). In view of the chronicity of PD, there is a need to investigate strategies to prevent relapse.

Based on preliminary studies demonstrating the possible value of maintenance strategies (e.g., Jansson et al., 1986; Öst, 1989), researchers have focused on developing more comprehensive and effective maintenance strategies for preventing exacerbations or full relapse (e.g., Arch & Craske, 2011). For instance, White and colleagues (2013) found that among patients who had responded well to an initial course of CBT for PD, with or without agoraphobia, nine monthly sessions of maintenance CBT, encouraging the continued use of PCT skills and relapse prevention strategies after treatment, reduced the risk of relapse and decreased functional impairment compared to patients who did not receive maintenance CBT. This evaluation suggests that maintenance therapy can be an effective strategy in the long-term management of PD. Further research that examines whether similar effects could be obtained with less frequent or fewer maintenance sessions is needed.

Future Directions

Although CBT approaches to treating PD and agoraphobia are highly efficacious and are becoming more widely accepted, there are still unresolved issues, especially when considering initial resistance by some to treatment and relapse following treatment by others. As a result, researchers have begun to test new combination or sequential treatments to address treatment-resistant individuals and specific maintenance programs for those who have had a successful treatment experience. In addition to brief adaptations of traditional CBT protocols, novel approaches such as mindfulness and acceptance strategies and physical exercise may enhance treatment and perhaps reduce barriers to treatment dissemination for selected individuals. Further, the development of core treatment principles as found in new unified transdiagnostic interventions (Barlow et al., 2011a) may facilitate dissemination. The state of current research on these transdiagnostic approaches will be reviewed in the final section of this chapter.

SPECIFIC PHOBIA

In the *DSM-5*, a specific phobia is defined as a marked and persistent fear cued by the presence or anticipation of an object or situation. The fear must be considered excessive or unreasonable and must be associated with functional impairment or subjective distress. In addition, the specific phobia must not be better accounted for by another *DSM-5* disorder (APA, 2013). The primary characteristics of specific phobia have not been changed from the *DSM-IV* (APA, 1994), which replaced the diagnosis of simple phobia listed in the *DSM-III-R* (APA, 1987).

Five subtypes of specific phobias are included in the *DSM-5:* animal, natural-environmental, blood-injection-injury, situational, and other. The "other" type serves as a catch-all category for specific phobias such as choking or vomiting that do not readily fall into any of the first four subtypes. These subtypes vary according to age of onset, gender composition, patterns of comorbidity, and type of physiological reaction to the phobic situation, as well as other important variables such as natural course and type of treatment indicated. For example, the mean age of onset for animal, blood, storm, and water phobias tends to be in early childhood, whereas the mean ages of onset for situational height and flight phobias are in adolescence (Antony & Barlow, 2002; Becker et al., 2007; Öst, 1987).

The *DSM-5* (formerly *DSM-IV and DSM-IV-TR*) diagnosis of specific phobia, when considered overall, is the most prevalent anxiety disorder (Kessler et al., 2012). Approximately 12.5% of the population has developed or will develop at least one phobia in their lifetime (Kessler et al., 2005). Yet when specific phobias are given as primary diagnoses, the clinician is not likely to observe an additional clinical diagnosis. In other words, principal diagnoses of specific phobias seen in the clinic tend to have lower rates of comorbidity than principal diagnoses of most other Axis I disorders (Moras, Di Nardo, Brown, & Barlow, 1994). Another characteristic of specific

phobia is that people tend to evidence multiple feared objects or situations. In an analysis of data from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) study, Stinson and colleagues (2007) found that, of the 4,030 individuals with a lifetime history of a specific phobia, only 28.9% had a single phobia. The remaining cases had two (21.2%), three (15.9%), four (11.4%), or more than four (22.5%) phobias. The NESARC study also found that animal phobias were the most prevalent, followed by a fear of heights and being in closed places such as an elevator (4.7%, 4.5%, and 3.2% of the population, respectively).

Gender differences are marked in specific phobia, with the lifetime prevalence for women noted to be 15.7% of the population compared with 6.7% for men. Interestingly, this gender difference in prevalence is most pronounced for animal phobia and least apparent for height, flying, and blood-injury-injection phobias (Antony & Barlow, 2002). Women also tend to experience a greater number of types of phobic fear than men (Sigström et al., 2011).

Treatments for Specific Phobias

A consensus has developed that the treatment of choice for a wide spectrum of specific phobias is exposure-based procedures, particularly in vivo exposure. Although imaginal exposure has been shown to produce fear reduction (Baker, Cohen, & Saunders, 1973) and should be used if situational in vivo exposure treatment is not feasible, in vivo exposure is generally accepted as the most powerful treatment for specific phobias (APA, 1994; Antony & Barlow, 2002; Barlow, 1988, 2002; Marks, 1987). The small number of studies that compare in vivo exposure to alternative exposure modalities (e.g., imaginal exposure or in virtuo exposure from virtual reality environments) indicate that in vivo exposure is associated with greater improvements by the end of treatment. However, in vivo exposure and other exposure methods appear more similar in their continued performance during longer follow-up periods (Wolitzky-Taylor, Horowitz, Powers, & Telch, 2008).

In vivo exposure treatment often appears deceptively simple, yet there are many facets to the procedure (Antony & Barlow, 2002). During initial treatment sessions, the therapist gathers more specific information about the patient's feelings, thoughts, and behaviors concerning the phobic object or situation. The patient is informed that systematic, repeated in vivo exposure will allow the patient to become desensitized to the phobic object or situation. The clinician also lets patients know that all in vivo exposures will be predictable and under their control, and he or she teaches patients a variety of adaptive coping strategies to use throughout treatment. Finally, the clinician and patient create a hierarchy of feared situations concerning the phobic object or situation and formulate a treatment plan consisting of in vivo exposure practices.

Extensive literature exists demonstrating the effectiveness of in vivo exposure treatments for specific phobias. Over the past few decades, in vivo exposure has been successfully used to treat most types of specific phobia (Antony & Barlow, 2002). For example, clinical investigators have demonstrated the effectiveness of in vivo exposure to treat phobias of animals (e.g., Öst, 1989; Öst, Ferebee, & Furmark, 1997; Öst, Salkovskis, & Hellström, 1991), heights (e.g., Bourque & Ladouceur, 1980), flying (e.g., Howard, Murphy, & Clarke, 1983; Öst, Brandberg, & Alm, 1997), and enclosed spaces (e.g., Öst, Johansson, & Jerremalm, 1982; Powers, Smits, & Telch, 2004). In addition, in vivo exposure has been used to treat fear of dentists (Jerremalm, Jansson, & Öst, 1986b; Liddell, Di Fazio, Blackwood, & Ackerman, 1994), as well as choking phobia (McNally, 1986, 1994), with good results. Blood-injection-injury phobias also have been successfully treated with in vivo exposure, although these phobias and their treatments are unique and are described below (Öst, 1989; Öst & Sterner, 1987).

Although exposure-based treatments for specific phobias are considered to be fairly straightforward, they are composed of many factors that may have an impact on the clinical results of treatment. These factors include the duration and temporal spacing of exposure sessions, the level of therapist involvement, and the incorporation of additional treatment components into exposure sessions. The following discussion reviews the available empirical evidence regarding these factors.

In general, it appears that massed exposure sessions result in the most robust clinical improvement in specific phobias (for a review of the literature, see Zlomke & Davis, 2008). In as little as one session of therapist-guided exposure, 90% of people with animal or injection phobias and 80% of people with claustrophobia have been found to be much

improved or completely recovered (Öst, 1989; Öst, Alm, Brandberg, & Breitholtz, 2001). In one study, Öst and colleagues (2001) randomly assigned 46 patients with claustrophobia to one of four conditions: one session of exposure (3 hours maximum), five sessions of exposure, five sessions of cognitive therapy, or a waitlist. At posttreatment, 80% of those who received one session of exposure showed evidence of immediate improvement compared to 81% of those who received five sessions of exposure and 79% who received cognitive therapy. All treatments performed better than the waitlist, of whom 18% saw clinical improvement. Results were maintained at a 1-year follow-up; thus, the one-session exposure treatment was the shortest treatment to provide equivalent results.

Rowe and Craske (1998) examined the benefits of an expanding-spaced exposure schedule versus massed exposure. In this model, sessions begin close together and gradually spread out as treatment progresses. They found that massed exposure led to significantly more fear reduction in a group of spider phobics. However, there is mixed evidence regarding which exposure schedule is less likely to be associated with a return of fear following treatment; for example, a replication study by Lang and Craske (2000) did not find a difference between exposure schedules on the likelihood of return of fear. These findings also support new information on the mechanisms of fear reduction alluded to in the previous section, noting that immediate fear reduction is less important than the creation of new memories reflecting successful coping with fear across a variety of situations (Craske et al., 2008, 2012).

The degree of therapist involvement in exposure treatment is also considered to be an important component of treatment for specific phobias. Although relatively few studies have directly examined the influence of the therapist's presence, most empirical findings point to the importance of therapist involvement during exposure (e.g., Hellström & Öst, 1995; Öst et al., 1991). For example, Öst and colleagues (1991) found that whereas 71% of persons with spider phobia improved with therapist-assisted exposure treatment, only 6% of persons who engaged in self-directed exposures evidenced clinical improvement. In a follow-up study, Hellström and Öst (1995) found that the manner in which self-help treatment is disseminated affects the outcome for individuals with spider phobias. In this study, five different treatments were compared: (a) a single session of therapist-assisted exposure, (b) a spider phobia–specific manual used in the home, (c) a spider phobia–specific manual used in the clinic, (d) a nonspecific manual used in the home, and (e) a nonspecific manual used in the clinic. The percentages of individuals who were significantly improved were 80%, 10%, 63%, 9%, and 10%, respectively. These findings suggest that self-help manuals can be beneficial to individuals diagnosed with specific phobias when they are used in a clinic setting.

Other empirical studies have shown that certain types of specific phobias require adaptation of exposure-based procedures that incorporate additional treatment components. For example, individuals with blood-injection-injury phobia tend to have a physiological reaction that can often inspire a fainting response. This physiological reaction, known as *vasovagal syncope*, consists of an immediate rise and fall in heart rate and blood pressure when the person encounters the phobic stimulus. A physical strategy that prevents the fainting response that results from this reaction has been developed and added to exposure treatment. This coping strategy, known as *applied tension*, serves to temporarily sustain the patient's blood pressure and heart rate at an increased level by completing tensing and releasing all large muscle groups (arms, torso, and legs) in 15-second intervals. When patients begin applied tension before the injection procedure begins and continue until after the procedure is over, the possibility of fainting is eliminated. This technique has been empirically validated as an additional component of exposure treatment (Öst & Sterner, 1987). In addition, Hellström, Fellenius, and Öst (1996) showed that a single session of applied tension along with a maintenance program of self-exposure is as effective as a five-session course of the same treatment.

Several treatment manuals for the specific phobias exist. The program developed and manualized at our center presents general information regarding the nature and treatment of specific phobias, as well as detailed treatment information for several of the most common specific phobias (Antony, Craske, & Barlow, 2006). The treatments presented in this manual also incorporate additional treatment strategies to be used in conjunction with in vivo exposure treatments, such as cognitive strategies and interoceptive exposure.

Cognitive strategies are included to combat cognitive distortions and anxious thought patterns, and interoceptive exposures desensitize patients to the physical sensations individuals often associate with the phobic object or situation.

Finally, during the past 10 to 15 years, researchers and clinicians alike have increasingly taken advantage of technological advances for the treatment of specific phobias. For example, a number of investigators have begun to use virtual reality to expose patients to simulated situations such as heights (Rothbaum et al., 1995), flying (Rothbaum, Hodges, & Smith, 1999), and spiders (Carlin, Hoffman, & Weghorst, 1997). Although a large number of studies examining the effectiveness of VRE have been conducted, many lack treatment comparison groups and/or control groups and an adequately large sample size. In the literature to date, controlled trials with larger samples have predominantly been conducted with patients experiencing a fear of flying, spiders, and heights (e.g., Krijn et al., 2004; Michaliszyn, Marchand, Bouchard, Martel, & Poirier-Bisson, 2010; Rothbaum et al., 2006). One meta-analysis conducted by Parsons and Rizzo (2008) found that VRE exhibited large average random effects for the treatment of phobias related to spiders, heights, and flying (range of effects: .92 to 1.59), although some studies analyzed were not RCTs.

Some research has examined whether VRE treatment is equivalent to in-person exposures. For instance, two controlled trials by Rothbaum and colleagues compared VRE treatment, standard exposure treatment, and waitlist for individuals with a fear of flying (Rothbaum, Hodges, Smith, Lee, & Price, 2000; Rothbaum et al., 2006). In both studies, 45 (Rothbaum et al., 2000) and 75 (Rothbaum et al., 2006) patients with a flying phobia were randomized to one of the three treatment conditions. Results from both studies indicated that VRE and standard exposure treatment were both superior to waitlist control, with no differences between VRE and standard exposure. VRE and standard exposure were shown to be effective by decreases in symptoms as measured by standardized questionnaires, by the number of participants who actually flew on a real airplane following treatment, on self-ratings of improvement, and on patient satisfaction with treatment. The gains observed in treatment were maintained at a 6-month follow-up and a 12-month follow-up (in the 2006 study only, as the 2000 study did not have a 12-month assessment). In the earlier study, 93% of VRE participants and 93% of standard exposure participants had flown during the 6-month follow-up. In the later study, 81% of VRE participants and 70% of standard exposure participants had flown during the 12-month follow-up.

Other studies examining the efficacy of VRE treatment for fear of flying have consistently found VRE treatment to be more effective at decreasing fear and avoidance of flying when compared with attention-placebo group treatment (Maltby, Kirsch, Mayers, & Allen, 2002), cognitive treatment, and waitlist control (Mühlberger, Weidemann, & Pauli, 2003). In an interesting version of VRE treatment, Garcia-Palacios, Hoffman, Carlin, Furness, and Botella (2002) randomly assigned 23 patients with a fear of spiders to either waitlist control or VRE treatment with tactile stimulation. In this study, tactile stimulation consisted of patients feeling a "hairy" fabric similar to the sensation of feeling a spider while watching a virtual spider. They found VRE treatment with tactile stimulation to be more effective than waitlist control on all outcome measures, including self-report and behavioral tests.

Although VRE treatments clearly appear to hold some promise as a valuable form of treatment for specific phobias, an important consideration is whether they can generalize to naturalistic settings. One concern is the often substantial number of dropouts that are found in VRE treatment outcome studies (Krijn, Emmelkamp, Olafsson, & Biemond, 2004). Research suggests that the major contributing factor to dropout rates in these studies is the degree to which the patient feels "present" in the experience; this involves feeling that one is in the present world rather than in the virtual world. Krijn and colleagues (2004) found that the reported level of "presence" during VRE treatments was highly correlated with treatment dropout, with lower degrees of "presence" associated with higher dropout rates. In addition, other patient factors such as degree of absorption and hypnotizability may mediate the effectiveness of VRE treatments (Wiederhold & Wiederhold, 2000). As our understanding of the nature of anxiety and technological innovations advances, it is clear that VRE will continue to offer interesting, and perhaps more effective, treatment options for the treatment of specific phobias.

Future Directions

Although a great deal of treatment outcome research exists for specific phobias, much remains to be learned. For example, researchers have only just begun to examine differences among the specific phobia subtypes, and additional information in this area could improve treatments for specific phobias (for a review, see LeBeau et al., 2010). Just as patients with blood-injection-injury phobias benefit from the use of applied tension coupled with exposure therapy, many patients with other specific phobia subtypes might respond more robustly to exposure treatments tailored to their phobic object or situation. For example, treatment may emphasize targeting fears that tend to differ according to subtype. Approximately half of individuals with an animal phobia indicate that the focus of their fear revolves around feelings of disgust and revulsion. In comparison, individuals with natural environment or situational fear subtypes tend to focus their fear on perceptions of danger or harm instead (82% and 52% of those with natural environment and situational phobias, respectively). For individuals with a blood-injection-injury phobia, the focus of the fear tends to be on physical symptoms (37%) and internal feelings such as disgust (37%; Lipsitz, Barlow, Mannuzza, Hofmann & Fyer, 2002).

Moreover, in this era of managed care, when cost-effectiveness is considered to be of utmost importance, further research should be conducted to determine which of the many specific phobias can be treated in just one therapist-assisted in vivo exposure session. Although some information has been gained regarding such intensive treatments for patients with certain animal and injection phobias, as well as blood, claustrophobia, and flying phobias (Hellström, Fellenius, & Öst, 1996; Öst, 1989; Öst, Alm, Brandberg, & Breitholtz, 2001; Öst, Brandberg, & Alm, 1997), more research may help provide support for the efficacy of this treatment modality for other common specific phobias such as elevators, heights, and darkness. One of the best recent examples of research in the domain of single-session exposure treatment was a large multisite RCT conducted with children and adolescents (Ollendick et al., 2009), the quality of which will, it is hoped, be emulated in future treatment research across the lifespan. Lastly, further research should continue to explore the efficacy of virtual reality therapy. Additional controlled trials with adequately large sample sizes and treatment comparison or control groups are still needed, particularly for specific phobias that have not been studied to the extent that fear of spiders, heights, and flying have in the past.

SOCIAL ANXIETY DISORDER

SAD (formerly social phobia in the *DSM-IV*) is estimated to be the second most prevalent of all anxiety disorders, with a lifetime prevalence of 10.7% (Kessler et al., 2012). Moreover, SAD is the fourth most prevalent of all mental disorders, exceeded only by major depressive disorder, alcohol abuse, and specific phobia (Kessler et al., 2005). This finding is truly remarkable, especially since SAD (previously social phobia) was not included as a separate diagnostic category until the *DSM-III* (APA, 1980).

According to the *DSM-5* (APA, 2013), individuals with SAD fear a number of social and performance situations because of concerns that they will act in a way that will be humiliating or embarrassing or that they will visibly manifest anxiety symptoms (e.g., sweating, shaking, or blushing). For patients with SAD, the fear and avoidance of people typically result in several areas of impairment, including occupational, academic, and social functioning (cf. Heimberg & Magee, 2014). Although the primary characteristics of SAD did not significantly change between the *DSM-IV-TR* (APA, 2000) and the *DSM-5*, the *DSM-5* now includes a *performance-only* subtype, where fear is restricted to speaking or performing in public, and it no longer includes the *generalized* subtype, once defined as fear that is present in most social situations. The median age of onset of SAD is estimated to be 13 years, with 95% of patients reporting onset before age 35 (Kessler et al., 2005). According to Brown and colleagues (2001a), 72% of 186 individuals with a principal diagnosis of SAD seen in a clinic setting also experienced lifetime major comorbid Axis I disorders such as major depressive disorder (44%), dysthymia (17%), alcohol abuse (15%), GAD (14%), drug abuse (11%), obsessive-compulsive disorder (10%), and specific phobia (10%). There is additional evidence that from 25% to 89% of individuals with SAD also meet criteria for avoidant personality disorder (cf. Marques et al., 2012).

Little is known about the etiology of SAD, but numerous studies have examined possible factors, including behavioral inhibition, genetics, biological

mechanisms, developmental factors, conditioning, and cognitive models (Rapee & Spence, 2004). Barlow and colleagues (Barlow, 1988; Barlow et al., 2014a; Barlow, Chorpita, & Turovsky, 1996; Hofmann & Barlow, 2002), invoking the "triple vulnerability" theory again, hypothesize that one must be biologically vulnerable to anxious apprehension to develop SAD and also evidence both general and specific psychological vulnerabilities. If we focus on biological vulnerabilities specifically, there is considerable evidence that genetics plays a role in SAD. In a study of 2,163 female twins, Kendler, Neale, Kessler, Heath, and Eaves (1992) found that proband-wise concordance for SAD was greater in monozygotic (24.4%) than dizygotic (15.3%) twin pairs. This biological vulnerability may express itself in exaggerated reactivity to social evaluation situations. That is, for reasons of evolutionary significance, we are biologically vulnerable to the effects of anger, criticism, and other means of social disapproval. Alternatively, the vulnerability could be a more nonspecific diathesis to experience anxiety generally.

As in all anxiety disorders, a generalized psychological vulnerability also exists in which individuals learn that important, personally salient events in their lives, particularly challenging or threatening events, are unpredictable and uncontrollable (Gallagher, Bentley, & Barlow, 2014). In addition, research suggests that at least some patients with SAD are predisposed to focus anxious apprehension on events involving social evaluation (the specific psychological vulnerability; Barlow et al., 2014a). Anxiety in social evaluative situations involving performance forms the basis from which a false alarm (panic attack) develops in specific social situations. Of course, in some cases, individuals may have direct experience with a traumatic form of social rejection or humiliation, resulting in a true alarm. Another pathway to the acquisition of SAD occurs when socially anxious individuals occasionally experience some performance deficits, even without an encounter with an alarm. Subsequent anxious apprehension in the future may lead to additional performance deficits, which sets off the vicious cycle of anxious apprehension (Hofmann & Barlow, 2002). Although the pathways of acquisition may vary, they have a biological vulnerability, general and specific psychological vulnerabilities, as well as triggering events in common.

Research on CBT for SAD has substantially increased in recent years. The most common approaches include SST, relaxation techniques, exposure-based methods, and multicomponent cognitive-behavioral treatments (e.g., Heimberg & Juster, 1995; Heimberg & Magee, 2014). In this section, as above, empirical studies are evaluated according to the template created by the American Psychological Association to guide the development of practice guidelines described above (APA, 2002; American Psychological Association Task Force on Psychological Intervention Guidelines, 1995 [see Table 14.1]; Barlow & Barlow, 1995). As mentioned in Table 14.1, we have greater confidence in the efficacy of a treatment depending on its absolute and relative efficacy. All studies individually reviewed are type 1 unless otherwise noted.

Social Skills Training

The rationale for SST is based on the concept that people with SAD are deficient in verbal and nonverbal social skills. Heimberg and Juster (1995) pointed out that although social skills deficits were inferred from poor social behavior, the term was often confused with performance deficits. They also concluded that although nine studies used SST as a treatment condition, with some resulting in significant improvement, all but one failed to include appropriate control groups. Therefore, it has not been possible to conclude that training in social skills was the component that led to positive outcomes (Heimberg & Juster, 1995). Similarly, Donahue, Van Hasselt, and Hersen (1994) concluded that the heterogeneity of the samples and the paucity of controlled comparisons have not permitted definitive conclusions on SST's efficacy. Due to the recognized cognitive contributions in the maintenance of social anxiety, as well as the fact that most adults with SAD have adequate social skills, therapy in recent years has targeted cognitive and behavioral interventions for the treatment of this disorder (Ponniah & Hollon, 2008).

Referring to the aforementioned template of treatment efficacy, we cannot definitively state at this time that SST is superior to even a waitlist control because of the methodological limitations in most studies. This conclusion gains credence given that the only controlled study of SST, completed over two decades ago, found that 15 weeks of SST did not result in better clinical outcomes than a waitlist control group (Marzillier, Lambert, & Kelley, 1976). More recently,

another RCT that examined interpersonal therapy with and without SST did not find a significant benefit of SST for those with SAD (Stravynski et al., 2000).

Although SST by itself does not appear to be efficacious, there is some indication that combined SST and exposure holds some promise (Turner, Beidel, Cooley, Woody, & Messer, 1994). In this type 3 pilot study of a comprehensive multicomponent treatment, 11 of 13 patients with severe (generalized) SAD showed moderate to high end-state functioning at posttreatment, although pretreatment status could not be calculated because there were no pretreatment Clinical Global Impression (CGI) ratings; moreover, there was no control group. Another investigation compared the efficacy of cognitive-behavioral group therapy (CBGT) with and without SST (Herbert, Gaudiano, & Rheingold, 2005). The authors found significant improvement in social anxiety symptoms for both groups, although the combined group produced the largest effect sizes. These preliminary findings suggest that additional controlled clinical trials testing this combined treatment are needed. Furthermore, additional dismantling studies must be conducted to explore whether the SST component itself leads to additional improvement above and beyond the gains made from the other components. Obviously, targeting SST specifically to the patients with clearly assessed social skill deficits should produce the most substantial effects.

Relaxation Treatments

The effectiveness of relaxation training and other strategies targeting arousal reduction for social anxiety has not yet been adequately evaluated (Heimberg & Juster, 1995; Heimberg & Magee, 2014). Two groups of investigators have concluded that progressive muscle relaxation alone is not an effective treatment (Al-Kubaisy et al., 1992; Alström, Nordlund, Persson, Harding, & Ljungqvist, 1984). There has been some indication by Öst, Jerremalm, and Johansson (1981) and Jerremalm, Jansson, and Öst (1986a) that applied relaxation, including application training in which relaxation skills are used during anxiety-producing role-plays, is an effective treatment for SAD (cf. Heimberg & Juster, 1995); however, other research suggests that the combination of exposure and applied relaxation does not appear to be superior to cognitive therapy (Clark et al., 2006). In the three controlled clinical trials conducted in this area (Alström et al., 1984; Jerremalm et al., 1986a; Öst et al., 1981), applied relaxation was inferior to self-instruction training, exposure, and supportive counseling and was no better than SST (Donahue et al., 1994). At this time, there is no strong body of literature to support relaxation procedures alone as an effective treatment for SAD.

Exposure and Cognitive Therapy

As we have noted, there is a growing body of literature in support of multifaceted treatment for SAD based on exposure to feared social situations and cognitive therapy (Ponniah & Hollon, 2008). Social anxiety is partially maintained by the avoidance of anxiety-producing situations and the negative reinforcement that occurs as a result (Donahue et al., 1994). Barlow (1988; Hofmann & Barlow, 2002) views some form of exposure as a central part of any psychological treatment for social anxiety; many others would agree. The essential part of exposure is to have a patient repeatedly confront the situation he or she fears. The exposures can be conducted in vivo, with situations encountered in the natural environment or through imaginal exercises. Many treatment programs involve simulated social interactions in which the therapist (and confederates, if necessary) role-play the anxiety-producing social situation. The cognitive component of treatment addresses the role of fear of negative evaluation by identifying and modifying maladaptive cognitions that occur in these situations (Donahue et al., 1994). Although many current treatments for SAD are conducted in a group format (to facilitate exposure), there is also evidence that individual treatment protocols are as, if not more, effective (Mörtberg, Clark, Sundin, & Aberg Wistedt, 2007; Stangier, Heidenreich, Peitz, Lauterbach, & Clark, 2003).

In an early study, Mattick, Peters, and Clarke (1989) randomly assigned 43 patients with SAD to guided exposure alone, cognitive restructuring alone, guided exposure and cognitive restructuring, or a waitlist. All active treatment conditions were significantly better than the waitlist on a behavioral avoidance test, as well as self-report measures of negative evaluation and irrational beliefs. Patients in the combined condition evidenced the most improvement on the behavioral avoidance test. The authors concluded that

exposure therapy combined with cognitive restructuring was the most effective intervention overall.

Heimberg and colleagues (1990) compared a CBGT package, consisting primarily of in-session exposure exercises, cognitive restructuring, and homework exercises, to a credible placebo condition. This placebo condition, called educational supportive group therapy, was a nondirective supportive group treatment that also consisted of psychoeducation about SAD. Both groups improved significantly at posttreatment, but CBGT patients were more improved on some key measures at both posttreatment and at the 6-month follow-up. Moreover, a 5-year follow-up on a portion of the patients from the original study indicated that individuals who received CBGT were more likely to be improved and to maintain their gains relative to the educational support group (Heimberg, Salzman, Halt, & Blendell, 1993). This investigation provides further support for combination treatments involving both exposure and cognitive restructuring.

More recently, Hofmann and colleagues compared the efficacy of CBGT, exposure group therapy, and a waitlist control group for individuals with SAD (Hofmann, 2004; Hofmann, Moscovitch, Kim, & Taylor, 2004). Ninety participants (30 per group) received 12 weekly sessions of group treatment. The CBGT treatment protocol was developed by Heimberg (1991), and the exposure group treatment protocol consisted of repeated in-session in vivo exposures to social situations (including video feedback, didactic training, and weekly homework assignments) and was conducted without explicit cognitive restructuring procedures (Hofmann, 1999). At posttreatment, the two active treatment groups were both significantly better than the waitlist control group, according to two self-report measures of social anxiety and a behavioral stress test, although CBGT and exposure group therapy did not differ from each other. However, at a 6-month follow-up, individuals who received CBGT reported significantly less social anxiety, suggesting that adding cognitive restructuring to an exposure-based treatment protocol may aid in maintaining treatment gains. CBGT has also recently been found to have comparable or superior outcomes to mindfulness-based group treatments for SAD, providing further evidence of its strength as an intervention (Kocovski, Fleming, Hawley, Huta, & Antony, 2013; Koszycki, Benger, Shlik, & Bradwejn, 2007).

Rapee, Gaston, and Abbott (2009) were interested in understanding whether it is important to target factors that may be specific to social anxiety, such as overestimating the likelihood and cost of negative social evaluation, attentional bias toward an excessively negative self-appraisal, and engaging in subtle behavioral strategies that reinforce negative self-perception. They compared standard cognitive restructuring plus in vivo exposure to an "enhanced" program that also included a greater emphasis on hypothesis testing of beliefs through in vivo exposures, obtaining specific performance feedback, and engaging in attention retraining. These two treatments were then also compared to a nonspecific stress management treatment in a sample of 195 individuals with SAD. They found that the enhanced treatment showed the greatest improvements in posttreatment diagnostic severity, anxiety during a speech, although it did not significantly differ from the standard treatment self-report measures of social anxiety symptoms and life impairment. The enhanced condition also showed the greatest improvements on the perceived cost of negative evaluation and negative views of one's skills and appearance, both of which mediated differences between treatments on changes in diagnostic severity. Thus, there is some evidence that providing a more specific treatment tailored to cognitive factors specific to social anxiety may be beneficial.

Clark and colleagues also have examined whether a treatment emphasizing cognitive restructuring could be beneficial to patients with social anxiety, although they did include behavioral experiments, which often contain a significant exposure component. In a sample of 62 individuals with SAD, they compared the efficacy of 14 weekly sessions of individual cognitive therapy to individual exposure treatment plus applied relaxation as well as a waitlist (Clark et al., 2006). The cognitive therapy was based on the model for maintenance of social anxiety developed by Clark and Wells (1995) and included several specific components: (a) developing a personal model of social anxiety for each patient that is consistent with the general model presented; (b) safety behaviors and self-focused attention experiments; (c) shifting focus of attention to the social situation; (d) video feedback; (e) behavioral experiments; (f) identifying problematic anticipatory and postevent processing; and (g) challenging dysfunctional assumptions. Results from the trial showed that cognitive therapy was superior to the individual exposure plus relaxation

on all social anxiety measures at posttreatment and at the 3-month follow-up. At the 1-year follow-up, differences between conditions were less marked, but cognitive therapy continued to outperform individual exposure plus relaxation on most of the social anxiety measures.

In two later randomized trials, Clark's cognitive therapy was compared with interpersonal psychotherapy (Stangier, Schramm, Heidenreich, Berger, & Clark, 2011) and psychodynamic therapy (Leichsenring et al., 2013). CT was found to have superior response rates in comparison to both interpersonal psychotherapy (66% vs. 42%) and psychodynamic therapy (60% vs. 52%) at posttreatment. Taken together, results from these studies suggest that cognitive therapy can have strong outcomes and can outperform waitlist and alternative psychotherapies.

To date, only a small number of studies have compared effective pharmacotherapy treatments to exposure and cognitive therapy elements. In the first published study of this nature, 65 patients with SAD were assigned randomly to one of the four following conditions: CBGT, alprazolam with instructions for self-directed exposure, phenelzine with instructions for self-directed exposure, or placebo with instructions for self-directed exposure (Gelernter et al., 1991). All treatments, including the combination of a placebo plus self-exposure instructions, were associated with substantial improvements in severe and chronic social anxiety, although the results failed to demonstrate definitively the superiority of one treatment over another.

An important multisite (the State University of New York at Albany, Center for Stress and Anxiety Disorders, and the New York State Psychiatric Institute) collaborative project directed by Richard Heimberg and Michael Liebowitz randomly assigned 133 individuals with SAD to one of the following four treatment conditions: CBGT, phenelzine, a psychological placebo (educational supportive group therapy), and a pill placebo (Heimberg et al., 1998). Results indicated that CBGT and phenelzine were equally effective after 12 weeks of treatment, with approximately 60% of patients completing treatment in each group showing substantial improvement. Both were superior to supportive group therapy and pill placebo, which produced improvement rates of approximately 27% and 33%, respectively. After 12 weeks, phenelzine was more effective than CBGT on some self-report measures.

Following the acute phase of the study, responders to this trial entered a 6-month maintenance phase followed by a 6-month treatment-free phase (Liebowitz et al., 1999). No significant differences were detected between the phenelzine patients and CBGT patients during the maintenance phase or the treatment-free phase, although the relapse rate in the phenelzine group (3/14) was higher than in the CBGT group (0/14) at the end of the treatment-free phase.

Another small set of studies have examined whether combination therapy confers additional benefits in comparison to monotherapy. For instance, Clark and colleagues compared cognitive therapy, fluoxetine combined with self-exposure, and placebo combined with self-exposure in patients with generalized SAD (Clark et al., 2003). At posttreatment (16 weeks), results indicated that the results in the patients receiving cognitive therapy were superior to those in patients in other two groups (which did not differ from each other) on all measures of social anxiety. Following the posttreatment assessment, individuals in the placebo-plus-exposure condition were withdrawn from the study, and the remaining patients entered a 3-month booster phase where up to three additional treatment sessions were administered. In addition, patients in the fluoxetine-plus-exposure condition maintained the full dose of fluoxetine. Following the booster session, the cognitive therapy condition was superior to fluoxetine-plus-exposure on five measures of social anxiety. These findings were maintained at the 12-month follow-up, suggesting both the superiority and the durability of cognitive therapy as compared with fluoxetine plus exposure. In addition, the effect sizes for the cognitive therapy condition were double those reported by Heimberg and colleagues (Heimberg et al., 1998).

Another large-scale, multisite RCT compared five treatment conditions for 295 participants diagnosed with SAD: fluoxetine, comprehensive cognitive-behavioral group therapy (CCBT, a modification of CBGT that includes a social skills training component), pill placebo, and their combination (Davidson et al., 2004). Although participants in the fluoxetine condition were significantly improved after 4 weeks (as compared with all other treatment conditions), by the end of 14 weeks there were no significant differences between the four active treatments on measures of social anxiety symptoms, and all active treatments were better than placebo. In addition, response

rates did not differ between the fluoxetine-only group, the CCBT group, the fluoxetine-plus-CCBT group, and the placebo-plus-CCBT group (all significantly better than placebo).

Other more recent RCTs have compared the combination of other medications with CBT. Blanco, Heimberg, and colleagues (2010) compared CBGT, phenelzine sulfate, pill placebo, and CBGT plus phenelzine in a sample of 128 individuals with SAD. After 12 weeks of acute treatment and an additional 12 weeks of intensive continuation treatment, those in the combined treatment and phenelzine groups experienced significantly greater improvements on a number of continuous self-report and clinician-rated measures, with the combined treatment seeing the largest effects. Contrary to prior research (Heimberg et al., 1998), the CBGT group did not exhibit significant differences from the placebo group on continuous measures of symptom severity at 12 weeks. At the end of the continuation phase (at 24 weeks), the combined treatment was still superior, and the two monotherapies performed more similarly. After 24 weeks, 78.1% of the combined treatment group responded (CGI score ≤ 2), compared to 52.9%, 48.6%, and 33.3% of those receiving CBT, phenelzine, or pill placebo respectively.

Similar to the previous discussion of PD treatment, a series of studies conducted in recent years have also examined the benefit of augmenting CBT with DCS for those with SAD (Guastella et al., 2008; Hofmann et al., 2006, 2013). Results from these studies have been mixed: Whereas the two earlier studies by Hofman and Guastella showed a moderate benefit of augmenting CBT with DCS, a larger, multisite RCT conducted by Hofman and colleagues (2013) did not. Hofmann and colleagues randomized 169 individuals with SAD to 12 weeks of CBT augmented with DCS or CBT with pill placebo. While DCS augmentation was associated with a 24% to 33% faster rate of improvement in symptom severity and remission rates, at posttreatment there were no significant differences in response or remission rates between the two conditions.

Based on the empirical research, we can conclude that combined exposure and cognitive therapy treatments are superior to waitlist, nonspecific therapy, and, in some cases, alternative therapies. It is unclear at this point whether the combination of CBT and pharmacotherapy is superior to monotherapy. There is some evidence to suggest the benefit of combination CBT and phenelzine over monotherapy, mixed evidence supporting the augmentation of CBT with DCS, and little evidence suggesting any benefit to combination CBT and fluoxetine.

Psychological Intervention Guidelines

If we return to the psychological intervention guidelines template mentioned above, exposure-based therapies and cognitive therapy are the only treatments for SAD that attain the highest level of treatment efficacy, "better than alternative therapy." Moreover, there is some evidence to support the idea that combining exposure with cognitive restructuring is even more effective than exposure alone (Butler et al., 1984; Hofmann et al., 2004; Mattick & Peters, 1988; Mattick et al., 1989).

Table 14.3 (adapted from Barlow & Lehman, 1996) indicates that combining exposure and cognitive therapy is more effective than exposure alone or educational supportive group psychotherapy in all but one case. In this study (Hope, Heimberg, & Bruch, 1995), CBGT and exposure alone were equally effective, and both were superior to waitlist control. In addition, the four studies involving Clark and Wells' (1995) cognitive therapy indicate superior performance compared to exposure, interpersonal, and psychodynamic therapies. Both Heimberg's CBT and Clark and Wells' cognitive therapy are first-line treatments according to the NICE clinical guidelines (NICE, 2013).

It is less clear whether the combination of psychotherapy and medications is more effective than psychotherapy alone. As we have noted, existing studies that have evaluated the combination of psychotherapy and medications versus psychotherapy alone have produced mixed findings (e.g., Blanco et al., 2010; Davidson et al., 2004; Gelernter et al., 1991; Guastella et al., 2008; Hofmann et al., 2006). Future research will be needed to clarify under what conditions combination treatment is beneficial. For instance, Smits and colleagues (2013) found a moderating effect of in-exposure success for the benefit of augmenting exposure therapy with DCS. In other words, when exposure sessions ended in low fear, individuals who received DCS reported significantly greater improvement at the next session compared to those who received placebo.

TABLE 14.3 Controlled Trials of Psychosocial Treatments for Social Anxiety Disorder

Adapted from Barlow, D. H., & Lehman, C. (1996). Advances in the psychosocial treatment of anxiety disorders: Implications for national health care. *Archives of General Psychiatry*, 53, 727–735.

In sum, looking at other treatment approaches, at this time we cannot definitively state that SST or relaxation is better than no therapy or in combination with other treatments, like exposure. This is partially due to the methodological limitations of these studies.

Future Directions

While more research is needed to confirm the effectiveness of these treatments, a greater focus on dissemination also is warranted. Along these lines, recent evidence suggests that using a CBT-based therapist guide and corresponding client workbook for SAD can be effective, aiding in dissemination (Goldin et al., 2012; Ledley et al., 2009). In addition, group treatment for SAD can be conducted in an intensive format over a period of 1 to 2 weeks, as opposed to several months, with patients continuing to improve 1 to 5 years after treatment (Mörtberg, Berglund, & Sundin, 2005; Mörtberg, Clark, & Bejerot, 2011). Similar to panic, agoraphobia, and specific phobias, virtual reality is also a possible avenue for increasing the dissemination of treatments for SAD, with some recent evidence suggesting that it can be as effective as standard group therapy (Anderson et al., 2013; Hedman et al., 2011; Klinger et al., 2005). Short-term, intensive treatments or virtual reality treatments would facilitate dissemination by reducing costs and therapist involvement, thus allowing efficacious treatments to be more readily available to clinicians and patients.

GENERALIZED ANXIETY DISORDER

The diagnostic criteria for GAD have undergone substantial modification over the past three decades (Brown, O'Leary, & Barlow, 2001b). In the past, the diagnostic category of GAD, first formulated in 1980 (APA, 1980), resulted in enormous confusion (Barlow, 1988, 2002; Barlow & Wincze, 1998). This was partly due to its residual status, which meant that the diagnosis of GAD could not be assigned if a person met criteria for any other mental disorder (Brown et al., 2001b). This convention was based on the notion that generalized anxiety was an integral part of many disorders and therefore could not be easily separated from the general clinical presentation. In the *DSM-III-R* (APA, 1987), for the first time key defining features (e.g., excessive worry and persistent somatic concerns) were presented that elevated GAD beyond a strictly residual category (Brown et al., 2001b). These criteria were further delineated and sharpened by the *DSM-IV* and *DSM-IV-TR* (APA, 1994, 2000), as the number of associated physical symptoms associated with worry was reduced and the lack of control over worry was highlighted as a diagnostic feature. The diagnostic criteria for the *DSM-5* have not changed from *DSM-IV*, and recent estimates suggest the lifetime prevalence of GAD to be 6.2% (APA, 2013; Kessler et al., 2012).

As a result of changes in the diagnostic criteria and new data on prevalence, the number of research studies on important characteristics of GAD, as well as empirical treatment outcome studies, has increased in recent years. However, given that GAD may be the "basic" anxiety disorder in the sense that generalized anxiety is a consistent component of other anxiety disorders (with the possible exception of specific phobia), treatments for GAD have received surprisingly little attention (Barlow, 1988, 2002; Brown et al., 2001b). In fact, Dugas and colleagues have consistently found that GAD is one of the least studied anxiety disorders over the past 20 years, second only to specific phobias (Dugas, 2000; Dugas, Anderson, Deschenes, & Donegan, 2010). However, of the relatively small number of publications focused on GAD, approximately 44% have been on treatment research in the past 15 years (Dugas et al., 2010).

Our model (Barlow, 1988, 2000, 2002) of the etiology of GAD suggests that biological and psychological vulnerabilities line up to create a diathesis for chronic anxiety. Stress-related negative life events trigger neurobiological reactions such as increased corticotropin-releasing factor, chronic activation of the hypothalamic-pituitary-adrenocortical axis, and the sense that events are proceeding in an uncontrollable and unpredictable way. The focus of attention is shifted from the task at hand to a maladaptive self-evaluative mode, which further increases arousal. This results in increased vigilance and the narrowing of attention to the threat or challenge. This arousal-driven cognitive process continues to escalate in a negative feedback loop, resulting occasionally in performance disruption, attempts to cope, including situational avoidance, if possible, and/or a maladaptive worry process that seems to serve as a method of avoiding core negative affect (Barlow, 2000, 2002; Borkovec, 1994; Craske, 1999).

Until recently, clinical outcome studies have demonstrated only modest treatment gains for GAD compared to treatment gains with other anxiety disorders. These less satisfying results have been hypothesized to result from, among other things, the high rates of comorbidity found in patients with GAD and the fact that GAD tends to be chronic, as patients often recall a lifelong history of the disorder (cf. Brown et al., 2001a).

Given the vagueness of earlier criteria, initial studies on the treatment of GAD used nonspecific treatment approaches such as relaxation or biofeedback. It has only been in the past two decades, since the *DSM-IV* was introduced, that more rigorous controlled trials of treatment for GAD have been conducted, using more specific treatment techniques such as cognitive and behavior therapy as well as combinations of several treatment components aimed at targeting the key features of the disorder.

To properly evaluate the question of treatment choice, one must consider both the efficacy of the treatment and the clinical utility of that technique. In this section, as above, the treatment techniques reviewed focus on treatment efficacy. However, because there are fewer treatment outcome studies for GAD (relative to the other disorders reviewed in this chapter) and because many studies test multiple active treatments, this section is organized in three categories of increasing confidence in treatment efficacy: (a) better than no therapy (RCTs), (b) better than nonspecific therapy (RCTs), and (c) better than alternative therapy (RCTs).

Better than No Therapy

Some researchers have found that active treatment is preferable to no therapy but that different active treatments may not exhibit differential efficacy. In a study conducted in our center (Barlow, Rapee, & Brown, 1992), 65 patients meeting the *DSM-III-R* criteria for GAD were randomized to one of four treatment groups: applied progressive muscle relaxation, cognitive restructuring, a combination of relaxation and cognitive restructuring, or a waitlist control. All patients in the active treatment conditions received 15 hour-long sessions. Treated patients were significantly better compared with those in the waitlist control group. However, as stated above, differential efficacy was not found among active treatment components. Moreover, differential dropout rates were encountered among the active treatments (8% in the combination group to 38% in the relaxation group).

More recently, two separate studies have been conducted comparing a new CBT for GAD compared with a waitlist control group (Dugas et al., 2003; Ladouceur et al., 2000). Based on recent research suggesting the role of intolerance of uncertainty in GAD, the authors used a treatment protocol that specifically targets worry (e.g., components are aimed to target four aspects of GAD: intolerance of uncertainty, erroneous beliefs about worry, poor problem orientation, and cognitive avoidance). In the first trial using an individual treatment protocol, 26 patients were included (14 received immediate treatment, 12 were assigned to a delayed-treatment waitlist control). Results indicated that, compared to the waitlist control, patients in the treatment condition showed greater improvements on outcome measures that were maintained through the 1-year follow-up (Ladouceur et al., 2000). Additionally, 77% no longer met criteria for GAD following treatment. In the second trial, which included treatment components of awareness training (i.e., learning to be aware of worries) and cognitive exposure (i.e., each patient recorded a "worst fear" on an audiotape and listened to the recording daily, until the scenario no longer provoked anxiety), 52 GAD patients received 14 sessions of group therapy for their symptoms (Dugas et al., 2003). Of these, 25 received immediate treatment and 27 were assigned to a delayed-treatment control condition. At posttreatment, treated patients demonstrated significant improvement on all measures compared with waitlist patients, and results were maintained through the 24-month follow-up. The authors suggest that group CBT may be a viable and less costly option for individuals with GAD (Dugas et al., 2003).

Another newer treatment approach for GAD draws from traditional components of CBT, including psychoeducation, monitoring, and relaxation exercises, as well as strategies from other therapies such as Acceptance and Commitment Therapy (ACT; Hayes, Strosahl, & Wilson, 2011), Dialectical Behavior Therapy (DBT; Linehan, 1993), and MBCT (Segal, Williams, & Teasdale, 2002). The new treatment, Acceptance-Based Behavior Therapy (ABBT) for GAD, encourages acceptance and awareness of worry, rather than thought challenging, and mindful action as an alternative to the habitual inaction that often results from the worry associated with GAD (Orsillo, Roemer, & Barlow, 2003). A small-scale RCT comparing ABBT and delayed treatment in 31 individuals with GAD found that ABBT was associated with greater improvements in GAD severity, worry, and depressive symptoms at posttreatment that were maintained through the 3- and 9-month follow-up periods (Roemer, Orsillo, & Salters-Pedneault, 2008). At posttreatment, 75% of participants treated with ABBT were categorized as responders to treatment versus 8.3% of those in the delayed-treatment condition.

Better than Nonspecific Therapy

Several controlled clinical trials have found that a specific treatment for GAD is better than nondirective treatment (Borkovec & Costello, 1993; Borkovec et al., 1987; Gosselin, Ladouceur, Morin, Dugas, & Baillargeon, 2006). In an early study (Borkovec et al., 1987), 30 patients who met the *DSM-III* criteria for GAD were randomly assigned to one of two groups: progressive muscle relaxation with cognitive therapy or progressive muscle relaxation with nondirective therapy. Overall, all patients improved substantially by the end of treatment and also at the 6-to 12-month follow-up, as shown by clinician ratings, self-report questionnaires, and daily self-monitoring. However, the group receiving cognitive therapy was superior to the group receiving nondirective therapy on all but one posttreatment outcome measure. In addition, patients receiving cognitive therapy attributed more of their improvement to the cognitive component of treatment than patients receiving nondirective therapy did to the general psychotherapy

they received. The authors concluded that cognitive therapy contains an active ingredient above and beyond the nonspecific psychotherapy treatment factors.

Similar results were found when Gosselin and colleagues (2006) examined whether CBT facilitated a benzodiazepine tapering program. Sixty-one patients with GAD were randomized to undergo a 12-week gradual medication discontinuation protocol combined with either CBT or a nonspecific psychological treatment. Patients who received CBT were approximately twice as likely to discontinue benzodiazepines than the nonspecific treatment group (74% vs. 37%) at posttreatment, and results were maintained over a year-long follow-up period. Patients who underwent CBT were also more likely to no longer meet criteria for GAD at posttreatment (36% vs. 80%).

Better than Alternative Therapy

A final group of studies has been conducted that compares at least two efficacious psychotherapy treatments to each other. According to the template, demonstrated efficacy in this category results in the highest level of confidence in a given treatment. Although most investigations of this type have not resulted in significant differences emerging among active treatments (Barlow et al., 1992; Blowers et al., 1987; Borkovec & Mathews, 1988; Durham & Turvey, 1987; Hayes-Skelton et al., 2013; White & Keenan, 1992), a few empirical studies have demonstrated the superiority of one active treatment over another (Butler, Fennell, Robson, & Gelder, 1991; Dugas et al., 2010; Durham et al., 1994; Wells et al., 2010).

In an empirical investigation, 57 patients meeting the *DSM-III-R* criteria for GAD were randomly assigned to one of three treatment groups: CBT, behavior therapy, or a waitlist control group (Butler et al., 1991). In this controlled clinical trial, independent assessments were conducted before treatment, at the end of treatment, at a 6 month follow-up, and at an 18 month follow-up. Treatment lasted for up to 12 sessions; patients and their therapists could agree to conclude treatment after a minimum of 4 sessions if the patients' anxiety levels were low and stable. The behavior therapy package consisted of progressive muscle relaxation, reducing avoidance through graduated exposure, and building confidence by reinitiating pleasurable activities. The rationale for behavior therapy was that anxiety is maintained by avoidance of anxiety-producing situations, the person's reaction to the symptoms, and loss of confidence. The CBT package consisted of cognitive therapy as described by Beck and Emery (1985), as well as behavioral assignments. The rationale for CBT treatment was that anxiety is maintained by anxious thoughts and lack of self-confidence, which can be controlled by recognizing anxious thoughts, seeking helpful alternatives, and taking action to test these alternatives. Results showed a superiority of CBT over behavior therapy, as demonstrated through measures of anxiety, depression, and cognition. However, the patients in the behavior therapy group had improved significantly on all but one measure of anxiety and maintained their gains 6 months later.

As noted in an earlier section, Borkovec and Costello (1993) compared the efficacy of CBT, applied relaxation, and nondirective treatment in a sample of 55 patients who met the *DSM-III-R* criteria for GAD. For this study, patients in the nondirective treatment condition were told that the goals of treatment were to enhance self-understanding and to discover things they could do differently to affect how they feel. All three treatments were reported to be highly credible to the patients. The relaxation and CBT treatment conditions did not differ significantly from each other but were both superior to ND at posttreatment. However, during a 1-year follow-up, 57.9% of patients receiving CBT met a high end-state functioning criterion (meaning they were close to "cured"), whereas only 33.3% of patients in the relaxation group and 22.2% of patients receiving nondirective therapy met this criterion.

Additional research has also suggested that a comprehensive CBT package is not necessarily more efficacious than the individual protocol components. Borkovec, Newman, Pincus, and Lytle (2002) compared three treatments for GAD: (a) applied relaxation training combined with self-control desensitization, (b) cognitive therapy, and (c) their combination (CBT). Contrary to expectations, there were no significant differences among the three groups on self-report or clinician-rated measures, suggesting that applied relaxation, self-control desensitization, and cognitive therapy are not necessarily more efficacious when used in combination.

In comparisons of CBT approaches to pharmacological treatment, CBT has also been shown to be superior to benzodiazepines in several controlled

clinical trials (Lindsay, Gamsu, McLaughlin, Hood, & Espie, 1987; Power et al., 1990; Power, Jerrom, Simpson, Mitchell, & Swanson, 1989). In one study (Power et al., 1990), 101 patients meeting the *DSM-III* criteria for GAD were randomly assigned to one of the following 10-week treatment conditions: CBT, diazepam, placebo, CBT plus diazepam, or CBT plus placebo. Posttreatment and 6-month follow-up measures indicated the superiority of all CBT treatments, especially CBT alone and the CBT-plus-diazepam combination. For more information on psychopharmacological treatments of GAD, please refer to Chapter 13.

More recently, three newer forms of CBT have been compared to an alternative treatment (applied relaxation) in a series of controlled trials (Dugas et al., 2010; Hayes-Skelton, Roemer, and Orsillo, 2013; Wells et al., 2010). Dugas and colleagues (2010) compared their form of CBT, which targets intolerance of uncertainty, to relaxation and a delayed-treatment waitlist condition in a sample of 65 adults with GAD. Participants completed 12 weeks of CBT or relaxation training and were followed for 24 months. At posttreatment, they found CBT was superior to waitlist on overall GAD severity as assessed by clinician severity ratings and measures of pathological worry, somatic symptoms of GAD, and global clinical improvement. Relaxation was only superior to waitlist on overall severity of GAD. CBT was superior to relaxation on global clinical improvement but not other measures. However, the CBT condition was associated with significant improvements in worry, trait anxiety, and global clinical improvement over the 2-year follow-up period, whereas the relaxation condition was not, suggesting some additional benefit of CBT over relaxation training.

Metacognitive therapy, yet another new form of CBT, consists of 8 to 12 weekly individual sessions and focuses on modifying erroneous negative metacognitive beliefs, positive metacognitive beliefs, and unhelpful thought-control strategies (Wells & King, 2006). This therapy is based on the idea that metacognitive processes involved in worry are particularly important to the development of GAD, specifically beliefs about the dangerousness and uncontrollability of worry (Wells, 1995). A small RCT comparing metacognitive therapy and applied relaxation (N = 20; Wells et al., 2010) found that 80% of individuals with GAD who participated in metacognitive therapy recovered versus 10% of participants in the relaxation group. Recovery was defined using trait anxiety scores, although significant improvements were found in worry and depression as well. Participants who underwent metacognitive training maintained their recovery status over a 6- and 12-month follow-up and continued to outperform the relaxation group over time (70% recovery rate for the metacognitive group at 6 and 12 months vs. 20% for the relaxation group at both follow-up assessments). However, while these results are promising, the small sample size and low rates of response to applied relaxation indicate a need to confirm the findings from this RCT.

Taking this literature a step further, van der Heiden, Muris, and van der Molen (2012) recently conducted an RCT comparing metacognitive therapy and Dugas and colleagues' version of CBT, referred to here as Intolerance of Uncertainty Therapy (IUT; Dugas et al., 2003). The sample included 126 patients diagnosed with GAD who were randomized to metacognitive therapy, IUT, or a delayed-treatment condition. The active treatment conditions consisted of up to 14 weeks of individual sessions, and participants completed assessments before treatment, at the end of treatment, and at a 6-month follow-up. Both metacognitive therapy and IUT outperformed delayed treatment on reductions in worry, trait anxiety, and depressive symptoms, as well as the percentage of clients no longer meeting diagnostic criteria for GAD at posttreatment (metacognitive therapy, 93%; IUT, 80%; delayed treatment 5%). Improvements were maintained at the 6-month follow-up. When examining the intent-to-treat sample, patients in the metacognitive therapy condition exhibited significantly greater reductions in worry, depressive symptoms, and trait anxiety than the IUT group, although differences were less pronounced when examining the subset of the sample who completed treatment.

Although promising results were found with both treatment conditions and some suggested additional benefit of metacognitive therapy over IUT, further research is needed to have a better understanding of the comparative effects of these treatments. Van der Heiden and his colleagues noted the performance of IUT may not have been fully representative in this trial, as they made some changes to the protocol and the developers of IUT themselves made a change to the protocol while the study was being conducted (Dugas & Robichaud, 2007). In this trial, reevaluation of positive beliefs about worry was moved to later in the protocol and patients engaged in exposure

to worry images not conducive to problem solving instead of listening to recordings of the worry images on a looped tape. While this study was under way, Dugas and colleagues added uncertainty recognition and behavioral exposures to their treatment.
