

THOMAS J. NECHYBA

MICROECONOMICS

AN INTUITIVE APPROACH

WITH CALCULUS

2ND EDITION

APPLICATIONS INCLUDED IN THIS TEXT

Chapter 2

EVERYDAY APPLICATIONS

Watching a Bad Movie
Renting Car vs. Taking Taxis
Dieting and Nutrition
Setting up a College Trust Fund

BUSINESS APPLICATIONS

Pricing and Quantity Discounts
“Supersizing”
Frequent Flyer Perks
Choice in Calling Plans

POLICY APPLICATIONS

Food Stamp Programs and Other Types of Subsidies
Public Housing and Housing Subsidies
Taxing Goods vs. Lump Sum Taxes
Public Schools and Private School Vouchers
Tax Deductions and Tax Credits

Chapter 3

EVERYDAY APPLICATIONS

Robots as Labor-Saving Products
Investing for Retirement
Different Interest Rates for Borrowing and Lending

BUSINESS APPLICATIONS

Present Value of Winning Lottery Tickets
Picking Savings Accounts
Compound Interest over the Long Run
Pricing Government Bonds
Buying Houses with Annuities
A Trick for Calculating the Value of Annuities

POLICY APPLICATIONS

Wage Taxes and Budget Constraints
Proportional vs. Progressive Wage Taxes
Social Security (or Payroll) Taxes
AFDC vs. a Negative Income Tax
The Earned Income Tax Credit
Three Proposals to Deal with the Social Security Shortfall

Chapter 4

EVERYDAY APPLICATIONS

Rating Movies on a Numerical Scale
Did 9/11 Change Tastes?
Tastes of a Cocaine Addict

BUSINESS APPLICATIONS

Tastes for Cars and Product Characteristics
Investor Tastes over Risk and Return

POLICY APPLICATIONS

Ideology and Preferences of Politicians
Subsistence Levels of Consumption

Chapter 5

EVERYDAY APPLICATIONS

Personality and Tastes for Current and Future Consumption
Thinking about Old Age
Tastes for Paperclips
Inferring Tastes for “Mozartkugeln”
Syllabi-Induced Tastes over Exam Grades

Chapter 6

EVERYDAY APPLICATIONS

Price Fluctuations in the Housing Market
Different Interest rates for Borrowing and Lending

BUSINESS APPLICATIONS

Quantity Discounts and Optimal Choices
Retail Industry Lobbying for Daylight Savings Time

POLICY APPLICATIONS

Food Stamp vs. Food subsidies
Gasoline Taxes Tax Rebates
AFDC and Work Disincentives
Cost of Living Adjustments of Social Security Benefits

Chapter 7

EVERYDAY APPLICATIONS

Housing Price Fluctuations
Turkey and Thanksgiving

BUSINESS APPLICATIONS

Sam’s Club and the Marginal Consumer
Are Gucci Products Giffen Goods

POLICY APPLICATIONS

Tax Deductibility and Tax Credits
Substitution Effects and Social Security Cost of Living Adjustments
Fuel Efficiency, Gasoline Consumption and Gas Prices
Public Housing and Housing Subsidies

Chapter 8

BUSINESS APPLICATIONS

Merchandise Exchange Policies

POLICY APPLICATIONS

Savings Behavior and Tax Policy
The Negative Income Tax
The Earned Income Tax Credit
Advising Congress on Savings Subsidies and Substitution Effects
International Trade and Child Labor
Subsidizing Savings and Taxing Borrowing
Tax Revenues and the Laffer Curve

Chapter 9

EVERYDAY APPLICATIONS

Backward-Bending Labor Supply

BUSINESS APPLICATIONS

Price Discounts, Substitutes, and Complements
Good Apples vs. Bad Apples

POLICY APPLICATIONS

Tax and Retirement Policy

Chapter 10

EVERYDAY APPLICATIONS

Teacher Pay and Professional Basketball Salaries
Ordering Appetizers
To Trade or Not To Trade Pizza Coupons
To Join or Not To Join the Local Pool
To Take or Not to Take the Bus

BUSINESS APPLICATIONS

Pricing at Disneyland
Negotiating an Endorsement Deal and a Bribe

POLICY APPLICATIONS

Distortionary Taxes
Price Subsidies
Taxing Interest on Savings
International Trade and Child Labor
Efficient Land Taxes

Chapter 11

EVERYDAY APPLICATIONS

Workers as Producers of Consumption
Studying for an Exam

BUSINESS APPLICATIONS

Optimal Response to Labor Regulations
Technological Change in Production

POLICY APPLICATIONS

Politicians as Producers of Good Feelings
Determining Optimal Class Size

Chapter 12

EVERYDAY APPLICATIONS

To Study or to Sleep?
Fast Food Restaurants and Grease

BUSINESS APPLICATIONS

Fast Food Restaurants and Grease
Investing in Smokestack Filters under Cap and Trade

POLICY APPLICATIONS

Investing in Smokestack Filters under Cap and Trade
Taxes on Firms

Chapter 13

BUSINESS APPLICATIONS

Switching Technologies
Switching Technologies: Short-run vs. Long Run
Fixed Amount of Land for Oil Drilling
Minimum Wage Labor Subsidy
Business Taxes

POLICY APPLICATIONS

Fixed Amount of Land for Oil Drilling
Minimum Wage Labor Subsidy
Business Taxes

Chapter 14

EVERYDAY APPLICATIONS

Fast Food Restaurants and Grease

BUSINESS APPLICATIONS

Fast Food Restaurants and Grease
Brand Names and Franchise Fees
“Economic Rent” and Profiting from Entrepreneurial Skill
Capital Gains Taxes
Using License Fees to Make Positive Profit
Business Taxes
Minimum Wage Labor Subsidy

POLICY APPLICATIONS

Capital Gains Taxes
Using License Fees to Make Positive Profit
Business Taxes
Minimum Wage Labor Subsidy
School Vouchers and the Private School Market
Public School Teacher Salaries, Class Size, and Private School Markets
Pollution Taxes on Output

Chapter 15

EVERYDAY APPLICATIONS

Labor-Saving Technologies

BUSINESS APPLICATIONS

Disneyland Pricing Revisited
License Fees and Surplus without Income Effects

POLICY APPLICATIONS

License Fees and Surplus without Income Effects
Redistribution of Income without Income Effects
Deadweight Loss from Subsidy of Mortgage Interest
Markets, Social Planners, and Pollution
Anti-Price Gauging Laws

Chapter 16

EVERYDAY APPLICATIONS

Children, Parents, Baby Booms, and Baby Busts
Parents, Children, and the Degree of Substitutability across Time

BUSINESS APPLICATIONS

Valuing Land in Equilibrium
Hiring an Assistant

POLICY APPLICATIONS

Distortionary Taxes and Redistribution
Distortionary Taxes in General Equilibrium
The Laffer Curve in General Equilibrium

Chapter 17

EVERYDAY APPLICATIONS

Gambling on Sporting Events
Teenage Sex and Birth Control
Gambling with Different Beliefs
Venice and Regret

BUSINESS APPLICATIONS

Choosing a Mafia for Insurance
Diversifying Risk along the Business Cycle
Diversifying Risk along the Business Cycle in General Equilibrium
Local vs. National Insurance

POLICY APPLICATIONS

More Police or More Jails?
More Police or More Teachers?
Enforcement vs. Education

Chapter 18

EVERYDAY APPLICATIONS

Scalping College Basketball Tickets

BUSINESS APPLICATIONS

Minimum Wage Laws
Usury Laws
Subsidizing Corn Through Price Floors

POLICY APPLICATIONS

Minimum Wage Laws
Usury Laws
Subsidizing Corn Through Price Floors
Rent Control
NYC Taxi Cab Medallions
Kidney Markets
Oil Shocks and Gasoline Prices

Chapter 19

BUSINESS APPLICATIONS

City Wage Taxes
Land Use Policies
Price Floors for Corn: Is It a Tax or a Subsidy?

POLICY APPLICATIONS

City Wage Taxes
Land Use Policies
Price Floors for Corn: Is It a Tax or a Subsidy?
Rent Control: Is It a Tax or a Subsidy?
Incidence of U.S. Social Security Taxes
Mortgage Interest Deductibility, Land Values, and the Equilibrium Rate of Return
The Split-Rate Property Tax

Chapter 20

EVERYDAY APPLICATIONS

Quality of Life Indexes
Trade, Migration, and the Price of a Haircut
Compensating Wage Differentials and Increased Worker Safety
Adaptive Expectations and Oil Price Instability

BUSINESS APPLICATIONS

Compensating Wage Differentials and Increased Worker Safety
Adaptive Expectations and Oil Price Instability
The Risks of Short-Selling
Pricing Call and Put Options
General Equilibrium Effects of a Property Tax
Local Differences in Property Taxes

POLICY APPLICATIONS

General Equilibrium Effects of a Property Tax
Local Differences in Property Taxes
U.S. Immigration Policy
Trade Barriers against “Unfair” Competition

Chapter 21

EVERYDAY APPLICATIONS

Children’s Toys and Gucci Products

BUSINESS APPLICATIONS

Fishing in the Commons
The Externality when Fishing in the Commons
Network Externalities and the Battle between Microsoft and Apple
Pollution that Increases Firm Costs—The Market Outcome

POLICY APPLICATIONS

The Externality when Fishing in the Commons
Pollution that Increases Firm Costs—Barney’s Solution
Pollution that Increases Firm Costs—Policy Solutions
Social Norms and Private Actions

Chapter 22

EVERYDAY APPLICATIONS

Non-Random “Selection” is Everywhere

BUSINESS APPLICATIONS

Competitive Provision of Health Insurance

POLICY APPLICATIONS

Expanding Health Insurance Coverage
Moral Hazard versus Adverse Selection in Health Care Reform
Statistical Profiling in Random Car Searches

continued

APPLICATIONS INCLUDED IN THIS TEXT *continued*

Chapter 23

EVERYDAY APPLICATIONS

Diamonds Are a Girl's Best Friend

BUSINESS APPLICATIONS

Diamonds Are a Girl's Best Friend
Monopoly Pricing in Health Insurance Markets
Second Degree Price Discrimination in Health Insurance Markets
Labor Unions Exercising Market Power
Monopsony: A Single Buyer in the Labor Market
Taxing Monopoly Output
Two Natural Monopolies: Microsoft vs. Utility Companies

POLICY APPLICATIONS

Monopoly Pricing in Health Insurance Markets
Second Degree Price Discrimination in Health Insurance Markets
Labor Unions Exercising Market Power
Monopsony: A Single Buyer in the Labor Market
Taxing Monopoly Output
Two Natural Monopolies: Microsoft versus Utility Companies
Some Possible "Remedies" to the Monopoly Problem
Pollution and Monopolies
Regulating Market Power in the Commons

Chapter 24

EVERYDAY APPLICATIONS

Splitting the Pot
Another Way to Split the Pot
Real-World Mixed Strategies
Burning Money, Iterated Dominance, and the Battle of the Sexes
Bargaining Over a Fixed Amount
Auctions
Education as a Signal
To Fight or Not to Fight
Reporting a Crime

BUSINESS APPLICATIONS

Bargaining Over a Fixed Amount
Auctions
Monopoly and Price Discrimination
Carrots and Sticks: Efficiency Wages and the Threat of Firing Workers
Education as a Signal
To Fight or Not to Fight

POLICY APPLICATIONS

Negotiating with Pirates, Terrorists (and Children)
Education as a signal
To Fight or Not to Fight
Reporting a Crime
Some Prisoner's Dilemmas

Chapter 25

BUSINESS APPLICATIONS

Entrepreneurial Skill and Market Conditions
Quitting Time: When to Exit a Declining Industry
Financing a Strategic Investment under Quantity Competition
Financing a Strategic Investment under Price Competition
Deal or No Deal—Acquisitions of Up-Start Firms by Incumbents
Production Quotas under Cartel Agreements

POLICY APPLICATIONS

Production Quotas under Cartel Agreements
Mergers, Cartels, and Antitrust Enforcement
Subsidizing an Oligopoly
Government Grants and Cities as Cartels

Chapter 26

EVERYDAY APPLICATIONS

Cities and Land Values

BUSINESS APPLICATIONS

Mergers and Antitrust Policy in Related Product Markets
Advertising as Quality Signal
Price Leadership in Differentiated Product Markets
The Evolution of the Fashion Industry
Deterring Entry of Another Car Company
The Software Industry

POLICY APPLICATIONS

Mergers and Antitrust Policy in Related Product Markets
Lobbying for Car Import Taxes
The Software Industry
To Tax or Not to Tax Advertising

Chapter 27

EVERYDAY APPLICATIONS

Sandwiches, Chess Clubs, Movie Theaters, and Fireworks
Competitive Local Public and Club Good Production
Raising Money for a Streetlight through a "Subscription Campaign"

BUSINESS APPLICATIONS

Competitive Local Public and Club Good Production
Raising Money for a Streetlight through a "Subscription Campaign"
The Marketing Challenge for Social Entrepreneurs

POLICY APPLICATIONS

Competitive Local Public and Club Good Production
Demand for Charities and Tax Deductibility
Do Antipoverty Efforts Provide a Public Good?
Distortionary Taxes and National Security
Social Norms and Private Actions
The Pork Barrel Commons
Local and National Public Goods as Pork Barrel Projects

Chapter 28

EVERYDAY APPLICATIONS

Why Vote?
"Winner-Take-All" Elections and the U.S. Electoral College
To Enter or Not to Enter the Race
Citizen Candidates

BUSINESS APPLICATIONS

Voting with Points

POLICY APPLICATIONS

Voting with Points
Interest Groups, Transactions Costs, and Vote Buying
Political Coalitions and Public School Finance Policy
Government Competition, Leviathan, and Benevolence
The Pork Barrel Commons and the "Law of 1/N"

Chapter 29

EVERYDAY APPLICATIONS

Reference Points, Happiness, and Envy
Extreme Altruism and Normative Economics
Framing the Options: Praying while Smoking, and Fighting Pandemics
Teaser Rates on Credit Cards and Mortgages
Impatient versus Present-Biased Students
Endowment Effects and Housing Markets

BUSINESS APPLICATIONS

Teaser Rates on Credit Cards and Mortgages
Endowment Effects and Housing Markets
The Equity Premium Puzzle
Increased Liquidity, Procrastination, and National Savings

POLICY APPLICATIONS

Impatient versus Present-Biased Students
Increased Liquidity, Procrastination, and National Savings
First- and Second-Best Rawlsian Income Redistribution
Confirmation Bias, Politics, Research, and Last-Minute Studying
Smoothing the Business Cycle versus Fostering Economic Growth: Psychology Meets Normative Macroeconomics

BRIEF CONTENTS

Chapter 0: Foundational Preliminaries (web-based chapter)	
Chapter 1: Introduction	1
PART 1: Utility-Maximizing Choice: Consumers, Workers, and Savers	21
Chapter 2: A Consumer's Economic Circumstances	25
Chapter 3: Economic Circumstances in Labor and Financial Markets	49
Chapter 4: Tastes and Indifference Curves	75
Chapter 5: Different Types of Tastes	113
Chapter 6: Doing the "Best" We Can	143
Chapter 7: Income and Substitution Effects in Consumer Goods Markets	180
Chapter 8: Wealth and Substitution Effects in Labor and Capital Markets	215
Chapter 9: Demand for Goods and Supply of Labor and Capital	245
Chapter 10: Consumer Surplus and Deadweight Loss	277
PART 2: Profit-Maximizing Choice: Producers (or "Firms")	321
Chapter 11: One Input and One Output: A Short-Run Producer Model	324
Chapter 12: Production with Multiple Inputs	367
Chapter 13: Production Decisions in the Short and Long Run	413
PART 3: Competitive Markets and the "Invisible Hand"	463
Chapter 14: Competitive Market Equilibrium	466
Chapter 15: The "Invisible Hand" and the First Welfare Theorem	505
Chapter 16: General Equilibrium	535
Chapter 17: Choice and Markets in the Presence of Risk	578
PART 4: Distortions of the "Invisible Hand" in Competitive Markets	629
Chapter 18: Elasticities, Price-Distorting Policies, and Non-Price Rationing	633
Chapter 19: Distortionary Taxes and Subsidies	673
Chapter 20: Prices and Distortions across Markets	712
Chapter 21: Externalities in Competitive Markets	744
Chapter 22: Asymmetric Information in Competitive Markets	791
PART 5: Distortions of the "Invisible Hand" from Strategic Decisions	837
Chapter 23: Monopoly	841
Chapter 24: Strategic Thinking and Game Theory	885
Chapter 25: Oligopoly	950
Chapter 26: Product Differentiation and Innovation in Markets	989
Chapter 27: Public Goods	1040
Chapter 28: Governments and Politics	1094
PART 6: Considering How to Make the World a Better Place	1129
Chapter 29: What Is Good? Challenges from Psychology and Philosophy	1131
Chapter 30: Balancing Government, Civil Society, and Markets	1180

CONTENTS

Chapter 1: Introduction	1	<i>Accompanying Technology Tools</i>	18
What Is Microeconomics?	2	<i>Modular Online Mini-Lectures</i>	18
<i>Economics as a Science</i>	2	Onward	19
<i>Rationality, Self-Interest, and Indiana Jones</i>	2		
<i>Social Consequences, Pencils, and Global Warming</i>	2		
Economics, Incentives, and Economic Models	3		
<i>Economic Models, Simplicity, and Picasso</i>	4		
<i>Economic Models, Realism, and Billiard Players</i>	4		
<i>An “Unintended” Consequence of Learning through Economic Models</i>	5		
Predicting versus Judging Behavior and Social Outcomes	6		
<i>Positive Economics: How to Predict Real Outcomes</i>	7		
<i>Normative Economics: How to Judge Outcomes</i>	8		
<i>Efficiency: Positive or Normative?</i>	8		
The “Non-Dismal” Science: Some Basic Lessons	9		
<i>Must There Be a Loser for Every Winner?</i>	9		
<i>Can “Good” People Behave “Badly”?</i>	10		
<i>Order: Spontaneous or Created?</i>	10		
The Plan for this Book	11		
<i>Part 1: Individual Choice</i>	12		
<i>Part 2: Competitive Firm Choice</i>	12		
<i>Part 3: Competitive Equilibrium and the Invisible Hand</i>	13		
<i>Part 4: Distortions of the “Invisible Hand” under Competition</i>	14		
<i>Part 5: Distortions of the “Invisible Hand” from Strategic Decision Making</i>	14		
<i>Part 6: Stepping Back to Ask “What Is Good?”</i>	14		
Succeeding in this Course	15		
<i>Parts A and B Chapter Structure and Flexibility</i>	15		
<i>Preparing for the Course through “Chapter Zero”</i>	16		
<i>Within-Chapter Exercises and the Study Guide</i>	16		
<i>End-of-Chapter Exercises</i>	17		
		Part 1: Utility-Maximizing Choice: Consumers, Workers, and Savers	21
		Chapter 2: A Consumer’s Economic Circumstances	25
		2A. Consumer Choice Sets and Budget Constraints	25
		<i>Shopping on a Fixed (or “Exogenous”) Income</i>	26
		<i>Kinky Budgets</i>	30
		<i>Modeling More General Choices</i>	31
		<i>“Endogenous” Incomes That Arise from Endowments</i>	33
		<i>Modeling Constraints Graphically or Mathematically?</i>	35
		2B. Consumer Choice Sets and Budget Equations	35
		<i>Shopping on a Fixed Income</i>	36
		<i>Kinky Budgets</i>	38
		<i>Choice Sets with More Than Two Goods</i>	39
		<i>Choice Sets That Arise from Endowments</i>	40
		Chapter 3: Economic Circumstances in Labor and Financial Markets	49
		3A. Budgets for Workers and Savers	49
		<i>Our Choice Sets as Workers</i>	50
		<i>Constraints We Face in Planning for the Future</i>	53
		<i>Putting It All into a Single Model</i>	56
		3B. Choice Sets and Budget Equations for Workers and Savers	58
		<i>Choice Sets of Workers</i>	59
		<i>Choice Sets as We Plan for the Future</i>	60
		<i>Putting It All in a Single Model</i>	63
		Chapter 4: Tastes and Indifference Curves	75
		4A. The Economic Model of Tastes	75
		<i>Two Fundamental Rationality Assumptions about Tastes</i>	76

Three More Assumptions	77	7B. The Mathematics of Income and Substitution Effects	194
Graphing Tastes	81	The Impact of Changing Income on Behavior	194
4B. Tastes and Utility Functions	87	The Impact of Changing Opportunity Costs on Behavior	196
Two Fundamental Rationality Assumptions	87	Price Changes: Income and Substitution Effects Combined	201
Three More Assumptions	88		
Representing Tastes with Utility Functions	91		
Chapter 4: Appendix	100	Chapter 8: Wealth and Substitution Effects in Labor and Capital Markets	215
Chapter 5: Different Types of Tastes	113	8A. Wealth Effects, Substitution Effects, and Endowments	215
5A. Different Types of Indifference Maps	113	An Increase in the Price of Gasoline for George Exxon	216
Substitutability along an Indifference Curve: Coke, Pepsi, and Iced Tea	114	A Change in Wages	217
Some Common Indifference Maps	118	A Change in (Real) Interest Rates	221
"Essential" Goods	121	8B. Constrained Optimization with Wealth Effects	227
5B. Different Types of Utility Functions	122	George Exxon and the Price of Gasoline	227
Degrees of Substitutability and the "Elasticities of Substitution"	123	A Change in Wages	229
Chapter 5: Appendix	134	A Change in (Real) Interest Rates	234
Chapter 6: Doing the "Best" We Can	143	Chapter 9: Demand for Goods and Supply of Labor and Capital	245
6A. Choice: Combining Economic Circumstances with Tastes	143	9A. Deriving Demand and Supply Curves	245
The "Best" Bundle of Shirts and Pants To Buy or Not to Buy	147	Demand for Goods and Services	246
More than One "Best" Bundle? Non-Convexities of Choice	150	Labor Supply	251
Sets and Tastes	150	Demand and Supply Curves for Financial Capital	253
Learning about Tastes by Observing Choices in Supermarkets or Laboratories	154	9B. Demand and Supply Functions	258
6B. Optimizing within the Mathematical Model	155	Demand for Goods and Services	259
Optimizing by Choosing Pants and Shirts To Buy or Not to Buy: How to Find Corner Solutions	160	Labor Supply	265
Non-Convexities and First Order Conditions	163	Demand for and Supply of Financial Capital	268
Estimating Tastes from Observed Choices	165	Chapter 10: Consumer Surplus and Deadweight Loss	277
Chapter 6: Appendix	166	10A. Measuring Consumer Welfare in Dollars	278
Chapter 7: Income and Substitution Effects in Consumer Goods Markets	180	Consumer Surplus	278
7A. Graphical Exposition of Income and Substitution Effects	181	MWTP and Own-Price Demand Curves	282
The Impact of Changing Income on Behavior	181	What's So Bad about Taxes? Or, Why Is the Bucket Leaking?	285
The Impact of Changing Opportunity Costs on Behavior	184	Deadweight Loss Measured on MWTP Curves	290
Price Changes: Income and Substitution Effects Combined	188	10B. The Mathematics of Consumer Welfare and "Duality"	295
		Duality of Utility Maximization and Expenditure Minimization	295
		Taxes, Deadweight Losses, and Consumer Welfare	301
		Chapter 10: Appendix	305

**PART 2: Profit-Maximizing Choice:
Producers (or “Firms”) 321**

**Chapter 11: One Input and One
Output: A Short-Run Producer Model 324**

11A. A Short-Run One-Input/One-Output Model 325
Technological Constraints Faced by Producers 325
“Tastes” for Profits 330
Choosing the Production Plan that Maximizes Profit 333
Changing the Economic Environment 337
Two-Step Profit Maximization 343

11B. The Mathematics of the Short-Run Model 348
Technological Constraints Faced by Producers 349
“Tastes” for Profits 350
Choosing the Production Plan that Maximizes Profits 351
Labor Demand, Output Supply, and “Real Optima” 352
Two-Step Profit Maximization 355

**Chapter 12: Production with
Multiple Inputs 367**

12A. An Intuitive Development of the Two-Input Model 368
Profit Maximization with Two-Input Producer Choice Sets 369
Two-Input Production Sets: Isoquants and Returns to Scale 371
Cost Minimization on the Way to Profit Maximization 381
Bringing Cost Minimization and Profit Maximization Together 387

12B. The Mathematics behind the Multiple-Input Model 387
Producer Choice Sets and Production Functions 388
Isoprofit Planes and Profit Maximization 393
Cost Minimization on the Way to Profit Maximization 396
Duality in Producer Theory 399

Chapter 12: Appendix 401

**Chapter 13: Production Decisions
in the Short and Long Run 413**

13A. Changes in Producer Behavior as Conditions Change 414
Different Types of Costs and Expenses in the Short and Long Run 414

Output Supply in the Short and Long Run 424
Input Demand and Changes in the Economic Environment 430

13B. Transitioning from Short- to Long-Run Mathematically 439
Expenses and Costs 439
Output Supply and Changes in the Economic Environment 443
Input Demand and Changes in the Economic Environment 449

**PART 3: Competitive Markets
and the “Invisible Hand” 463**

**Chapter 14: Competitive Market
Equilibrium 466**

14A. Equilibrium: Combining Demand and Supply Curves 467
Equilibrium in the Short Run 467
A Market (or Industry) in Long-Run Equilibrium 471
Changing Conditions and Changing Equilibria 476
An Overview of Changes Affecting Firms and Industries 486

14B. The Mathematics of Industry (or Market) Equilibrium 487
Industry Equilibrium in the Short Run 488
An Industry in Long-Run Equilibrium 489
Changing Conditions and Changing Equilibrium 491

**Chapter 15: The “Invisible Hand”
and the First Welfare Theorem 505**

15A. Welfare Analysis in Equilibrium 506
Consumer and Worker Surplus 506
“Producer Surplus” or Profit 511
The Invisible Hand and the First Welfare Theorem 514
Conditions Underlying the First Welfare Theorem 519

15B. Equilibrium Welfare Analysis: Preliminaries and an Example 521
Consumer Surplus 521
Producer Surplus 524
The First Welfare Theorem 525

Chapter 16: General Equilibrium 535

16A. A Graphical Exposition of General Equilibrium 536

<i>A Pure Exchange Economy</i>	536	<i>Calculating Equilibria under Price Floors and Price Ceilings</i>	655
<i>The Fundamental Welfare Theorems and Other Results</i>	544	Chapter 19: Distortionary Taxes and Subsidies	673
<i>A Simple “Robinson Crusoe” Production Economy</i>	548	19A. Taxes and Subsidies in Competitive Markets	674
<i>General Equilibrium Analysis and Policy</i>	552	<i>Who Pays Taxes and Receives Subsidies?</i>	674
16B. The Mathematics of Competitive General Equilibrium	554	<i>Deadweight Loss from Taxation Revisited</i>	679
<i>A Pure Exchange Economy</i>	554	<i>Taxing Land: An Efficient Real-World Tax</i>	685
<i>The Fundamental Welfare Theorems and Other Results</i>	560	<i>General versus Partial Equilibrium Tax Incidence</i>	688
<i>A Simple “Robinson Crusoe” Production Economy</i>	562	19B. The Mathematics of Taxes (and Subsidies)	689
Chapter 16: Appendix	566	<i>Tax Incidence and Price Elasticities</i>	689
Chapter 17: Choice and Markets in the Presence of Risk	578	<i>Deadweight Loss from Taxation When Tastes Are Quasilinear</i>	691
17A. An Intuitive Model of Choice in the Presence of Risk	579	<i>Deadweight Loss from Taxes in Labor (and Capital) Markets</i>	695
<i>Risky Choices Involving Money</i>	579	<i>Taxing Land</i>	699
<i>Risky Choices Involving Multiple “States of the World”</i>	588	<i>A Simple Example of General Equilibrium Tax Incidence</i>	700
<i>General Equilibrium with Uncertainty</i>	592	Chapter 20: Prices and Distortions across Markets	712
17B. The Mathematics of Choice in the Presence of Risk	597	20A. Exporters, Importers, and Speculators	713
<i>“Utility” and Expected Utility</i>	597	<i>Buying Low and Selling High</i>	713
<i>Risky Choices Involving Multiple “States of the World”</i>	603	<i>Restricting Trade through Tariffs or Import Quotas</i>	717
<i>General Equilibrium with Risk</i>	606	<i>Immigration versus Outsourcing</i>	723
Chapter 17: Appendix 1	613	<i>Trading across Time</i>	727
Chapter 17: Appendix 2	615	20B. The Mathematics of Trading across Markets	730
PART 4: Distortions of the “Invisible Hand” in Competitive Markets	629	<i>Trade, Tariffs, and Quotas</i>	730
Chapter 18: Elasticities, Price-Distorting Policies, and Non-Price Rationing	633	<i>A Numerical Example</i>	732
18A. Interactions of Markets and Price-Distorting Policies	634	Chapter 21: Externalities in Competitive Markets	744
<i>Elasticities and the Division of Surplus</i>	634	21A. The Problem of Externalities	744
<i>Price Floors</i>	641	<i>Production Externalities</i>	745
<i>Price Ceilings</i>	647	<i>Consumption Externalities</i>	752
<i>The Politics of “Concentrated Benefits and Diffuse Costs”</i>	650	<i>Externalities: Market Failure or Failure of Markets to Exist?</i>	756
<i>A Note on General Equilibrium Considerations</i>	651	<i>Smaller Externalities, the Courts, and the Coase Theorem</i>	759
18B. The Mathematics of Elasticities and Price Distortions	652	21B. The Mathematics of Externalities	763
<i>Elasticities</i>	652	<i>Production Externalities</i>	764
		<i>Consumption Externalities</i>	769
		<i>Externalities and Missing Markets</i>	769
		<i>Small “Markets” and the Coase Theorem</i>	774
		Chapter 21: Appendix	776

PREFACE

TO STUDENTS

As a student, I often felt both alienated and insulted by textbooks: alienated because they seemed to make no attempt to speak *to* rather than *at* me, insulted because they seemed to talk *down* to me by giving me lots of “visuals” (like pictures of monkeys—seriously) to keep me awake and by feeding me endless definitions to memorize—all while never acknowledging the obvious conceptual limits of what was being presented.

I have therefore tried to write a book that is a little different and that I think I might have liked to use when I was a student. Some have commented that you might not like it because it doesn't lend itself to memorizing definitions for exams. Others find it strange that I address you so directly throughout much of the book and that I occasionally even admit that this or that assumption we make is in many ways “silly.”

I don't actually have anything against monkeys or definitions or assumptions that seem “silly,” but my experience with students over the years tells me that you do not mind being challenged a bit and actually enjoy being part of a conversation rather than committing one to memory. The modern world has few rewards for people who are really good at memorizing but offers much to those who can conceptualize ideas and integrate them with one another. Economics offers a path to practice this—and it does so in a way that can be exciting and interesting, interesting enough to not actually require monkey pictures even if it is sometimes frustrating to get through some of the details.

I will say more about much of this in Chapter 1—so I'll try to avoid repeating myself here and instead just offer a few points on how best to use this text:

1. You may want to review parts of **Chapter 0** (which is not included in the print version of the text, but available through MindTap) to review some basics before proceeding to Chapter 2.
2. Attempt the **within-chapter exercises** as you read—and check your answers with those in the **Study Guide** or those included directly into the MindTap eReader. (My students, on whom I conducted quasi-controlled experiments during the initial drafting of this text, have done considerably better on exams when using within-chapter exercises and solutions.)
3. When skimming chapters, make sure the points emphasized in the margins of the text make sense—and focus on sections of the chapter where they don't.
4. Graphs with purple bars at the bottom can be unpacked directly within the MindTap eReader, and almost all graphs are available to view as animated and narrated videos that can be accessed through MindTap. While some of the video animations are long, you can skip ahead and use chapter markers to locate the part of the video you are most interested in.
5. Look for interesting applications in **end-of-chapter exercises**, but know that some of these are designed to be challenging. Don't get frustrated if they don't make sense at first. It helps to work with others to solve these (assuming your instructor allows this). All odd numbered exercises are accompanied by the † symbol that denotes exercises with solutions provided in the **Study Guide**. These solutions can also be accessed directly within the MindTap eReader.
6. While you will often feel like you are getting lost in details within chapters, the **Introductions** (to the Parts as well as the Chapters) and the **Conclusions** (in each chapter) attempt to keep an eye on the big picture. Don't skip them!

7. The book has an extensive **Glossary** and **Index** but develops definitions within a narrative rather than pulling them out within the text. Use the Glossary to remind yourself of the meaning of terms and the Index to find where the associated concepts are discussed in detail. But resist the temptation to memorize too much. The terms aren't as important as the concepts.
8. As the book goes to press, I am developing an online course consisting of short lecture modules as well as links to animations and worked out solutions. This course will be accessible through the EcoTeach Center at Duke (<http://econ.duke.edu/ecoteach>).

TO INSTRUCTORS

When I was first asked to teach microeconomics, I was surprised to learn that the course had been one of the least popular in my department. It was unclear what the goals of the course were—and without such clarity at the outset, students had come to view the course as a disjointed mess of graphs and math with little real-world relevance and no sense of what value it could add. As I came to define what goals I would like *my* course to develop, I had trouble finding a text that would help my students aim toward these goals without over-emphasizing just one or two to the exclusion of others. So we largely de-emphasized textbooks—but something was working: the course had suddenly become one of the most popular in the department!

I have therefore attempted to build a framework around the five primary goals that I believe any microeconomics course should accomplish:

1. It should present microeconomics not as a collection of unrelated models but **as a way of looking at the world**. People respond to incentives because they try to do the best they can given their circumstances. That's microeconomics in a nutshell—and everything—*everything*—flows from it.
2. It should persuade that microeconomics does not just change the way *we think* about the world—it also tells us a lot about **how and why the world works** (and sometimes doesn't work).
3. It should not only get us to think more clearly about economics but also **to think more clearly in general**—without relying on memorization. Such *conceptual thinking skills* are the very skills that are most sought after and most rewarded in the modern world.
4. It should directly confront the fact that few of us can move from memorizing to conceptual thinking without **applying concepts directly**, but different students learn differently, and instructors need the *flexibility* to target material to *their* students' needs.
5. Finally, it should provide students with a **roadmap for further studies**—a sense of what the most compelling next courses might be given *their* interests.

I am thus trying to provide a flexible framework that keeps us rooted in a *way of thinking* while developing a *coherent overview* to help us better understand the world around us. Half the text builds up to the most fundamental result in all of economics—that self-interested individuals will—*under certain conditions and without intending to*—give rise to a spontaneous order that has great benefits for society. But the second half probes these “certain conditions” and develops insights into how firms, governments, and civil society can contribute to human welfare when markets by themselves “fail.” Future courses can then be seen as sub-fields that come to terms with these “certain conditions.”

While the material in the full text is more than enough for a two-semester sequence, the text offers a **variety of flexible paths for a one-semester course**. In each chapter, you can emphasize an intuitive A part or link it to a more mathematical B part; and, while the last part of the text relies heavily on game theory, the underlying narrative can also be developed through

a non-game theoretic approach. Substantive paths include some focused on *theory*, others focused on *policy*, and yet others focused on *business*, with all paths including core material as well as optional topics. Throughout, the models build in complexity, with applications woven into the narrative (rather than being relegated to side-boxes). They are then further developed in an extensive array of exercises that get students—not me or you—to apply concepts to *Everyday*, *Business*, and *Policy* settings.

For more details on how you might use the various parts of the text and its accompanying tools, I hope you will have a look at the **Instructor’s Manual** that I have written to go along with the text.

While the student study guide includes answers to all odd numbered end-of-chapter exercises (in addition to answers to within-chapter exercises), answers to all end-of-chapter exercises are available to instructors. Here are just a few examples of how you might weave through the book depending on your focus. (These are depicted in more detail in the instructor edition of the text.)

1. Traditional Theory Emphasis:

Ch. 1–23 (with Ch. 3, 8, the latter sections of 9 and 13 optional) plus
Ch. 29–30 optional

2. Theory Emphasis with Game Theory:

Ch. 1–18 (with 3, 8, the latter sections of 9, 13, and 18 optional) plus
Ch. 23–27 (with 28 through 30 optional)

3. Business Focus:

Ch. 1–18 (with Ch. 3, 8, 16, the latter sections of 9, 13, and 18 optional) plus
Ch. 23–26

4. Policy Focus:

Ch. 1–15 (with Ch. 3, 8, and the latter sections of 9 and 13 optional), plus
Ch. 18–23, 28–30 (with Ch. 24–27 optional depending on level of game theory usage)

If you have suggestions for improvements to the text for the next edition, please feel free to contact me directly through my Duke email address.

ACKNOWLEDGMENTS

In addition to all those acknowledged in the first edition to the text, I would like to thank the Cengage team that has shepherded the second edition to its conclusion: Mike Worls, product director, Tara Singer, associate product manager, Colleen Farmer, senior content project manager, Michelle Kunkler, senior art director, and Kevin Kluck, manufacturing planner. Most visible to me has been the extraordinary efforts of Leah Wuchnick who has been the content developer and the answer to my many silent prayers leading up to undertaking this project. I could not have hoped for a better partner. Of course, Leah worked with a dedicated team on her end, and their efforts—while less visible to me—are equally appreciated.

Throughout the past few years, I have used the text in my microeconomics course at Duke, and so I must thank the many hundreds of students who, through their use of the materials and their many comments, have continued to improve the content. In addition, I have heard from students and instructors from around the world, and I hope some of them will see at least some of their comments reflected in this edition. Above all, I appreciate the encouragement from many who have found the text helpful and have made the effort to reach out.

Finally, it turns out that I have a full time job and a busy family life—and a project like this could not be seen to completion without the patient understanding of many who fill in the inevitable gaps that arise when one’s focus shifts a bit. To all my colleagues, particularly those in the EcoTeach center and those in the Social Science Research Institute at Duke, thank you for not making me feel too guilty for the “blocked out” times on my calendar. And above all—to Stacy, Ellie, Jenny, and Katie—thank you always for being there.

Thomas J. Nechyba
Durham, NC

FURTHER ACKNOWLEDGMENTS

The author and editorial team at Cengage Learning would also like to acknowledge the feedback and assistance of many instructors who reviewed this text in various drafts and participated in several focus groups concerning its development. Their time and comments have been invaluable in crafting the final product.

Foundational Preliminaries

In principle, this textbook presumes no prior knowledge of economics and thus essentially starts from scratch. However, it is undoubtedly true that an introductory level economics course (or some equivalent high school AP course) will give you a bit of a head start in the sense that some concepts—particularly toward the middle of the text—will already be familiar. The mathematical B-parts of the chapters presume a basic comfort level with algebra and some selected pre-calculus topics as well as the ability to take a derivative of a single-variable function. The primary higher-level mathematical technique utilized in the text—optimization methods using partial derivatives—is developed in the text without any presumption that you have seen this before—although again, you have a bit of a head start if you have taken multi-variable calculus (which is typically covered in the third course of a college calculus sequence).

This preliminary chapter is meant to get everyone “onto the same page” to minimize the gap between those with and those without prior economics and advanced math preparation. Particularly, in part A of the chapter we will review some basics of graphing the kinds of objects that we will graph in the A-parts of the book chapters and will apply them to some of the ideas you will have seen in an introductory course. In part B of this chapter, we will analogously cover the mathematical basics that you encounter in the B-parts of the book chapters—up to but not including the multi-variable calculus concepts that are directly developed within the text.

0A

SOME GRAPHICAL PRELIMINARIES

The graphs in the A-parts of the text are ways of representing underlying mathematical objects that could in principle be treated without graphs (as developed in the B-parts). The great advantage of graphs is that they often more clearly illustrate economic intuitions that are sometimes not immediately apparent in a more traditional mathematical development of the same concepts. It is for this reason that economists rely so much on graphs and often illustrate their ideas graphically even if they have developed them in much more general form through mathematical models. Even the seasoned professional economist will find himself or herself drawing the kinds of pictures we develop in the A-parts of chapters to help make sense of answers that they get from solving mathematical equations. Math helps us to make sure that we are not playing tricks on ourselves when we just draw graphs, but the graphs often help us understand what is really going on underneath the math.

0A.1 Graphing Points and Sets

In this section, we'll review some basic issues related to graphing points and sets, and we will use modified versions of actual graphs from the text to illustrate the underlying concepts. Most of what we draw throughout the text is represented in two-dimensional graphs, with an x -axis and a y -axis that measure different types of variables like price and quantity. But these two-dimensional graphs are usually just “slices” of higher dimensional graphs—slices in which we hold something else fixed in order to be able to illustrate what we are focusing on in just two dimensions. We will sometimes remind ourselves of this and will find that keeping this in mind can help us visualize more complex ideas while not overly straining our graphing skills.

0A.1.1 Points and Sets in One Dimension Let's consider first the idea of a *point*. In one dimension, we usually think of a point as represented by a real number drawn from the number line that ranges from minus infinity to infinity. Such a real number might be an *integer* by which we simply mean a whole number (like 2 or 5 or 12); or it might be a *rational* number that can be represented as a fraction that divides one integer by another (like $4/3$ or $2/9$); or it might be an *irrational* number that lies on the real number line but cannot be represented as a fraction of one integer divided by another (such as $\sqrt{2}$ or π).¹

A *set* of points in one dimension is then some subset of the real number line. The magenta interval from zero to 1 in Graph 0.1, denoted as $[0,1]$, is an example of a set of points in one dimension. There are lots of properties of sets that we could define, but the one that appears frequently in the textbook is that of *convexity*. It is a pretty straightforward concept: A set of points is said to be *convex* if the straight line that connects any two points in the set is fully contained in the set. For instance, consider the magenta set $[0,1]$: No matter which two points in that set we pick, the line that connects the points lies on the real number line and within the magenta set $[0,1]$. Thus, $[0,1]$ is a convex set.

But now consider the green set that is made up of the segment $[0,1]$ and $[2,3]$, a set we would call the *union* of $[0,1]$ and $[2,3]$, denoted as $[0,1] \cup [2,3]$. We have now created a set that has a “hole” in it because it starts at 0, stops at 1 and then starts again at 2. This implies that we can pick a pair of numbers like 0.5 and 2.5 from the set $[0,1] \cup [2,3]$ —with the line that connects the two points not fully contained in the set $[0,1] \cup [2,3]$. This is because the line that connects 0.5 to 2.5 contains the dashed interval $[1,2]$ that represents the “hole” in our set. As a result, we would say that the set $[0,1] \cup [2,3]$ is not a convex set, and we will therefore call it a *non-convex set*. Notice that, in order for a set to be non-convex, all we have to do is find one pair of points from the set such that the line connecting those points lies at least partially outside the set. The fact that we can also find pairs of points whose connecting line lies fully in the set is irrelevant—for the set to be convex, *all* lines connecting *any* pair of points from the set must fully lie within the set.

A set is convex if the line connecting any two points (in the set) is itself fully contained in the set.

A set that is not convex is called non-convex.

GRAPH 0.1 Sets of One-Dimensional Points

¹Irrational numbers can also be defined as numbers with non-ending and non-repeating decimals. As it turns out, almost all real numbers are irrational even though we often use rational numbers as approximations.

Consider the set $[0,1)$, which includes the point 0, all the points in between 0 and 1 but not the point 1. Is this set convex? What about the union of this set with the point 1? What about the union of this set with the point 1.1?

EXERCISE
0A.1

Is the set of all rational numbers a convex set? What about the set of all non-integers? Or the set of all irrational numbers?

EXERCISE
0A.2

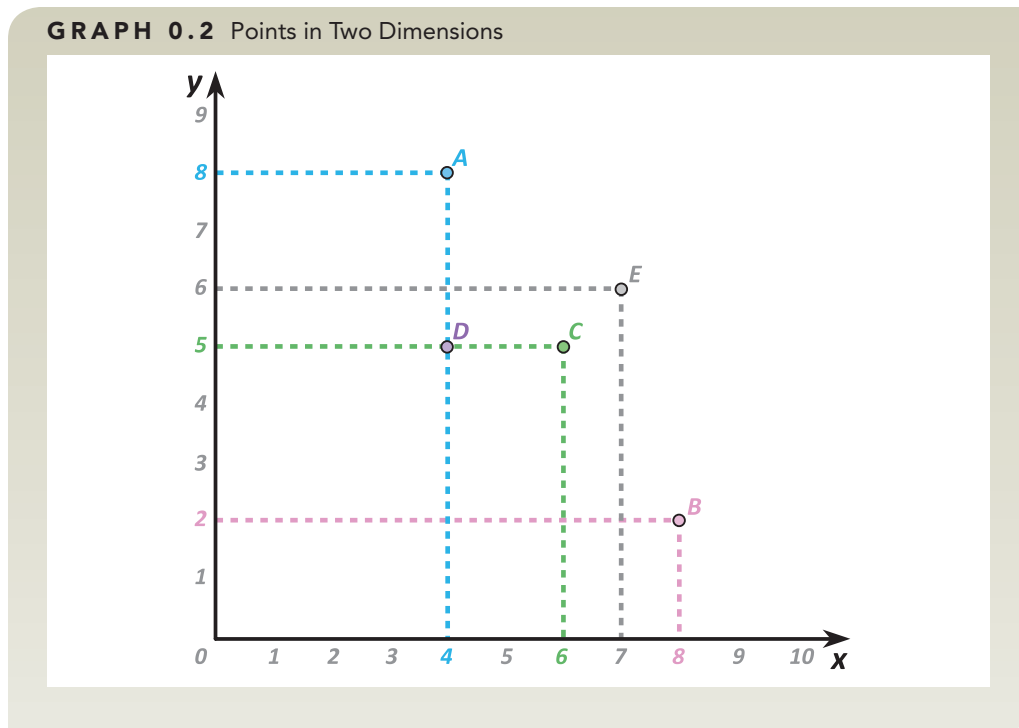

0A.1.2 Points and Sets in Two Dimensions If we understand the idea of points and sets in one dimension, it is a small step to understanding the same concepts in two dimensions. While a point in one dimension is *one* number from the real number line, a point in two dimensions is a pair of *two* numbers from the real number line. For instance, the point $(4,8)$ is a point that measures 4 units on the horizontal x -axis of a graph and 8 units on the vertical y -axis of a graph, a point such as the point denoted by A in Graph 0.2.

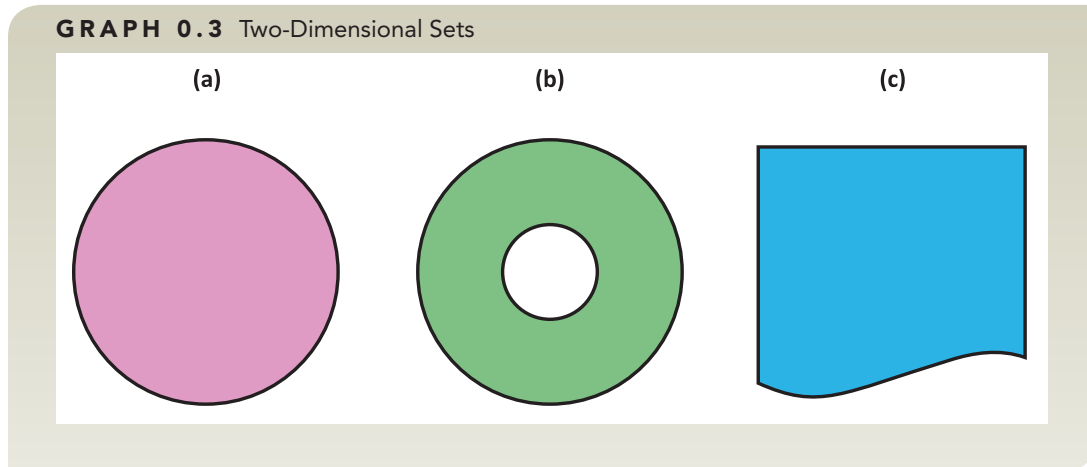

Describe points B , C , D and E in Graph 0.2 as a pair of real numbers.

EXERCISE
0A.3

Of course there is no more reason to restrict ourselves to points made up of integer values when we are in two dimensions than when we are in one dimension. The green dashed line segment between points C and D in Graph 0.2, for instance, contains points that have non-integer x -values (ranging from 4 to 6) while holding the y -value fixed at 5, and the dashed blue line segment between A and D contains points that have non-integer y -values (ranging from 5 to 8) while holding the x -value constant at 4. You can then quickly see that every “point” in the graph is in fact a *point* described by a pair of numbers, one referring to the x -dimension and another referring to the y -dimension.

GRAPH 0.2 Points in Two Dimensions

GRAPH 0.3 Two-Dimensional Sets

Once we understand the concept of a point in two dimensions, we can then again define sets of points as simply collections of points. For instance, we could define the set $\{A, B, C, D, E\}$ as the set of the five points graphed in Graph 0.2. And a set will again be *convex* if and only if all line segments that connect any two points in the set are fully contained within the set.²

EXERCISE
0A.4

Which of the sets in Graph 0.3 is/are not convex?

One particular type of set is the set of points that form a *line segment*. You will remember from an algebra class that any line in a two-dimensional graph can be represented by the equation

$$y = b + mx \quad (0.1)$$

Equations of lines with vertical intercept b and slope m can be written in the form $y = b + mx$.

where b represents the vertical intercept of the line and m represents its slope. Graph 0.4, for instance, contains a blue line segment that lies on the line with vertical intercept of 20 (at point B) and slope of -2 . The line on which the blue segment lies is thus represented by the equation $y = 20 - 2x$. From the graph, we can calculate the value of the slope as the “rise” over the “run” as we move from one point on the line to another. Going from C to F , for instance, we go down by 2 (to E), which is a negative “rise” of 2, and 1 to the “right” (from E), which is a positive “run” of 1. This gives us

$$\text{Slope} = \frac{\text{rise}}{\text{run}} = \frac{-2}{1} = -2. \quad (0.2)$$

EXERCISE
0A.5

Can you use points A and B to arrive at the same value for the slope? What about the points D and F or the points D and C ?

The line segment in Graph 0.4 is itself a set of points—that is, the set of points with positive x - and y -values that lie on the line described by the equation $y = 20 - 2x$. It is in some sense no different than a line segment on the real number line except that it is placed into the two-dimensional plane. So long as we are simply defining the points on a line segment as a set, we are thus defining an object no different from what we defined in one dimension, with the idea of

²We will re-visit Graph 0.2 in the context of tastes and consumer goods in Chapter 4, where the x -axis will denote the number of pants in a consumer’s basket, and the y -axis will denote the number of shirts.

convexity no different than it was in the previous section. But we could also use the line to define the boundary of a set that truly is two- rather than one-dimensional. The shaded area below the blue line in Graph 0.4, for instance, is the set of all points (with positive x - and y -values) that lie below the line—or the set of all points such that

$$y < 20 - 2x, x > 0 \text{ and } y > 0. \quad (0.3)$$

Such a set is again said to be *convex* if and only if you can take *any* two points within the set, connect them with a straight line segment and have the *whole* line segment contained within the set.³

Is the shaded set in Graph 0.4 a convex set?

EXERCISE
0A.6

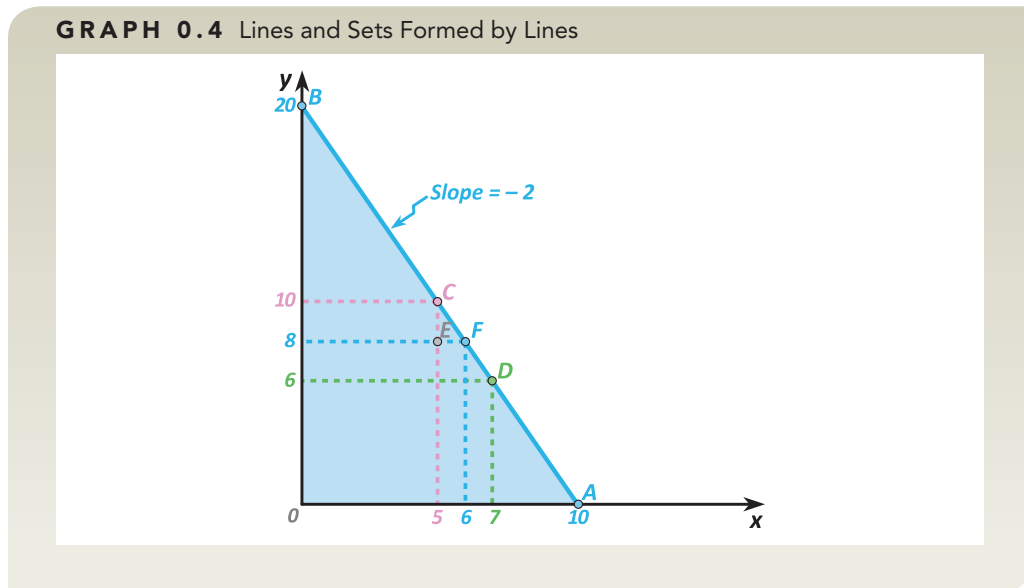

Suppose the blue line in Graph 0.4 had a kink in it. This kink could point “inward” (i.e., toward the origin) or “outward” (i.e., away from the origin). For which of these would the shaded area underneath the kinked line become a non-convex set?

EXERCISE
0A.7

0A.1.3 Three-Dimensions and Two-Dimensional “Slices” When we graph in two dimensions, we are necessarily limiting ourselves to considering how two—and only two—variables are related to one another. The line in Graph 0.4, for instance, tells us how the variable y on the vertical axis is related to the variable x on the horizontal axis (through the equation $y = 20 - 2x$). But we will see that it is sometimes useful to think about how two variables are related to a third variable. In such cases, we would need a three-dimensional graph to illustrate the full set of relationships that are of interest to us. An example of such a three-dimensional graph is given in Graph 0.5 where, in addition to the x and y variables, we now also have a z variable on the axis pointing toward you.

Just as a point in one dimension is described by just a number on the real number line, and a point in two dimensions is described by a pair of numbers indicating the x - and the y -value, a point in three dimensions is described by a triple of numbers—indicating the x -, y -, and z -values of the point. In Graph 0.5, for instance, the point $D = (5, 5, 10)$ is a point with x - and y -values

GRAPH 0.4 Lines and Sets Formed by Lines

³In Chapter 2, with “pants” on the x -axis and “shirts” on the y -axis, sets of this type will denote the set of affordable baskets of pants and shirts (given some money budget and given prices for pants and shirts).

GRAPH 0.5 Three-Dimensional Points and Sets

of 5 and a z -value of 10. It lies on the shaded plane that connects the points A , B , and C , which occur on the three axes of the graph, and this plane is itself a set of points in three dimensions.

The equation for the shaded plane is given by

$$4x + 2y + z = 40. \quad (0.4)$$

The intercepts on each axis can then easily be identified by setting the values of variables on the other axes to zero. For instance, the z -intercept at C occurs where y and x are both set to zero—which, according to equation (0.4), implies $z = 40$.

EXERCISE 0A.8

Check to see that the other intercepts (at B and A) are correctly labeled based on equation (0.4).

EXERCISE 0A.9

Is the plane in Graph 0.5 a convex set?

When one variable in a three-dimensional graph is held fixed, the resulting “slice” can be graphed in two dimensions.

Suppose then that x , y , and z are three economic variables, and that we know that, for the application at hand, $z = 0$. In that case, we could simply look at the two dimensions of the graph that hold z fixed at zero—which reduces the graph to just the x - and y -axes. We would then be left with a line that has y intercept of 20 and x intercept of 10—that is, a line described by the equation $y = 20 - 2x$ just as the one we graphed in Graph 0.4. The two-dimensional graph in Graph 0.4 is therefore a two-dimensional “slice” of the three-dimensional graph in Graph 0.5 when z is held fixed at 0.

0A.1.4 Switching between “Slices” as “Shifts in Curves” But z might not be appropriately set to zero—that is, the relevant “slice” for our purposes might lie at some level of z greater than zero. In Chapter 2, for instance, we will have an application where x represents “pants,” y represents “shirts” and z represents “socks.” The three-dimensional plane in Graph 0.5

GRAPH 0.6 Slices of Three-Dimensional Graphs

represents the set of baskets of pants, shirts, and socks that are affordable to a consumer. But suppose the consumer has already decided to buy 10 socks and we wanted to illustrate her remaining affordable baskets of shirts and pants. The appropriate “slice” of the graph is then one that occurs at $z = 10$ —which is graphed as the magenta slice in panel (a) of Graph 0.6.

Given the equation (0.4) that describes the three-dimensional plane, what is the equation that describes the magenta line segment, which intersects with the plane in panel (a)?

EXERCISE 0A.10

In the two-dimensional x/y graph in panel (b), this change in the z variable from 0 to 10 then appears as a *shift* in the line segment. This is a general insight which will apply to many of the graphs we draw in the text: If a two-dimensional graph arises from some third variable being held fixed, changing that third variable is equivalent to shifting to a different “slice” of an underlying three-dimensional graph—with that shift appearing as a shift in a line or curve when projected onto the x/y graph.

When a two-dimensional graph arises from holding a third variable fixed, then changing the value of that third variable will cause a shift in the two-dimensional graph.

0A.2 Demand and Supply Curves

If you have ever taken a class in economics, you have no doubt graphed demand and supply curves. We will not actually graph these fully within the text until we have done some work on what’s behind these curves, because it is only then that we really understand fully what these curves actually mean. But, since you are probably already familiar with some basics of demand and supply curves, we can use them here to illustrate some of the reasons behind the *movements along curves* and *shifts of curves* that you have seen before.

0A.2.1 The Demand Curve A *demand curve* typically relates the quantity x demanded by a consumer to the price p_x of the good in question. It is therefore a two-dimensional graph, with

GRAPH 0.7 Movements along and Shifts in Demand Curves

x on the horizontal axis and p_x on the vertical. And when we graph such a demand curve, we are necessarily *holding all else fixed* and simply illustrating how the consumer's behavior changes as p_x changes.

In panel (a) of Graph 0.7, for instance, the magenta curve illustrates how the demand for x (on the horizontal axis) changes when the price of x (on the vertical axis) changes. As p_x increases, we slide up *along the demand curve*, and as p_x falls, we slide down *along the demand curve*.

But a consumer's decision about how much of a good x to buy does not usually depend only on the price p_x . The consumer's income I , for instance, might also play a role in determining how the consumer responds to price changes. When we plot a demand curve in panel (a), we therefore assume that I is fixed—which is equivalent to assuming that we are operating on a “slice” of a three-dimensional object that relates x to both p_x and I . This implies that when income changes, we move to a different “slice” of the underlying three-dimensional object—which is shown as a *shift in the demand curve* as illustrated in panel (b) of the graph.

In fact, a consumer's demand for x generally depends not only on p_x and I but also on the price of other goods. Were we to graph the three-dimensional demand function that relates x to p_x and I , this three-dimensional graph would then itself be a “slice” of a higher dimensional object that relates x also to other prices—and those other prices are held fixed when we graph the three-dimensional demand function just as they are in the two-dimensional graph of panel (a). And again, as prices of other goods change, the demand curve itself will shift as indicated in panel (b).

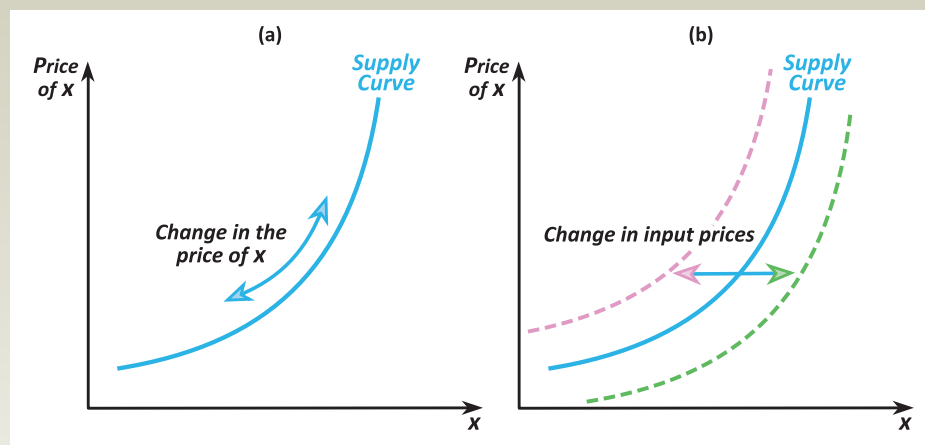

Demand curves typically hold other variables fixed, like income. When these other variables change, the demand curve shifts.

EXERCISE 0A.11 Suppose I like eating steak and will eat more steak as my income goes up. Which way will my demand curve for steak shift as my income increases? Can you think of any goods for which my demand curve might shift in the other direction as my income increases?

EXERCISE 0A.12 Coffee and sugar are *complements* for me in the sense that I use sugar in my coffee. Can you guess which way my demand curve for coffee will shift as the price of sugar increases?

EXERCISE 0A.13 Ice tea and coffee are *substitutes* for me in the sense that I like both of them but will only drink a certain total amount of liquids. Can you guess which way my demand curve for coffee will shift as the price of iced tea increases?

0A.2.2 The Supply Curve Supply curves are similar to demand curves in that they relate a *quantity* on the horizontal axis to a *price* on the vertical. But now the interpretation of the

GRAPH 0.8 Movements along and Shifts in Supply Curves

curve is one of supply rather than demand—that is, the curve illustrates how the quantity of x that is supplied changes as the price of x changes, *all else being held constant*. As the price of x increases, we therefore move up *along the supply curve* to determine the quantity of x that is supplied—as illustrated in panel (a) of Graph 0.8.

But again, the quantity that is supplied by a firm (or by the market) will depend on other factors—factors such as the input prices (like wages) that firms have to pay in order to produce. As these other factors change, the supply curve will *shift*. Put differently, the full description of the quantity supplied is a function of factors other than p_x —implying a multidimensional object from which the supply curve is drawn as a “slice” that holds these other factors fixed. And when one of those other factors changes, we switch to a different “slice” of the underlying relationship, which then appears as a shift in the supply curve (as illustrated in panel (b) of the Graph).

Supply curves typically hold input prices fixed. When input prices change, supply curves shift.

How would the supply curve for a firm shift if the general wage rate in the economy increases?

EXERCISE 0A.14

Would you expect the supply curve for a firm that produces x to shift when the price of some other good y (that is not used in the production of x) increases?

EXERCISE 0A.15

If the supply curve depicts the supply curve for a *market* composed of many firms, we may also see shifts in the supply curve that arise from the *entry* of new firms or the *exit* of existing firms. How would the market supply curve shift as firms enter and exit?

EXERCISE 0A.16

0A.2.3 Price Elasticities of Demand and Supply In many applications, we will consider how responsive consumers and producers are to price changes. Economists describe the responsiveness of behavior to prices by appealing to a concept known as *price elasticities*. We will introduce this concept more formally in Chapter 18 as the percentage change in quantity that arises from a one percent change in price. For now, we simply emphasize that elasticities capture *responsiveness* in behavior.

Elasticities capture responsiveness of behavior to changes in economic variables like prices.

Consider for instance two consumers who currently consume a quantity x^* at price p^* . Observing such consumption tells us one point on each of the consumers’ demand curve—and since they are consuming the same amount at the same price, we know that this same point lies

GRAPH 0.9 Price Elasticities

on both consumers' demand curves. But without observing more choices at different prices, we can't tell whether the two consumers in fact share the same demand curve or whether their demand curves just happen to intersect at the quantity x^* and price p^* .

In panel (a) of Graph 0.9, we illustrate two demand curves consistent with observing the two consumers making the same consumption decision at price p^* . But the magenta demand curve for consumer 1 is steeper than the green demand curve for consumer 2 at the point at which the two curves intersect. This implies that, when price rises from p^* to p' , the green consumer 2 will *respond more* than the magenta consumer 1: In particular, the green consumer reduces her consumption to x'' while the magenta consumer only reduces it to x' . We would then say that consumer 2's response to a price increase is *more elastic* (i.e., more responsive) than consumer 1's.

EXERCISE 0A.17

Is consumer 2's consumption also more elastic than consumer 1's when price falls?

At the point at which two demand curves intersect, it is then pretty easy to determine whose behavior is more price *elastic*—it must be the person whose demand curve is shallower. As we will see in Chapter 18, however, it is misleading to use slopes of demand curves as the measure of price elasticity. This is in part because slopes can change if we simply measure output differently (i.e., kilos instead of pounds of rice; cans of soda versus liters of soda; etc.), but a measure of consumer responsiveness should not depend on how we measure output.

EXERCISE 0A.18

Do slopes similarly change if we measure price differently—that is, if we measure price in euros instead of dollars?

EXERCISE 0A.19

In panel (b) of Graph 0.9, the supply curves of two producers who both produce x^* at the price p^* are illustrated. Which producer is more price elastic when price increases? What about when price decreases?

Another way to see the need for a unit-free measure of consumer responsiveness to price is to think of “responsiveness to price changes” in terms of what happens to consumer spending. When price increases, a consumer might spend less because she buys fewer goods, but she might also spend more because the remaining goods she does buy are more expensive. If the consumer is relatively unresponsive to price increases, we would expect the latter to outweigh the former—and consumer spending would increase as price rises. If, on the other

GRAPH 0.10 Spending and Price Elasticities

hand, the consumer is relatively responsive to price changes, we would expect the reverse to be true.

You can see this in the three panels of Graph 0.10, a graph that will appear again in Chapter 18. Here we have a linear demand curve and we consider how a consumer’s spending changes as price increases from \$50 to \$100 in panel (a), from \$175 to \$225 in panel (b) and from \$300 to \$350 in panel (c). The shaded blue area in each panel is the *reduction in spending* from the fact that the consumer buys less at the higher price; the shaded magenta area in each panel is the *increase in spending* from the fact that the goods that are still bought at the higher price now cost more. Whenever the magenta area is larger than the blue area, a consumer’s spending increases with a price increase; and whenever the blue area is larger than the magenta area, a consumer’s spending decreases with a price increase.

Slopes of demand and supply curves are not generally a reliable way to capture responsiveness.

How much does the consumer spend when price is \$50? How much does she spend when price increases to \$100?

EXERCISE 0A.20

What is the size of the blue shaded area in panel (a)? What about the magenta area? Is the difference between the magenta and the blue area the same as the increase in spending you calculated in exercise 0A.20?

EXERCISE 0A.21

If the slope of the demand curve were a good measure of price responsiveness, we would expect the same slope to imply the same impact on consumer spending for a similarly sized price increase. But Graph 0.10 clearly illustrates that, for a demand curve with the same slope throughout, consumer spending might respond positively or negatively to an increase in price.

0A.3 The Concept of Equilibrium

An *equilibrium* is a state of the world in which everyone is doing the best he can given how everyone else is behaving—that is, given what everyone is doing, no one wants to do anything differently. In many circumstances, this requires us to think carefully about not only how everyone currently behaves but also how that might change if some player changes his behavior. Such *strategic thinking* about how our actions interact with those of others is usually treated with the tools of *game theory*, a topic introduced in Chapter 24. But game theory is not always necessary to think about equilibrium, as you may already know from previous economics courses.

In an equilibrium, everyone is doing the best he can, given what everyone else is doing.

0A.3.1 Competitive Equilibrium The most important case in which we do not have to think about game theory when thinking about equilibrium arises in *competitive settings*. We use the term

GRAPH 0.11 Competitive Equilibrium

competitive to describe “large” economic settings—settings in which each individual is sufficiently “small” relative to the economic environment such that nothing a single individual can do will impact how anyone else behaves. In such a case, there is no need for an individual to “think strategically”—that is, to think about how others might behave differently if he himself behaves differently.

In any previous economics course, for instance, you will almost certainly have graphed *market demand* and *supply curves* in the same picture. In that picture, you imagined many consumers whose actions together form the market demand curve, and many producers whose actions together form the market supply curve. And because there are many consumers and many producers, no single producer or consumer has any power to shift the market demand or supply curve.

The two panels of Graph 0.11, for instance, illustrate magenta market demand curves and blue market supply curves. These curves intersect at the quantity x^* and the price p^* , an intersection that you will probably recall as the *equilibrium* in the graph—a quantity and price at which consumers and producers trade. The reason this intersection represents an equilibrium lies in the fact that, were the price ever to be anything other than p^* in this market, some individuals could do better by doing something different.

If the price occurred *above* p^* (as indicated by the green dashed line in panel (a) of the graph), consumers would only demand the magenta quantity x' while producers would want to sell the blue quantity x'' . This implies that producers would not be able to sell all the goods they produce, which in turn implies that a single producer can do better by charging a price just below the green price, thus guaranteeing that he will sell his goods while everyone else charges the green price. Thus, as long as the price lies above p^* , individual firms will have an incentive to lower their price.

Similarly, if the price fell *below* p^* (as indicated in panel (b) of the graph), consumers would want to buy the magenta quantity x' that is now *larger* than the blue quantity x'' that producers are willing to sell at that price. Thus, a number of consumers will not be able to purchase the products they want at the green price. Firms might recognize lines of consumers outside their stores, or consumers might recognize that they can improve their chances of getting the products they want if they offered a higher price. Thus, as long as the price lies below p^* , individuals have an incentive to raise the price.

It is only when price is at p^* that every consumer who wants the product at that price can buy it, and every firm that is willing to sell at that price will in fact be able to sell it. A firm could offer a lower price—but that would mean it would do worse because it can already sell all the goods it can produce (given it is small relative to the market) at p^* . And any firm that

When price in a competitive market deviates from the ‘equilibrium price’ at the intersection of demand and supply, producers and/or consumers have an incentive to change behavior in ways that drive price to the equilibrium price.

GRAPH 0.12 Increase in Equilibrium Price

tries to price above p^* will find all consumers going to its competitors. At the intersection point, everyone in the market is therefore doing the best he can.

A *price ceiling* is a government-enforced maximum legal price. In order for such a price ceiling to have an impact on the price at which goods are traded, would it have to be set above or below the equilibrium price p^* ?

EXERCISE
0A.22

If a price ceiling changes the price at which goods are traded, would you expect a “shortage” or a “surplus” of goods to emerge? How would the magnitude of the shortage or surplus be related to the price elasticity of demand?

EXERCISE
0A.23

A *price floor* is a government-enforced minimum legal price. Repeat the previous two questions for a price floor instead of a price ceiling.

EXERCISE
0A.24

0A.3.2 Changes in Competitive Equilibria But real-world markets are often not in equilibrium for very long—things constantly change, shifting market demand and supply curves and thus putting upward or downward pressure on prices. An increase in labor costs, for instance, will cause an increase in costs for firms, and this in turn will imply that firms will require a higher price for any output they are willing to sell. As a result, the supply curve shifts “up” or “to the left” as depicted by the new green supply curve in panel (a) of Graph 0.12, with the new equilibrium now occurring at the intersection of the green supply curve with the magenta demand curve. Alternatively, perhaps a general increase in consumer income has consumers demand more of x at any given price, thus causing the demand curve to shift “to the right” or “up” as illustrated in panel (b) of Graph 0.12. The new equilibrium then occurs at the intersection of the new green demand curve with the blue supply curve.

Notice that in both cases, the equilibrium price increases from the initial p^* to the new p' . But in panel (a), this is accompanied by a reduction in output (from x^* to x') while in panel (b) it is accompanied by an increase in output (from x^* to x''). When the upward pressure on price comes from a shift in the supply curve, we slide up the demand curve (as indicated by the magenta arrow in panel (a))—which leads to the reduction in output as consumers are no longer willing to buy as much at the new higher price. But when the upward pressure on price comes

When input prices change, market supply curves shift, giving rise to a new equilibrium price. When consumer income changes, market demand shifts, again causing a new equilibrium price to emerge.

GRAPH 0.13 Decrease in Equilibrium Price

from a shift in demand, we slide up the supply curve (as indicated by the blue arrow in panel (b))—which leads to an increase in price that our consumers are willing to pay, and that induces our firms to produce the additional quantity.

By knowing what happens to *both* price and output in a market, we can then identify which curves must have shifted disproportionately more. If a price increase occurs alongside an increase in market output, it must be that the primary cause of the price increase lies on the demand side (as in panel (b)); but if the price increase occurs alongside a decline in market output, we must be looking at a supply-side phenomenon (as in panel (a)).

EXERCISE 0A.25

Can you come to similar conclusions about decreases in market prices by looking at Graph 0.13?

0A.3.3 Price Elasticities and Changes in Market Equilibrium As we have seen, price increases arise from upward shifts in demand and/or supply curves—and the direction of accompanying quantity changes depends on which of the two curves is primarily responsible for the change in price. An understanding of the *direction* of market price and output changes then emerges from tracing through the impact of shifts in demand and supply curves. An understanding of the relative *magnitudes* of price and output changes, on the other hand, takes us back to price elasticities.

Graph 0.14, for instance, illustrates the same upward shift in the market supply curve for a relatively *inelastic* (or “unresponsive”) demand curve in panel (a) and a relatively *elastic* (or “responsive”) demand curve in panel (b). When consumers are relatively unresponsive to price changes (as in panel (a)), we see that the shift in supply results in a large increase in price but only a small reduction in output, whereas when consumers are relatively responsive (as in panel (b)), the reverse is true. Graph 0.15 illustrates the same idea for shifts in demand curves when supply is relatively price elastic (in panel (a)) and relatively price inelastic (in panel (b)). *Price inelasticities therefore lead to large market price changes relative to output changes as market curves shift.*

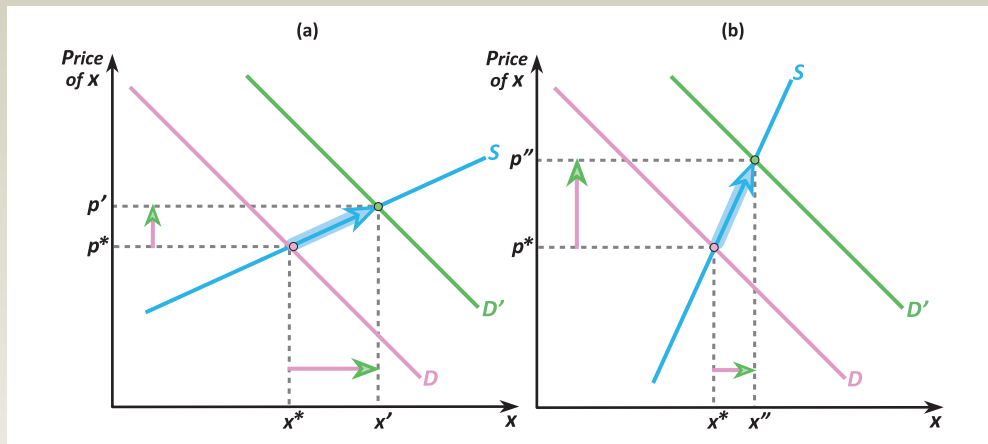

This has important implications for the impact of policies such as per-unit taxes. Suppose, for instance, that a per-unit tax is levied on producers of the x good. In other words, suppose that firms will have to pay an amount t for every unit of x they sell. This is, in effect, an increase in production costs of t per unit—which implies that a producer who was willing to produce at

The more unresponsive behavior is to price, the greater the impact on price from shifts in supply and demand curves.

GRAPH 0.14 Price Elasticity of Demand and Changes in Market Equilibria

GRAPH 0.15 Price Elasticity of Supply and Changes in Market Equilibria

price p will now only produce at price $(p + t)$. As a result, the market supply curve shifts up by t when the per-unit tax is imposed.

The fact that a tax is levied on firms, however, does not mean that firms will bear the full burden of the tax. Put differently, producers of x will seek to pass some of the burden onto consumers in the form of higher prices. But the degree to which producers are able to do this in equilibrium will depend on the price elasticity of demand. You can see this in Graph 0.14 where the same upward shift in supply leads to a large increase in price in panel (a) but only a small increase in price in panel (b). If this upward shift in supply is caused by a per-unit tax on firms, the firms will therefore be able to pass a significantly larger fraction of the tax onto consumers (in the form of higher prices) if consumers are relatively price-*inelastic*. This should, of course make intuitive sense: If consumers don't respond to price changes a lot, then it is easier to pass costs onto consumers without market output being dramatically impacted.⁴

The burden of a tax is more easily shifted onto consumers if consumer behavior is relatively unresponsive to price changes.

⁴In Chapter 19, we will see that it in fact does not matter whether the government imposes a tax on the consumer or the producer side of the market: the equilibrium distribution of the tax burden will depend entirely on the relative price elasticities of demand and supply.

In Graph 0.14, we can also see the impact that taxes have on economic activity. Since a per-unit tax on firms causes an upward shift of the supply curve, output will fall as a tax is increased. But output will fall significantly more as consumers become more price elastic in their behavior—with the reduction in output in panel (b) of Graph 0.14 being significantly larger than in panel (a).

EXERCISE 0A.26 Suppose that, instead of taxing the sale of x , the government subsidized consumer purchases of x . Thus, consumers will be paid an amount s for each good x they buy. Can you use Graph 0.15 to determine whether firms will benefit from such a consumer subsidy—and how the per-unit benefit for firms depends on the price elasticity of demand?

EXERCISE 0A.27 If the goal of consumer subsidies is to raise economic output in a market, will the government be more likely to succeed in markets with high or low price elasticities of supply?

0B

SOME MATHEMATICAL PRELIMINARIES

Math intimidates many students—but my students also often tell me that, once they understand the underlying economics, the math isn't actually that bad. I think my students are right—while the B-parts of the text use calculus, there is relatively little beyond a first calculus course that's really necessary. If you know how to take a derivative, you are pretty much set in terms of the math you will need. The real key is to understand the economics enough to set up the math problems.

At the same time, I recognize from my own experience that solving math problems can get frustrating when careless mistakes slip in. Such mistakes can introduce hours of detective work as we try to find where we went wrong—not because the math is “hard,” but just because we are not good at finding mistakes once we make them. For this reason, while the word “calculus” often intimidates, the real key to avoiding the frustrations of solving math problems often lies in a thorough comfort level with *pre-calculus* and basic *algebra* concepts. We forget how to work with exponents or simple systems of equations if we haven't done it in a while—and then we start making careless mistakes that trip us up. This section is therefore intended to provide some basic review of some of the most important pre-calculus and elementary calculus concepts.

0B.1 Functions and Sets Defined with Functions

Functions are simply rules that assign values to points. As discussed in part A, when a point lies in one dimension, it is simply described by a value on the real number line, which we now denote as \mathbb{R}^1 , or as \mathbb{R}_+^1 if we restrict ourselves to only positive real numbers. Similarly, a point that lies in two dimensions (such as the points in Graph 0.2) is described by a pair of numbers from two different real number lines—one pointing in the horizontal direction (the x -axis) and another pointing in the vertical direction (the y -axis). We will therefore denote such a point as lying in \mathbb{R}^2 , or in \mathbb{R}_+^2 if we restrict ourselves to the positive quadrant (as we do in Graph 0.2). And a point that lies in N dimensions is analogously defined by N real numbers, each indicating the value it takes on each of the N dimensions. We will denote such a point as lying in the space \mathbb{R}^N that is formed from N real number lines, or in \mathbb{R}_+^N if we consider only positive values on each dimension.

A rule that assigns values to points in N dimensions can then be written as

$$f: \mathbb{R}^N \rightarrow \mathbb{R}^1. \quad (0.5)$$

Functions are rules that assign values to points.

GRAPH 0.16 A Function from (a) \mathbb{R}_+^1 to \mathbb{R}_+^1 and from (b) \mathbb{R}_+^2 to \mathbb{R}_+^1 .

This notation is read as follows: The function f takes points that lie in the space \mathbb{R}^N and assigns to these points a value from the real number line \mathbb{R}^1 . Graph 0.16, for instance, plots the function $f(x) = x^2$ for $x > 0$ —a function $f: \mathbb{R}_+^1 \rightarrow \mathbb{R}_+^1$; that is, a function that takes points from the (positive portion of the) one-dimensional x -axis and assigns to them a (positive) value $f(x)$. To the x -value 1, it assigns the value $f(1) = 1^2 = 1$, and to the x -value 2 it assigns the value $f(2) = 2^2 = 4$. The function $f(x_1, x_2) = x_1^{0.5}x_2^{0.5}$, on the other hand, is a function $f: \mathbb{R}_+^2 \rightarrow \mathbb{R}_+^1$ that takes points from the two-dimensional plane \mathbb{R}_+^2 and assigns a value from \mathbb{R}_+^1 . To the two-dimensional point $(x_1, x_2) = (1, 1)$, for instance, it assigns the value $f(1, 1) = 1^{0.5}(1)^{0.5} = 1$, and to the point $(x_1, x_2) = (4, 4)$, it assigns the value $f(4, 4) = 4^{0.5}(4)^{0.5} = 2(2) = 4$. This function is graphed in panel (b) of Graph 0.16.

Consider the function $f(x, y, z) = xy + z$. How would you describe this function in terms of the notation of equation (0.5)? What value does the function assign to the points $(0, 1, 2)$, $(1, 2, 1)$, and $(3, 2, 4)$?

**EXERCISE
OB.1**

Functions such as these can then be used to define sets of points. For instance, the set of points that lie underneath the function graphed in panel (a) of Graph 0.16 can be described by the expression

$$\{(x, y) \in \mathbb{R}_+^2 \mid y \leq x^2\}. \quad (0.6)$$

This is read as “the set contains points in \mathbb{R}_+^2 for which the y component is less than or equal to the x component squared.” The portion of the expression that precedes the vertical line $|$ describes a *necessary condition* that points in the set must satisfy; that is, the points must lie in the positive quadrant of two-dimensional space. The portion of the expression that follows the vertical line $|$, on the other hand, describes the *sufficient condition* for points to lie within the set; that is, the relationship between the y component and the x component must be such that y is less than or equal to x^2 .

How would you write the expression for the set of points that lie above the function in panel (a) of Graph 0.16? Which is different from expression (0.6): the necessary or the sufficient condition?

**EXERCISE
OB.2**

You can then similarly use *any* function to describe a set. The set of points that lie underneath the function described in panel (b) of Graph 0.16 is simply

$$\{(x_1, x_2, y) \in \mathbb{R}_+^3 \mid y \leq x_1^{1/2} x_2^{1/2}\}. \quad (0.7)$$

EXERCISE 0B.3 Is this set a convex set? What about the set described in expression (0.6) and the set defined in exercise 0B.2?

0B.1.1 Functions and “Slices” of Functions In part A, we described the fact that “slices” of three-dimensional graphs that hold one variable fixed can be represented in two dimensions—with changes in the fixed variable resulting in *shifts* of two-dimensional curves. The equation for the three-dimensional plane in Graph 0.6, for instance, is $4x + 2y + z = 40$, which reduces to $4x + 2y = 40$ when the variable z is fixed to 0, or to $4x + 2y = 30$ when z is fixed to 10 (resulting in the parallel shift of the line graphed in panel (b) of Graph 0.6).

The same logic, of course, applies to more complicated functions. In the top portion of panel (a) of Graph 0.17, for instance, we graph the function $u(x_1, x_2) = x_1^{0.5} x_2^{0.5}$ —equivalent to the function $f(x_1, x_2)$ graphed in panel (b) of Graph 0.16 but now viewed from a different angle. If we fix x_1 to the value 4, this function then becomes

$$v(x_2) = u(4, x_2) = 4^{1/2} x_2^{1/2} = 2x_2^{1/2}, \quad (0.8)$$

a function that can be graphed in two dimensions as illustrated in panel (b) of Graph 0.17.

GRAPH 0.17 Demand Functions and Demand Curves

Demand curves are inverse slices of more complicated demand functions.

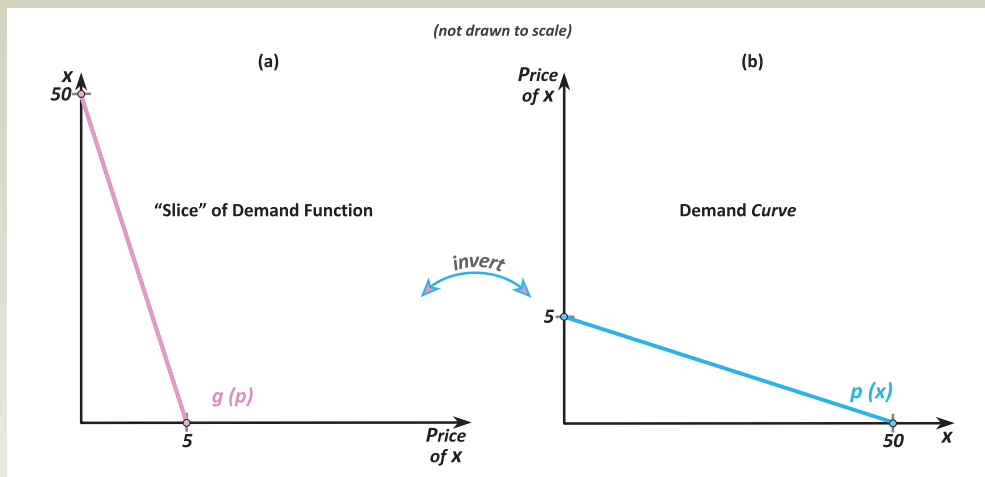

OB.1.2 Demand Functions and Demand Curves Suppose, for instance, that a consumer’s demand for good x can be described by the function $f(p_x, I)$ where p_x denotes the price of the good and I denotes the consumer’s income. This implies that the consumer’s demand choice for the good x depends on two variables—price and income, with $f: \mathbb{R}_+^2 \rightarrow \mathbb{R}_+^1$. Perhaps the function takes the form $f(p_x, I) = (I/2) - 10p_x$. If income is 100 and the price of x is 2, this implies that the consumer will demand $f(2, 100) = (100/2) - 10(2) = 50 - 20 = 30$. Put differently, the demand function assigns a value of 30 to the point $(p_x, I) = (2, 100)$, but, more generally, the function gives us a way of describing the consumer’s demand choice for any pair of p_x and I .

When you have graphed demand curves in previous classes, however, you probably only graphed the relationship of the consumer’s demand choice with the price p_x . If the consumer’s demand function is $f(p_x, I) = (I/2) - 10p_x$, you therefore implicitly held income I fixed and only considered the “slice” of the demand function with I held to a particular value. For instance, if you know the consumer’s income is 100, we can write the slice of the demand function on which the consumer operates as $g(p_x) = f(p_x, 100) = (100/2) - 10p_x = 50 - 10p_x$. This slice of the demand function, graphed in panel (a) of Graph 0.18, is a function $g: \mathbb{R}_+^1 \rightarrow \mathbb{R}_+^1$ —a function that assigns to every p_x value the number $g(p_x)$. And when you graphed the demand curve, you almost certainly ended up putting p_x on the vertical axis and x on the horizontal—implying that you did not graph $g(p_x)$ but rather its inverse. With $g(p_x) = 50 - 10p_x$, the inverse is derived by simply replacing $g(p_x)$ by x and solving for p_x —giving us the demand curve

$$p_x(x) = 5 - \frac{x}{10} \tag{0.9}$$

that is graphed in panel (b) of Graph 0.18. We thus write the demand curve as a function $p_x: \mathbb{R}_+^1 \rightarrow \mathbb{R}_+^1$, a function that assigns to every x -value a price p_x . We do this simply because it is a convention in economics to graph demand curves with quantity x on the horizontal and price p_x on the vertical axis—even though price for an individual consumer really is not a function of x but rather the quantity demanded x is a function of price. Were we to graph demand curves the way a mathematician would think about them, we would graph the $g(p_x)$ function—the function that treats the quantity consumed by the consumer as a function of the price. Put differently, when we graph demand curves we are really graphing *inverse slices of demand functions*.

GRAPH 0.18 Slicing $u(x_1, x_2)$ to get $v(x_2)$

EXERCISE 0B.4 Suppose that the quantity of the good x that is demanded is a function of not only p_x and I but also p_y , the price of some other good y . How would you express such a demand function in the notation of equation (0.5)?

EXERCISE 0B.5 Following on exercise 0B.4, suppose the demand function took the form $f(p_x, p_y, I) = (I/2) + p_y - 2p_x$. How much of x will the consumer demand if $I = 100$, $p_x = 20$ and $p_y = 10$?

EXERCISE 0B.6 Using the demand function from exercise 0B.5, derive the demand curve for when income is 100 and $p_y = 10$.

0B.1.3 Shifts in Demand Curves We have just seen that a demand curve is typically the inverse of a function $g: \mathbb{R}_+^1 \rightarrow \mathbb{R}_+^1$, a function that assigns the quantity of x demanded by a consumer for different prices p_x of the good. When the function $g(p_x)$ is derived from a demand function $f: \mathbb{R}_+^2 \rightarrow \mathbb{R}_+^1$ that depends not only on p_x but also on some other variable like income I , g is a “slice” of f that holds the other variable fixed at some value. In the previous section, for instance, we derived $g(p_x) = 50 - 10p_x$ from $f(p_x, I) = (I/2) - 10p_x$ by assuming that $I = 100$.

Now suppose that our consumer gets a new job and her income increases from 100 to 200. We can then derive the consumer’s new demand function *given her income is 200* as $\bar{g}(p_x) = 100 - 10p_x$.

EXERCISE 0B.7 Verify the last sentence of the previous paragraph.

Notice that g and \bar{g} differ only in the intercept term, with the intercept increasing from 50 to 100 but the slope remaining -10 . The increase in income has therefore caused a parallel shift in the g function. The demand curves before and after the income change are the inverses of g and \bar{g} , which we can write as

$$p_x(x) = 5 - \frac{x}{10} \quad \text{and} \quad \bar{p}_x(x) = 10 - \frac{x}{10}. \quad (0.10)$$

Again, we see the demand curve shifts up as a result of the increase in income—with the intercept term doubling but the slope term remaining the same.

The general point we have now made repeatedly is that *single-variable functions that are derived from multi-variable functions by holding some variables fixed are “slices” of the multivariable functions that shift as the fixed variables are changed*. This gives rise to a common distinction between “a change in the quantity demanded” when price rises and “a shift in demand” when something else (like income) changes. The former is a movement along a demand curve—and the latter is a shift in that curve.

EXERCISE 0B.8 On a graph with p_x and I on the lower axes and x on the vertical axis, can you graph $f(p_x, I) = (I/2) - 10p_x$? Where in your graph are the slices that hold I fixed at 100 and 200? How do these slices relate to one another when graphed on a two-dimensional graph with p_x on the horizontal and x on the vertical axis?

EXERCISE 0B.9 Return to exercise 0B.5 and suppose that $I = 100$ and $p_y = 10$. What is $g(p_x)$? How does it change when p_y increases to 20? How does this translate to a shift in the demand curve?

The same relationship between demand functions and demand curves exists for supply functions and supply curves. Suppose, for instance, that supply is a function of the wage rate ω and the output price p and is given by the supply function $f(\omega, p) = p - 5\omega$. Illustrate the “slice” of the supply function that holds ω fixed to 10, and then derive from it the supply curve. (Hint: You should get two graphs analogous to Graph 0.18.)

EXERCISE
OB.10

What happens in your two graphs from exercise OB.10 when ω changes to 5?

EXERCISE
OB.11

OB.1.4 Parameters versus Variables In essence, “slicing” multi-dimensional functions as we have done earlier simply involves changing some of the *variables* into *parameters*. The function $u(x_1, x_2) = x_1^{0.5}x_2^{0.5}$ in Graph 0.17 has two variables— x_1 and x_2 . When “slicing” the function at $x_1 = 4$ to obtain $v(x_2) = 2x_2^{0.5}$, we are simply treating the x_1 variable as a parameter set equal to 4.

When we derive a slice of a function by holding a variable fixed, we treat that variable as a parameter.

More generally, we will often express parameters in the form of Greek letters—like α , β , and γ —to differentiate them from variables in our functions. You will, for instance, see functions like $u(x_1, x_2) = x_1^\alpha x_2^\beta$ —where the exponents simply stand in for some value to be assigned later. Notationally we clarify what is a variable and what is a parameter by how we write the function, with $u(x_1, x_2)$ indicating that there are two variables called x_1 and x_2 , and a function $f(x_1, x_2, y)$ indicating that there is an additional y variable. Put differently, variables represent the components of the points that the function assigns numbers to—and parameters simply alter what precise values are assigned to those points.

OB.1.5 Solving Systems of Equations: Equilibrium In many of the applications developed in this text, we will need to solve systems of equations. The simplest application of this arises in the calculation of market output and prices when presented by supply and demand curves. Suppose, for instance, you are given the equation of a demand curve

$$p_d(x) = A - \alpha x \quad (0.11)$$

and a supply curve

$$P_s(x) = B + \beta x. \quad (0.12)$$

Note that these functions are written as functions of only x —implying that A , B , α , and β are parameters, with the capital letters giving the intercepts and the Greek letters giving the slopes (as depicted in Graph 0.19).

The equilibrium price p^* occurs at the intersection of these curves—with the price p_s read off the supply curve equal to the price p_d read off the demand curve. We can therefore set the demand and supply curves equal to one another; that is,

$$B + \beta x = A - \alpha x \quad (0.13)$$

and solve for x to get the market output level x^* . Subtracting B and adding αx to both sides, we get $(\alpha + \beta)x = A - B$, and dividing both sides by $(\alpha + \beta)$, we get the equilibrium quantity

$$x^* = \frac{A - B}{\alpha + \beta}. \quad (0.14)$$

As is obvious from Graph 0.19, both demand and supply curves pass through the same price p^* at the equilibrium output level x^* . We can therefore plug our expression for x^* from equation (0.14) into either the demand curve from equation (0.11) or the supply curve from equation (0.12). Using the demand curve, we get

Solving for a competitive equilibrium in a market involves setting supply equal to demand and solving for the intersections point.

GRAPH 0.19 Equilibrium as the Solution to a System of Equations

$$p^* = A - \alpha x^* = A - \alpha \left(\frac{A - B}{\alpha + \beta} \right) = \frac{\alpha A + \beta A - \alpha A + \alpha B}{\alpha + \beta} = \frac{\beta A + \alpha B}{\alpha + \beta}, \quad (0.15)$$

and using the supply curve, we similarly get

$$p^* = B - \beta \left(\frac{A - B}{\alpha + \beta} \right) = \frac{\alpha \beta + \beta B + \beta A - \beta B}{\alpha + \beta} = \frac{\beta A + \alpha B}{\alpha + \beta}. \quad (0.16)$$

EXERCISE 0B.12 Can you tell how equilibrium price changes as A and B change? Can you make intuitive sense of this by linking changes in parameters to changes in Graph 0.19?

EXERCISE 0B.13 Can you do the same for the equilibrium quantity?

Often, of course, the systems of equations we have to solve in an economic model are more complex—instead of 2 equations (supply and demand) and 2 unknowns (quantity and price), we might have 3 equations and 3 unknowns or 4 equations and 4 unknowns. As these systems become more complex, we tend to turn to increasingly sophisticated mathematical software packages that can do the work for us, but we'll frequently solve systems of at least 3 equations (and 3 unknowns) by hand.

There are multiple ways one can go about solving this. Consider a system of 3 variables (x , y , and z) and 3 equations. One method that's often easy to implement is to simply solve the first equation for x in terms of y and z , and then to substitute x in the second and third equations with the expression for x in terms of y and z . We then have a system of two equations and two unknowns (y and z) that we can solve for y and z in terms of just the parameters of the equations. Substituting those solutions back into the first equation then also gives us x in terms of just the parameters.

But often there are even simpler ways of solving some of the systems of equations we'll encounter. In Chapter 6, for instance, we encounter the system of equations

$$\begin{aligned}\frac{1}{2}x_1^{-1/2}x_2^{1/2} - 20\lambda &= 0 \\ \frac{1}{2}x_1^{1/2}x_2^{-1/2} - 10\lambda &= 0 \\ 200 - 20x_1 - 10x_2 &= 0\end{aligned}\tag{0.17}$$

where x_1 , x_2 , and λ are variables.⁵ Many of our systems of equations in the text will take this form, and we will solve these by re-writing the first two equations as

$$\begin{aligned}\frac{1}{2}x_1^{-1/2}x_2^{1/2} &= 20\lambda \\ \frac{1}{2}x_1^{1/2}x_2^{-1/2} &= 10\lambda\end{aligned}\tag{0.18}$$

and then dividing the equations by one another to cancel λ and get the equation

$$\frac{x_2}{x_1} = 2.\tag{0.19}$$

This can then be written as $x_2 = 2x_1$ and substituted into the third equation (that lacks a λ variable) to give us

$$200 - 20x_1 - 10(2x_1) = 0\tag{0.20}$$

which then easily solves to give us $x_1 = 5$. Substituting this back into $x_2 = 2x_1$, we also get $x_2 = 10$.

In this Chapter 6 problem, it turns out we do not care about the value of λ . Suppose, however, we did. How would you derive it's value?

EXERCISE
OB.14

For most students, the process of solving the kinds of systems of equations we will encounter will quickly become relatively clear. However, in my experience, students often struggle with the nitty-gritty algebraic operations required to solve some of these—and so we turn to a brief review of some of these operations.

OB.2 Algebraic Operations

There are several algebraic concepts and techniques that appear frequently throughout the text. One involves solving systems of equations, a concept we already covered. Others involve working with exponents, quadratic equations and logarithms, each of which is discussed next.

OB.2.1 Rules for Working with Exponents A *positive integer exponent* simply indicates how many times we multiply the number (or variable) underneath the exponent. For instance, $2^3 = 2(2)(2) = 8$ and $x^4 = x(x)(x)(x)$. Anything with a zero exponent is equal to 1—that is, $2^0 = 1$ and $x^0 = 1$. A *negative exponent* indicates we are dividing rather than multiplying—that is, $2^{-3} = 1/(2^3) = 1/(2(2)(2)) = 1/8$ and $x^{-4} = 1/(x^4)$. Finally, a *fractional exponent*

⁵While we typically use Greek lower case letters to signify parameters rather than variables, this is not the case in the *Lagrange method* of optimization that is introduced in Chapter 6.

It is important to recall the basic rules of working with exponents.

implies we are taking a “root”—that is, $2^{1/2} = \sqrt{2}$ and $2^{1/3} = \sqrt[3]{2}$. Essentially everything you need to know about how to work with exponents follows from these four facts, but I am still amazed how often a careless mistake with exponents ends up costing me hours of backtracking when I solve the kinds of problems we will solve in the text.

It’s useful, then, to keep the following rules for working with exponents in mind:

1. Anything taken to the exponent 0 is equal to 1: $x^0 = 1$.
2. Anything taken to the exponent 1 is equal to itself: $x^1 = x$.
3. Add exponents when multiplying: $x^m x^n = x^{(m+n)}$.
4. Subtract exponents when dividing: $\frac{x^m}{x^n} = x^{(m-n)}$.
5. Multiply exponents when you have an exponent on top of an exponent: $(x^m)^n = x^{mn}$.
6. Negative exponents imply division: $x^{-n} = \frac{1}{x^n}$.
7. Fractional exponents imply taking roots: $x^{1/n} = \sqrt[n]{x}$ and $x^{m/n} = (\sqrt[n]{x})^m$.
8. Keep track of exponents associated with different variables: $(xy)^n = x^n y^n$ and $(\frac{x}{y})^n = \frac{x^n}{y^n}$.

EXERCISE
OB.15

Can you prove Rules 3 through 5 by just using the definition of exponents?

EXERCISE
OB.16

Simplify the following: $\frac{x^{3/2} y^{1/2}}{x^{1/2} y^{-1/2}}$.

EXERCISE
OB.17

Simplify the following: $\left(\frac{x^{4/5} y^2}{x^{-1/2} y^4}\right)^{-2}$.

OB.2.2 Quadratic Equations, Factoring, and the Quadratic Formula A quadratic equation can be written in the form

$$ax^2 + bx + c = 0 \quad (0.21)$$

where a , b , and c are parameters. Such equations typically have two solutions, but in economic applications only one of the two solutions is typically economically meaningful.

Sometimes, the left-hand side of the quadratic equation can be easily *factored*—that is, it can be decomposed into a product of two objects (known as *factors*) that, when multiplied together, give us back the left-hand side of the equation. For instance, the left-hand side of $x^2 + 2x - 8 = 0$ can be factored as $(x + 4)(x - 2)$, with the two factors of $(x + 4)$ and $(x - 2)$ giving back the expression $x^2 + 2x - 8$ when multiplied out. The quadratic equation can then be written as $(x + 4)(x - 2) = 0$ —which can hold only if at least one of the factors is equal to zero. Thus, we can conclude that there are two solutions to the quadratic equation: $x = -4$ and $x = 2$. In many economic applications, only positive solutions have economic meaning—which would then allow us to conclude that the latter is the economically meaningful solution.

When quadratic equations cannot easily be factored, the quadratic formula can be used to solve them.

EXERCISE
OB.18

Solve the following quadratic equation by factoring: $2x^2 + 2x - 12 = 0$.

EXERCISE
OB.19

An equation is still quadratic if $b = 0$. Solve the following quadratic equation by factoring: $x^2 - 4 = 0$.

EXERCISE
OB.20

Does the quadratic equation $x^2 + 4x + 4 = 0$ have two solutions?

It is often not, however, possible to factor a quadratic equation straightforwardly. The *quadratic formula* then gives an easy way to factor any quadratic equation—and thus to find the solutions to any quadratic equation. In particular, any quadratic equation can be written as

$$ax^2 + bx + c = a\left(x - \frac{-b + \sqrt{b^2 - 4ac}}{2a}\right)\left(x - \frac{-b - \sqrt{b^2 - 4ac}}{2a}\right), \quad (0.22)$$

with the terms in parentheses generated by the quadratic formula. This formula simply states that the solutions to a quadratic equation $ax^2 + bx + c = 0$ are always

$$\frac{-b + \sqrt{b^2 - 4ac}}{2a} \text{ and } \frac{-b - \sqrt{b^2 - 4ac}}{2a}. \quad (0.23)$$

Use the quadratic formula to verify your answer to exercises OB.18, OB.19, and OB.20.

EXERCISE
OB.21

Solve the quadratic equation $3x^2 + 8x + 4 = 0$.

EXERCISE
OB.22

OB.2.3 Rules for Working With Natural Logarithms We often use logarithms in economic applications. The most common logarithm, and the one you probably first learned in your pre-calculus classes, is the *logarithm to the base 10*. This “base 10” logarithm of a number x , denoted $\log_{10} x$, is simply the exponent to which 10 would have to be raised to equal x ; that is, since $10^2 = 100$, $\log_{10} 100 = 2$.

Rather than using this “base 10” logarithm, however, we tend to instead use the *natural logarithm* defined as the logarithm to the base e (where e is an irrational constant approximately equal to 2.718).⁶ The natural logarithm of a number x , usually denoted $\ln(x)$, is then the exponent to which e would have to be raised to equal x .

GRAPH 0.20 $\ln(x)$ in (b) is the Inverse of e^x in (a)

⁶Logarithms to any positive base vary only by a constant multiplier from the natural logarithm and can therefore be defined in terms of natural logarithms.

A related concept is that of an *exponential function* defined as $f(x) = e^x$, with the natural logarithm representing the *inverse of the exponential function*. This is illustrated in Graph 0.20 where panel (a) plots the exponential function e^x while panel (b) plots the (natural) logarithm function $\ln(x)$ (or $\log_e(x)$).

There are a few basic rules of logarithms that you'll have to keep in mind in applications that come up throughout the text. These are:

1. Logarithms turn multiplication into addition:

$$\ln(xy) = \ln(x) + \ln(y). \quad (0.24)$$

2. Logarithms turn division into subtraction:

$$\ln\left(\frac{x}{y}\right) = \ln(x) - \ln(y). \quad (0.25)$$

3. The inverse relationship between exponential functions and (natural) logarithmic functions imply

$$e^{\ln(x)} = x \text{ and } \ln(e^x) = x. \quad (0.26)$$

4. Logarithms are defined only for strictly positive values, with $\ln(0)$ undefined and $\ln x$ approaching negative infinity as x approaches 0.

5. The natural log is positive for x -values that exceed 1 and negative for x -values that fall below 1; that is,

$$\ln 1 = 0, \ln x > 0 \text{ when } x > 1 \text{ and } \ln x < 0 \text{ when } 0 < x < 1. \quad (0.27)$$

It is important to recall the basic rules of working with natural logarithms.

EXERCISE OB.23

Re-write the following as an expression with a single \ln term: $\ln(2x) + \ln(y) - \ln(x)$.

EXERCISE OB.24

Simplify the following: $\ln e^{(x^2 + xy)}$.

EXERCISE OB.25

Solve the following for x : $\ln e^{(x^2 + 4)} = \ln e^{4x}$.

Derivatives are slopes, and it is important to recall the basic rules of working with derivatives.

0B.3 Some Basic Calculus

The textbook uses a single multi-variable concept heavily—the concept of *partial derivatives*. If you have taken a full calculus sequence prior to this course, you will have seen this concept already. If you have not, you will quickly see that it is a simple extension of single variable derivatives that you would have learned in your first calculus course. We leave the extension of derivatives to partial derivatives to the Appendix of Chapter 4 and review here only the single-variable calculus concepts you'll need.

0B.3.1 Single-Variable Derivatives The derivative of a single-variable function $f(x)$ is simply the slope of that function. The first derivative of $f(x)$ is sometimes denoted as $f'(x)$ but more commonly as $\frac{df}{dx}$. Some frequently used rules for differentiating different types of functions include:

1. Derivatives of constants are equal to zero; that is, when γ is a constant, $\frac{d(\gamma)}{dx} = 0$.
2. Functions with constant slopes have derivatives equal to that constant; that is, $\frac{d(\gamma x)}{dx} = \gamma$.
3. Derivatives of higher-order polynomials follow the rule: $\frac{d(\gamma x^n)}{dx} = n\gamma x^{(n-1)}$.

4. The derivative of the sum of two functions is equal to the sum of the derivative of the functions; that is,

$$\frac{d(f(x) + g(x))}{dx} = \frac{df(x)}{dx} + \frac{dg(x)}{dx}. \quad (0.28)$$

5. The derivative of the natural log of x is the inverse of x : $\frac{d(\ln x)}{dx} = \frac{1}{x}$.
 6. The derivative of the exponential function is the exponential function: $\frac{d(e^x)}{dx} = e^x$.
 7. The derivative of the sin function is a cosine: $\frac{d(\sin x)}{dx} = \cos x$.
 8. The derivative of the cos function is a negative sine: $\frac{d(\cos x)}{dx} = -\sin x$.

Show that Rule 2 follows from Rule 3.

EXERCISE
OB.26

Differentiate the following with respect to x : $f(x) = 3x^3 + 2x^2 + x + 4$.

EXERCISE
OB.27

Next, suppose you have a function $f(x)$ and another function $g(x)$ —and suppose that these functions are multiplied, giving us $f(x)g(x)$. The derivative of this new function is then determined using the *product rule*, which states

$$\frac{d(f(x)g(x))}{dx} = \frac{df(x)}{dx}g(x) + f(x)\frac{dg(x)}{dx} \quad (0.29)$$

Use the product rule to differentiate the function $(x + 3)(2x - 2)$ with respect to x .

EXERCISE
OB.28

Multiply the function in exercise OB.28 out and solve for its derivative with respect to x without using the product rule. Do you get the same answer?

EXERCISE
OB.29

Similarly, if a function is formed by dividing $f(x)$ and $g(x)$, the derivative of that new function can be evaluated using the *quotient rule*:

$$\frac{d\left(\frac{f(x)}{g(x)}\right)}{dx} = \frac{\frac{df(x)}{dx}g(x) - f(x)\frac{dg(x)}{dx}}{(g(x))^2} \quad (0.30)$$

Use the quotient rule to solve for the first derivative of $\frac{(x+3)}{2x-2}$.

EXERCISE
OB.30

Finally, the *chain rule* applies to instances where a function $g(x)$ becomes the argument in a function $f(x)$ —that is, when we create the function $f(g(x))$ and differentiate it. For instance, suppose $f(x) = x^2$ and $g(x) = (x^3 - 2)$. Making $g(x)$ the argument in $f(x)$ implies $f(g(x)) = (x^3 - 2)^2$. The chain rule then tells us that

$$\frac{df(g(x))}{dx} = \frac{df(g)}{dg} \frac{dg(x)}{dx}. \quad (0.31)$$

Differentiating $f(g(x)) = (x^3 - 2)^2$ with respect to x then implies taking the derivative $\frac{df(g)}{dg} = 2(x^3 - 2)$ as well as the derivative $\frac{dg(x)}{dx} = 3x^2$ to give us

$$\frac{df(g(x))}{dx} = 2(x^3 - 2)(3x^2) = 6x^5 - 12x^2. \quad (0.32)$$

EXERCISE
0B.31

Multiply out $(x^3 - 2)^2$ and take the derivative without using the chain rule. Do you get the same result?

EXERCISE
0B.32

In exercise 0B.30, you used the quotient rule to evaluate the derivative of $\frac{(x+3)}{2x-2}$. This function could alternatively be written as $(x+3)(2x-2)^{-1}$. Can you combine the product rule and the chain rule to solve again for the derivative with respect to x ? Is your answer the same as in exercise 0B.30?⁷

EXERCISE
0B.33

Derive the derivative of $f(x) = \ln(x^2)$ using the chain rule. Then, use Rule 1 from our logarithm section to re-write $f(x)$ in such a way that you don't have to use the chain rule. Check whether you get the same answer.

0B.3.2 Example: Price Elasticities As we will see in Chapter 18, price elasticities of demand can be derived from demand functions for different points on the demand curve. You may know from a previous course, or you can see the idea developed in Section 18B.1, that the price elasticity of demand ϵ_d is defined as

$$\epsilon_d = \frac{dx(p)}{dp} \frac{p}{x(p)}. \quad (0.33)$$

In Graph 0.10 (replicated here as Graph 0.21), for instance, we graphed a demand curve $p(x) = 400 - 0.5x$ —which is the inverse of the demand function $x(p) = 800 - 2p$. The derivative of this function with respect to p is $\frac{dx(p)}{dp} = -2$. Using the price elasticity formula, we can then derive the price elasticity of this demand curve at different prices as

$$\epsilon_d = \frac{dx(p)}{dp} \frac{p}{x(p)} = -2 \left(\frac{p}{800 - 2p} \right) = -\frac{p}{400 - p}. \quad (0.34)$$

To calculate the price elasticity at a particular point on the demand curve, we just have to plug in the price we are interested in. At a price of 75 (midway between the higher and lower

GRAPH 0.21 Spending and Price Elasticities

⁷ This exercise illustrates that the quotient rule is in some way superfluous because we can always re-write a fraction in a form that allows us to apply the product rule with the chain rule.

price in panel (a) of the Graph), the formula gives us the price elasticity $-75/(400-75) \approx -0.23$. For the similar “in between price” of 200 in panel (b), on the other hand, the formula tells us that price elasticity is equal to $-200/(400 - 200) = -1$; and at the “in between price” of 325 in panel (c), we get the price elasticity of $-325/(400 - 325) \approx 4.33$.

Thus, the price elasticity is increasing in absolute value as we move up the demand curve. At low prices, a small price elasticity (in absolute value) indicates relatively little responsiveness of behavior to price—giving us the result that spending actually increases as price rises (because the magenta area is bigger than the blue area in panel (a)). At high prices, on the other hand, the large price elasticity (in absolute value) indicates relatively more responsiveness of behavior to price—with spending falling as price increases (as in panel (c) where the magenta area is now smaller than the blue area). At the midpoint of the demand curve (where price is 200), we get the price elasticity of -1 where changes in prices lead to roughly the same amount of spending.

We have seen that price elasticities vary along linear demand curves. Consider now the demand curve given by the equation $x(p) = \alpha/p$. Is the same true for this demand function?

EXERCISE
OB.34

OB.3.3 Finding Maxima and Minima One of the main uses of calculus in economics emerges from *optimization problems*. Consumers do the best they can given their circumstances—that is, they “optimize” their well being subject to their constraints. Firms try to “optimize” profits. In fact, economics derives much of its identity from viewing human behavior as emerging from individuals solving optimization problems. In Chapter 6, we will begin to investigate the economics behind optimization. For now, all we hope to do is simply illustrate the usefulness of calculus in the process of optimizing single-variable mathematical functions.

Calculus is used to solve economic optimization problems.

GRAPH 0.22 Finding the Maximum of a Function $f(x) = x^{1/2}(20 - 2x)^{1/2}$

Consider, for instance, the function $f(x) = x^{1/2}(20 - 2x)^{1/2}$, which is illustrated in Graph 0.22 (and which takes on economic meaning in Chapter 6). From the graph, it is clear that the function attains its highest point at $x = 5$. It is also clear from the graph that the very definition of a “maximum” implies that the slope of the function must be zero at that maximum. Put differently, it has to be true that the derivative of the function is equal to zero at the point where the function attains its maximum.

The derivative of the function $f(x) = x^{1/2}(20 - 2x)^{1/2}$ is

$$\frac{df(x)}{dx} = \frac{1}{2}x^{-1/2}(20 - 2x)^{1/2} - x^{1/2}(20 - 2x)^{-1/2}. \quad (0.35)$$

EXERCISE OB.35

Verify that this is correct.

Setting this derivative equal to zero implies that

$$\frac{1}{2}x^{-1/2}(20 - 2x)^{1/2} = x^{1/2}(20 - 2x)^{-1/2}. \quad (0.36)$$

Multiplying both sides by $x^{1/2}$ and by $(20 - 2x)^{1/2}$ gives us

$$x = \frac{20 - 2x}{2} = 10 - x. \quad (0.37)$$

Solving for x , we get $x = 5$ —precisely where the maximum occurs in the graph.

Of course it is not true that a derivative of zero implies a maximum for the function. A function with a U-shape (as opposed to the inverse U-shape in Graph 0.22) will have a zero slope (and thus a zero derivative) at its *minimum* rather than at a *maximum*. But it is true that the derivative of a function is equal to zero at any maximum—even if it is also true that the derivative of a function is zero at a minimum.

EXERCISE OB.36

Evaluate the following statement: A derivative of zero is a necessary but not a sufficient condition for us to identify a maximum of a function.

OB.3.4 (Integrals) The concept of an integral is used only in a few sections of the text, and in each case you can easily skip those sections if you are not comfortable with the idea. In essence, an integral is simply a way of measuring areas under curves—something that can easily be done using basic rules of geometry when functions are linear.

CONCLUSION

This chapter began with an overview of some basic concepts used in the graphs that we will develop throughout the text, concepts such as *points*, *sets*, *convexity*, and the idea of lower-dimensional graphs as “slices” of higher dimensional graphs. The latter of these then gives us a way of thinking about the common Econ 1 distinction between “movements along curves” and “shifts of curves”: When some variables are “fixed,” the resulting “slices” we graph will move as the fixed variables are changed. Perhaps the most intuitive example is the difference between a price change moving us along a demand curve and an income change shifting the demand curve. In part B of the chapter we then formalized some of these ideas—and provided an overview of the most useful pre-calculus and single-variable calculus concepts used throughout the text.

Introduction

Do safer cars necessarily result in fewer traffic deaths? Is it sensible to subsidize domestic U.S. oil drilling in an effort to make the United States less dependent on unstable regions of the world? Would outlawing live Christmas trees help to reduce deforestation? Should we impose laws against “price gouging”? Is boycotting companies that use cheap labor abroad a good way to express our outrage at the dismal working conditions in those countries? Would it be better for workers to require their employers to pay their Social Security taxes rather than taxing the workers directly? Should we tax the sales by monopolies so that these companies don’t earn such outrageous profits?

Many people would instinctively answer “yes” to each of these questions. Many economists would say “no,” or at least “not necessarily.” Why is that?

One possible answer is that economists are social misfits who have different values than “real people.” But I don’t think that’s typically the right answer. By and large, economists are an ideologically diverse group, distributed along the political spectrum much as the rest of the population. Most of us live perfectly normal lives, love our children, and empathize with the pain of others. Some of us even go to church. We do, however, look at the world through a somewhat different lens, a lens that presumes people respond to incentives and that these responses aggregate in ways that are often surprising, frequently humbling, and sometimes quite stunning. What we think we know isn’t always so, and, as a result, our actions, particularly in the policy realm, often have “unintended” consequences.

I know many of you are taking this course with a hidden agenda of learning more about “business,” and I certainly hope that you will not be disappointed. But the social science of economics in general, and microeconomics in particular, is about much more than that. Through the lens of this science, economists see many instances of remarkable social order emerging from millions of seemingly unconnected choices in the “marketplace,” spontaneous cooperation among individuals on different ends of the globe, the kind of cooperation that propels societies out of the material poverty and despair that has characterized most of human history. At the same time, our lens clarifies when individual incentives run counter to the “common good,” when private interests unravel social cooperation in the absence of corrective nonmarket institutions. Markets have given rise to enormous wealth, but we also have to come to terms with issues such as economic inequality and global warming, unscrupulous business practices, and racial discrimination. Economics can certainly help us think more clearly about business and everyday life. It can also, however, teach some very deep insights about the world in which we live, a world in which incentives matter.

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

1.1

WHAT IS MICROECONOMICS?

Micro-economics investigates the social consequences of the interaction of rational beings that pursue their perceived self-interest.

In science, we formulate models that generate hypotheses—and then we test those hypotheses with data.

By “rational” we mean that people are goal-oriented, and “perceived self-interest” is not necessarily the same as “selfishness.”

We will define *microeconomics* as the *science* that investigates the *social consequences* of the interaction of *rational* beings that pursue their *perceived self-interest*.¹ At first glance, this description of human beings as “rational” and “self-interested” sounds a bit naive and vaguely callous. After all, most people would not characterize their fellow citizens as always “rational,” and we know first hand that some of our most meaningful experiences derive from stepping outside of our “self.” For those who are used to thinking of “scientists” as wearing white coats and protective goggles in research laboratories, the use of the word “science” to characterize what economists do may also seem odd, as may the definition’s emphasis on “social” consequences. It’s perhaps useful, then, to say a bit more about this definition.

1.1.1 Economics as a Science

Let’s begin with a few words about *science*. Obviously, economics is not a science in exactly the same way that physics or chemistry are science: We don’t generally have laboratories in which we smash atoms into each other or mix fuming chemicals. But in another sense it *is* similar. Science progresses through the formulation and testing of models that generate hypotheses, and in this sense, economics is in fact by and large a science. Most economists, as we will discuss more in Section 1.2, formulate models that are rooted in economic theory and then check to see whether the hypotheses that emerge are rejected by real-world observations. Some economists actually do perform experiments, but most look at data from the real world to see whether our predictions hold. You will learn more about how this *testing* of hypotheses is done if you go on to take statistics and econometrics courses, but in this course, you will mainly learn about the underlying theory and models that most economists use to formulate their hypotheses.

1.1.2 Rationality, Self-Interest, and Indiana Jones

In these models, we assume that people are *rational* and in pursuit of their *perceived self-interest*. While we will use the term “rational” in other ways once we define tastes in Chapter 4, for now we simply take it to mean that individuals seek to do “the best they can given their circumstances.” We don’t mean that people are rational in some deeper philosophical sense; all we really mean is that they are deliberative in trying to achieve their goals. Those goals might include improving the welfare of others they care about, and they may include goals that make sense to them but don’t make sense to others. Someone who sacrifices personal consumption to improve her children’s well-being may be thought of as “unselfish,” but improving her children’s well-being may still be in her perceived “self-interest” if making her children happy also makes her happy. That seems quite noble, but not everything that one individual finds “worthwhile” might be worthwhile in some deeper sense. The businessman may seek to maximize his own profit when he could be saving starving children instead; the politician may seek to win elections when she could be making a “worthwhile” difference in people’s lives by doing something unpopular; the drug addict may seek to get his next fix when he might be “better off” checking himself into a rehab center. Nevertheless, each of these individuals is directing his or her actions toward a goal he or she perceives to be worthwhile and in his or her self-interest.

Some time ago, I watched one of the popular Indiana Jones movies starring Harrison Ford and Sean Connery. Sean Connery plays Harrison Ford’s father, and together they find themselves in an unfortunate position. Sean Connery lies in a cave, mortally wounded, and Harrison Ford faces the following dilemma: On the other side of the cave, there are a number of potions in different

¹ This definition actually applies also to macroeconomics, but *microeconomists* are particularly focused on beginning their analysis with *individual* behavior.

containers. Most of these potions are deadly poisons, but one is a magical elixir that, if consumed by someone mortally wounded, will heal instantly. Harrison Ford runs to the potions and agonizes over which to take. He settles on one and decides to test it himself before giving it to his father.

I guess it seems unselfishly heroic that Harrison Ford would put his own life in jeopardy before subjecting his father to the possible ingestion of a poison, but it also violates what economists think of as rational self-interest. We are not disturbed by the fact that Harrison Ford cares deeply about his father; given that he does, the goal of saving his father falls within the realm of his perceived self-interest. What bothers us is the fact that Harrison Ford appears not to choose rationally given the goal he is attempting to achieve, at least so long as we are willing to assume that preserving his own life, all else being equal, is also in Harrison Ford's perceived self-interest. The rational course of action in this case would have been for Harrison Ford to settle on one of the potions, run with the potion to the other side of the cave where his mortally wounded father lies, and say: "Dad, you are going to die any minute. This potion may kill you, which will happen anyway if you don't take it. But if it's the right potion, it will save your life. So drink the potion and don't think I don't care about you just because I don't first take the risk of killing myself only to watch you also die during my final moments. One of us surviving is better than none, even if both of us surviving is better still."

The example illustrates two points: First, self-interest is not necessarily the same as "selfishness." The latter presumes you care only about yourself; the former leaves open the possibility that others may contribute to your perception of your own well-being. Often, selfishness and self-interest coincide, but not always. Second, "rational" simply means that we pick the best available course of action to achieve our self-interested goal. Harrison Ford does not violate our presumption of self-interest when he cares deeply about his father, but his behavior does violate rationality unless he places no value on his own life. In testing the potion first, Harrison Ford is not doing "the best he can given his circumstances."

1.1.3 Social Consequences, Pencils, and Global Warming

Ultimately, we don't just try to understand rational, self-interested behavior per se, although that is an important aspect of microeconomics. What we are really after is understanding the *social consequences* of the interaction of rational, self-interested individual behavior. It may be interesting to think about how Robinson Crusoe behaves on an island by himself, but it is more interesting to understand how the world changes as he and his friend Friday interact once Friday comes on the scene. More interesting still is what happens when hundreds, thousands, or even millions of rational, self-interested individuals pursue their individual goals *given that everyone else is doing the same*. Economists call the outcome of these interactions an "equilibrium," and it is in this equilibrium that we find the social consequences of individual behavior.

In his famous PBS series *Free to Choose*, Milton Friedman holds up a pencil and makes the initially preposterous claim that no one in the world knows how to make that pencil. It seems silly at first, but at the same time it is absolutely true if we seriously think about whether anyone knows how to make a pencil *from scratch*. One would have to know which trees to harvest for the wood, how to make the tools to harvest the trees, what chemicals to use to treat the wood once it is cut into the right shape, how to drill the hole to make room for the lead and how to make the tools to drill the hole. That does not begin to scratch the surface, because we also have to know everything about where to get the materials to eventually make the lead (and how to make it and all the necessary tools required for that), how to do the same for the metal cap that holds the eraser, how to make the eraser, and how to create the paint and paintbrushes to coat the outside of the pencil. When you really think about it, tens of thousands of people somehow cooperated across all the continents in the world to make the pencil Friedman was holding, and almost none of those tens of thousands of people were aware that they were participating in a process that would result in a pencil.

The "social consequences" of individual behavior are captured in "equilibrium" where all people are doing the best they can given their circumstances.

Economists are fascinated by the fact that pencils are produced despite the fact that no one knows how to produce them and despite the fact that no one is charged with coordinating all these people and materials into the production of pencils. We are fascinated by the fact that cooperation on such massive scale can simply emerge from the bottom up without the individuals knowing that they are cooperating with one another. We are even more fascinated by the fact that the cooperation emerges purely from the rational, self-interested choices that individuals make along the way, each one simply trying to earn a living, to do the best he or she can given the circumstances. This is a *social consequence* of the interaction of rational, self-interested behavior, one that is guided by the impersonal forces of market prices that tell individuals where to work, what to produce, whom to sell to, etc. If you can see how it might be fascinating that pencils get produced and delivered to my local store for pennies, don't get me started on my fascination about really complicated products that seem to pop up all over the place without anyone really coordinating the millions of people involved.

Of course not all social consequences of rational, self-interested behavior are so rosy. We will see that the same economic lens that explains how people cooperate to make pencils also explains how global warming is not tamed by the same forces, how relative (as opposed to absolute) poverty persists, how concentrated power distorts markets, and how some goods might never get produced unless nonmarket institutions intervene. Understanding when we can rely on individual self-interest to give rise to cooperation—and when such self-interest impedes cooperation—is one of the key themes of this book and one of the central goals of microeconomics. With such an understanding, we can then formulate ways of changing the circumstances in which decisions are made to bring those decisions more in line with social goals: to change the *social consequences* of rational, self-interested behavior by *altering the incentives* people face along the way.

1.2

ECONOMICS, INCENTIVES, AND ECONOMIC MODELS

When boiled down to its essentials, economics is then all about an exploration of the simple premise that *people respond to incentives* because they generally *attempt to do the best they can given their circumstances*. It is a simple premise but one that leads to a rich framework through which to analyze many small and large debates in the world in a logical and rigorous manner. Yet despite all of my idealistic musings about the important issues that economics can help us to understand better, you will notice that much of this book is devoted to the building of rather cold economic “models” that, at least initially, seem to be starkly disconnected from such grand objectives. In fact, many students initially think of these models as involving *simplistic* and *unrealistic* characterizations of what we are as human beings. And in certain ways, they are undeniably right. Nevertheless, I would like to convince you at the outset that such models represent the only real method through which economists can make any sense at all of the underlying issues we are concerned about. In the process, we also get an “unintended consequence” of learning through economic models: We learn to think more conceptually, to move beyond memorization to a method of linking seemingly unconnected events in ways that translate to life well beyond economics.

1.2.1 Economic Models, *Simplicity*, and Picasso

Consider the way we model consumers in the first section of this book. As you will see in the coming chapters, we will essentially view them as cold individuals who rationally calculate the costs and benefits of different alternatives using a mechanical characterization of “tastes” as a guide. “Economic man,” as characterized in many of the models that we start with, boils down to a machine that seems to have little moral standing beyond that of a vacuum cleaner. It is not a full characterization of all the complexity that underlies the human condition, and it omits some of the very aspects of our makeup that make us “human.” I have often mentioned in

my classes that I would be deeply depressed if I truly thought that my wife was nothing more than “economic woman.” The most important factors I considered when proposing marriage to her had virtually nothing to do with our simple model of decision making.

But economics does not attempt to paint a full picture of who we are as human beings. You will no doubt find meaning in your studies of philosophy or psychology or art or religion as you try to complete the picture of what it means to you to say that we are human. Economics simply tries to provide a framework for systematically studying aspects of human decision making that relate to our desire to pursue our perceived self-interest in different institutional settings, and how such self-interested decision making affects society as a whole. For this purpose, it would be maddening to try to come to real conclusions using a fully laid out picture of the complex beings we are, because much of what makes us so complex has little bearing on the questions economists ultimately aim to answer. Simplicity in models therefore becomes a virtue so long as the models can predict well what we are trying to predict.

I often try to illustrate this explicitly to my students by telling them of my ignorance of abstract art and of the insights into such art I have gained from the following example: I am told that, somewhere in a museum, there exists a series of 27 paintings by Picasso. The first of these paintings is one that I could understand: It is a realistic depiction of a particular scene, perhaps a girl holding a watering can in a beautiful garden. The second painting in the series is almost identical to the first but contains somewhat less detail. Similarly, each of the next 25 paintings in the series takes away some more detail, leaving the last painting with nothing but some unrecognizable streaks of paint on a canvas. This last painting, I am told, is Picasso’s interpretation of the “essence” of the first painting. I have never seen this series of 27 paintings and am not sure it even exists. But I am told that I would have a much better understanding of what makes the first painting great if I could make the effort to view this series because I would truly see how the last painting captures something profound that gets lost to a simpleton like me as I view the first pretty picture in the series.²

Economic models are like the last painting in this series. They are constructed to strip away all the complexity, all the noise that gets in the way of a sound analysis of particular economic problems and leave us with the essence of individual decision making that matters for the questions at hand. They will not tell us whether there is a God or why we like to stare at the stars at night or why we fall in love. But they can be powerful tools that allow us to understand aspects of the world that would remain impenetrable without the use of simplified models. For this reason, I ask you to resist the temptation of dismissing models—in economics or elsewhere—by simply noting that they are simplistic. A measuring tape is simplistic, but it is a useful tool to the carpenter who attempts to build a piece of furniture, much more useful than the more complex microscopic tools a neurosurgeon might use to do his work. In the same way, it is precisely because they are simple that many economic models become useful tools as we try to build an understanding of how individual decision making impacts the world.

Simplicity of models is a virtue so long as the models predict behavior well.

1.2.2 Economic Models, Realism, and Billiard Players

Here is another analogy (again used by the late economist Milton Friedman) to illustrate a slightly different aspect of economic models. Suppose we were watching an ESPN tournament of the best billiard players in the world. These players are typically not expert physicists who can calculate the precise paths of billiard balls under different circumstances using the latest knowledge of underlying equations that govern the behavior of billiard balls. But suppose we wanted to arrive at a useful model that could predict the next move of each of the billiard players, and suppose I suggested to you that we should model each billiard player as an expert physicist who can instantly

² The closest I have actually come to seeing a series of Picasso paintings like the one I described is Picasso’s suite of 11 lithographs entitled “Bull” at the Museum of Modern Art in New York. And admittedly I didn’t actually see it in the museum (since I have never set foot in it), but Joe Keefer, one of my students, pointed me to some Web sites that picture the 11 lithographs. I am not sure I see the “essence” in the last one, so I am still hoping those 27 paintings are out there somewhere.

access the latest mathematical complexities in physics to predict the best possible next move. The model is absurd in the sense that it is completely unrealistic; many of these players have not even completed high school. But my guess is that it would do pretty well at predicting the next move of the best billiard players, better than virtually any other model I could come up with.

Or consider the problem of predicting the growth of a particular plant: Which branches will grow leaves this season and in which direction? One possible model would assume that the plant consciously calculates, using the latest knowledge of biologists and other scientists, how to distribute the nutrients it gains from the soil to various branches optimally, taking into consideration the path of the sun (and thus the distribution of resulting sun light), the rotation of the earth, etc. The model is once again absurd in the sense that we are pretty sure there is no conscious mind in the plant that is capable of accessing all the relevant facts and making the appropriate calculations. Nevertheless, a model that assumes the presence of such a mind within the plant may well be a useful model to help us predict how the plant will grow.

Models, regardless of what they aim to predict, thus do not have to be realistic. They can be, and it sometimes might help our understanding if they are. But at the same time, not all aspects of economic models need to be fully realistic. Consider again the case of our consumer model that is introduced in the next several chapters. In these chapters, we seem to be assuming that individuals can map their tastes into complicated graphs or, alternatively, that they use multivariable calculus to analyze choice alternatives using mathematical functions of which few people are aware. This is absurd in the same way as it is absurd to assume that billiard players are expert physicists or plants are expert biologists. But, in the same way that these assumptions help us predict the next moves of billiard players and the next steps in the growth of a plant, our assumptions about consumers allow us to predict their economic choices. Thus, just as I hope you will not dismiss models because of their simplicity, I also hope you will not dismiss them if they appear to be unrealistic in certain ways.

Good models—models that predict well—do not have to be realistic in some literal sense.

1.2.3 An “Unintended” Consequence of Learning through Economic Models

Economists love to point out “unintended consequences,” consequences that don’t immediately come to mind when we contemplate doing something. So I can’t resist pointing out an unintended consequence of learning to use economic models to think about real-world problems. The models we’ll be using are specialized in some sense, but they are general in the sense that each model can be applied to many different real-world problems. In fact, once you get really comfortable with the way economists model behavior, it all really boils down to one single model, or at least one single conceptual approach. And as you internalize this conceptual approach to thinking about the world, you will find that your conceptual thinking skills become much sharper, and that has implications that go far beyond economics.

Our high schools, especially in the United States, seem to focus primarily on developing the ability to memorize and regurgitate, and many students in beginning economics classes often blame instructors for expecting more of them. I urge you to resist that temptation. The modern world expects more than good memorization skills from you. Those who succeed in the modern world have developed higher conceptual thinking skills that have virtually nothing to do with memorization. Memorization does not get us very far these days.

I will never forget my conversations with employers of Duke’s economics majors when I first served as Director of Undergraduate Studies. They impressed me with their full understanding of what it is that we can and cannot do in economics classes. We *cannot* prepare you for the details of the tasks you might be asked to perform in the business world. These details vary too much from place to place, and universities are not good places to learn them. Professors are rarely good business people, and most of us spend most of our lives in an academic setting, the proverbial ivory tower. Colleges and universities are therefore typically not good at purely preprofessional training. Employers know this and are more than happy to provide such training on the job.

What we *can* do is train your conceptual muscle, the muscle that allows you to progress beyond viewing each new situation you encounter as a new problem to be solved from scratch and permits you to learn from situations that share some features in common. Put differently, we can use the framework of economics to develop skills that allow you to translate knowledge across time and space. The nightmare employee in the modern world is the person who cannot do this, the person who can memorize a technical handbook but cannot make the leap from one customer to the next and from one computer application to the next. Independent and increasingly complex thinking is rewarded above all else. Employers therefore rely on colleges and universities to prepare you for this, or at the very least to signal to them which of our students have mastered these skills.

Economics is one of the disciplines that can signal mastery of conceptual thinking to employers, and I believe it furthermore provides an interesting platform on which to develop such mastery. Many other college majors, if taught well, can accomplish the same, but economics has a particular appeal to many of you because it concerns itself with issues and problems that young people often care about deeply. Nevertheless, a good economics major can also be complemented by other course work that builds those same skills. Statistics, computer science, and mathematics offer obvious complementary training. You will make a mistake if you pick your course work to avoid classes, both in economics and outside, simply because they are conceptually challenging and difficult. Many of you would tell me, as many of my students have in the past, that you are not a “math person” or a “computer person.” Forget about that; someone somewhere along the way made you think that there are “math people” or “computer people,” but in the end such people are rare,³ and few college students are unable to work hard and build their conceptual thinking skills sufficiently to do basic college mathematics, computer science, or statistics.⁴ My main message to you in this digression on the unintended consequence of mastering economics is not to neglect the development of your conceptual muscle, to resist the temptation to dismiss the use of models to think about the world just because it seems hard at first. A conceptual approach to life will ultimately make all of your studies, all of your leisure, and all of your work more deeply meaningful.

1.3

PREDICTING VERSUS JUDGING BEHAVIOR AND SOCIAL OUTCOMES

Aside from learning to “think better” or “think more conceptually,” what is the real point of these models, these simplified versions of reality whose virtue might lie in their simplicity and whose lack of realism should not necessarily disturb us? The point for most economists, as we have already suggested, is to *predict* behavior, and to predict the social consequences of that behavior. For this vast majority of economists, a model is then “good” if it predicts well. The self-interested goals individuals pursue matter in the analysis because they help us predict how behavior will change as circumstances change; but, to the economist interested in prediction, the deeper philosophical question of whether some goals are inherently more “worthwhile” than others is irrelevant. What matters for predicting what you will do if I raise the price of gasoline is how much you desire gasoline, not whether it is morally good or bad to desire gasoline. Whether

³ They do exist. My brother is one of them. We once took a college math course together, and I worked ten times as hard as he did and ended up getting a worse grade. And he thinks math is “fun” just for its own sake. I don’t understand it. But I have come to terms with the fact that I will have to struggle some with math while my brother lives happily in his little “math world.” I wonder if the colors are the same in that world—or if there even are colors.

⁴ This is not to say that you should not also study Shakespeare or Milton or Morrison, Picasso or Mozart, King or Gandhi, Freud or Chesterton or Plato or any number of other works that evoke your passions and interests. Ultimately, much of what makes life worth living involves building a well-rounded foundation that allows you to explore intellectual interests in all areas as you journey through life.

it might be “good” or “bad” to raise the price of gasoline is a very different question, one that presumes some deeper philosophical views about how to *judge* what is “good” and “bad.”

The fact that most economists are not in the philosophy business—and therefore not in the business of, as a first priority, telling us what’s “good” and what’s “bad”—is not to say that each economist has concluded that there are no objective standards for what is ultimately in our best interest, for what is ultimately “good for the soul.” As human beings, almost all of us, explicitly or implicitly, hold to such standards and wish that we and the rest of the world would abide by them more frequently. Most of us believe the drug addict would indeed be better off if he or she checked into a treatment center, that the politician ought to care about more than the next election, and that the business person should care about starving children. But most economists, *in their role as economists*, are in the business of predicting how changing incentives will change actual behavior of people who may have quite different ideas about what is worthwhile than the economist who is modeling them. What matters for their behavior is what *they* think is worthwhile, not what I think *should be* worthwhile if only they would have the sense to see it.

1.3.1 Positive Economics: How to Predict Real Outcomes

The branch of economics that concerns itself primarily with such predictions is known as *positive economics*, and it is the branch of economics that is in a real sense “value free.” In the economist’s pursuit to predict what will actually happen as incentives change, there is not the luxury of making value judgments about what people ought to be like; there is simply the taking of people’s goals as given and attempting to analyze real behavior that follows from these goals and the incentive structures within which people attempt to translate those goals to real outcomes. If you are a policy maker who is attempting to determine the best way to lower infant mortality or improve low-income housing or provide a more equitable distribution of educational opportunities, it is important to get the best *positive* economic analysis of each of the policy alternatives you are considering. After all, it is important to know what the real impact of each policy will be before we attempt to choose the “best” policies. The same is true if you are a business person who tries to price your goods; you need to know how people will actually respond to different prices, not just how you would like them to respond. It’s even true for the father of young children who tries to alter incentives to stop the little tykes from screaming so much; if promises of candy will do the trick, it is candy that will be given out even if junior *should* know that broccoli would be so much healthier.

Positive economics aims to use models to predict. It does not judge what outcomes are good or bad.

1.3.2 Normative Economics: How to Judge Outcomes

There is, however, a second branch of economics known as *normative economics* that goes beyond a value-free analysis of what will happen as incentives change. Once the positive economist tells us his or her best prediction of what will happen as a result of various possible policy alternatives, a normative economist will try to use tools that capture explicit value judgments about what outcomes are “good” and what outcomes are “bad” to determine which of the policies is the best for society. Normative economists thus draw on disciplines such as political philosophy to formalize mechanisms through which to translate particular values into policy recommendations based on a positive analysis of the likely impact of different incentives.

Much of this book concerns itself with positive (rather than normative) economics by attempting to build a framework through which we can predict the impact of different institutions on individual decision making. We will have to be careful along the way, however, because the positive models we develop are often used for policy analysis in ways that allow particular normative value judgments to “slip in.” We will treat normative economics more explicitly at the end of the book in Chapter 29.

Normative economics develops ways of thinking about what outcomes are “good” in some deeper philosophical sense.

1.3.3 Efficiency: Positive or Normative?

You will notice the term *efficient* (or *Pareto efficient*) appears throughout the text, often with a normative connotation that efficiency is somehow a good thing. We will define a situation as efficient if there is no way (given the resources available) to change the situation so as to make some people better off without making anyone worse off. And within this definition, we find our “value-free” notion of “better off” and “worse off”; that is, we will consider someone to be better off if *she* thinks she is better off, and we will consider someone as worse off if *he* thinks himself worse off. In that sense, the statement “situation *x* is efficient” is simply a positive statement that could be restated to say “there is no way to change things so that someone thinks she is better off without making someone else think he is worse off.”

Given this definition of efficiency, you can see how one might tend to be concerned about *inefficiencies*. An *inefficient* situation is one where we can see how to make some people better off without making anyone else worse off. But we should also be careful not to assume immediately that moving toward greater efficiency is always “good” in some bigger philosophical sense. A policy that increases the wealth of the rich by a lot while leaving the wealth of the poor unchanged is probably a policy that moves us to greater efficiency, as is a policy that makes the poor a lot wealthier while leaving the wealth of the rich unchanged. I suspect that most of us think one of these policies is “better” than the other. And some might think that the first policy, because it increases inequality, is actually “bad” even if it really doesn’t make anyone worse off. Similarly, as we will see in Chapter 18, allowing a healthy poor person to sell his or her kidney to someone who needs it and can pay a lot for it may indeed make both of them better off, and yet there are many who would have moral concerns over such transactions. We will see other examples of this throughout the text and will return to an explicit discussion of “what is good” and its relation to efficiency in Chapter 29.

The concept of efficiency can be used in a simply descriptive way, but it is often interpreted as a normative statement when that is not necessarily called for.

1.4

THE “NON-DISMAL” SCIENCE: SOME BASIC LESSONS

Once we get over the initial skepticism of models and the underlying assumptions we make about human behavior, studying microeconomics has a way of changing how we think about ourselves and those we interact with and the implications for the larger world we occupy. Often economics stands accused of being a “dismal science,” a term that goes back to the 19th century.⁵ Perhaps this is because people think that, because we study how people respond to incentives, we are trying to “make people selfish.” Or perhaps it is because economists engaged in policy discussions often point out that there are trade-offs in life and that politicians too often promise something for nothing. But I actually think that economics provides a rather uplifting, or non-dismal, view of the world. This is something that can be seen in three very basic insights that run counter to predispositions that many of us share before we study economics. If, at the end of this course, these insights have not become part of you, then you have missed the forest for the trees.

1.4.1 Must There Be a Loser for Every Winner?

First, psychologists tell me that we appear to be “built” in a way that makes us think that whenever there is a winner, there must be a loser. To the extent that this is true, this colors our view of the world in a way that is neither healthy nor correct. Economists have developed

⁵ Originally, the term was introduced by the historian Thomas Carlyle in the mid-1800s. Contrasting economics to Nietzsche’s conception of a “gay science” that produces life-enhancing knowledge, Carlyle described economics as “not a ‘gay science’ ... no, a dreary, desolate and, indeed, quite abject and distressing one; what we might call ... the dismal science.” His work was in response to Thomas Malthus’s admittedly depressing (and erroneous) theories, which actually led Carlyle to advocate a reintroduction of slavery as preferable to the misunderstood forces of supply and demand.

There are many situations in which everyone wins and no one loses.

a fundamentally different mind-set because our study began (and begins in this book) with the study of voluntary trade where one party chooses to give up something in exchange for something the other party has to offer. In such trades, there is typically no loser; the fact that I am willing to give up \$2 every day to buy a warm, frothy cup of cappuccino at my local coffee shop clearly makes me better off (since I could just stop doing it if I did not think it was worth it). Similarly, the coffee shop owner is better off because she values the cup of cappuccino at less than \$2. We trade, and by trading the world has just become a better place because no one was hurt and two of us are better off. Internalizing the lesson that *there are many situations when everyone can win* is part of becoming an economist. In fact, much of the unprecedented wealth that now exists in the world has arisen precisely because individuals continuously identify situations in which voluntary interactions make everyone better off, and in the absence of understanding this, we might often be tempted to restrict such interactions without understanding the negative impact this might have. Of course we will also see many situations that involve winners and losers, and situations when nonmarket institutions are needed to discipline voluntary interactions, but the mere presence of a winner does not imply the offsetting presence of a loser.

1.4.2 Can “Good” People Behave “Badly”?

Bad behavior may arise from bad character, but it often arises instead from bad incentives.

Second, psychologists also tell me that we are “built” to attribute the nature of actions we observe to the inherent character of the person who is acting. When we see someone do something that is “bad,” we tend to think that we are dealing with a “bad” person, and when we see someone do something “good,” we tend to think that this implies we are dealing with a “good” person. No doubt there are “bad” people who do “bad things” because of their predispositions, and there are many “good” people who do “good things” for the same reason. But the economist has another view to add to this: *Often people do what they do because of the incentives they face, not because of any inherent moral predisposition.* In one of our early end-of-chapter exercises, for instance, I will ask you to think about the incentives faced by someone on welfare under the old welfare system in the United States. You will notice that under this system, those on welfare were taxed at 100% when they worked; that is to say, their welfare benefits were cut by \$1 for every \$1 that they earned in the labor market. When we notice that individuals under this system do not work (or work primarily in black market activities), is it because they are “lazy” or “bad,” or is it because they are facing truly perverse incentives that would make anyone look like they are in fact “lazy” or “bad”? Internalizing this basic skepticism of attributing actions too quickly to moral predispositions sets us up to think about behavior very differently: *Changing behavior for the better suddenly does not necessarily require a remaking of the soul; sometimes all it takes is identifying some really bad incentives and changing those.*

1.4.3 Order: Spontaneous or Created?

Finally, there is a third way in which we seem to be “built” that stands contrary to how economists think: Whenever we see something that is working, something that is creating order in an otherwise disorderly setting, we tend to think that there must be *someone* that deliberately created the order. And, the more complex the order is, the more we tend to think that someone must be in charge of it all. But our study of markets will tell us a different story. Consider the complex “order” that is New York City: millions of people interacting with one another, getting food, going to work, finding a place to live, etc. If you think about it, it is an enormously complex order, even more complex than the order that gives rise to the unplanned existence of pencils. For instance, I am told that on any given day, there is only about two or three days’ worth of food left in New York City; yet no one even thinks about this when we take for granted that all sorts of foods will always be available at any time we go to any of the stores in New York. In fact, if the *New York Post* were to publish a large front page headline proclaiming “Only Two Days of Food Left in City!” we might just see a panic, but that headline would be basically true on any given day.

Complex economic order can emerge spontaneously without the need for a designer of that order.

Is there a “commissioner of food distribution” who makes sure that food continuously flows into the city to just the right places at just the right times? Is there anyone in charge of this process? The answer is no; no one is in charge, but the complex order nevertheless has emerged from the individual actions of millions of people. And, whenever governments have tried to “take charge” of such issues as food distribution, our experience has been that the order breaks down and food disappears from the store shelves. *Under certain circumstances, order can thus emerge spontaneously and without a single planner*, and understanding when this is the case (and when it is not) sets economists apart from others.⁶

Saying that “order” can emerge spontaneously without someone designing it is not, as we will see, the same as saying that the spontaneously emerged order is “good.” In some cases, we will identify circumstances when this is the case, circumstances when individual incentives are aligned in such a way as to produce socially desirable outcomes. In other circumstances, however, we will raise serious doubts about the social effects of the spontaneous order of the marketplace and thus suggest nonmarket institutions that are required for this order to produce socially desirable outcomes. Put differently, we will identify when individual incentives have to be nudged by nonmarket institutions for the order that emerges spontaneously to be “good” in some sense. But the point here, and the point many noneconomists miss, is that the existence of order rather than chaos simply does not imply the existence of an intelligent design of that order.

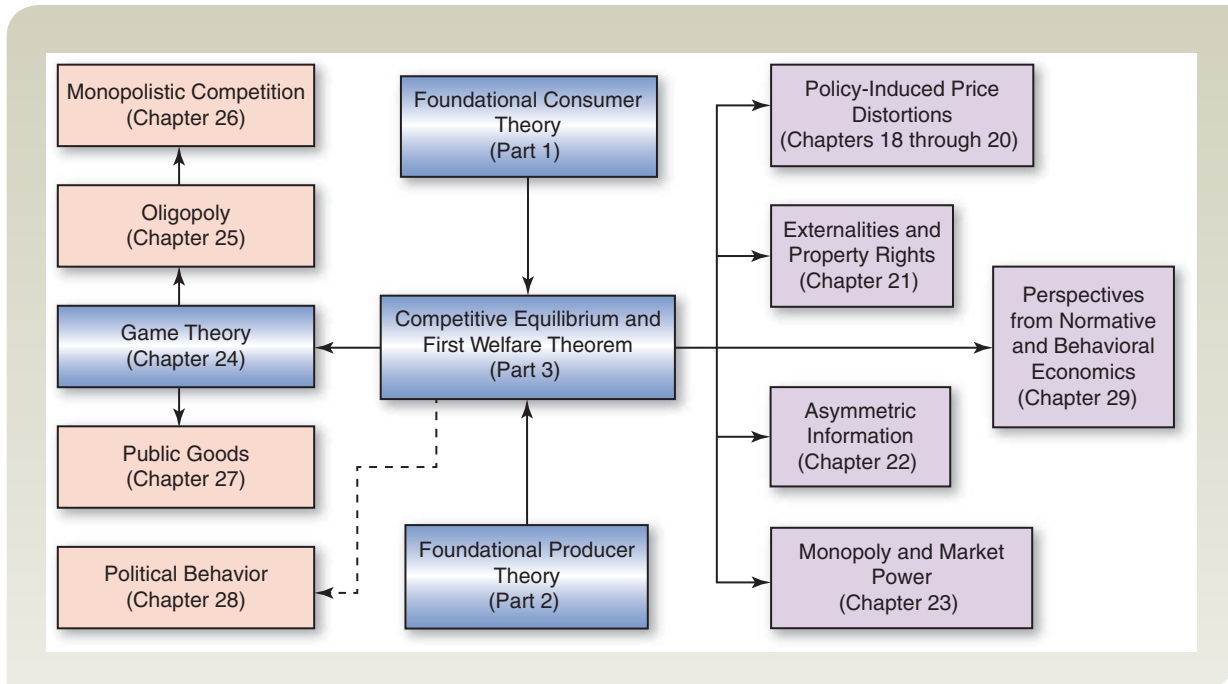

1.5

THE PLAN FOR THIS BOOK

As I have indicated in this chapter, I believe that economics and economic models can help us understand big and important questions that intellectuals have struggled with throughout the ages. This will not be immediately apparent as you work your way through the first chapters of this book, chapters that build some basic building blocks of economic models. Many textbook authors do not believe that students will have the patience to sit through tedious details of model building before addressing the important and “hot” topics in microeconomics. You deserve better than this, but you need to have the patience to bear with me. I ask this of all my students in the first class, and I have found students to be quite willing to learn in an intellectually honest way when I tell them from the outset that this is what I am trying to do.

The material in this book is also quite comprehensive and covers more than what would typically be covered in one semester. To select the right path through the book, it is helpful to have an overall picture of how the different parts are set up and relate to one another. In the introduction to each of the Parts of the book, you will find a flow chart that indicates which chapters (and sometimes which sections in chapters) are most central and which are more optional and less central to continuing in the book. The flow chart presented here gives an overall picture of how the text is set up and how the parts connect to one another. For instructors, the inside front cover of the textbook contains some extensive flow charts illustrating different possible paths through the book depending on what focus is most desired. These paths include one that involves no game theory, one that emphasizes game theory, one that is geared toward business and industrial organization, and one that is focused on public policy.

⁶The “fact” that the existence of “order” necessitates some creator of the order is, of course, often invoked as an argument for the existence of God. I am personally quite open to the possible existence of God and even the possibility that we might in some way engage with such a God, but I have never found the argument for the existence of God on the grounds that “someone must have created all this complexity” very persuasive. I think this is because I am an economist, and I know of too many instances when order emerges without a creator.

1.5.1 Part 1: Individual Choice

The consumer utility maximizing model gives rise to demand curves for goods and supply curves for labor and capital.

The first chapters of this book, Chapters 2 through 10 lumped together as Part 1, are devoted to building the basic model used by economists to investigate choices made by individuals in their roles as consumers, workers, and people who plan for the future (savers and borrowers).⁷ It is one basic underlying model, but it gives rise to somewhat different features as it is applied to the different roles we take as consumers, workers, and savers. Individuals are viewed as having tastes—over different kinds of goods, over leisure and work, over consuming today and making sure they can still consume in the future. In general, they would like to have more of everything, but they are constrained by limited resources such as income and time. As a result, they try to “do the best they can” given the economic circumstances and incentives they face. Choices that we observe thus result from combining tastes and economic circumstances, and this in turn produces demand curves (or functions) for goods as well as supply curves (or functions) for labor and capital.

1.5.2 Part 2: Competitive Firm Choice

The model of profit-maximizing firms gives rise to supply curves for goods and demand curves for labor and capital.

Part 2 of the book then focuses on the choices made by individuals in their roles as producers (or “firms”). You will notice that this section is shorter, encompassing Chapters 11 through 13. This is not because the producer model is in any way less important or less interesting than the consumer/worker/saver model. Rather, in the development of the latter we have already built many of the tools that can then be easily modified and recast into the producer setting. In fact, you could think of consumers as producers: They produce their own individual happiness using

⁷ Some instructors prefer to begin with a review of basic supply and demand graphs, and some review the basic math necessary for a mathematical treatment of material at the beginning of the course. This textbook therefore offers an additional Chapter 0 (web chapter). In part A, it provides an overview of basic supply and demand (as typically covered in a Principles text), and in part B it proceeds to review some basic underlying math. This is discussed further in Section 1.6.

as inputs goods, leisure, and future consumption just as a producer of computers uses labor and capital as inputs. Nevertheless, there are important differences between producers and consumers that are explored in this part of the text. The analysis of competitive firm choice then leads to the concepts of supply curves (or functions) for goods as well as demand curves (or functions) for labor and capital.

As we work through these foundational Parts 1 and 2 of the book, we ultimately build from fundamentals to the commonly used supply and demand curves that often appear in the first chapter of an intermediate microeconomics book. These appear only later in our text because it is not possible to fully appreciate what these curves really mean without first knowing what is behind them. Put differently, demand and supply curves follow from individual decision making and can be understood once the process by which they arise is understood. You will probably notice along the way that, for instance, demand curves in consumer goods markets don't always mean what you might have been led to believe in a principles course, nor do supply curves in labor markets mean precisely what you might think. And you will see that one can make fairly big mistakes in using such demand and supply curves incorrectly.⁸

1.5.3 Part 3: Competitive Equilibrium and the Invisible Hand

Part 3 then brings consumers and producers together in competitive market settings where individuals behave non-strategically. When economists use the term “non-strategically,” they are thinking of settings in which individuals have no impact on the economic environment in which they make decisions because each individual is a very small part of what generates that environment. When I go to the store to buy milk, I am one of millions of consumers who purchase milk, and my decisions on how much milk to purchase have no impact whatsoever on the milk market. I have no market power in this case, no way to influence how much milk is available or at what price milk will be sold. Similarly, milk may be produced by so many different dairy farmers that each one of them is small relative to the whole market, and no single milk producer can therefore influence the price of milk. We refer to such settings as “perfectly competitive,” and within such environments, there is no point for individuals to think a whole lot about how their actions influence the economic environment in which they operate. In this sense, there is no point to thinking “strategically” in perfectly competitive environments.

It is in such idealized settings that economists have arrived at a powerful insight: *Under certain circumstances*, self-interested behavior is not inconsistent with the collective “good,” and markets can generate socially desirable outcomes that could not be achieved under government planning. This insight, known as the First Welfare Theorem, lies at the heart of the economist's understanding of the world, both in terms of the positive light in which it casts competitive markets *and* in terms of the limits to competitive markets that it highlights. Put differently, the insight tells us that markets are “efficient” under certain circumstances but may need “correction” under others. (This is sometimes referred to as the “invisible hand” of the market.) When markets are efficient, there is no *efficiency role* for nonmarket institutions (like government). But we might still see a role for nonmarket institutions because, as we will point out, efficiency does not necessarily imply justice or fairness or equity. When markets are efficient but result in outcomes we consider inequitable, for instance, nonmarket institutions have a potential *distributional role* to play. Our understanding of the limits of markets to produce efficient (and equitable) outcomes then motivates the remainder of the text.

The competitive equilibrium emerges from supply and demand generating bottom-up prices, and—under certain circumstances—gives rise to an efficient spontaneous order.

⁸ You can test yourself by thinking about the following in light of your previous economics training: Suppose you were told that the labor supply curve is perfectly inelastic (or perfectly vertical), and suppose you were asked whether there is any deadweight loss in this case from taxing labor. Your answer is probably that there is no such deadweight loss because of the inelasticity of labor supply. That answer is almost certainly wrong, as you will see once you become comfortable with what actually lies behind the labor supply curve.

1.5.4 Part 4: Distortions of the “Invisible Hand” under Competition

Part 4, consisting of Chapters 18 through 22, focuses on instances when *competitive* markets fail to produce efficient outcomes. As we will see, in Chapters 18 through 20, this can happen when market prices are “distorted” through policies like price controls or taxes. Prices contain information that is necessary for the competitive market to function efficiently, and interference with the price mechanism distorts that information. But we will see in Chapter 21 that inefficiencies can also arise in competitive markets when our actions in markets have direct “externality” costs or benefits for nonmarket participants, as when production decisions result in pollution. And, as we will see in Chapter 22, inefficiencies can arise when information relevant to market transactions is not shared equally by buyers and sellers, giving one side the opportunity to take advantage of the other. Thus, in both the case of externalities and the case of asymmetric information, an efficiency role emerges for nonmarket institutions to bring individual incentives in line with the social “good.”

It is not necessary that Part 4 is read immediately following the foundational chapters of Part 3. Your instructor might instead choose to follow the exploration of competitive equilibrium (in which all individuals are “small” relative to the market) with an analysis of strategic thinking when some individuals in the market are “large” and can thus shape the economic environment. This would take you straight from chapters in Part 3 to 5.

1.5.5 Part 5: Distortions of the “Invisible Hand” from Strategic Decision Making

Part 5 then extends our analysis to situations in which *strategic* considerations by individuals create additional reasons why self-interest and the collective “good” may not be fully aligned. Bill Gates is not a “small” producer of operating systems, and his company can directly alter the economic environment in which it operates through the decisions it makes. As a result of this “market power,” the potential emerges that those who have such power will strategically use it to gain an advantage over others. We therefore leave the purely competitive environment of the earlier parts of the book as we think about strategic decision making. This can happen not only in monopoly settings (covered in Chapter 23) but also when industries are dominated by a few small firms (known as oligopolies and covered in Chapter 25), and the link from market power to profit can create important business strategies that rely on differentiating products from those of other firms (covered in Chapter 26). Such business strategies can lead to extraordinary innovation that drives dynamic modern economies while at the same time conveying market power that, at least in the moment, may give rise to inefficiencies. The game theory lens we develop in Chapter 24 not only helps us understand strategic business behavior but can also help us understand behavior in civil society settings, such as when groups try to provide public goods but individuals within groups try to “free ride” on the contributions by others. Finally, a focus on strategic thinking can help us understand (covered in Chapter 28) how democratic political processes can be manipulated by individuals who operate within democratic institutions, or how public policy can be captured by concentrated interests at the expense of taxpayers more generally.

1.5.6 Part 6: Stepping Back to Ask “What Is Good?”

Finally, Part 6 concludes with a consideration of how what we have learned can help us think about what is good and how to make the world a better place. We ask how we might think about what is “good” from a social point of view and what tools we have at our disposal to get closer to what we determine to be “good.” While economists have developed tools to think about this, we

When prices get distorted, when behavior gives rise to externalities, and when certain information is not equally accessible to both sides of the market, the market’s efficiency breaks down.

Game theory allows us to analyze strategic decision making, a key to understanding market power by firms, political power in government, and the “free rider” problem in civil society.

will see that these tools are viewed skeptically from the vantage point of other disciplines like philosophy and psychology. Psychologists have raised doubts about the type of “rationality” that is assumed in many economic models, which has led to a new subdiscipline called behavioral economics. And, philosophers may have more sophisticated notions of “social welfare” than those implicitly used by many economists and have thus helped to shape the field of normative economics. Chapter 29 therefore explicitly confronts these challenges from other disciplines and explores ways they can be incorporated into economic models.

Once we settle on a definition of “the good” and an understanding of the limits of “rationality,” government policies provide one possible avenue through which individual incentives can be aligned to allow decentralized decision making to lead to “better” outcomes, but an economic analysis of how governments behave inevitably leads to the conclusion that governments themselves also fail due to individual incentives not being aligned with collective interests. It is therefore not immediately obvious whether government interventions that *could* solve market failures will actually do so when framed within imperfect democratic institutions. A second alternative for addressing market failures lies in what we have and will call “civil society” institutions—institutions that arise from the voluntary cooperation of individuals in such communities as families, churches, and local organizations in which participation is not strictly governed by explicit market prices. However, there is often little reason to believe that these institutions will automatically result in ideal outcomes, either, as individuals strategically free ride on one another’s efforts.

Throughout the text, we develop the insights that can lead us to think about such “big picture” issues more clearly, and we return to them at the end. The text therefore concludes in a final chapter where we ask how the main themes of the book—themes about markets, governments, and civil society—can come together to help us build a framework for thinking about a healthy society. The chapter is not intended to give you “the answer,” but rather it is designed to illustrate the considerations that might go into the formation of a coherent view of a balanced society in which the various problems raised throughout the text are addressed as best they can be. Economists, like everyone else, are far from agreement on this, both because our definitions of what is “good” will differ and because we are in many instances only beginning to understand how governments and civil society institutions operate within market settings. Nevertheless, I believe it is the questions we can raise in this final chapter that are among the most interesting for economists to think about.

Insights from philosophy have helped shape normative economics while insights from psychology have given rise to behavioral economics.

An understanding of markets and its limits can help us think about the appropriate balance between markets, government, and civil society.

1.6 SUCCEEDING IN THIS COURSE

If I have succeeded in writing the kind of book I set out to write, the course you are taking will not be exactly like the courses offered at other universities that also use this text. The material is enough to fill two semesters, giving flexibility to instructors both in terms of *what topics* to emphasize and *how much math* to use. I’ll say a bit more in Section 1.6.1 about the structure of the text that facilitates this flexibility before outlining some of the methods that you can use to maximize your chances of succeeding in the course *regardless* of exactly how this textbook is employed in your course.

1.6.1 Parts A and B Chapter Structure and Flexibility

Each chapter in this book has two distinct yet closely connecting parts. Part A requires no mathematical sophistication, while part B usually generalizes the intuitions and graphical approach from the A parts using basic first-semester calculus plus a few additional multivariable calculus tools that are developed as needed. The text in the B parts frequently references graphs and intuition from A parts, and indications are given in A parts as to how the mathematical B parts can

help us generalize what we have learned. Still, it is possible to focus solely on the A parts and leave the more mathematical treatment of the material for another time.

A side benefit of this structure lies in the unique flexibility that your instructor has to develop topics in ways that are most appropriate for your school's curriculum. Some, for instance, may choose to use only the A parts, providing you with a full intuitive treatment of microeconomics while also giving you a platform to explore the mathematical side of economics either on your own or in future course work. Others will choose to use only the B parts, allowing those who are struggling with the intuition to use the A parts as a resource. Or your instructor may choose to use both A and B parts for some topics but not for others, or to use some parts in lectures and have others developed in breakout sections led by teaching assistants. Since I am a positive economist who claims no particular insight on what people's tastes should be in different settings, I don't presume to make value judgments about which approach is "best"—my guess is that the answer is (as is so often the case in economics) "it depends" and that your instructor can figure this out better than a textbook writer. At the same time, we should not lose sight of the fact that all the material is rooted in the same underlying conceptual framework, a framework that is supported in a variety of ways not only by the material contained in the text but also by the wealth of resources accessible through the MindTap platform on which many of you will read the text.

1.6.2 Preparing for the Course through "Chapter Zero"

The first of these materials is captured in Chapter 0 (that is not contained in the text version of the book). Like virtually all the text chapters, it contains an A and a B part. The A part reviews some material related to the graphical approach taken in the A parts of the text and applies it to a basic review of supply and demand as you probably encountered it in a previous economics course. Many intermediate microeconomics texts actually begin with an extensive treatment of supply and demand, but we take the view in this book that it makes more sense to focus first on the concepts that lie beneath supply and demand before using the framework extensively. Still, the supply and demand framework allows us to illustrate some of the graphing concepts we use (beginning in Chapter 2) within a setting that is familiar to most of you from previous course work.

Part B of Chapter 0 then serves an analogous function to the B parts in upcoming chapters. It introduces some mathematical analogs to the graphics concepts in part A and reviews the most fundamental pre-calculus and single variable calculus concepts used in the text. Depending on whether or not your course will incorporate part B material from the textbook, it may make sense to review this portion of Chapter 0 before proceeding.

1.6.3 Within-Chapter Exercises and the Study Guide

Many textbooks come with student study guides, usually written by someone other than the textbook author. In this text, I have taken a different approach. Within-chapter exercises (that I wrote as the text was written) are incorporated throughout the body of the text, and these are intended to get you to confront the concepts immediately rather than simply absorb them through reading. Like any good social scientist, I have experimented on my own students over the years, in some years providing them with the answers to within-chapter exercises so that they can immediately see whether they understand the relevant material; in other years holding back and not providing the solutions. The results have been dramatic: When students have access to the solutions to within-chapter exercises as they read the text, their performance on exams is far better. I have therefore written the Study Guide around solutions to exercises, giving not just "the answer" but also the reasoning behind the answer, and these same answers are integrated into the MindTap

Answers to within-chapter exercises are available in the Study Guide and within MindTap.

eReader. My hope is that students who use this textbook at other universities will do what my own students have done: Read the chapter and do the exercises along the way. With the solutions available in the Study Guide and within MindTap, you can immediately check yourself and then focus on those concepts that are most challenging to you.

The nature of the within-chapter exercises mirrors the nature of each part of the chapters, with exercises in the A parts focusing on intuitive and graphical developments of concepts and exercises in B parts developing the mathematical techniques and linking them to intuitions. Some exercises are *conceptually* more demanding than most, and these are labeled (*). Others are especially *computationally* demanding, and these are labeled (**). You will find that the material may at first “make sense” as you read it, but the exercises are not always as easy as you initially thought. This is because concepts such as those developed in this text can be understood at various levels, and doing these exercises as you read the text gets you to deeper levels of understanding than what you would get from just reading the explanations within the text. Just as Newton’s laws of motion become more meaningful as we apply them to particular settings, the economic way of thinking about the world becomes “real” only as we apply it to increasingly complex settings.

1.6.4 End-of-Chapter Exercises

One reason the book is as long as it is can be found at the end of each chapter where you typically find ten pages or so of end-of-chapter exercises. These differ from the within-chapter exercises in that they take the material to an even deeper level, asking you to integrate concepts you have learned with one another and apply them to new settings. It is one thing to apply Newton’s second law of motion to a particular setting but yet another to combine it with Newton’s third law. The same is true as we combine concepts within economic models. And just as the text is divided into A and B parts, these exercises have A and B parts, with the A parts not dependent on the B parts but the B parts often benefitting from an initially intuitive way of approaching the problem (in the A part). While the first exercises at the end of each chapter simply develop the concepts more deeply, the later exercises are developed as three types of applications: *Everyday Applications*, *Business Applications*, and *Policy Applications*. As the text progresses, you will notice that these become longer, usually divided into parts that build up to a bigger-picture understanding of the application at hand.⁹ In many ways, these application exercises take the place of worked-out applications in side boxes within many textbooks, asking you to engage in the development of the applications rather than simply presenting them without your engagement.

Often the more assertive of my students tell me that some of these exercises “have nothing to do with what was covered in class.” That is true only in the narrowest sense. They indeed are not simply reviews of examples covered in the text; rather, they are applications of concepts to new situations. The concepts are the same as those covered in the text, but the settings in which they emerge are indeed new. Our aim in this course should be to gain a sufficiently deep understanding of concepts so that we cannot just apply them to examples we have seen but also see them operating all around us. The applications exercises are intended to sharpen that conceptual level of understanding and help develop an understanding of microeconomics that is more than just the sum of its parts. To succeed at these questions, you have to be able to overcome the instinct that you should “just know the answer” as you read the question and develop the confidence that the question contains the ingredients to reason toward an answer. They are meant to be challenging—so don’t be intimidated.

⁹ Sometimes, end-of-chapter exercises are written with a view toward applications that will be discussed in future chapters. Using these end-of-chapter exercises along the way will therefore also help in the reading of future chapters.

Worked out solutions to odd numbered end-of-chapter exercises are available in the Study Guide and within MindTap.

When students come to see me to work through problems, they are often surprised that I, having written each of the questions, don't "just know the answer," and I suspect they sometimes think that I am just faking "not knowing" the answer. But I genuinely do have to re-reason through the problems to arrive at many of the answers, and you should not think that the answers should always "be obvious." If they were, we would not need all the tools we are developing. My advice to approaching these questions is to work in groups with other students, talking through the questions and helping each other out along the way. Much of the learning happens in this back-and-forth between students rather than just from reading textbooks or listening to lectures. Your instructor also has fully worked out solutions to all the questions in the text and may decide to make some or all of these available to you as you go through the course. The Study Guide and the MindTap eReader contain worked out solutions for odd numbered end-of-chapter exercises. As a reminder, these exercises are denoted with a (†) in the end of chapter materials.

1.6.5 Accompanying Technology Tools

Both the graphical and the mathematical analysis in the book will challenge you in new directions. In my experience, students are often frustrated in two ways: First, graphs in textbooks and class notes often become so complicated that it is difficult to see exactly how they were built (and how you can use such graphs when you analyze problems during homework and exams). Second, few of us come with built-in mathematical intuitions that allow us to easily picture what various functions look like in graphs and how these functions change as elements within the functions change. The graphics technology that is accessible through the MindTap platform is aimed at addressing these frustrations, as is the development of graphs across panels within the text.

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

Some of the graphs in the text can be unpacked directly within the MindTap eReader. These are denoted by a purple bar at the bottom of the graph with a call-out "Go to MindTap to interact with this graph." These interactive graphs can be built up over a few steps with brief accompanying explanations. Almost all of the graphs in the text also have video animations that allow you to bring the book graphics "alive" in a narrated fashion. These animations begin with a blank sheet, much like the blank sheet you face when you start on a homework or exam problem. You can then watch as the graph is built—at your own pace while you listen to me explain what is happening at each stage. While most of these video animations take only a few minutes, some can last ten minutes or more, but all of them have chapter markers that allow you to skip back and forth at your will. All of this is accessible through the MindTap platform.¹⁰

I use many of these computer animations in my classes when I first present material, and students have almost unanimously reported to me that they have learned much of the material by then spending time on their own with the animations as they study for the course. If your instructor is also using the computer graphics in lectures, you have the added benefit of not having to struggle to keep up with your notes as you feverishly try to replicate graphs on paper because you know you can replay them at any time and at your own pace.

1.6.6 Modular Online Mini-Lectures

As the work on this second edition is nearing completion, I am beginning work on constructing an online course to accompany the text. This course will consist of mini-lectures and connect to the video animations that are also available in MindTap. It will furthermore feature modules in

¹⁰ If you decide to listen to me (rather than press "mute") as you play the animations, you will detect an accent that I have done my best to suppress but that nevertheless stays with me. Long ago I taught science to second graders, one of whom commented that "he sounds a lot like Arnold Schwarzenegger." (Arnold and I are both originally from Austria.)

which I will work through key problems and provide hints on how to better tackle the material, and it will contain some interactive modules that allow you to explore some of the mathematical and graphical ideas in more depth. This course is being set up for use at Duke University but will be generally available to anyone who is interested. I therefore invite you to check it out as I build it up. It will be accessible through the EcoTeach Center at Duke (<http://econ.duke.edu/ecoteach>), and I hope to have an initial version of the course up by the time this edition of the text comes out.

1.7 ONWARD

I hope that this brief overview of what we are trying to accomplish helps to put the coming chapters into focus. I also hope that it will help you keep an eye on the forest—the big picture of what we are trying to do—as you slog through the trees that often don't look nearly as interesting. Aristotle told us long ago that the higher the pleasure of an activity, the greater the pain as we develop the skills to find the pleasure. Microeconomics and seeing the world through the lens of an economist can be exhilarating even if getting there is sometimes frustrating.

One final note before moving onward: You have probably noticed that this book is a bit on the long side. The reason for this, as mentioned earlier, is that it is a book intended to be sufficiently comprehensive for a two-semester microeconomics sequence, with additional space taken up by lots of application exercises. There are many paths through the book, but none of them will get you through in a single semester. So don't let the volume be daunting. Perhaps you can hold on to the book as a reference guide while you make your way through college (and keep it out of the used book market that hurts sales of new books. After all, I only get royalties on new book sales.).

Utility-Maximizing Choice: Consumers, Workers, and Savers

Chapter 2 A Consumer's Economic Circumstances

Chapter 3 Economic Circumstances in Labor and Financial Markets

Chapter 4 Tastes and Indifference Curves

Chapter 5 Different Types of Tastes

Chapter 6 Doing the "Best" We Can

Chapter 7 Income and Substitution Effects in Consumer Goods Markets

Chapter 8 Wealth and Substitution Effects in Labor and Capital Markets

Chapter 9 Demand for Goods and Supply of Labor and Capital

Chapter 10 Consumer Surplus and Deadweight Loss

Imagine that you and I go to our local supermarkets in our respective towns. Do you think we will come out with the same amount of milk in our baskets? Probably not—but why not?

If I ended up buying more milk, the obvious explanation is that I like milk more than you do. We all have different likes and dislikes, and we behave differently in all sorts of ways because of that. But maybe our likes and dislikes are quite similar, and we behaved differently because we faced different *circumstances*: You might already have a refrigerator full of milk while I am all out; I might make more money than you and thus have more to spend on everything, including milk; or perhaps milk is expensive where you live but cheap where I live. Differences in our behavior can thus emerge from two very distinct sources: different tastes and different circumstances.

We spend much of our life making choices—little choices about how much milk to buy and big choices about what career to train for, whom (if anyone) to marry, whether to borrow money to go to college, how much to save for retirement, and so on. But all these choices have one thing in common: They are shaped by our tastes on the one hand and our circumstances on the other. We try to do what is *best* (for us) given what is *possible* (for us). What is possible is limited by a lot of factors such as our abilities, our income or wealth, and the prices that we face in the marketplace. We call these limitations our *economic circumstances* or *constraints*. It is only once we know what is possible that we can then ask *what is best*. And the answer to that question will depend on our *tastes* or *preferences*. In terms of mathematical language, we choose by *optimizing subject to our constraints*.

This basic method of choosing applies to many different settings and lies at the core of how economists think about the behavior we observe. *Consumers* choose the best combination of goods and services given their scarce resources and given the prices they face in stores. *Workers* choose where to work and how much to work given their level of skill and expertise and given the wages that employers pay. *Savers* make choices about how much to consume now and how much to put away for the future given their current and expected future resources and given the rates of return their investments can produce. The choices we make as consumers, workers, and savers are different, but the underlying method of choosing the best option given what is possible is conceptually the same. For this reason, we will develop our model of consumer, worker, and saver choices simultaneously because it really is the same model.

In Chapters 2 and 3, we begin with the first part of choice by modeling the economic circumstances or constraints that consumers (in Chapter 2), workers, and savers (in Chapter 3) face when making choices. We will see the beginning of what we alluded to in Chapter 1: the role that *incentives* play in structuring the options from which individuals can choose. At the most basic level, these incentives are captured by the *prices* that individuals face—prices of goods and services in stores, wages in the workplace, and interest rates (or rates of return) in financial markets. These prices create the fundamental trade-offs we face—determining what we will call the *opportunity cost* of choosing one thing rather than another. We will also see how these opportunity costs and thus our underlying incentives can be altered by *policy* when taxes, subsidies, or regulations alter the economic circumstances individuals face and thus change the possible options from which individuals can choose.

In Chapters 4 and 5, we then proceed with the second part of choice by modeling the tastes that individuals bring to their choice problem. When I first started studying economics, I thought finding ways of modeling individual tastes was really quite intriguing, and I continue to think so. The challenge is for us to find *systematic ways of modeling tastes without falling into the trap of treating everyone's tastes as if they were the same*. Tastes differ in important ways, but there are also some fundamental regularities in tastes that we can use to help us out. In Chapter 4, we discuss these regularities and show how we can capture a wide class of different tastes if we are willing to stipulate some basic (and largely commonsense) characteristics that most people share. In Chapter 5, we then get a little more specific and discuss different types of tastes that might be appropriate in different economic models.

With the two parts that determine choice behavior defined, Chapter 6 then combines these parts and illustrates how individuals make their choice given particular economic circumstances and given their tastes. In this chapter, we get some initial glimpse into two important insights: First, while tastes, and therefore the trade-offs that individuals are willing to make, may differ a lot across individuals, *on the margin* they will be the same if individuals all face the same prices. Put differently, on the way into a store, you and I might be willing to make all sorts of deals with each other because you own different things than I do and we both have different tastes. Coming out of the store, however, we will have altered what we own in such a way that, since our tastes are now the same on the margin, we will no longer be able to find trades that we are willing to make with each other. This implies a second important insight: When we all face the same prices in the marketplace, all gains from trade happen in the marketplace, obviating any need for us to barter with one another. We therefore begin to see the important role that prices play in creating “order” and allocating scarce resources.

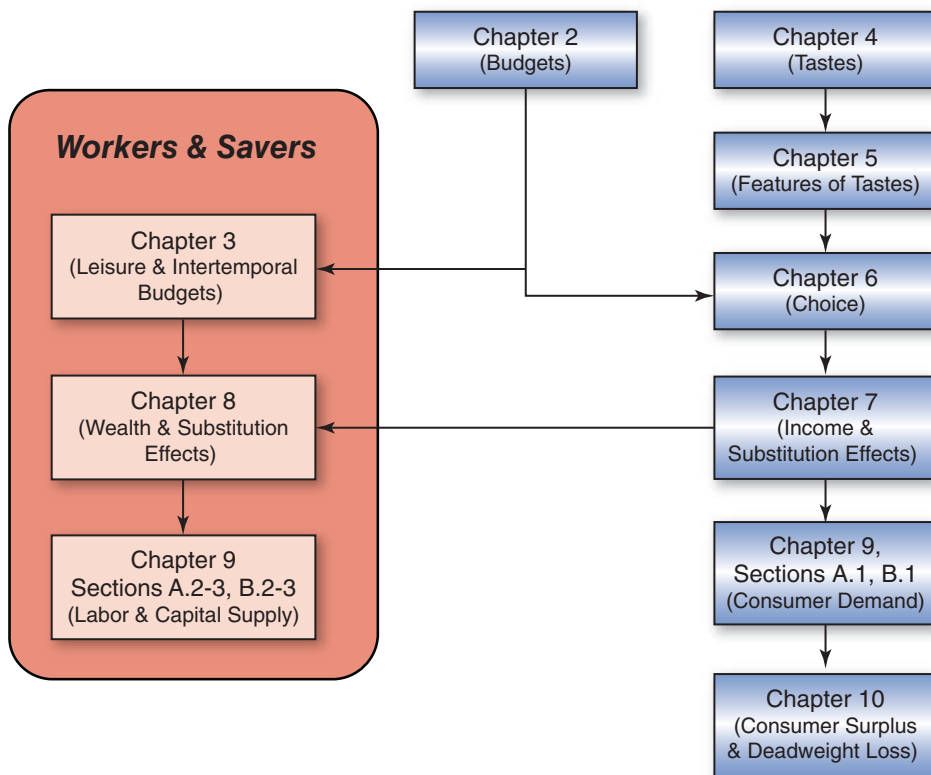

Chapters 7 and 8 then illustrate how behavior changes when economic circumstances change. What happens when prices or incomes in an economy are altered, when taxes or subsidies are imposed, when governments introduce incentives to work or save? In Chapter 7, we begin by showing that changes in our economic circumstances can be separated into two different types of changes: those that impact our income or wealth without altering the fundamental trade-offs we face in the market and those that alter these trade-offs without impacting our real income or wealth. We call the former *income effects* and the latter *substitution effects*, and real-world changes in economic circumstances tend to have some of each. In Chapter 8, we extend these concepts to choices of workers and savers. In both cases, we begin to differentiate between *distortionary* and *non-distortionary* policies, between policies that fundamentally alter the trade-offs we face in the world (and thus give rise to substitution effects) and policies that only redistribute wealth without changing trade-offs (and thus only give rise to income effects). The former, we will see, create inefficiencies or deadweight losses while the latter do not.

All this builds up to the final two chapters in this Part 1 of our text: a derivation of *consumer demand* (and *labor supply* as well as *demand and supply for capital*) from the underlying choice problems that individuals solve, and a derivation of *individual welfare in markets*. Chapter 9 illustrates how some common demand and supply curves (and functions) that you have probably encountered in a previous class represent changes in economic behavior induced by changing economic circumstances. When the price of wine goes up, we buy less wine, not because we like wine any less, but rather because our circumstances have changed. In Chapter 10, we then ask how much better off consumers are when given the opportunity to participate in markets, which is a concept known as *consumer surplus*. Here we will see some of the payoff from having done all the preliminary work investigating what underlies demand curves because we will see how some important consumer welfare changes arise from substitution effects but not from income effects. We will see that demand curves are typically not the appropriate curves along which to measure changes in consumer welfare and thus define a related curve (that focuses only on substitution effects), which we will call *marginal willingness to pay* (or compensated demand).

When you have completed this part of the book, you will have developed a conceptual overview of how economists analyze individual choice in a world of scarcity, whether the choice is between apples and oranges, between working and vacationing, or between consuming and investing. You will become comfortable with the idea that people do what they do because of their likes and dislikes (i.e., their tastes) *and* because of the trade-offs and constraints they face. What they do might change because their tastes change, or, probably much more often, because the economic circumstances they face change. Economists do not know much about how and why tastes change, but we do know a lot about how changes in circumstances affect behavior. This knowledge is often summarized in economic relationships like demand curves, but it is important to keep in mind that these are ultimately just short hand ways of depicting what emerges from the interaction of tastes and circumstances. While some business behavior (i.e., marketing

and advertising) might be aimed at changing people's tastes, much of business activity is aimed at altering trade-offs (i.e., economic circumstances) in ways that change consumer behavior. And the reason that economists play such a large role in policy making is that most policy making is about changing individual economic circumstances, and thus inducing a change in behavior that is desired by policy makers.

The following diagram outlines the flow of the chapters in this part of the text, with the shaded readings building on one another to build the consumer model. The non-shaded chapters develop the closely related worker and saver models but could be omitted if the primary emphasis of a course was on the consumer model.

A Consumer's Economic Circumstances

CHAPTER

2

In this chapter, we will begin to formalize what we mean when we say that people make the best choices they can *given their circumstances*.¹ The logical first step is to find ways of describing how our individual circumstances place limits on the kinds of choices that are available to us. Economists refer to these limits as *constraints*, and we refer to all the options we can choose from, given our constraints, as our *choice set*. Most of us would love, for instance, to go on many exotic vacations, to work only when we feel like it, to retire early, and to forget about constantly worrying about the future. But it is simply not possible to do everything we want because our limited resources place constraints on our choice sets. So, we have to determine what kinds of choices are actually possible for us given who we are, and only once we know what choices are *possible* can we decide which of these choices is *best*. This chapter introduces ways of characterizing what choices are possible in our roles as consumers, and Chapter 3 uses the tools introduced here to clarify the choice sets we face as workers and as people who plan for the future by saving or borrowing.

We will begin by focusing entirely on the underlying economic concepts that are relevant for thinking about the individual circumstances consumers face. In the process, we will notice that there are some limits to how easily we can model individual circumstances using only words and graphs, and part B of the chapter will then proceed to demonstrate how economists are using the language of mathematics to generalize intuitions that emerge in the more intuitive and graphical exposition of the material in part A of the chapter. This, as was mentioned in Chapter 1, will characterize many of the chapters throughout this text: a pure focus on economics followed by an exposition of the mathematics that helps economists say more about the world than we otherwise could.

2A

CONSUMER CHOICE SETS AND BUDGET CONSTRAINTS

Consumers constantly make decisions about how much to consume of different goods. They are constrained not only by what financial resources they command but also by the prices that they face when they make their choices. Typically, they have little control over these prices since most consumers are individually “small” relative to the market and therefore have no power to influence the prices that are charged within the marketplace. It would, for instance, not even

¹No prior chapter required as background. No calculus required for part B.

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

occur to most of us to try to haggle about the price of a gallon of milk at the check-out counter of our local supermarket. We will therefore assume for now that consumers are *price takers*, or economic agents who cannot influence the prices in the economy. And while our decisions as workers and investors determine how much money we will have to devote to consumption decisions, we will begin our analysis by assuming that the amount of money we can spend has already been determined by previous decisions. Chapter 3 will then focus on how we can model the circumstances under which these previous decisions are made.

2A.1 Shopping on a Fixed (or “Exogenous”) Income

In our role as consumers, we often enter a store with a general idea of what kinds of purchases we would like to make and a fixed income or money budget we can allocate to these purchases. At the beginning of the school year, I might enter Walmart with clear instructions from my wife that I can spend up to \$200 on new pants and shirts that I need given my waistline has just expanded during our recent summer vacation. This is my fixed income for purposes of this analysis, and it represents a type of income we will refer to as *exogenous*. *Income is defined as exogenous if its dollar value is unaffected by prices in the economy.* In this case, regardless of how much Walmart charges for pants and shirts, I will always have exactly \$200 available to me.

As I look around the store, I discover that I can purchase shirts for \$10 and pants for \$20. I now have all the information necessary to determine the *choice set* I face given the *constraints* imposed by my \$200 income and the prices of pants and shirts. I could, for instance, purchase 10 pants and no shirts, thus spending my total \$200 income. Alternatively, I could purchase 20 shirts and no pants or any combination of pants and shirts such that the total expense does not add up to more than \$200.

2A.1.1 Graphing Choice Sets We can depict this graphically in a two-dimensional picture that has the number of pants on the horizontal axis and the number of shirts on the vertical. Point *A* in Graph 2.1 depicts the choice of 10 pants and no shirts while point *B* depicts the choice of

GRAPH 2.1 Budget Constraint and Choice Set

Go to MindTap to interact with this graph.

20 shirts and no pants. The line that connects points *A* and *B* represents other choices that also cost exactly \$200. For instance, point *C* represents 5 pants and 10 shirts, which implies a \$100 expense on pants (5 times \$20) and another \$100 expense on shirts (10 times \$10). Point *D* represents 7 pants and 6 shirts, which again adds up to a \$200 total expenditure.

We will refer to the line connecting points *A* and *B* as the *budget line* or the *budget constraint*. The end points, or intercepts, of the budget line are determined by the fixed income divided by the price of the good on each axis: 200 divided by 20 in the case of pants, and 200 divided by 10 in the case of shirts. For a particular income and a particular set of prices, this *budget line represents all combinations of goods that, if chosen by a particular consumer, would leave no additional money left in his or her budget*. Points below the budget line, on the other hand, represent combinations of goods that, if chosen by the consumer, would still leave some additional unspent money. For instance, point *E* represents 8 shirts and 5 pants, which cost only \$180 and would thus leave \$20 unspent. Together, the budget line and all shaded points below the budget line represent the choices that are *possible* for a consumer who has a \$200 income devoted to spending on pants and shirts that are priced at \$20 and \$10 respectively. Thanks to my wife's generosity and Walmart's low prices, this is my *choice set* at Walmart.

Choices that lie on budget lines exhaust all resources.

Now suppose that I currently have 10 shirts and 5 pants (point *C*) in my shopping cart, but I decide that I really would like to have 6 instead of 5 new pants. Since pants are twice as expensive as shirts, I know I will have to put 2 shirts back on the rack to be able to afford one more pair of pants. That's exactly what the budget constraint tells me: As I move to 6 pants, I can only afford 8 shirts rather than the 10 I started with in my shopping cart. Put differently, in going from point *C* to point *F*, I traded 2 shirts on the vertical axis for 1 pair of pants on the horizontal axis, which implies a slope of -2 (since the slope of a line is the change in the variable on the vertical axis (shirts) divided by the change in the variable on the horizontal axis (pants)). You could of course equally well have calculated the slope of this line by simply looking at the end points: In going from point *B* to point *A*, you have to give up 20 shirts to get 10 pants, giving again a slope of -2 .

This slope of the budget line arises from the fact that pants cost twice as much as shirts, and it represents the trade-off I face when I chose to buy one more pair of pants. Economists call this trade-off *opportunity cost*. *The opportunity cost of any action is the next best alternative one gives up by undertaking this action.*² In our example, the opportunity cost of buying one more pair of pants is the 2 shirts I have to give up. Of course we can also talk of the opportunity cost of buying one more unit of the good on the vertical axis. In our example, if I want to buy one more shirt, I have to give up half a pair of pants. Given that pants cannot easily be split into two halves, it might sound silly to say that the opportunity cost of one shirt is half a pair of pants, but this statement contains the same information as the statement that the opportunity cost of one pair of pants is 2 shirts: Pants are twice as expensive as shirts. *In general, the opportunity cost of the good on the horizontal axis (in terms of the good on the vertical axis) is the slope of the budget line, whereas the opportunity cost of the good on the vertical axis (in terms of the good on the horizontal axis) is the inverse of the slope of the budget line.*

The slope of the budget line is an opportunity cost.

The slope of the budget constraint can also be determined more directly by simply understanding how the prices a consumer faces translate into opportunity costs. In our example, I face a \$20 price for pants and a \$10 price for shirts, and the slope of my budget constraint is -2 or, in absolute value, the opportunity cost of one pair of pants in terms of shirts. This opportunity cost arises from the fact that pants are twice as expensive as shirts, with *the slope of the budget*

²The opportunity cost of you reading this chapter is the next best thing you could be doing with your time right now. The fact that you are still reading means that you must think reading these words is the best possible way to spend your time in this moment. I am flattered.

constraint simply being given by the (negative) ratio of the price of the good on the horizontal axis (pants) divided by the price of the good on the vertical axis (shirts).³

EXERCISE 2A.1 Instead of putting pants on the horizontal axis and shirts on the vertical, put pants on the vertical and shirts on the horizontal. Show how the budget constraint looks and read from the slope what the opportunity cost of shirts (in terms of pants) and pants (in terms of shirts) is.

2A.1.2 An Increase (or Decrease) in Fixed Incomes Now suppose that my wife felt particularly generous this year and, instead of the customary \$200 money budget for end-of-summer clothing purchases, she has allocated \$400 for this purpose. As a result, I could now purchase as many as 20 pants (assuming I buy no shirts) or as many as 40 shirts (assuming I purchase no pants), which means that point *A* shifts to the right by 10 pants and point *B* shifts up by 20 shirts. This results in a parallel shift of my budget constraint from the initial blue to the final magenta budget line in Graph 2.2.

Income changes cause parallel shifts in budget lines.

Notice that the set of choices available to me has clearly become larger, but the trade-off I face, the opportunity cost of pants (in terms of shirts) or shirts (in terms of pants), has not changed. This is because my *opportunity cost is determined by Walmart's prices*, not by my wife's generosity. It does not matter whether you, I, or Bill Gates enters Walmart to buy shirts and pants—each of us faces the same trade-offs even though our overall budgets may be quite different.

GRAPH 2.2 An Increase in "Exogenous" Income

³As explained in more detail in Section B, you can also simply derive this mathematically. Letting income be denoted by I , pants by x_1 , shirts by x_2 , and the prices of pants and shirts by p_1 and p_2 respectively, any combination of x_1 and x_2 will lie on the budget constraint if all income is spent. Put differently, if $p_1x_1 + p_2x_2 = I$, then the sum of my spending on pants (p_1x_1) and my spending on shirts (p_2x_2) is exactly equal to my income I . Solving this equation for x_2 , the good on the vertical axis, the budget constraint can be written as $x_2 = I/p_2 - (p_1/p_2)x_1$, which is an equation with intercept I/p_2 and slope $-(p_1/p_2)$.

To be slightly more precise, the opportunity cost is determined by the *ratio* of Walmart's prices. Suppose, for instance, that instead of giving me an additional \$200, my wife had given me a 50% off coupon for shirts and pants. In that case, the real price of a shirt would have dropped to \$5 and the real price of pants would have dropped to \$10, which would enable me to buy as many as 40 shirts (if I buy no pants) and as many as 20 pants (if I buy no shirts). Thus, a decline in all prices by the same percentage is equivalent to an increase in income; it merely shifts the budget constraint out without changing its slope. In fact, economists would say that in both scenarios—when my fixed income went up by \$200 and when all prices fell by 50%—my *real* income doubled (because I could now afford twice as much as before) while relative prices remained unchanged (because the trade-off between the goods as expressed in the slope of the budget constraint did not change).

Demonstrate how my budget constraint would change if, on the way into the store, I had lost \$300 of the \$400 my wife had given to me. Does my opportunity cost of pants (in terms of shirts) or shirts (in terms of pants) change? What if instead the prices of pants and shirts had doubled while I was driving to the store?

EXERCISE 2A.2

2A.1.3 A Change in Price Now suppose that, instead of giving me an extra \$200, my wife showed her generosity by giving me a 50% off coupon for pants (but not for shirts) together with my usual \$200 money budget. With this coupon, she tells me, I can purchase any number of pants and receive half off. As a result, while the posted price for a pair of pants is \$20, each pair only costs me \$10 once I present the coupon at the cash register.

To see how this changes my budget line, we can go through the same exercise as before and find the intercepts of the new budget line by asking how much of each good we could buy if we spent nothing on the other good. This is illustrated in Graph 2.3. Since pants now cost only \$10 a pair, I can purchase as many as 20 pairs with my \$200 money budget (assuming I buy no shirts),

A price change causes the slope of budget lines to change.

GRAPH 2.3 A Decrease in Price

and I can similarly buy as many as 20 shirts at \$10 each (assuming I buy no pants). Thus point A shifts from 10 to 20 as a result of the lower price of pants, but point B does not change since the price of shirts remains the same and my overall money budget is still \$200. My budget line then rotates out from the initial blue budget line to the new magenta budget line, with the slope changing from -2 to -1 . This slope again reflects the opportunity cost of one pair of pants (in terms of shirts): Since pants and shirts now both cost \$10 each, I have to give up one shirt for every additional pair of pants I would like to purchase.

EXERCISE 2A.3 How would my budget constraint change if instead of a 50% off coupon for pants, my wife had given me a 50% off coupon for shirts? What would the opportunity cost of pants (in terms of shirts) be?

2A.2 Kinky Budgets

Suppose I now arrive at the store and discover some fine print on the 50% off coupon that limits the discount to the first 6 pants. Thus, rather than facing a price of \$10 per pair of pants for any number of pants that I buy, I now know that the \$10 price applies only to the first 6 pairs and that each additional pair costs \$20. In economics jargon, the *marginal price*—the price of one more pair of pants—changes from \$10 to \$20 after the 6th pair of pants.

To see what this does to my budget constraint, we can again begin by determining where the intercepts of the new budget constraint lie. If I were to purchase only pants (and no shirts), I would be able to purchase 13 pairs: the first 6 at \$10 each (for a total of \$60) and another 7 at \$20 each (for an additional \$140). Thus, point A lies at 13 pants on the horizontal axis, as illustrated in Graph 2.4a. Point B remains unchanged at 20 shirts on the vertical axis. But because the trade-off between shirts and pants changes once I have 6 pants in my shopping cart, the slope of the budget constraint must change at that point as well. If I purchase

GRAPH 2.4 Kinked Budget Constraints

exactly 6 pants, I will be able to afford 14 shirts, which implies that point G is on my budget constraint. Between point G and point B , I purchase fewer than 6 pairs of pants and thus face a price of \$10 for both pants and shirts. The line segment connecting point G and B therefore has a slope of -1 , indicating an opportunity cost of one shirt for each pair of pants. The line segment connecting G and A , on the other hand, has a slope of -2 , which reflects the higher price of pants for any pair above 6 and the higher opportunity cost (in terms of shirts) I face once I purchase more than 6 pants. My new budget constraint therefore starts at point B with a shallow slope of -1 , has a kink at point G where I have exactly 6 pants in my shopping cart, and then switches to a steeper slope of -2 .

Kinked budget constraints of this type occur whenever the price of a good changes as I am purchasing more of it. This can result in a budget constraint like the one we just derived in Graph 2.4a where the kink points out toward the northeast of the graph, but, under different circumstances, it could also result in a kink that points in toward the southwest of the graph. Suppose, for instance, that the 50% off coupon was such that I can only get a discount if I purchase more than 6 pants and that this discount applies to each pair of pants after the initial 6 I purchase. You can verify for yourself that this would result in the budget constraint in Graph 2.4b. Some important real-world examples of kinked budget constraints will appear in end-of-chapter exercises and in Chapter 3 as we think of cases where government policies directly generate such kinks.

Suppose that the two coupons analyzed were for shirts instead of pants. What would the budget constraints look like?

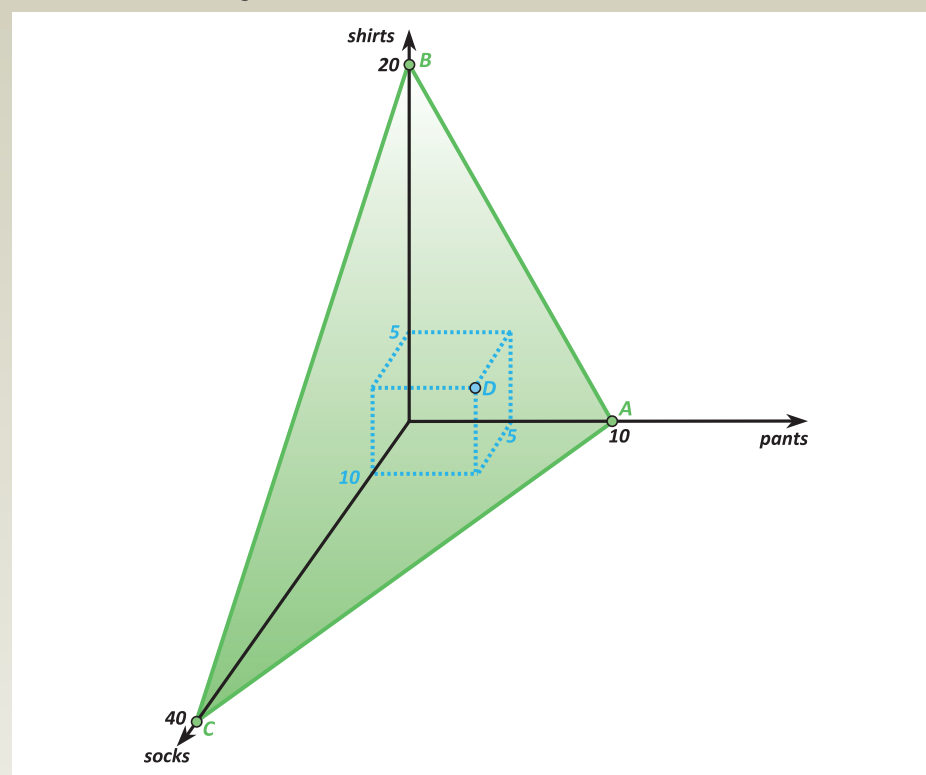

EXERCISE
2A.4

2A.3 Modeling More General Choices

Although two-good examples like the previous ones are useful because they allow us to illustrate budget constraints in a two-dimensional picture easily, they are of course a little artificial since most consumers do not go to stores with the intention of purchasing only two types of goods. (If my wife were not so strict about checking my receipts when I get home, even I might sneak in a candy bar with my pants and shirts.) To generalize such examples beyond choices over two goods, we could use mathematical equations (as is done in part B of this chapter) instead of graphical illustrations. Alternatively, we could illustrate such choice sets in more complicated graphs, although this becomes quite difficult as our illustrations would have to become more than two-dimensional. Or we can employ a technique that treats whole categories of goods as if they were a single good. We will now explore the latter two alternatives.

2A.3.1 Graphing Choice Sets with Three Goods Throughout the summer, I wear sandals. And, despite the fact that I have to endure endless and merciless mocking from my fashion-conscious wife for this, I always wear socks with my sandals. As a result, I usually need new socks for the fall semester.

Suppose, then, that my wife had sent me to the store to purchase shirts, pants, *and* socks. Our illustrations then have to become three-dimensional. In Graph 2.5, we plot pants on one axis, shirts on another, and socks on yet another axis, and just as in the two-good examples, begin by finding the intercepts on each axis illustrating how much of each good we could purchase if we purchased none of the others. Suppose the price of shirts and pants were \$10 and \$20 and the price of socks were \$5, and suppose that my exogenous income or money budget is again \$200. On the axis labeled “number of pants,” my intercept is then 10: The number of pants I could purchase if I spent all of my money on pants alone. Similarly, the intercept on the shirt axis is 20,

GRAPH 2.5 Budget Constraint with 3 Goods

Go to MindTap to interact with this graph.

and the intercept on the socks axis is 40. We can then proceed by illustrating what my budget constraint would look like if I purchased no socks but limited myself to only shirts and pants by connecting A and B . This budget constraint is equivalent to the one we plotted in Graph 2.1. But we can also illustrate the constraint if I limited myself to only socks and shirts by connecting points B and C , and the constraint if I limited myself to only socks and pants by connecting points A and C . Finally, my full budget constraint is formed by the shaded plane that connects points A , B , and C . For instance, point D with 10 pairs of socks, 5 shirts, and 5 pairs of pants lies on this plane because this combination of goods in my shopping basket costs exactly \$200 (\$50 for socks, \$50 for shirts, and \$100 for pants).

While it is therefore possible to illustrate budget constraints graphically with three goods, you can see that it would become increasingly difficult to graph such constraints for more than three goods because we would have to get comfortable with drawing objects in more than three dimensions. Nevertheless, we are able to analyze more general choice sets graphically by focusing on the choice over a good that we are particularly interested in analyzing and creating, for purposes of the analysis, a second *composite good* that represents all other goods.

2A.3.2 Modeling Composite Goods Suppose, for instance, that I am going to the store with my \$200 to purchase not only pants but also a variety of other goods that I will need to get ready for the academic year (including shirts and socks but also office supplies, drinks for my office refrigerator, and of course flowers for my wife). And suppose further that I am particularly

interested in modeling how my budget constraint changes as the price of pants changes. We could reduce our implicit multigood model by putting pants on the horizontal axis and a *composite good representing all other goods I am interested in* on the vertical. We can define this composite good as “dollars spent on goods other than pants.” This definition of a composite good then ensures that 1 dollar spent on goods other than pants costs me exactly 1 dollar. Implicitly our analysis will have to assume that only the price of pants changes while all other prices remain the same, or alternatively that all other prices change by the same proportion while the price of pants remains the same.⁴

With the aid of the modeling assumption of a composite good, we can then illustrate my choice set over pants and “other goods” exactly as we did in Section 2A.1 when we modeled the choice between pants and shirts. On the horizontal axis, point *A* would again lie at 10 pants because that is the most I can afford if I spend my entire income on pants and I purchase no other goods. Point *B* on the vertical axis would lie at 200 because I can purchase 200 units of the composite good (i.e., \$200 worth of “other goods”) if I do not purchase any pants. Connecting points *A* and *B* gives me a budget line with slope -20 , indicating that the opportunity cost of a pair of pants is 20 units of the composite good or \$20 worth of “other good consumption.” We could then model how an increase or decrease in my fixed income, a change in the price of pants, or coupons of the kind introduced in Section 2A.3 would affect this budget constraint.

A composite good aggregates many goods into one.

Revisit the coupons we discussed in Section 2A.3 and illustrate how these would alter the choice set when defined over pants and a composite good.

EXERCISE
2A.5

True or False: When we model the good on the vertical axis as “dollars of consumption of other goods,” the slope of the budget constraint is $-p_1$, where p_1 denotes the price of the good on the horizontal axis.

EXERCISE
2A.6

2A.4 “Endogenous” Incomes That Arise from Endowments

Suppose that I have done my clothes shopping at the original prices (i.e., without coupons) and with my original money budget of \$200. I come home with 10 shirts and 5 pants and proudly show them off to my wife who quickly informs me that she thinks I should have gotten more pants and fewer shirts. The problem, however, is that I have lost the receipt and therefore cannot get a refund under Walmart’s return policy. But, my wife quickly reminds me, I *can* receive a store credit for the full value of any merchandise at Walmart’s posted prices. Thus, as I enter Walmart for the second time, I arrive with no money but rather with an *endowment* of 10 shirts and 5 pants. *An endowment is a bundle of goods owned by a consumer and tradable for other goods.* A defining feature of endowments is that, because the consumer owns the endowment bundle, *he or she can always choose to consume that bundle regardless of what prices of goods in the market happen to be.* In fact, if you are ever unsure of whether a particular bundle is indeed an endowment bundle, you can simply ask yourself whether it is true that the consumer could consume this bundle regardless of what the prices in the economy were. If the answer is yes, then the bundle is an endowment bundle for this consumer.

A consumer can always consume her endowment no matter how prices change.

As I stand in line at the customer service desk, I contemplate what my budget constraint looks like now that I have no money but just an endowment bundle of 10 shirts and 5 pants (labeled point *E* in Graph 2.6). I know that I can always stick with my current shirts and pants, so the point

⁴The conditions under which it is theoretically sound to aggregate goods into a composite good are well understood but beyond the scope of this text. The interested reader can explore more under the topics of *Hicksian separability* and *functional separability* in a graduate text.

GRAPH 2.6 Price Change with Endowments

Go to MindTap to interact with this graph.

“5 pants, 10 shirts” must lie on my budget constraint. What the rest of the constraint looks like depends on what the currently posted prices are at Walmart. If pants still sell for \$20 a pair and shirts still sell for \$10 each, then I could return my 5 pants, receive \$100 in store credit and use it to buy 10 additional shirts, thus ending up with 20 shirts and no pants. Alternatively, I could trade in my 10 shirts for \$100 store credit and buy 5 more pants, thus ending up with 10 pants and no shirts. Or I could do something in between. If the price of pants and shirts is unchanged from when I originally purchased the pants and shirts, my budget constraint is therefore exactly the same as it was when I first entered the store with \$200 in Graph 2.1 and replicated as the blue line in Graph 2.6.

As I approach the customer service representative, however, I am surprised to see a new poster in the window proclaiming: “All pants on sale at 50% off.” As it turns out, pants just went on sale and now only cost \$10 a pair rather than the \$20 I paid for them. Given Walmart’s policy on returns without receipts, I will therefore only get \$10 in store credit for each pair of pants. How does this change my choice set?

Well, I still have the option of leaving the store with my 5 pants and 10 shirts, so point *E* remains on my budget constraint. But if I now return my 5 pants, I only receive a \$50 store credit and thus can only get 5 more shirts. Point *B* therefore shifts down by 5 shirts. At the same time, if I return my 10 shirts, I still get a \$100 store credit, but now, because pants are cheaper, I can get as many as 10 extra pairs of pants! So, point *A* shifts out by 5 pairs of pants, and the new (magenta) budget constraint has a slope of -1 that reflects the new opportunity cost of a pair of pants (given that they now cost the same as shirts). Notice, however, that now the budget line rotates through point *E*, the endowment point, when the price of pants changes, not through point *B* as it did when the price changed and I was on a fixed income (in Section 2A.3). This will always be true for budget constraints that arise from endowment bundles rather than fixed incomes.

When budgets arise from endowments, price changes cause rotations of budget lines around the endowment.

Notice that when budget constraints arise from endowments, the amount of money available to the consumer is *not* fixed (as it was when my wife simply sent me to the store with \$200). Rather, the money available to me depends on the prices of the goods I am endowed with, since I have to sell some of my endowment in order to get money. We will refer to such incomes as *endogenous* to differentiate them from the fixed (or *exogenous*) incomes analyzed earlier.

It may not seem all that common that we find ourselves with a basket of goods (like pants and shirts) as an endowment, and so this exercise might look a little contrived. However, as we will see in Chapter 3, our budget constraints are indeed often determined by endowments when we think of our roles in other sectors of the economy such as the labor market or the financial markets. We are, for instance, endowed with a certain amount of time that we can allocate to various purposes (including gainful employment). We also often accumulate a set of assets (like bank deposits, mutual funds, coin or stamp collections, real estate, etc.), which can be treated like an endowment that can be converted into consumption depending on the value of the endowment.

2A.5 Modeling Constraints Graphically or Mathematically?

We have shown thus far how we can model simple choice sets for consumers facing different circumstances. How much choice a consumer has ultimately depends on (1) the prices of goods and (2) the size of the consumer's available income. The latter can be determined either "exogenously" by a fixed dollar amount that is available to the consumer, or it can arise "endogenously" from the value of some endowment that the consumer can trade for other consumption. A first step to modeling the circumstances that are most relevant to particular choices is therefore simply to identify these two elements, prices and incomes, of the consumer's individual circumstances.

Economic circumstances arise from prices and incomes.

In addition, however, we have to recognize that our models cannot possibly include all the complexity of the real world when we try to analyze individual decisions that consumers make. The point of modeling decisions is, as we suggested in Chapter 1, to draw out the essence of the problem we are investigating in order to better analyze the most essential aspects of the problem. In modeling the circumstances under which consumers make choices, we therefore have to decide which aspects of the complex "real world" are critical for the particular choices we are modeling and which aspects are, for purposes of our model, "noise" that we can abstract away from.

Often, we will conclude that a particular situation can be adequately modeled within the graphical framework we have developed so far. But other times economists will find that, while the graphical framework helps them understand the intuition behind a more complex model, they nevertheless require more complexity to model the essence of a particular situation fully. In those cases, economists turn to mathematics as a language that allows for the introduction of greater complexity. But it is important to understand that this more mathematical approach simply involves a different way of discussing the same underlying economic concepts we have just discussed without the use of mathematical equations, and it is important for those who use the mathematical approach ultimately to translate their insights back into words that give expression to the underlying economics. Section B therefore turns to a development of the mathematical tools that can help us generalize models in Section 2A while maintaining our focus on the economic choices made by individuals.

2B

CONSUMER CHOICE SETS AND BUDGET EQUATIONS

In the language of mathematics, "doing the best they can" means that consumers solve an "optimization problem," and "given their circumstances" means that this optimization problem is a "constrained optimization problem." In this chapter, we will develop the mathematical language to formalize the notion of choice sets and budget constraints, and later we will proceed to defining the full constrained optimization problem that consumers face. Each section in this part of the chapter corresponds to a similar section in part A; Section 2B.1, for instance, discusses

the mathematics behind the ideas in Section 2A.1. So, if you find yourself losing track of the economic ideas from part A and you discover it is all suddenly looking like “just math,” you may find it helpful to turn back to the analogous section in part A and thus create a better link for yourself between the mathematics and the underlying economics.

2B.1 Shopping on a Fixed Income

We began our discussion of choice sets in Section 2A by envisioning me being sent to Walmart to shop for pants and shirts with a fixed, or exogenous, income. Suppose again that this fixed income is \$200 and that the price of pants is \$20 and the price of shirts is \$10. The *choice set* we derived in Graph 2.1 is simply the set of all combinations of pants and shirts that cost no more than \$200, and the *budget line* or *budget constraint* is the combination of pants and shirts that cost exactly \$200.

2B.1.1 Defining Choice Sets and Budget Lines Mathematically Letting pants be denoted by the variable x_1 and shirts be denoted by the variable x_2 , we can define the choice set formally as

$$\{(x_1, x_2) \in \mathbb{R}_+^2 \mid 20x_1 + 10x_2 \leq 200\}. \quad (2.1)$$

The curly brackets “{ }” indicate that we are defining a *set* of points. The vertical line “|” is read as “such that.” Everything preceding “|” defines the geometric space within which the points of the set lie, and everything following “|” defines the conditions that must be satisfied in order for a point in that geometric space to lie within the choice set we are defining. More specifically, the symbol \mathbb{R}_+^2 is used to represent the two-dimensional space of nonnegative real numbers, and the symbol \in is read as “is an element of.” Thus, the mathematical expression “ $(x_1, x_2) \in \mathbb{R}_+^2$ ” simply says that the set contains points with 2 components (x_1 and x_2) that are nonnegative real numbers. But not all points with 2 components that are nonnegative real numbers are in the choice set—only points that represent bundles that cost no more than \$200. The mathematical statement following “|” therefore indicates precisely that points that lie in the space defined before “|” are part of the set we are defining only if $20x_1 + 10x_2 \leq 200$. We then read the full expression as: “This set contains all combinations of (x_1, x_2) in which both x_1 and x_2 are nonnegative real numbers *such that* 20 times x_1 plus 10 times x_2 is less than or equal to 200.”

There is a logical structure to this formulation of sets that is worth pointing out even more precisely. The statement preceding “|” provides the *necessary condition* for a point to lie in the set we are defining, while the statement following “|” provides the *sufficient conditions*. In order for you to become President of the United States, it is a necessary condition that you were born a U.S. citizen. As many candidates find out every four years, that is not, however, sufficient to become president; you also have to get a plurality of votes in sufficiently many states to gather the required Electoral College majority. Similarly, in order for a point to lie in my choice set under the circumstances described, it is a necessary condition for that point to consist of two nonnegative real numbers. But that is not sufficient because many points that have two nonnegative real numbers represent bundles of goods that are not affordable given my exogenous income of \$200. The choice set is then fully defined when both necessary and sufficient conditions are stated explicitly.

A set is described by both necessary and sufficient conditions.

EXERCISE 2B.1

What points in Graph 2.1 satisfy the necessary but not the sufficient conditions in expression (2.1)?

To define the set of points that lie *on* the budget line (as opposed to *within* the choice set), we start by recognizing that these points lie within the same geometric space as the choice set, and thus must necessarily consist of points defined by two nonnegative real numbers. However, the

sufficient condition for such points to be part of the budget line is different from the sufficient condition for such points to be part of the choice set. In particular, the inequality in the constraint $20x_1 + 10x_2 \leq 200$ is replaced with an equality because the budget line represents the set of goods that cost *exactly* \$200. We can thus define the *budget line* as the set of bundles that lie on the boundary of the choice set:

$$\{(x_1, x_2) \in \mathbb{R}_+^2 \mid 20x_1 + 10x_2 = 200\}. \quad (2.2)$$

More generally, we can define choice sets without reference to a particular set of prices or incomes. Rather, we can simply indicate the price of pants as p_1 , the price of shirts as p_2 , and income as I . With these three pieces of information that constitute the consumer's *economic circumstances*, we defined a consumer's choice set C as

$$C(p_1, p_2, I) = \{(x_1, x_2) \in \mathbb{R}_+^2 \mid p_1x_1 + p_2x_2 \leq I\}. \quad (2.3)$$

The notation $C(p_1, p_2, I)$ indicates that the precise nature of my choice set depends on what value is taken by the prices of the goods and by my income level; or, put differently, it indicates that the choice set C is a function of the prices (p_1, p_2) and income level I . When I plug in the values 20, 10, and 200 for the two prices and my income, I get precisely the set defined in equation (2.1). Similarly, we can define the budget line B as

$$B(p_1, p_2, I) = \{(x_1, x_2) \in \mathbb{R}_+^2 \mid p_1x_1 + p_2x_2 = I\}, \quad (2.4)$$

where the inequality in equation (2.3) is replaced with an equality.

We can then examine the mathematical formulation of a budget line and demonstrate how it relates to the graphical intuitions we built in Section 2A. Beginning with the equation $p_1x_1 + p_2x_2 = I$ contained within the set defined in (2.4), we can subtract p_1x_1 from both sides and then divide both sides by p_2 to get

$$x_2 = \frac{I}{p_2} - \frac{p_1}{p_2}x_1. \quad (2.5)$$

Notice that in a graph (such as Graph 2.1) with x_1 on the horizontal and x_2 on the vertical axis, this expression of the equation defining a budget line shows an intercept of (I/p_2) on the vertical axis and a slope of $(-p_1/p_2)$, which is precisely what we concluded intuitively in Section 2A. For instance, with the numbers in our example, (I/p_2) is equal to $(200/10)$ or 20, which indicates that I could purchase as many as 20 shirts with my \$200 if all I bought were shirts. Similarly, the slope $(-p_1/p_2)$ is equal to $(-20/10)$ or (-2) , which indicates an opportunity cost of 2 shirts for 1 pair of pants.

2B.1.2 An Increase (or Decrease) in the Fixed Income Our next step in Section 2A was to illustrate what happens as my income increases from \$200 to \$400. Notice that this exogenous income is represented by the variable I in equation (2.5). Thus, when the fixed income changes, only the first term (I/p_2) in equation (2.5) changes. This is the vertical intercept term in the equation, indicating that the intercept on the x_2 -axis will shift up as my fixed income increases. The second term in equation (2.5) remains unchanged, indicating that the slope of the budget line $(-p_1/p_2)$ remains the same. A change in the x_2 -axis intercept without a change in the slope adds up to a parallel shift outward of the budget line, precisely as we concluded intuitively in Graph 2.2. The choice set has become larger, but the trade-off between the goods as represented by the slope of the budget line has remained the same.

Using equation (2.5), show that the exact same change in the budget line could happen if both prices simultaneously fell by half while the dollar budget remained the same. Does this make intuitive sense?

**EXERCISE
2B.2**

2B.1.3 A Change in Price Another scenario explored in Section 2A involved a 50% off coupon for pants, a coupon that effectively lowers the price of pants (p_1) from \$20 to \$10. Going back to equation (2.5), notice that p_1 does not appear in the intercept term (I/p_2) but does appear in the slope term ($-p_1/p_2$). The x_2 -axis intercept thus remains unchanged but the slope becomes shallower as p_1/p_2 becomes smaller in absolute value. This is precisely what we concluded intuitively in Graph 2.3.

EXERCISE 2B.3 Using the mathematical formulation of a budget line (equation (2.5)), illustrate how the slope and intercept terms change when p_2 instead of p_1 changes. Relate this to what your intuition would tell you in a graphical model of budget lines.

2B.2 Kinky Budgets

Kinked budget lines of the kind explored in Section 2A.2 are somewhat more difficult to describe mathematically. Consider, for instance, the example of a 50% off coupon for only the first 6 pairs of pants that I purchase. We graphed the choice set that emerges for someone with an income of \$200 facing a (before-coupon) price of \$20 for pants and \$10 for shirts in Graph 2.4a. There, we derived intuitively the result that my budget line will be initially flatter (up to 6 pants) before becoming steeper at the kink point when the effective price of pants changes from \$10 to \$20.

Were we to write down this choice set mathematically, we would simply have to translate the fact that the price of pants changes after the 6th pair into the set notation we developed earlier. And we would need to recognize that, if we buy more than 6 pairs of pants, we in effect have an additional $0.5(6p_1) = 3p_1$ in income because that is how much the coupon gave us back. For instance, when $p_1 = 20$, the coupon was worth \$60 if we buy 6 or more pants. We could, then, define the choice set as

$$C(p_1, p_2, I) = \{(x_1, x_2) \in \mathbb{R}_+^2 \mid 0.5 p_1 x_1 + p_2 x_2 \leq I \text{ for } x_1 \leq 6 \text{ and} \\ p_1 x_1 + p_2 x_2 \leq I + 3p_1 \text{ for } x_1 > 6\}. \quad (2.6)$$

Graph 2.4a is a graphical depiction of this set when $p_1 = 20$, $p_2 = 10$, and $I = 200$. The budget line itself is then defined by two line segments, one for $x_1 \leq 6$ and one for $x_1 > 6$; or, stated formally,

$$B(p_1, p_2, I) = \{(x_1, x_2) \in \mathbb{R}_+^2 \mid 0.5 p_1 x_1 + p_2 x_2 = I \text{ for } x_1 \leq 6 \text{ and} \\ p_1 x_1 + p_2 x_2 = I + 3p_1 \text{ for } x_1 > 6\}. \quad (2.7)$$

EXERCISE 2B.4 Convert the two equations contained in the budget set (2.7) into a format that illustrates more clearly the intercept and slope terms (as in equation (2.5)). Then, using the numbers for prices and incomes from our example, plot the two lines on a graph. Finally, erase the portions of the lines that are not relevant given that each line applies only for some values of x_1 (as indicated in (2.7)). Compare your graph with Graph 2.4a.

EXERCISE 2B.5 Now suppose that the 50% off coupon applied to all pants purchased after you bought an initial 6 pants at regular price. Derive the mathematical formulation of the budget set (analogous to equation (2.7)) and then repeat the previous exercise. Compare your graph with Graph 2.4b.

2B.3 Choice Sets with More Than Two Goods

As we discussed in Section 2A, we are often confronted by the fact that realistic models of economic behavior involve choices over more than two goods. The mathematical formulation of choice sets permits us one way of extending our analysis to settings where choices over many goods can be analyzed. Alternatively, as we noted in Section 2A, we can employ the simplifying assumption that categories of goods can be combined and treated as a composite good.⁵ We explore each of these alternatives in turn.

2B.3.1 Choice Sets with 3 or More Goods When faced with three rather than two goods, we illustrated in Graph 2.5 that our choice sets would now have to be plotted in three dimensions. When faced with more than three goods, we no longer have easy graphical techniques to represent choice sets. With the mathematical tools developed here, however, it becomes quite simple to extend two-good models to many goods.

Suppose, for instance, that we return to the example of me going to Walmart, only now I am sent to purchase pants, shirts, and socks. Let's denote those goods by x_1, x_2 , and x_3 and let's similarly denote their prices by p_1, p_2 , and p_3 . In order for a particular bundle (x_1, x_2, x_3) to lie within the choice set, it must then be true that the total cost of the bundle is no greater than my exogenous income I . The cost of each component of the bundle is simply the price of that component times the quantity, and the sum of these is equal to the full cost $p_1x_1 + p_2x_2 + p_3x_3$. My choice set is then a simple extension of the choice set we defined for two goods in equation (2.3):

$$C(p_1, p_2, p_3, I) = \{(x_1, x_2, x_3) \in \mathbb{R}_+^3 \mid p_1x_1 + p_2x_2 + p_3x_3 \leq I\}, \quad (2.8)$$

with the corresponding budget constraint defined by

$$B(p_1, p_2, p_3, I) = \{(x_1, x_2, x_3) \in \mathbb{R}_+^3 \mid p_1x_1 + p_2x_2 + p_3x_3 = I\}. \quad (2.9)$$

The equation in this definition of the budget constraint then defines the triangular plane that we graphed in Graph 2.5 for the values $p_1 = 20$, $p_2 = 10$, $p_3 = 5$, and $I = 200$.

By now you can probably quite easily see how the definition of choice sets and budget lines extends when we face choices over more than 3 goods. For the general case of n different goods with n different prices, we would simply extend (2.8) and (2.9) to:

$$C(p_1, p_2, \dots, p_n, I) = \{(x_1, x_2, \dots, x_n) \in \mathbb{R}_+^n \mid p_1x_1 + p_2x_2 + \dots + p_nx_n \leq I\}, \quad (2.10)$$

and

$$B(p_1, p_2, \dots, p_n, I) = \{(x_1, x_2, \dots, x_n) \in \mathbb{R}_+^n \mid p_1x_1 + p_2x_2 + \dots + p_nx_n = I\}. \quad (2.11)$$

While it is therefore no longer possible to graph these mathematical descriptions of sets, nevertheless is quite easy to formulate them using equations. As we explore the consumer model in more detail in the upcoming chapters, you will then see how these equations can be used to formulate a quite general model of choice behavior.

2B.3.2 Choice Sets with Composite Goods We of course also noted in Section 2A that we often find it useful in our graphical models to focus on one good that is of particular interest and to model all other consumption goods as a *composite good* denominated in dollars. We will often refer to this composite good as “dollars of other consumption.” One convenient benefit of such a model is that the price of the composite good is by definition 1 ($p_2 = 1$); 1 dollar of

⁵As noted in part A, there are several conditions under which it is theoretically sound to aggregate goods into a composite good. One such condition, known as *functional separability*, requires that the prices of the goods to be aggregated always move together in the same proportion. A second condition, known as *Hicksian separability*, involves assumptions about tastes. Either condition allows us to use the concept of a composite good. A detailed discussion of these two conditions is beyond the scope of this text, but the interested reader can learn more by referring to H. Varian, *Microeconomic Analysis*, 3rd ed. (New York: W. W. Norton and Company, 1992).

consumption of other goods costs 1 dollar. This implies that the slope of the budget line simply becomes the price of the good we are concerned with (rather than the ratio of prices that it typically is), and the vertical intercept becomes simply the exogenous income rather than income divided by the price of good 2.

To see this, we could simply write down the equation of a budget line with x_2 as the composite good as

$$p_1x_1 + x_2 = I, \quad (2.12)$$

leaving out the price for the composite good, which is just 1. Subtracting p_1x_1 from both sides, we get

$$x_2 = I - p_1x_1, \quad (2.13)$$

with the equation of a line with vertical intercept I and slope $-p_1$. Note that this is simply the same equation as equation (2.5) with p_2 set to 1.

2B.4 Choice Sets That Arise from Endowments

So far, we have assumed that my income level or money budget for my consumption choices is fixed or exogenous. This is a reasonable assumption when we analyze consumer choices where specific amounts have been budgeted for certain categories of goods (like shirts and pants) or when we analyze the consumption choices of someone on a fixed income. In other cases, however, the money that can be devoted to consumption is not *exogenous*; rather it arises *endogenously* from the decisions a consumer makes and from the prices he or she faces in the market. Important examples of this include our choices of selling our time in labor markets and our financial assets in capital markets. These are treated more explicitly in Chapter 3. For now, we simply illustrate the mathematics behind our example from Section 2A in consumer markets.

In particular, we assumed in Section 2A.4 that I returned to Walmart with 10 shirts and 5 pants knowing that Walmart will give me store credit for the value of my returns at the prices Walmart is currently charging. How much of a store credit I will get from Walmart now depends on the prices of shirts and pants that Walmart charges at the time of my return. My income can then be expressed as

$$I = 5p_1 + 10p_2, \quad (2.14)$$

since Walmart will give me its current price for pants, p_1 , for each of my 5 pants and its current price for shirts, p_2 , for each of my 10 shirts. My choice set is then composed of all combinations of pants and shirts such that my total spending is no more than this income level; that is,

$$C(p_1, p_2) = \{(x_1, x_2) \in \mathbb{R}_+^2 \mid p_1x_1 + p_2x_2 \leq 5p_1 + 10p_2\}. \quad (2.15)$$

Notice that the set C is now a function of only (p_1, p_2) because my income is “endogenously” determined by p_1 and p_2 as described in equation (2.14). When the inequality in (2.15) is replaced with an equality to get the equation for the budget line, we get

$$p_1x_1 + p_2x_2 = 5p_1 + 10p_2. \quad (2.16)$$

Subtracting p_1x_1 from both sides and dividing both sides by p_2 , this turns into

$$x_2 = 5 \frac{p_1}{p_2} + 10 - \frac{p_1}{p_2} x_1. \quad (2.17)$$

In Graph 2.6, we plotted this budget set for the case where Walmart was charging \$10 for both shirts and pants. When these prices are plugged into equation (2.17), we get

$$x_2 = 15 - x_1, \quad (2.18)$$

which represents the equation of a line with vertical intercept 15 and slope -1 . This is precisely the magenta budget line we derived intuitively in Graph 2.6.

More generally, we can denote someone's endowment as the number of goods of each kind a consumer has as he or she enters Walmart. For instance, we might denote my endowment of good 1 as e_1 and my endowment of good 2 as e_2 . (In our example $e_1 = 5$ and $e_2 = 10$.) We can then define my choice set as a function of my endowment and the prices of the two goods,

$$C(p_1, p_2, e_1, e_2) = \{(x_1, x_2) \mid p_1x_1 + p_2x_2 \leq p_1e_1 + p_2e_2\}, \quad (2.19)$$

where the left-hand side of the inequality represents my spending on the goods I purchase and the right-hand side represents my endogenous income from returning my endowment goods to Walmart.

Using the equation in (2.19), derive the general equation of the budget line in terms of prices and endowments. Following steps analogous to those leading to equation (2.17), identify the intercept and slope terms. What would the budget line look like when my endowments are 10 shirts and 10 pants and when prices are \$5 for pants and \$10 for shirts? Relate this to both the equation you derived and an intuitive derivation of the same budget line.

EXERCISE 2B.6

CONCLUSION

For consumer models in which individuals attempt to “do the best they can” given the “economic circumstances they face,” we began in this chapter by deriving ways of modeling “economic circumstances.” These circumstances are defined by what consumers bring to the table, whether in the form of an endowment or an exogenous income, and by the prices that they face. Together, these give rise to choice sets and budget constraints that define the set of options from which consumers can choose. These can be modeled graphically when the analysis permits restricting the number of goods to 2 or 3, or they can be represented mathematically for any arbitrary number of goods. The fundamental trade-offs or opportunity costs consumers face are then determined by relative prices, which appear as slopes in our graphs or equations.

Rarely, however, do we have the luxury of acting solely as consumers in the marketplace. In order to consume, we must generally earn income first, either by selling our leisure time in the labor market (i.e., working) or by selling something of value (e.g., a financial asset). And the economist assumes that we attempt to “do the best we can” given our “economic circumstances” whether we act as consumers, workers, or financial planners. We therefore next turn in Chapter 3 to defining choice sets and budget constraints that are relevant for other types of choices we make in the economy before moving on to consider more carefully what it means to “do the best” we can.

END-OF-CHAPTER EXERCISES

- 2.1[†]** Any good Southern breakfast includes grits (which my wife loves) and bacon (which I love). Suppose we allocate \$60 per week to consumption of grits and bacon, and we know that grits cost \$2 per box and bacon costs \$3 per package.
- A.** Use a graph with boxes of grits on the horizontal axis and packages of bacon on the vertical to answer the following:
- Illustrate my family's weekly budget constraint and choice set.
 - Identify the opportunity cost of bacon and grits and relate these to concepts on your graph.

*conceptually challenging

**computationally challenging

[†]solutions in Study Guide

- c. How would your graph change if a sudden appearance of a rare hog disease caused the price of bacon to rise to \$6 per package, and how does this change the opportunity cost of bacon and grits?
- d. What happens in your graph if (instead of the change in (c)) the loss of my job caused us to decrease our weekly budget for Southern breakfasts from \$60 to \$30? How does this change the opportunity cost of bacon and grits?
- B.** In the following, compare a mathematical approach to the graphical approach used in part A, using x_1 to represent boxes of grits and x_2 to represent packages of bacon.
- Write down the mathematical formulation of the budget line and choice set and identify elements in the budget equation that correspond to key features of your graph from part 2.1A(a).
 - How can you identify the opportunity cost of bacon and grits in your equation of a budget line, and how does this relate to your answer in 2.1A(b)?
 - Illustrate how the budget line equation changes under the scenario of 2.1A(c) and identify the change in opportunity costs.
 - Repeat (c) for the scenario in 2.1A(d).
- 2.2** Suppose the only two goods in the world are peanut butter and jelly.
- A.** You have no exogenous income, but you do own 6 jars of peanut butter and 2 jars of jelly. The price of peanut butter is \$4 per jar, and the price of jelly is \$6 per jar.
- On a graph with jars of peanut butter on the horizontal and jars of jelly on the vertical axis, illustrate your budget constraint.
 - How does your constraint change when the price of peanut butter increases to \$6? How does this change your opportunity cost of jelly?
- B.** Consider the same economic circumstances described in 2.2A and use x_1 to represent jars of peanut butter and x_2 to represent jars of jelly.
- Write down the equation representing the budget line and relate key components to your graph from 2.2A(a).
 - Change your equation for your budget line to reflect the change in economic circumstances described in 2.2A(b) and show how this new equation relates to your graph in 2.2A(b).
- 2.3[†]** Consider a budget for good x_1 (on the horizontal axis) and x_2 (on the vertical axis) when your economic circumstances are characterized by prices p_1 and p_2 and an exogenous income level I .
- A.** Draw a budget line that represents these economic circumstances and carefully label the intercepts and slope.
- Illustrate how this line can shift parallel to itself without a change in I .
 - Illustrate how this line can rotate clockwise on its horizontal intercept without a change in p_2 .
- B.** Write the equation of a budget line that corresponds to your graph in 2.3A.
- Use this equation to demonstrate how the change derived in 2.3A(a) can happen.
 - Use the same equation to illustrate how the change derived in 2.3A(b) can happen.
- 2.4*** Suppose there are three goods in the world: x_1, x_2 , and x_3 .
- A.** On a three-dimensional graph, illustrate your budget constraint when your economic circumstances are defined by $p_1 = 2, p_2 = 6, p_3 = 5$, and $I = 120$. Carefully label intercepts.
- What is your opportunity cost of x_1 in terms of x_2 ? What is your opportunity cost of x_2 in terms of x_3 ?
 - Illustrate how your graph changes if I falls to \$60. Does your answer to (a) change?
 - Illustrate how your graph changes if instead p_1 rises to \$4. Does your answer to part (a) change?
- B.** Write down the equation that represents your picture in 2.4A. Then suppose that a new good x_4 is invented and priced at \$1. How does your equation change? Why is it difficult to represent this new set of economic circumstances graphically?

2.5[†] Everyday Application: *Watching a Bad Movie*: On one of my first dates with my wife, we went to see the movie *Spaceballs* and paid \$5 per ticket.

- A.** Halfway through the movie, my wife said: “What on earth were you thinking? This movie sucks! I don’t know why I let you pick movies. Let’s leave.”
- In trying to decide whether to stay or leave, what is the opportunity cost of staying to watch the rest of the movie?
 - Suppose we had read a sign on the way into the theater stating “Satisfaction Guaranteed! Don’t like the movie half way through—see the manager and get your money back!” How does this change your answer to part (a)?

2.6 Everyday Application: *Renting a Car versus Taking Taxis*: Suppose my brother and I both go on a week-long vacation in Cayman and, when we arrive at the airport on the island, we have to choose between either renting a car or taking a taxi to our hotel. Renting a car involves a fixed fee of \$300 for the week, with each mile driven afterward just costing \$0.20, which is the price of gasoline per mile. Taking a taxi involves no fixed fees, but each mile driven on the island during the week now costs \$1 per mile.

- A.** Suppose both my brother and I have brought \$2,000 on our trip to spend on “miles driven on the island” and “other goods.” On a graph with miles driven on the horizontal and other consumption on the vertical axis, illustrate my budget constraint assuming I chose to rent a car and my brother’s budget constraint assuming he chose to take taxis.
- What is the opportunity cost for each mile driven that I faced?
 - What is the opportunity cost for each mile driven that my brother faced?
- B.** Derive the mathematical equations for my budget constraint and my brother’s budget constraint, and relate elements of these equations to your graphs in part A. Use x_1 to denote miles driven and x_2 to denote other consumption.
- Where in your budget equation for me can you locate the opportunity cost of a mile driven?
 - Where in your budget equation for my brother can you locate the opportunity cost of a mile driven?

2.7*[†] Everyday Application: *Dieting and Nutrition*: On a recent doctor’s visit, you have been told that you must watch your calorie intake and must make sure you get enough vitamin E in your diet.

- A.** You have decided that, to make life simple, you will from now on eat only steak and carrots. A nice steak has 250 calories and 10 units of vitamins, and a serving of carrots has 100 calories and 30 units of vitamins. Your doctor’s instructions are that you must eat *no more* than 2,000 calories and consume *at least* 150 units of vitamins per day.
- In a graph with “servings of carrots” on the horizontal axis and “servings of steak” on the vertical axis, illustrate all combinations of carrots and steaks that make up a 2,000-calorie-a-day diet.
 - On the same graph, illustrate all the combinations of carrots and steaks that provide exactly 150 units of vitamins.
 - On this graph, shade in the bundles of carrots and steaks that satisfy both of your doctor’s requirements.
 - Now suppose you can buy a serving of carrots for \$2 and a steak for \$6. You have \$26 per day in your food budget. In your graph, illustrate your budget constraint. If you love steak and don’t mind eating or not eating carrots, what bundle will you choose (assuming you take your doctor’s instructions seriously)?
- B.** Continue with the scenario as described in part A, letting carrots be denoted by x_1 and steak by x_2 .
- Define the line you drew in A(a) mathematically.
 - Define the line you drew in A(b) mathematically.
 - In formal set notation, write down the expression that is equivalent to the shaded area in A(c).
 - Derive the exact bundle you indicated on your graph in A(d).

2.8 Everyday Application: *Setting up a College Trust Fund:* Suppose that you, after studying economics in college, quickly became rich, so rich that you have nothing better to do than worry about your 16-year-old niece who can't seem to focus on her future. Your niece already has a trust fund that will pay her a nice yearly income of \$50,000 starting when she is 18, and she has no other means of support.

- A.** You are concerned that your niece will not see the wisdom of spending a good portion of her trust fund on a college education, and you would therefore like to use \$100,000 of your wealth to change her choice set in ways that will give her greater incentives to go to college.
- One option is for you to place \$100,000 in a second trust fund but to restrict your niece to be able to draw on this trust fund only for college expenses of up to \$25,000 per year for four years. On a graph with “yearly dollars spent on college education” on the horizontal axis and “yearly dollars spent on other consumption” on the vertical, illustrate how this affects her choice set.
 - A second option is for you to simply tell your niece that you will give her \$25,000 per year for four years and you will trust her to “do what’s right.” How does this impact her choice set?
 - Suppose you are wrong about your niece’s short-sightedness and she was planning on spending more than \$25,000 per year from her other trust fund on college education. Do you think she will care whether you do as described in part (a) or as described in part (b)?
 - Suppose you were right about her: She never was going to spend very much on college. Will she care now?
 - A friend of yours gives you some advice: Be careful. Your niece will not value her education if she does not have to put up some of her own money for it. Sobered by this advice, you decide to set up a different trust fund that will release \$0.50 to your niece (to be spent on whatever she wants) for every dollar that she spends on college expenses. How will this affect her choice set?
 - If your niece spends \$25,000 per year on college under the trust fund in part (e), can you identify a vertical distance that represents how much you paid to achieve this outcome?
- B.** How would you write the budget equation for each of the three alternatives discussed in part A?

2.9*† Business Application: *Pricing and Quantity Discounts:* Businesses often give quantity discounts. In the following, you will analyze how such discounts can impact choice sets.

- A.** I recently discovered that a local copy service charges our economics department \$0.05 per page (or \$5 per 100 pages) for the first 10,000 copies in any given month but then reduces the price per page to \$0.035 for each additional page up to 100,000 copies and to \$0.02 per each page beyond 100,000. Suppose our department has a monthly overall budget of \$5,000.
- Putting “pages copied in units of 100” on the horizontal axis and “dollars spent on other goods” on the vertical, illustrate this budget constraint. Carefully label all intercepts and slopes.
 - Suppose the copy service changes its pricing policy to \$0.05 per page for monthly copying up to 20,000 and \$0.025 per page for *all* pages if copying exceeds 20,000 per month. (*Hint:* Your budget line will contain a jump.)
 - What is the marginal (or “additional”) cost of the first page copied after 20,000 in part (b)? What is the marginal cost of the first page copied after 20,001 in part (b)?
- B.** Write down the mathematical expression for choice sets for each of the scenarios in 2.9A(a) and 2.9A(b) (using x_1 to denote “pages copied in units of 100” and x_2 to denote “dollars spent on other goods”).

2.10 Business Application: *Supersizing:* Suppose I run a fast-food restaurant and I know my customers come in on a limited budget. Almost everyone that comes in for lunch buys a soft drink. Now suppose it costs me virtually nothing to serve a medium versus a large soft drink, but I do incur some extra costs when adding items (like a dessert or another side dish) to someone’s lunch tray.

- A.** Suppose for purposes of this exercise that cups come in all sizes, not just small, medium, and large; and suppose the average customer has a lunch budget B . On a graph with “ounces of soft drink” on the horizontal axis and “dollars spent on other lunch items” on the vertical, illustrate a customer’s budget constraint assuming I charge the same price p per ounce of soft drink no matter how big a cup the customer gets.

- a. I have three business partners: Larry, his brother Daryl, and his other brother Daryl. The Daryls propose that we lower the price of the initial ounces of soft drink that a consumer buys and then, starting at 10 ounces, we increase the price. They have calculated that our average customer would be able to buy exactly the same number of ounces of soft drink (if that is all he bought on his lunch budget) as under the current single price. Illustrate how this will change the average customer's budget constraint.
 - b. Larry thinks the Daryls are idiots and suggests instead that we raise the price for initial ounces of soft drink and then, starting at 10 ounces, decrease the price for any additional ounces. He, too, has calculated that, under his pricing policy, the average customer will be able to buy exactly the same ounces of soft drinks (if that is all the customer buys on his or her lunch budget). Illustrate the effect on the average customer's budget constraint.
 - c. If the average customer had a choice, which of the three pricing systems—the current single price, the Daryls' proposal, or Larry's proposal—would he choose?
- B.** Write down the mathematical expression for each of the 3 choice sets, letting ounces of soft drinks be denoted by x_1 and dollars spent on other lunch items by x_2 .

2.11[†] Business Application: *Frequent Flyer Perks:* Airlines offer frequent flyers different kinds of perks that we will model here as reductions in average prices per mile flown.

- A.** Suppose that an airline charges 20 cents per mile flown. However, once a customer reaches 25,000 miles in a given year, the price drops to 10 cents per mile flown for each additional mile. The alternate way to travel is to drive by car, which costs 16 cents per mile.
- a. Consider a consumer who has a travel budget of \$10,000 per year, a budget that can be spent on the cost of getting to places as well as “other consumption” while traveling. On a graph with “miles flown” on the horizontal axis and “other consumption” on the vertical, illustrate the budget constraint for someone who only considers flying (and not driving) to travel destinations.
 - b. On a similar graph with “miles driven” on the horizontal axis, illustrate the budget constraint for someone that considers only driving (and not flying) as a means of travel.
 - c. By overlaying these two budget constraints (changing the good on the horizontal axis simply to “miles traveled”), can you explain how frequent flyer perks might persuade some to fly a lot more than he or she otherwise would?
- B.** Determine where the air-travel budget from A(a) intersects the car budget from A(b).

2.12* Business Application: *Choice in Calling Plans:* Phone companies used to sell minutes of phone calls at the same price no matter how many phone calls a customer made. (We will abstract away from the fact that they charged different prices at different times of the day and week.) More recently, phone companies, particularly cell phone companies, have become more creative in their pricing.

- A.** On a graph with “minutes of phone calls per month” on the horizontal axis and “dollars of other consumption” on the vertical, draw a budget constraint assuming the price per minute of phone calls is p and assuming the consumer has a monthly income I .
- a. Now suppose a new option is introduced: You can pay $\$P_x$ to buy into a phone plan that offers you x minutes of free calls per month, with any calls beyond x costing p per minute. Illustrate how this changes your budget constraint and assume that P_x is sufficiently low such that the new budget contains some bundles that were previously unavailable to our consumer.
 - b. Suppose it actually costs phone companies close to p per minute to provide a minute of phone service so that, in order to stay profitable, a phone company must on average get about p per minute of phone call. If all consumers were able to choose calling plans such that they always use exactly x minutes per month, would it be possible for phone companies to set P_x sufficiently low such that new bundles become available to consumers?
 - c. If some fraction of consumers in any given month buy into a calling plan but make fewer than x calls, how does this enable phone companies to set P_x such that new bundles become available in consumer choice sets?

**BUSINESS
APPLICATION**

**BUSINESS
APPLICATION**

- B.** Suppose a phone company has 100,000 customers who currently buy phone minutes under the old system that charges p per minute. Suppose it costs the company c to provide one additional minute of phone service but the company also has fixed costs FC (that don't vary with how many minutes are sold) of an amount that is sufficiently high to result in zero profit. Suppose a second identical phone company has 100,000 customers who have bought into a calling plan that charges $P_x = kpx$ and gives customers x free minutes before charging p for minutes above x .
- If people on average use half their "free minutes" per month, what is k (as a function of FC , p , c , and x) if the second company also makes zero profit?
 - If there were no fixed costs (i.e., $FC = 0$) but everything else was still as stated, what does c have to be equal to in order for the first company to make zero profit? What is k in that case?

2.13[†] Policy Application: *Food Stamp Programs and Other Types of Subsidies:* The U.S. government has a food stamp program for families whose income falls below a certain poverty threshold. Food stamps have a dollar value that can be used at supermarkets for food purchases as if the stamps were cash, but the food stamps cannot be used for anything other than food.

- Suppose the program provides \$500 of food stamps per month to a particular family that has a fixed income of \$1,000 per month.
 - With "dollars spent on food" on the horizontal axis and "dollars spent on nonfood items" on the vertical, illustrate this family's monthly budget constraint. How does the opportunity cost of food change along the budget constraint you have drawn?
 - How would this family's budget constraint differ if the government replaced the food stamp program with a cash subsidy program that simply gave this family \$500 in cash instead of \$500 in food stamps? Which would the family prefer, and what does your answer depend on?
 - How would the budget constraint change if the government simply agreed to reimburse the family for half its food expenses?
 - If the government spends the same amount for this family on the program described in (c) as it did on the food stamp program, how much food will the family consume? Illustrate the amount the government is spending as a vertical distance between the budget lines you have drawn.
- Write down the mathematical expression for the choice set you drew in 2.13A(a), letting x_1 represent dollars spent on food and x_2 represent dollars spent on nonfood consumption. How does this expression change in 2.13A(b) through (d)?

2.14 Policy Application: *Public Housing and Housing Subsidies:* For a long period, the U.S. government focused its attempts to meet housing needs among the poor through public housing programs. Eligible families could get on waiting lists to apply for an apartment in a public housing development and would be offered a particular apartment as they moved to the top of the waiting list.

- Suppose a particular family has a monthly income of \$1,500 and is offered a 1,500-square-foot public housing apartment for \$375 in monthly rent. Alternatively, the family could choose to rent housing in the private market for \$0.50 per square foot.
 - Illustrate all the bundles in this family's choice set of "square feet of housing" (on the horizontal axis) and "dollars of monthly other goods consumption" (on the vertical axis).
 - In recent years, the government has shifted away from an emphasis on public housing and toward providing poor families with a direct subsidy to allow them to rent more housing in the private market. Suppose, instead of offering the family in part (a) an apartment, the government offered to pay half of the family's rental bill. How would this change the family's budget constraint?
 - Is it possible to tell which policy the family would prefer?
- Write down the mathematical expression for the budget lines you drew in 2.14A(a) and 2.14A(b), letting x_1 denote hundreds of square feet of monthly housing consumption and x_2 denote dollars spent on non housing consumption.

2.15[†] Policy Application: *Taxing Goods versus Lump Sum Taxes:* I have finally convinced my local member of Congress that my wife's taste for grits is unnervingly strange and that the world should be protected from too much grits consumption. As a result, my member of Congress has agreed to sponsor new

legislation to tax grits consumption, which will raise the price of grits from \$2 per box to \$4 per box. We carefully observe my wife's shopping behavior and notice with pleasure that she now purchases 10 boxes of grits per month rather than her previous 15 boxes.

- A.** Putting “boxes of grits per month” on the horizontal and “dollars of other consumption” on the vertical, illustrate my wife's budget line before and after the tax is imposed. (You can simply denote income by I .)
- How much tax revenue is the government collecting per month from my wife? Illustrate this as a vertical distance on your graph. (*Hint:* If you know how much she is consuming after the tax and how much in other consumption this leaves her with, and if you know how much in other consumption she would have had if she consumed that same quantity before the imposition of the tax, then the difference between these two “other consumption” quantities must be equal to how much she paid in tax.)
 - Given that I live in the South, the grits tax turned out to be unpopular in my congressional district and has led to the defeat of my member of Congress. His replacement won on a pro-grits platform and has vowed to repeal the grits tax. However, new budget rules require her to include a new way to raise the same tax revenue that was yielded by the grits tax. She proposes simply to ask each grits consumer to pay exactly the amount he or she paid in grits taxes as a monthly lump sum payment. Ignoring for the moment the difficulty of gathering the necessary information for implementing this proposal, how would this change my wife's budget constraint?
- B.** State the equations for the budget constraints you derived in A(a) and A(b), letting grits be denoted by x_1 and other consumption by x_2 .

2.16 Policy Application: Public Schools and Private School Vouchers: Consider a simple model of how economic circumstances are changed when free public education is provided.

- A.** Suppose a household has an after-tax income of \$50,000, and consider its budget constraint with “dollars of education services” on the horizontal axis and “dollars of other consumption” on the vertical. Begin by drawing the household's budget line (given that you can infer a price for each of the goods on the axes from the way these goods are defined) assuming that the household can buy any level of school spending on the private market.
- Now suppose the government uses its existing tax revenues to fund a public school at \$7,500 per pupil; that is, it funds a school that anyone can attend for free and that provides \$7,500 in education services. Illustrate how this changes the choice set. (*Hint:* One additional point will appear in the choice set.)
 - Continue to assume that private school services of any quantity could be purchased but only if the child does not attend public schools. Can you think of how the availability of free public schools might cause some children to receive more educational services than before they would in the absence of public schools? Can you think of how some children might receive fewer educational services once public schools are introduced?
 - Now suppose the government allows an option: Either a parent can send her child to the public school or can take a voucher to a private school and use it for partial payment of private school tuition. Assume that the voucher is worth \$7,500 per year; that is, it can be used to pay for up to \$7,500 in private school tuition. How does this change the budget constraint? Do you still think it is possible that some children will receive less education than they would if the government did not get involved at all (i.e., no public schools and no vouchers)?
- B.** Letting dollars of education services be denoted by x_1 and dollars of other consumption by x_2 , formally define the choice set with just the public school (and a private school market) as well as the choice set with private school vouchers previously defined.

2.17*† Policy Application: Tax Deductions and Tax Credits: In the U.S. income tax code, a number of expenditures are “deductible.” For most tax payers, the largest tax deduction comes from the portion of the income tax code that permits taxpayers to deduct home mortgage interest (on both a primary and a vacation home). This means that taxpayers who use this deduction do not have to pay income tax on the portion of their income that is spent on paying interest on their home mortgage(s). For purposes of this exercise, assume that the entire yearly price of housing is interest expense.

- A.** *True or False:* For someone whose marginal tax rate is 33%, this means that the government is subsidizing roughly one-third of his or her interest/house payments.
- Consider a household with an income of \$200,000 that faces a tax rate of 40%, and suppose the price of a square foot of housing is \$50 per year. With square footage of housing on the horizontal axis and other consumption on the vertical, illustrate this household's budget constraint with and without tax deductibility. (Assume in this and the remaining parts of the question that the tax rate cited for a household applies to all of that household's income.)
 - Repeat this for a household with income of \$50,000 that faces a tax rate of 10%.
 - An alternative way for the government to encourage home ownership would be to offer a tax *credit* instead of a tax *deduction*. A tax credit would allow all taxpayers to subtract a fraction k of their annual mortgage payments directly from the tax bill they would otherwise owe. (*Note:* Be careful. A tax credit is deducted from tax *payments* that are due, not from the taxable income.) For the households in (a) and (b), illustrate how this alters their budget if $k = 0.25$.
 - Assuming that a tax deductibility program costs the same in lost tax revenues as a tax credit program, which household would favor which program?
- B.** Let x_1 and x_2 represent square feet of housing and other consumption, and let the price of a square foot of housing be denoted p .
- Suppose a household faces a tax rate t for all income, and suppose the entire annual house payment a household makes is deductible. What is the household's budget constraint?
 - Now write down the budget constraint under a tax credit as previously described.

Economic Circumstances in Labor and Financial Markets

As we noted in Chapter 2, the economic choices we make are not limited to the types of choices we face when we visit Walmart on a fixed or “exogenous” dollar budget.¹ After all, where does the money that we can spend on consumer goods come from in the first place? Before we can spend money, we must first generate it through some form of economic activity. For most of us, this activity involves work, or the giving up of our time in return for pay. Alternatively, we might generate money by borrowing or by cashing in savings from savings accounts, mutual funds, real estate investments, or other assets. In each of these scenarios, we are giving up some *endowment*, something whose value is determined by prices in the economy, to get money for consumption. This endowment may be our time when we work, an asset when we cash in our savings or our ability to consume income in the future when we borrow. We are, in effect, trading an endowment in order to generate the money that then can be treated as a fixed budget when we go into Walmart to shop for shirts and pants.

When I returned to Walmart with 5 pants and 10 shirts in Chapter 2, I returned with an endowment, and my *endogenous income* was then determined by the prices at which I could sell this endowment back to Walmart for store credit. In the same way, our economic circumstances in work/leisure and savings/borrowing decisions are shaped by the endowment that we bring to the table as well as the prices that the endowment commands in the market. If the decision involves selling our leisure time for work, the relevant “price” becomes the wage, and when the decision involves postponing consumption (through savings) or borrowing on future income (through taking out a loan), the relevant “price” will be the interest rate that we can earn or that we have to pay. Thus, the choice sets that we derive in this chapter are in essence no different than the choice set we thought about in Chapter 2 when I returned to Walmart with pants and shirts rather than with money; all that is different is that our endowment will not be in terms of pants and shirts, and the prices will involve wage rates and interest rates.

Wages and interest rates are also prices.

3A

BUDGETS FOR WORKERS AND SAVERS

We will begin by analyzing our choice sets as workers and then proceed to choice sets that arise as we think about saving and borrowing. As in the previous chapter, we start by focusing purely on economics and intuition, relying on graphical tools to generate our basic models of choice

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

¹Chapter 2 is recommended as prior reading for this chapter.

sets. Then, in Section 3B, we will translate some of that intuition into mathematical language in order to demonstrate how to generalize it.

3A.1 Our Choice Sets as Workers

As we have already noted, “work” involves giving up one of our most precious endowments: our time. Depending on our innate talents and characteristics as well as our educational background and work experience, our time may be worth more or less to employers (or to the market more generally if we are self-employed). Let’s assume that you are on summer break and have found a job with an employer who is willing to pay you \$20 per hour. Your employer is trying to determine how many other summer workers she needs to hire, and so she asks you how many hours per week you would like to work this summer. You now have to determine how much work is best for you given your circumstances. The more you work, the less leisure time you will have this summer but the more consumption goods you will be able to buy with your newfound wealth. The opportunity cost of taking 1 hour of leisure time is how much consumption you implicitly give up by not working during that hour, which is \$20 worth of consumption if your wage is \$20 per hour. Put differently, *the opportunity cost of an hour of leisure is the wage you could have earned in that hour.*

The wage is the opportunity cost of one hour of leisure.

3A.1.1 Graphing Leisure/Consumption Choice Sets Illustrating your choice set as you choose between consuming and leisuring is then no different than illustrating your choice set over pants and shirts, except that you begin with a particular endowment of leisure time rather than an exogenous dollar income. Suppose we put “hours of leisure per week” on the horizontal axis and “dollars of consumption per week” on the vertical, as in Graph 3.1. (Notice that we have chosen to make the analysis manageable by lumping all consumption into one composite consumption good as described in Chapter 2.) Let’s assume that, given your other obligations (not to mention your need for sleep and personal grooming), you potentially have 60 hours of

GRAPH 3.1 A Decrease in Wage

Go to MindTap to interact with this graph.

time available to allocate between work and play in any given week. This is your leisure time endowment. The intercept on the leisure axis is then at 60 hours (point E), indicating that one of your possible choices is to hold onto your 60 hours of leisure endowment and thus earn no money for consumption. Notice that you can consume this endowment bundle E regardless of what prices (including the wage) in the economy are, a characteristic we said in Chapter 2 is shared by all endowment points.

On the other extreme, you could sell your entire time endowment, that is, devote all of your time to work, and earn as much as \$1,200 per week. This gives you point B as the intercept on the consumption axis. Or you could do something in between, such as selling 40 hours of leisure (leaving you with 20 hours for play) and earning \$800 per week for consumption (point C). Connecting these, we get a (blue) budget constraint that illustrates all the possible combinations of consumption and leisure that are available to you per week given your circumstances. Notice that the slope of this line is -20 , which is exactly equal to the (negative) wage that we have identified as the opportunity cost of 1 hour of leisure in terms of dollars of consumption.

Now suppose a recession hits prior to the beginning of summer and, as a result, the best wage you can get is \$10 rather than \$20 per hour. How would this change the budget constraint that illustrates your trade-off between consumption and leisure?

Recall that we noted at the end of Chapter 2 that, when a choice set is derived from an endowment rather than some fixed dollar amount, the budget line will rotate through the endowment point when prices change. The wage in our current example is a price, the price employers have to pay in order to hire workers. The endowment in our example is point E , the point that illustrates the total amount of discretionary leisure time that you have available per week. As we have already noted, regardless of what the wage rate in the economy turns out to be, this point E is *always* available to you since it is your endowment point. Point E therefore does not change when the wage rate declines to \$10. Point B , on the other hand, does change; if you decided to sell all of your available leisure time, you could now only earn \$600 rather than \$1,200 per week for spending on consumption goods. The new (magenta) budget constraint therefore contains the endowment point E and has a slope equal to the new opportunity cost of leisure.

The slope of the consumption/leisure budget line is $-w$.

Illustrate what happens to the original budget constraint if your wage increases to \$30 per hour. What if your friend instead introduces you to caffeine, which allows you to sleep less and thus take up to 80 hours of leisure time per week?

EXERCISE
3A.1

3A.1.2 Government Policies and Labor Market Choice Sets The potential impacts of government policies on labor market decisions are so vast that entire subfields within economics are devoted to studying such impacts. Overtime regulations, mandates regarding benefits for employees, safety regulations, wage taxes, and subsidies: These are all examples of ways in which governments impact the types of choices available to individual employees and employers.

Consider, for instance, a regulation that requires employers to pay 50% overtime for any work done beyond 40 hours per week. One possible outcome of such a regulation is that employers do not permit employees the option of working for more than 40 hours per week. In the example of your summer job, this would not alter point E ; if you choose not to work at all (and take 60 hours of leisure), you would still not earn any money for consumption. Similarly, the opportunity cost of leisure would remain unchanged for the first 40 hours of leisure that you give up, implying that the budget constraint would remain the same between points E and C in Graph 3.2a. How the budget changes between points C and B , however, depends on what other labor market opportunities you have given that your current employer is no longer offering you the option of working beyond 40 hours per week. For instance, if your next best labor market

GRAPH 3.2 Possible Kinks in Labor Market Choice Sets under Overtime Regulation

opportunity involves a wage of \$10 per hour, you could sell your remaining 20 hours of leisure for a total of \$200, implying that the most consumption you could obtain by working 40 hours with your first employer and 20 hours in a second job is \$1,000. Point *B* therefore shifts down by \$200, and the slope of the budget constraint between 0 and 20 hours of leisure becomes -10 , reflecting the lower wage in the second job.

Of course, not all employers will choose to respond to overtime regulations by prohibiting work beyond 40 hours a week. If your employer permits you to choose freely the number of hours you work in the presence of overtime regulations, your budget constraint would change differently. While the segment between *E* and *C* would remain unchanged (since it deals with hours of work below 40 per week), the most consumption you could engage in if you worked the full 60 hours would increase to \$1,400 because your last 20 hours of leisure could now be sold for \$30 per hour: the \$20 wage plus the required 50% overtime pay. The resulting budget constraint would again be kinked at *C* but would now point inward rather than outward, as in Graph 3.2b.

Different kinds of taxes and subsidies also have important effects on the choice sets that workers face. Suppose, for instance, the government imposes a 25% tax on all wages and suppose that your employer continues to pay you only \$20 per hour.² Then your take-home pay is only \$15 per hour, and your budget constraint would rotate counterclockwise around the endowment point *E* (with a new consumption intercept of \$900 instead of \$1,200). While this is an example of a *proportional wage tax*, a tax that collects revenues from workers in strict proportion to their wage income, most real-world taxes are significantly more complicated. Often, tax rates imposed on wage income increase as income rises, but sometimes the reverse is true. For instance, while U.S. federal income tax rates increase with income, U.S. Social Security tax rates decrease (to zero) as income rises. And, for workers in low-income families, the United States has programs to subsidize wages up to a certain level of income through what is known as the *Earned Income Tax Credit*. These kinds of tax and subsidy systems can create important kinks in leisure/consumption budget sets, kinks that we explore more in end-of-chapter exercises.

²Under certain assumptions, employers and employees end up sharing the burden of a tax on wages, a scenario we are abstracting away from here. We will discuss this in more detail in later chapters.

3A.2 Constraints We Face in Planning for the Future

In our choices as consumers (Chapter 2), the prices of different goods and the money we have available for spending on these goods combine to form our choice sets. In our choices as workers (Section 3A.1), our available time endowment combined with the wage rates we are able to command in the market form similar choice sets that illustrate the trade-offs we face between working and leisure. We now turn to a final important set of trade-offs, those involving our planning for the future as we decide whether to delay immediate gratification by saving rather than consuming today or by limiting the degree to which we borrow against our future income. By saving, we generate an asset that, like the time we sell in labor markets, we can later sell in order to consume. By borrowing, on the other hand, we are in effect selling a future asset in order to consume today.

3A.2.1 Planning for Next Year: Intertemporal Budget Constraints Suppose that you have accepted a summer job for a total of 500 hours at \$20 per hour. You therefore know that you will earn a total of \$10,000 this summer. Suppose further that you would like not to work next summer because you and your significant other would like to go off to spend a summer exploring the Amazon. Your significant other is a philosopher, steeped in deep thought but utterly unconcerned about money and fully dependent on your financial support during summers. Both of you have full financial aid during the academic year and therefore need money only during summers.

Recognizing that it will be difficult to explore the Amazon on an empty stomach, you decide to plan for next summer with the income you earn this summer. We can illustrate the trade-offs you face by putting “dollars of consumption this summer” on the horizontal axis and “dollars of consumption next summer” on the vertical axis. (Notice that we have chosen to lump all forms of consumption in each summer period together and treat it as a composite good in order to make the analysis manageable in a two-dimensional picture.) You could decide to spend all your income this summer on current consumption, thus obtaining \$10,000 worth of consumption for you and your significant other this summer with nothing but your love to sustain you next summer (point *E* in Graph 3.3a). On the other extreme, you could starve yourselves this summer in anticipation of feasting next summer. In that case, you could put the \$10,000 in the bank and

Intertemporal budget constraints illustrate consumption trade-offs over time.

GRAPH 3.3 Different Types of Intertemporal Budget Constraints

earn interest for a year. Suppose the annual interest rate is 10%. This would permit you a maximum of \$11,000 in consumption next year if you choose to forego all consumption this summer (point B). Or you could choose any point on the line connecting points E and B , a line whose slope of -1.1 illustrates the opportunity cost of consuming a dollar this summer as \$1.10 in foregone consumption next summer. More generally, *the opportunity cost of consuming a dollar today is 1 plus the (annual) interest rate (expressed in decimal form) in foregone consumption one year from now*. Such budget constraints that illustrate trade-offs faced over time are often called *intertemporal budget constraints*.

Notice that, for purposes of this model, we are treating this summer's income as your endowment (point E). Regardless of what the prices are in the economy (where the interest rate is the important price for our current analysis), you can always choose to consume this endowment; that is, you can always choose simply to consume all \$10,000 now. As the interest rate changes, however, the rest of your budget constraint will rotate through that point. For instance, if the interest rate falls to 5%, the maximum you will be able to consume next summer is \$10,500 (point B' in Graph 3.3a), and the new slope (of the magenta budget line) illustrates the new opportunity cost of consuming a dollar this year.

Now suppose that your philosopher friend decides the Amazon cannot wait another day and that you must spend this rather than next summer traveling together through the rainforest. Since you have no savings, you can do this only by borrowing against your future income. Your employer agrees to write a note to the bank letting them know that you can work for her next year for a summer salary of \$11,000. Let's suppose the interest rate is still 10%. When plotting your budget constraint across the two summers, you know that one possibility would be for you to borrow nothing and thus have the entire \$11,000 for consumption next summer (point E' in Graph 3.3b). Alternatively, you could borrow the maximum amount the bank will lend you and consume all of it this year. Since the bank knows that you can pay back up to \$11,000 next summer, it will lend you up to \$10,000 now (knowing that this will mean that you will owe \$11,000 next year when the 10% interest has been figured into your debt). Point A therefore lies at \$10,000 on the "dollars of consumption this summer" axis.

Notice that now we are treating your income next summer as your endowment that you can consume regardless of what the interest rate is, which means that your budget line will rotate through point E' as the interest rate changes. Thus, for any given interest rate r (expressed in decimal form), the budget line will run through point E' with slope $-(1 + r)$, which is the opportunity cost of borrowing and consuming a dollar (and then having to pay it back with interest next year). Graph 3.3b illustrates a decrease in the interest rate from 10% to 5% as the change from the initial blue to the new magenta budget line.

Finally, suppose that you are able to convince your philosopher friend that it might be best to split your Amazon trip over two summers and thus to work both half of this summer and half of next summer. Your employer is willing to play along, giving you a \$5,000 summer salary this year and promising a \$5,500 summer salary next year. In this case, your endowment point—the point that does not depend on the interest rate—is given by a new point E'' (in Graph 3.3c) where you consume \$5,000 this year and \$5,500 next year. At an interest rate of 10%, you could save all of your current summer pay and consume a total of \$11,000 next summer, or you could borrow \$5,000 from the bank and consume as much as \$10,000 this summer (with no consumption next summer). As the interest rate changes, your budget line would continue to go through your endowment point E'' (since you can always just consume what you make when you make it) with a slope $-(1 + r)$. Graph 3.3c then illustrates a change in the interest rate from 10% to 5%.

The slope of the intertemporal budget is $-(1 + r)$.

EXERCISE 3A.2

Verify the dollar quantities on the axes in Graph 3.3a–c.

In each of the panels of Graph 3.3, how would the choice set change if the interest rate went to 20%?

EXERCISE
3A.3

3A.2.2 Planning for Several Years into the Future Our analysis becomes a little more complex as we think of planning beyond a year from now. Suppose, for instance, that you and your philosopher friend are required to go to summer school next summer in order to complete your degrees and thus you won't be able to go on your Amazon adventure until two years from now. Since you will be in school next summer, parental and financial aid support will fully cover your expenses between this summer and two summers from now, but you are responsible for covering this summer and your Amazon summer in two years. Again, suppose your summer job this year pays \$10,000 and the annual interest rate is 10%.

We can now illustrate your budget constraint across the two summers, with “dollars of consumption this summer” on the horizontal axis and “dollars of consumption two years from now” on the vertical. Point *E* in Graph 3.3a remains unchanged: You can always just decide to consume everything this summer and nothing two summers from now. But how much could you consume two years from now if you saved everything?

We know that if you put \$10,000 in the bank for a year, you will have \$11,000 in the bank one year from now. To see what you would have two years from now, we can just repeat the exercise and see how much interest you will get if you keep \$11,000 in the bank for one more year. Since 10% of \$11,000 is \$1,100, we can see that you could have as much as \$12,100 in consumption two summers from now if you consume none of your current summer income.

More generally, suppose the annual interest rate is r (expressed in decimal form). Keeping \$10,000 in the bank for a year will result in a bank balance of $\$10,000(1 + r)$. Keeping this new balance of $\$10,000(1 + r)$ in the bank for an additional year will give you a bank balance of this new amount times $(1 + r)$ two years from now, or $\$10,000(1 + r)(1 + r)$, or $\$10,000(1 + r)^2$. The opportunity cost of 1 dollar of consumption this summer is therefore $(1 + r)^2$. Then, if we think yet another summer ahead, we would have $(1 + r)$ times the bank balance after three summers, or $\$10,000(1 + r)^2(1 + r)$ or $\$10,000(1 + r)^3$. You can begin to see the pattern: Putting \$10,000 in the bank this summer will yield a bank balance of $\$10,000(1 + r)^n$ if we leave the account untouched for n summers.

So far, we have implicitly assumed that interest compounds yearly; that is, you begin to earn interest on interest only at the end of each year. Often, interest compounds more frequently. Suppose that you put \$10,000 in the bank now at an annual interest rate of 10% but that interest compounds monthly rather than yearly. Your monthly interest rate is then $10/12$ or 0.833%. Defining n as the number of months and using the information in the previous paragraph, how much would you have in the bank after one year? Compare this to the amount we calculated you would have when interest compounds annually.

EXERCISE
3A.4

Graph 3.4 is then a generalized version of the first two panels of Graph 3.3, where instead of thinking about the choice between consuming now and a year from now we are modeling the choice between consuming now and n years from now. In Graph 3.4a, we are assuming that $\$X$ is earned this summer and a portion of it potentially saved for use n summers later. Thus, the endowment point *E* lies on the horizontal axis. In Graph 3.4b, on the other hand, we are assuming that $\$Y$ will be earned n summers from now, and a portion of this may be borrowed for current consumption. Assuming the interest rate for borrowing and saving is the same, we then get two budget constraints with the same slope but with different endowment points.

GRAPH 3.4 Intertemporal Choice Sets when Planning n Years Ahead**EXERCISE 3A.5**

Suppose you just inherited \$100,000 and you are trying to choose how much of this to consume now and how much of it to save for retirement 20 years from now. Illustrate your choice set with “dollars of consumption now” and “dollars of consumption 20 years from now” assuming an interest rate of 5% (compounded annually). What happens if the interest rate suddenly jumps to 10% (compounded annually)?

3A.2.3 More Complex Financial Planning This two-period model used to analyze financial planning is limiting in the sense that it is difficult to model the full complexity of savings and consumption possibilities as consumers earn income over multiple periods and plan for consumption over those same periods. As we will see throughout this book, we will nevertheless be able to generate substantial intuitions using this two-period model. At the same time, we can use a more mathematical and less graphical approach to investigate choice sets that are difficult to handle in a graphical model. We turn to this more mathematical approach in Section B to this chapter. For those interested in finance applications, we also include end-of-chapter exercises 3.9 through 3.14 that tackle a number of more complex financial planning applications using the basic tools developed here.

3A.3 Putting It All into a Single Model

Between this chapter and Chapter 2, we have now demonstrated how to model choice sets for different types of individuals in the economy: consumers, workers, and financial planners (i.e., borrowers and savers). In the real world, of course, all three types are typically present in the same individual as we work in order to consume and plan for the future by saving or borrowing. While we will demonstrate throughout the book that it is often quite useful to model our choices as workers, consumers, and financial planners separately depending on the type of real-world

issue we are trying to address, it is in principle possible also to merge these separate models into a single framework in order to analyze simultaneously the full choice set faced by an individual that undertakes multiple roles within an economy. This is most easily done with the mathematical tools explored in part B of this chapter, but we can also get a glimpse of how this is accomplished in a somewhat more complex graphical model.

Suppose, for example, we return to your decision regarding how much to work this summer. In Section 3A.1, we analyzed the choice set you face when making this decision, but we assumed that your only two options were to consume or leisure *this summer*. Now suppose that your life is more complicated because you are simultaneously planning for the Amazon trip with your philosopher friend next summer. In Section 3A.2, we analyzed your choice set as you are planning for next summer, but we assumed that you had already decided how much you were going to work this summer. Now we can think about what your choice set will look like when you are trying to decide how much to work this summer *and* how you will split your consumption across this and next summer. We thus need a three-dimensional graph such as Graph 3.5, with leisure hours this summer on one axis and consumption this summer and next summer on the other two axes.

GRAPH 3.5 Consumption/Leisure Choice Set Combined with Intertemporal Choice

Go to MindTap to interact with this graph.

Suppose that you have up to 600 leisure hours this summer, 60 per week for 10 weeks. Also suppose that you can earn a wage of \$20 per hour and that the annual interest rate is 10%. Your endowment point, the point that remains in your choice set no matter what wages and interest rates prevail in the economy, is point E at which you simply consume all of your leisure time leaving you with no goods to consume this summer or next. If you decided to consume nothing next summer, your choice set would simply lie on the bottom plane of the graph defined by the budget line that connects A and E . This choice set is much like the choice sets we graphed in Section 3A.1 where you simply considered your trade-off between consuming and leisuring *this summer*. Similarly, if you decided to consume no leisure, your choice set would collapse to a two-dimensional picture in the vertical plane that contains the budget line connecting A and B . This is similar to the types of choice sets we analyzed in Section 3A.2 where you were simply choosing between consuming a given amount now or next year. Finally, in the panel containing E and B , we graph the choice set assuming that you will consume no goods this summer. In that case, for every hour that you work, you will make \$20 plus \$2 in interest, for a total of \$22 of consumption next summer. The opportunity cost of an hour of leisure time is therefore \$22 of foregone consumption a year from now, which is your wage w times $(1 + r)$.

Your “best” choice in a choice set such as this will of course most likely involve some leisuring this summer, some consumption now, and some consumption a year from now. All points that lie on the interior of the plane connecting A , B , and E represent such choices. For instance, if you decided to work for 500 hours (thus consuming 100 hours of leisure), your remaining choice set would be represented by the slice that contains point C where you spread your consumption between the two summers. This slice is exactly identical to the initial budget graphed in Graph 3.3a (where we simply assumed you had already chosen to earn \$10,000 this summer).

EXERCISE 3A.6* Draw a budget constraint similar to Graph 3.5 assuming you do not work this summer but rather next summer at a wage of \$22 per hour (with a total possible number of leisure hours of 600 next summer) and assuming that the interest rate is 5%. Where is the 5% interest rate budget line from Graph 3.3b in the graph you have just drawn?

Graphical models are “slices” of more complex models.

As you can see from Graph 3.5, the two-dimensional budget lines we typically draw can be viewed as “slices” of higher-dimensional choice sets where we simply hold certain choices fixed to derive the relevant slice. This is generally true of what we do in the A parts of this book. When we restrict ourselves to graphs, we are illustrating two-dimensional slices of more complicated mathematical objects. It is, in fact, true for *all* models, no matter how complicated they get. A model with 3 goods, for instance, is simply a 3-dimensional “slice” of a more complicated model, with the quantities of other goods held fixed. Models are, in the end, “slices” of reality.

3B

CHOICE SETS AND BUDGET EQUATIONS FOR WORKERS AND SAVERS

As in part A of this chapter, we will initially treat your choices as a worker and as a financial planner separately and then combine them toward the end of the section. Again, it is important that you not get lost in the mathematics that is introduced but rather that you develop the skills to translate the mathematics into the intuitions of the previous sections. To aid you in this process, this section is again structured in subsections that correspond to the subsections in the graphically based Section 3A.

3B.1 Choice Sets of Workers

In Section 3A, we simplified the choices workers face as leisuring (and thus not working) and consuming a composite good. Taking less leisure implies greater consumption opportunities as income is generated endogenously from reducing leisure hours and thus increasing hours committed to working. This model of worker choice sets can be translated into mathematics straightforwardly using the tools we already developed for consumer choice sets in Chapter 2.

3B.1.1 Translating the Leisure/Consumption Graph into Math We began in Section 3A.1.1 with an example in which we assumed you had a leisure endowment of 60 hours per week and could earn an hourly wage of \$20. Letting c denote “weekly dollars of consumption” and letting ℓ denote “weekly hours of leisure consumption,” your choice set was defined as all those combinations of c and ℓ where c is affordable given \$20 is earned for each of the 60 hours of leisure endowment that is not consumed. Put differently, you are constrained to a choice set of combinations of c and ℓ such that

$$c \leq 20(60 - \ell). \quad (3.1)$$

The budget line is simply the same equation with the inequality replaced by an equality. Taking this budget line equation and multiplying out the terms, this gives

$$c = 1200 - 20\ell, \quad (3.2)$$

which is exactly the equation we derived intuitively in Graph 3.1.

More generally, we could let our hours of leisure endowment be given by L and the hourly wage by w . Our choice set as a worker would then be given by

$$C(w, L) = \{(c, \ell) \in \mathbb{R}_+^2 \mid c \leq w(L - \ell)\}, \quad (3.3)$$

with a budget line given by

$$B(w, L) = \{(c, \ell) \in \mathbb{R}_+^2 \mid c = w(L - \ell)\}. \quad (3.4)$$

Notice that only a single price appears in the budget line equation— w , the price of labor. Implicitly we have again taken the price of c to be 1, since \$1 of consumption costs exactly \$1.

Of course there may be times that economists would like to model the components of c more specifically, perhaps to investigate how particular public policies toward labor income might influence not only our consumption overall but also our consumption of particular goods that might be more or less complementary to leisure. This would clearly be difficult with our graphical models of Section 3A, models that necessarily limit us to two dimensions. But with the mathematical tools developed in the previous chapter, it now becomes quite easy to extend our model of leisure/consumption choice sets to multiple consumption goods.

Suppose, for example, that we are interested in your weekly consumption of n different goods— x_1, x_2, \dots, x_n —and how your consumption of those goods relates to your decisions in the labor market where you have a weekly leisure endowment L that you can sell at wage w . Your choice set is then simply defined as all those combinations of the n different goods that you can afford at their market prices (p_1, p_2, \dots, p_n) given how much leisure you sold in the labor market; that is,

$$\begin{aligned} C(p_1, p_2, \dots, p_n, w, L) \\ = \{(x_1, x_2, \dots, x_n, \ell) \in \mathbb{R}_+^{n+1} \mid p_1x_1 + p_2x_2 + \dots + p_nx_n \leq w(L - \ell)\}. \end{aligned} \quad (3.5)$$

Graph the choice set in equation (3.5) when $n = 2$, $p_1 = 1$, $p_2 = 2$, $w = 20$, and $L = 60$.

EXERCISE
3B.1

3B.1.2 Government Policies and Labor Market Choice Sets As we noted in Section 3A, a variety of government policies have a direct impact on labor markets and thus on our choice sets of workers. We discussed in particular the potential impacts of overtime legislation and the possible kinks in budget lines within the leisure/consumption graph that might result. Such kinks can of course also be formalized within the mathematical framework explored here, as we have already shown for other examples in Section 2B.

EXERCISE
3B.2

Translate the choice sets graphed in Graph 3.2 into mathematical notation defining the choice sets.

One particular policy that labor economists often focus on relates to wage taxes. Suppose, for instance, that a government tax on wages results in a tax paid by workers of t percent (expressed in decimal form).³ Then instead of earning w for every hour of leisure that a worker chooses to sell in the labor market, he now only gets to take home $(1 - t)w$ because the government collects tw in wage taxes from the worker. This then changes the budget line in the leisure/consumption model from the equation that appears in (3.4) to

$$c = (1 - t)w(L - \ell). \quad (3.6)$$

As we multiply out some of the terms in parentheses, we can write this same equation as

$$c = (1 - t)wL - (1 - t)w\ell, \quad (3.7)$$

with the first term on the right-hand side representing the intercept term and the second term representing the slope. Graphically, this implies that the intercept term falls from wL —the amount of consumption we could have had before taxes had we consumed no leisure—to $(1 - t)wL$. Similarly, the slope term falls in absolute value, indicating that the slope of the budget line becomes shallower. Finally, we can verify our intuition that the intercept on the leisure axis remains unchanged by setting c to zero and solving for ℓ . Adding $(1 - t)w\ell$ to both sides and dividing by $(1 - t)w$ then gives us the result that $\ell = L$; our leisure when we have no other consumption is simply equal to our leisure endowment.

EXERCISE
3B.3

Suppose $w = 20$ and $L = 60$. Graph the budget constraint in the absence of taxes. Then suppose a wage tax $t = 0.25$ is introduced. Illustrate how this changes your equation and the graph.

EXERCISE
3B.4

How would the budget line equation change if, instead of a tax on wages, the government imposed a tax on all consumption goods such that the tax paid by consumers equaled 25% of consumption. Show how this changes the equation and the corresponding graph of the budget line.

3B.2 Choice Sets as We Plan for the Future

The second set of choice sets we introduced in Section 3A of this chapter involved graphical illustrations of trade-offs we face as we plan current and future consumption. Translating these into mathematical formulations involves exactly the same techniques as we have now applied for

³We will discuss how much of a wage tax is paid by workers rather than employers in Chapter 19.

consumer and worker choice sets, and the more general framework that arises from this again opens possibilities for analyzing significantly more complex decisions guided by the same economic intuitions developed with graphical techniques.

3B.2.1 Planning for Next Year: Intertemporal Budgets We began our discussion about saving and borrowing in Section 3A within an initially simple example of you and your friend saving some of your earnings from this summer to go on a trip to the Amazon next summer. We then investigated various changes in this scenario, considering the case of borrowing by assuming you will earn income next summer as well as the case where you split both your trip and your summer income between the two summers. These scenarios differed in terms of what endowment point we began with, or which bundle in the model was unaffected by changes in prices such as interest rates.

We can generalize our discussion on planning between two periods by simply letting e_1 and e_2 denote the amount of income you expect to earn this summer and next summer and letting r denote the interest rate in decimal form. (For simplicity, we will continue to assume here that the interest rate for borrowing and saving is the same and that interest compounds annually.) In the initial scenario in Section 3A, we assumed $e_1 = 10,000$ and $e_2 = 0$, whereas in the other scenarios we assumed first $e_1 = 0$ and $e_2 = 11,000$ and then $e_1 = 5,000$ and $e_2 = 5,500$. These are graphed in panels (a), (b), and (c) of Graph 3.3 respectively.

Your consumption set across the two summers is then a pair (c_1, c_2) , with c_1 representing consumption this summer and c_2 representing consumption next summer. This pair has to be feasible given the endowments you have and the interest rate you face in the market. We can see most easily how this translates to a budget line equation by first determining how much you *could have* available for consumption next summer *if you consumed nothing this summer*, which is just the sum of the endowments in the two summers ($e_1 + e_2$) plus the interest you could have earned between the two summers on the first summer's endowment (re_1) for a total of $(1 + r)e_1 + e_2$. Then, for every \$1 you want to consume this year, you will have to decrease your consumption next year by $(1 + r)$. So the most you will actually have for consumption next summer is what you could have had if you had consumed nothing this summer $(1 + r)e_1 + e_2$ minus $(1 + r)$ times your actual consumption this summer (c_1), or

$$c_2 \leq (1 + r)e_1 + e_2 - (1 + r)c_1, \quad (3.8)$$

which can also be written as

$$c_2 \leq (1 + r)(e_1 - c_1) + e_2. \quad (3.9)$$

When written in this form, the equation should have particular intuitive appeal: The term $(e_1 - c_1)$ is the difference between your period 1 endowment and your period 1 consumption, or just your savings. When you multiply what's in your savings account by $(1 + r)$, that gives you your savings account balance a year from now $(1 + r)(e_1 - c_1)$. Together with your year 2 endowment e_2 , that's the most you can consume next year.

Suppose $(e_1 - c_1)$ is negative; that is, suppose you are borrowing rather than saving in period 1. Can you still make intuitive sense of the equation?

**EXERCISE
3B.5**

Using equation (3.8) with $(1 + r)c_1$ added to both sides, we can then define your choice set as a function of your endowments and the interest rate:

$$C(e_1, e_2, r) = \{(c_1, c_2) \in \mathbb{R}_+^2 \mid (1 + r)c_1 + c_2 \leq (1 + r)e_1 + e_2\}. \quad (3.10)$$

Note that the budget constraint in equation (3.10) is written in terms of dollars *next* summer. It could equivalently be written in terms of dollars *this* summer by dividing both sides by $(1 + r)$, giving us

$$C(e_1, e_2, r) = \left\{ (c_1, c_2) \in \mathbb{R}_+^2 \mid c_1 + \frac{c_2}{(1+r)} \leq e_1 + \frac{e_2}{(1+r)} \right\}. \quad (3.11)$$

EXERCISE 3B.6 Use the information behind each of the scenarios graphed in Graph 3.3 to plug into equation (3.8) that scenario's relevant values for e_1 , e_2 , and r . Then demonstrate that the budget lines graphed are consistent with the underlying mathematics of equation (3.8), and more generally, make intuitive sense of the intercept and slope terms as they appear in equation (3.8).

3B.2.2 Planning for Several Years into the Future More generally, we demonstrated intuitively in Section 3A.2.2 that planning over multiple time periods is similar to planning over one period, except that the relevant opportunity cost of consuming a dollar today changes from $(1 + r)$ to $(1 + r)^n$, where n is the number of time periods over which we plan. For instance, if you plan to allocate income you expect to earn this summer and income you plan to earn n summers from now between consumption this summer and consumption n summers from now, your choice set is a simple extension of the choice set derived in the expression (3.10), with $(1 + r)$ replaced by $(1 + r)^n$:

$$C(e_1, e_n, r) = \{(c_1, c_n) \in \mathbb{R}_+^2 \mid (1 + r)^n c_1 + c_n \leq (1 + r)^n e_1 + e_n\}. \quad (3.12)$$

3B.2.3 More Complex Financial Planning When looking at the choice set as described in equation (3.12), an immediate question that might occur to us is what happened to all the summers in between the current summer and the summer n years from now? Are we not consuming or earning income in those summers? Should those not be part of our planning as well?

The answer, of course, is that we were limited in Section 3A by our graphical tools: We only had room to graph two dimensions and thus could only graph planning over two periods, whether those were 1 or n years apart. With a more mathematical approach, however, we can easily define much more complex choice sets in which individuals can see their full consumption possibilities across many periods at one time. Suppose, for instance, that I have some expectation about what I will earn not only this year but also for each of the upcoming $(n - 1)$ years. Thus, I have a total of n different “endowments” spread across n years, endowments we can denote (e_1, e_2, \dots, e_n) . Suppose further that I expect the annual interest rate across the next n years to be constant at r . If I consumed nothing until the last year, I would end up having the last year's endowment e_n plus the next to last year's endowment with one year's worth of interest on that endowment $((1 + r)e_{n-1})$, plus the second to last year's endowment (e_{n-2}) with two year's worth of interest on that endowment $((1 + r)^2 e_{n-2})$, and so on. Thus, if all my consumption occurred in the last year, I could consume

$$c_n = e_n + (1 + r)e_{n-1} + (1 + r)^2 e_{n-2} + \dots + (1 + r)^{n-1} e_{n-(n-1)}. \quad (3.13)$$

Now, for every dollar that I consume in the next to last period, the amount left over for my consumption in the last period declines by $(1 + r)$, and for every dollar that I consume in the second to last period, the amount left over for my consumption in the last period declines by $(1 + r)^2$, and so on. Thus, while I *could* consume in the last period as much as indicated in

equation (3.13), the *actual* amount I can consume depends on how much I consumed in the previous periods:

$$c_n = e_n + (1+r)e_{n-1} + (1+r)^2e_{n-2} + \cdots + (1+r)^{n-1}e_1 - (1+r)c_{n-1} - (1+r)^2c_{n-2} - \cdots - (1+r)^{n-1}c_1 \quad (3.14)$$

or, with consumption terms grouped on the left-hand side and two of the subscripts simplified,

$$c_n + (1+r)c_{n-1} + (1+r)^2c_{n-2} + \cdots + (1+r)^{n-1}c_1 = e_n + (1+r)e_{n-1} + (1+r)^2e_{n-2} + \cdots + (1+r)^{n-1}e_1. \quad (3.15)$$

Our two-period graphical simplification is then a special case of a more complex choice set, a simplification where the consumption and endowment terms for all but two periods are simply assumed to net out to zero. In our framework of individuals attempting to “do the best they can given their circumstances,” translating the graphical model into mathematics thus permits us to specify much richer and more realistic circumstances as we investigate how individuals might plan for the future. The basic insights developed here also allow us to investigate some common financial planning issues that are covered in end-of-chapter exercises 3.9 through 3.14 for those with a particular interest in finance-related topics.

Suppose you expect to earn \$10,000 this summer, \$0 next summer, and \$15,000 two summers from now. Using c_1 , c_2 , and c_3 to denote consumption over these three summers, write down your budget constraint assuming an annual (and annually compounding) interest rate of 10%. Then illustrate this constraint on a three-dimensional graph with c_1 , c_2 , and c_3 on the three axes. How does your equation and graph change if the interest rate increases to 20%?

EXERCISE 3B.7*

3B.3 Putting It All in a Single Model

At the conclusion of Section 3A, we briefly explored a three-dimensional graphical example in which a leisure endowment this summer can translate into consumption both this summer and next summer. Specifically, we graphed your choice set under the assumption that you had a particular leisure endowment this summer and you were simultaneously evaluating how much to work this summer and how much to consume over the next two summers, assuming that you would not work any more next summer.

Your income this summer thus depends on how much leisure ℓ you choose to consume this summer, with your income equal to your hourly wage w times the portion of your time endowment L not consumed as leisure, or $w(L - \ell)$. If you choose not to consume any of this income this summer and you put it all in the bank, you would have a total of

$$(1+r)w(L - \ell) \quad (3.16)$$

available for consumption next summer. And, for each dollar you do choose to consume this summer, you will have $(1+r)$ less in consumption next summer. Thus, your consumption c_2 next summer is equal to the most you could have consumed had you not consumed anything this summer minus $(1+r)$ times what you actually do consume this summer (c_1), or

$$c_2 = (1+r)w(L - \ell) - (1+r)c_1. \quad (3.17)$$

This (with the consumption terms grouped on one side of the equation) then defines the budget constraint as

$$B(L, w, r) = \{(c_1, c_2, \ell) \in \mathbb{R}_+^3 \mid (1+r)c_1 + c_2 = (1+r)w(L - \ell)\}. \quad (3.18)$$

EXERCISE
3B.8*

When $L = 600$, $w = 20$, and $r = 0.1$, show how equation (3.18) translates directly into Graph 3.5.

It is worth noting once again at this point that whenever we limit ourselves to graphical models in two dimensions, we are essentially holding something in a larger dimensional choice set fixed. For instance, when we graphed your initial choice set between consuming this summer and consuming next summer in Graph 3.3a, we assumed that your labor/leisure decision this summer had already been made and had resulted in 500 hours of labor. When analyzing consumption choices over two periods in a two-dimensional model, we therefore are really operating on a “slice” of a three-dimensional model, a slice where something has been held fixed. In our example, this slice occurs at the fixed leisure consumption of 100 hours (with the 500 remaining hours earning the \$10,000 income that makes \$10,000 of consumption this summer (or \$11,000 in consumption next summer) possible). Mathematically, this slice is simply

$$B(r) = \{(c_1, c_2) \in \mathbb{R}_+^2 \mid (1+r)c_1 + c_2 = (1+r)(10,000)\}, \quad (3.19)$$

where we have replaced labor income and time endowments with the “exogenous” current summer income of \$10,000. This slice is depicted graphically in Graph 3.5

In the same way, the three-dimensional Graph 3.5 is also a “slice” of a yet higher dimensional choice set where something else has been held fixed. For instance, we have assumed in Graph 3.5 that you have decided not to work (i.e., not to sell leisure) next summer, thus permitting us to focus only on three dimensions. Adding the possibility of working next summer is easy to handle mathematically but impossible to graph.

EXERCISE
3B.9

Define mathematically a generalized version of the budget constraint in expression (3.18) under the assumption that you have both a leisure endowment L_1 this summer and another leisure endowment L_2 next summer. What is the value of L_2 in order for Graph 3.5 to be the correct three-dimensional “slice” of this four-dimensional choice set?

CONCLUSION

We have now concluded our initial modeling of choice sets. The message that emerges from Chapters 2 and 3 is that there are many ways in which we can model such choice sets graphically and mathematically and that the best model for a particular application will depend on the application. In some instances, we are simply interested in the impact on consumer choices of a particular price change, and it may be sufficient simply to model the choice a consumer faces over the good of interest and a composite consumption good under some exogenous income. Other times, we may be interested in situations where both the trade-offs a consumer faces as well as the amount of available money to make choices depends on prices, wages, and/or interest rates as individuals sell endowments to purchase consumption goods. As we discussed in Chapter 1, the key for the economist is often to find the simplest possible model that captures the most important aspects of a particular question we are interested in answering.

We are not, however, yet ready to really analyze choice, only choice sets. To analyze what choices individuals will actually make fully, we need to find ways of modeling not only what choices are available to them but also how these available choices will be evaluated depending on the tastes of the choosing individuals. We will begin our analysis of tastes in Chapter 4.

END-OF-CHAPTER EXERCISES

- 3.1[†]** In this chapter, we graphed budget constraints illustrating the trade-off between consumption and leisure.
- A.** Suppose that your wage is \$20 per hour and you have up to 60 hours per week that you could work.
- Now, instead of putting leisure hours on the horizontal axis (as we did in Graph 3.1), put labor hours on the horizontal axis (with consumption in dollars still on the vertical). What would your choice set and budget constraint look like now?
 - Where on your graph would the endowment point be?
 - What is the interpretation of the slope of the budget constraint you just graphed?
 - If wages fall to \$10 per hour, how does your graph change?
 - If instead a new caffeine drink allows you to work up to 80 rather than 60 hours per week, how would your graph change?
- B.** How would you write the choice set over consumption c and labor l as a function of the wage w and leisure endowment L ?
- 3.2** In our treatment of leisure/consumption trade-offs, we have assumed that you are deriving income solely from wages.
- A.** Suppose now that your grandparents set up a trust fund that pays you \$300 per week. In addition, you have up to 60 hours of leisure that you could devote to work at a wage of \$20 per hour.
- On a graph with “leisure hours per week” on the horizontal axis and “weekly consumption in dollars” on the vertical, illustrate your weekly budget constraint.
 - Where in your graph is your endowment bundle?
 - How does your graph change when your wage falls to \$10?
 - How does the graph change if instead the trust fund gets raided by your parents, leaving you with only a \$100 payment per week?
- B.** How would you write your budget constraint described in 3.2A?
- 3.3^{**}** You have \$10,000 sitting in a savings account, 600 hours of leisure time this summer, and an opportunity to work at a \$30 hourly wage.
- A.** Next summer is the last summer before you start working for a living, and so you plan to take the whole summer off and relax. You need to decide how much to work this summer and how much to spend on consumption this summer and next summer. Any investments you make for the year will yield a 10% rate of return over the coming year.
- On a three-dimensional graph with this summer’s leisure (ℓ), this summer’s consumption (c_1), and next summer’s consumption (c_2) on the axes, illustrate your endowment point as well as your budget constraint. Carefully label your graph and indicate where the endowment point is.
 - How does your answer change if you suddenly realize you still need to pay \$5,000 in tuition for next year, payable immediately?
 - How does your answer change if instead the interest rate doubles to 20%?
 - In (b) and (c), which slopes are different than in (a)?
- B.** Derive the mathematical expression for your budget constraint in 3.3A and explain how elements of this expression relate to the slopes and intercepts you graphed.
- 3.4^{*}** Suppose you are a farmer whose land produces 50 units of food this year and is expected to produce another 50 units of food next year. (Assume that there is no one else in the world to trade with.)

*conceptually challenging

**computationally challenging

[†]solutions in Study Guide

- A.** On a graph with “food consumption this year” on the horizontal axis and “food consumption next year” on the vertical, indicate your choice set assuming there is no way for you to store food that you harvest this year for future consumption.
- Now suppose that you have a barn in which you can store food. However, over the course of a year, half the food that you store spoils. How does this change your choice set?
 - Now suppose that, in addition to the food units you harvest off your land, you also own a cow. You could slaughter the cow this year and eat it for 50 units of food. Or you could let it graze for another year and let it grow fatter, then slaughter it next year for 75 units of food. But you don’t have any means of refrigeration and so you cannot store meat over time. How does this alter your budget constraint (assuming you still have the barn from part (a))?
- B.** How would you write the choice set you derived in A(b) mathematically, with c_1 indicating this year’s food consumption and c_2 indicating next year’s food consumption?

3.5[†] Suppose you are a carefree 20-year-old bachelor whose lifestyle is supported by expected payments from a trust fund established by a relative who has since passed away. The trust fund will pay you \$ x when you turn 21 (a year from now), another \$ y when you turn 25, and \$ z when you turn 30. You plan to marry a rich heiress on your 30th birthday and therefore only have to support yourself for the next 10 years. The bank that maintains the trust account is willing to lend money to you at a 10% interest rate and pays 10% interest on savings. (Assume annual compounding.)

- A.** Suppose $x = y = z = 100,000$.
- What is the most that you could consume this year?
 - What is the most you could spend at your bachelor party 10 years from now if you find a way to live without eating?
- B.** Define your 10-year intertemporal budget constraint mathematically in terms of x , y , and z , letting c_1 denote this year’s consumption, c_2 next year’s consumption, and so on. Let the annual interest rate be denoted by r .

3.6 **Everyday Application: Robots as Labor-Saving Products:** Suppose that you have 60 hours per week of leisure time and that you can earn \$25 per hour in the labor market. Part of the reason you do not have more time to work is that you need to do a variety of household chores: cleaning, shopping for food, cooking, laundry, running errands, and so on. Suppose that those chores take 20 hours of your time per week. Suddenly you see an advertisement in the newspaper: “Personal Robot can do the following: clean, shop, cook, do laundry, run errands, and so on. Can be rented by the week.”

- A.** Suppose you learn that the weekly rental fee is \$250 and that the robot could indeed do all the things that you currently spend 20 hours per week doing (outside the 60 hours of leisure you could be taking).
- Illustrate your new weekly budget constraint assuming you decide to rent the robot. Be sure to incorporate the fact that you have to pay \$250 each week for the robot, but assume that there is no consumption value in having a robot other than the time you are saved doing chores you would otherwise have to be doing. Are you better off with or without the robot?
 - As it turns out, everyone else wants this robot as well, and so the rental price has increased to \$500 per week. How does this change your answer?
- B.** Incorporate the impact of the robot into the budget equation and illustrate how it leads to the graph you derived in 3.6A(a).

3.7[†] **Everyday Application: Investing for Retirement:** Suppose you were just told that you will receive a year-end bonus of \$15,000 from your company. Suppose further that your marginal income tax rate is 33.33%, which means that you will have to pay \$5,000 in income tax on this bonus. And suppose that you expect the average rate of return on an investment account you have set up with your broker to be 10% annually (and, for purposes of this example, assume interest compounds annually).

- A.** Suppose you have decided to save all of this bonus for retirement 30 years from now.
- In a regular investment account, you will have to pay taxes on the interest you earn each year. Thus, even though you earn 10%, you have to pay a third in taxes, leaving you with an after-tax return of 6.67%. Under these circumstances, how much will you have accumulated in your account 30 years from now?

- b. An alternative investment strategy is to place your bonus into a 401K “tax-advantaged” retirement account. The federal government has set these up to encourage greater savings for retirement. They work as follows: You do not have to pay taxes on any income that you put directly into such an account if you put it there as soon as you earn it, and you do not have to pay taxes on any interest you earn. Thus, you can put the full \$15,000 bonus into the 401K account, and you can earn the full 10% return each year for the next 30 years. You do, however, have to pay taxes on any amount that you choose to withdraw after you retire. Suppose you plan to withdraw the entire accumulated balance as soon as you retire 30 years from now, and suppose that you expect you will still be paying 33.33% taxes at that time. How much will you have accumulated in your 401K account, and how much will you have after you pay taxes? Compare this with your answer to (a); that is, to the amount you would have at retirement if you saved outside the 401K plan.
- c. *True or False:* By allowing individuals to defer paying taxes into the future, 401K accounts result in a higher rate of return for retirement savings.
- B.** Suppose more generally that you earn an amount I now, that you face (and will face in the future) a marginal tax rate of t (expressed as a fraction between 0 and 1), that the interest rate now (and in the future) is r , and that you plan to invest for n periods into the future.
- a. How much consumption will you be able to undertake n years from now if you first pay your income tax on the amount I , then place the remainder in a savings account whose interest income is taxed each year. (Assume you add nothing further to the savings account between now and n years from now.)
- b. Now suppose you put the entire amount I into a tax-advantaged retirement account in which interest income can accumulate tax-free. Any amount that is taken out of the account is then taxed as regular income. Assume you plan to take the entire balance in the account out n years from now (but nothing before then). How much consumption can you fund from this source n years from now?
- c. Compare your answers to (a) and (b) and indicate whether you can tell which will be higher.

3.8 Everyday Application: *Different Interest Rates for Borrowing and Lending:* Suppose we return to the example from the text in which you earn \$5,000 this summer and expect to earn \$5,500 next summer.

- A.** In the real world, banks usually charge higher interest rates for borrowing than they will give on savings. So, instead of assuming that you can borrow and lend at the same interest rate, suppose the bank pays you an interest rate of 5% on anything you save but will lend you money only at an interest rate of 10%. (In this exercise, it helps *not* to draw everything to scale much as we did not draw intertemporal budgets to scale in the chapter.)
- a. Illustrate your budget constraint with consumption this summer on the horizontal and consumption next summer on the vertical axis.
- b. How would your answer change if the interest rates for borrowing and lending were reversed?
- c. A set is defined as “convex” if the line connecting any two points in the set also lies in the set. Is the choice set in part (a) a convex set? What about the choice set in part (b)?
- d. Which of the two scenarios would you prefer? Give both an intuitive answer that does not refer to your graphs and demonstrate how the graphs give the same answer.
- B.** Suppose more generally that you earn e_1 this year and e_2 next year and that the interest rate for borrowing is r_B and the interest rate for saving is r_S . Let c_1 and c_2 denote consumption this year and next year.
- a. Derive the general expression for your intertemporal choice set under these conditions.
- b. Check that your general expression is correct by substituting the values from A(a) and (b) and check that you get a choice set similar to those you derived intuitively.

3.9† Business Application:** *Present Value of Winning Lottery Tickets:* The introduction to intertemporal budgeting in this chapter can be applied to thinking about the pricing of basic financial assets. The assets we will consider will differ in terms of when they pay income to the owner of the asset. In order to know how much such assets are worth, we have to determine their *present value*, which is equal to how much *current* consumption such an asset would allow us to undertake.

- A.** Suppose you just won the lottery and your lottery ticket is transferable to someone else you designate; that is, you can sell your ticket. In each of the following cases, the lottery claims that you won \$100,000. Since you can sell your ticket, it is a financial asset, but depending on how exactly the holder of the ticket receives the \$100,000, the asset is worth different amounts. Think about what you would be willing to actually sell this asset for by considering how much *current* consumption value the asset contains assuming the annual interest rate is 10%.
- The holder of the ticket is given a \$100,000 government bond that “matures” in 10 years. This means that in 10 years, the owner of this bond can cash it for \$100,000.
 - The holder of the ticket will be awarded \$50,000 now and \$50,000 10 years from now.
 - The holder of the ticket will receive 10 checks for \$10,000: one now, and one on the next nine anniversaries of the day he/she won the lottery.
 - How does your answer to part (c) change if the first of 10 checks arrived one year from now, with the second check arriving two years from now, the third arriving three years from now, and so on?
 - The holder of the ticket gets \$100,000 the moment he/she presents the ticket.
- B.** More generally, suppose the lottery winnings are paid out in installments of x_1, x_2, \dots, x_{10} , with payment x_i occurring $(i - 1)$ years from now. Suppose the annual interest rate is r .
- Determine a formula for how valuable such a stream of income is in present day consumption; that is, how much present consumption could you undertake given that the bank is willing to lend you money on future income?
 - Check to make sure that your formula works for each of the scenarios in part A.
 - The scenario described in part A(c) is an example of a \$10,000 payment followed by an annual “annuity” payment. Consider an annuity that promises to pay out \$10,000 every year starting 1 year from now for n years. How much would you be willing to pay for such an annuity?
 - How does your answer change if the annuity starts with its first payment now?
 - What if the annuity from (c) is one that never ends? (To give the cleanest possible answer to this, you should recall from your math classes that an infinite series of $1/(1 + x) + 1/(1 + x)^2 + 1/(1 + x)^3 + \dots = 1/x$.) How much would this annuity be worth if the interest rate is 10%?

**BUSINESS
APPLICATION**

3.10 Business Application: Picking Savings Accounts: Suppose you just won \$10,000 in the lottery. You decide to put it all in a savings account.

- A.** Bank A offers you a 10% annual interest rate that compounds annually, while Bank B offers you a 10% annual interest rate compounded every 6 months.
- How much will you have in the bank at the end of the year if you go with Bank A?
 - How much will you have if you put your money into Bank B?
 - What annual interest rate would Bank A have to offer to make you indifferent between accepting Bank B’s and Bank A’s offers?
 - Would the interest rate you calculated in (c) be sufficient for you to be indifferent between Bank A and Bank B if you planned to keep your money in the savings account for two years?
- B.** Suppose you place x in a savings account and assume that the account gives an annual interest rate of r compounded n times per year.
- Derive the general formula for how much y you will have accumulated one year from now in terms of x , n , and r . Check the answers you derived in (a) and (b) of part A.
 - If $x = 10,000$ and the annual interest rate $r = 0.1$, how much will you have at the end of the year if interest compounds monthly (i.e., $n = 12$)?
 - What if interest compounds weekly?
 - If you have to choose between an annual interest rate of 10.5% compounded annually or an annual interest rate of 10% compounded weekly, which would you choose?

**BUSINESS
APPLICATION**

- 3.11[†] Business Application: Compound Interest over the Long Run:** Uncle Vern has just come into some money (\$100,000) and is thinking about putting this away into some investment accounts for a while.
- A.** Vern is a simple guy, so he goes to the bank and asks what the easiest option for him is. The bank tells him he could put it into a savings account with a 10% interest rate (compounded annually).
- Vern quickly does some math to see how much money he'll have one year from now, five years from now, 10 years from now, and 25 years from now assuming he never makes withdrawals. He doesn't know much about compounding, so he just guesses that if he leaves the money in for 1 year, he'll have 10% more; if he leaves it in five years at 10% per year he'll have 50% more; if he leaves it in for 10 years he'll have 100% more and if he leaves it in for 25 years he'll have 250% more. How much does he expect to have at these different times in the future?
 - Taking the compounding of interest into account, how much will he really have?
 - On a graph with years on the horizontal axis and dollars on the vertical, illustrate the size of Vern's error for the different time intervals for which he calculated the size of his savings account.
 - True/False:* Errors made by not taking the compounding of interest into account expand at an increasing rate over time.
- B.** Suppose that the annual interest rate is r .
- Assuming you will put x into an account now and leave it in for n years, derive the implicit formula Vern used when he did not take into account interest compounding.
 - What is the correct formula that includes compounding?
 - Define a new function that is the difference between these. Then take the first and second derivatives with respect to n and interpret them.

- 3.12 Business Application: Pricing Government Bonds:** A relative sends you a U.S. government savings bond that matures in n years with a face value of \$100. This means that the holder of this bond is entitled to collect \$100 from the government n years from now.

**BUSINESS
APPLICATION**

- A.** Suppose the interest rate is 10%.
- If $n = 1$, how much *current* consumption could this bond finance, and how much do you therefore think you could sell this bond for today?
 - Does the bond become more or less valuable if the interest rate falls to 5%?
 - Now suppose that $n = 2$. How valuable is the bond if the interest rate is 10%?
 - What if $n = 10$?
- B.** Consider a bond that matures n years from now with face value x when the expected annual interest rate over this period is equal to r .
- Derive the general formula for calculating the current consumption that could be financed with this bond.
 - Use a derivative to show what happens to the value of a bond as x changes.
 - Show similarly what happens to the value as r changes. Can you come to a general conclusion from this about the relationship between the interest rate and the price of bonds?

- 3.13[†] Business Application: Buying Houses with Annuities:** Annuities are streams of payments that the owner of an annuity receives for some specified period of time. The holder of an annuity can sell it to someone else who then becomes the recipient of the remaining stream of payments that are still owed.

**BUSINESS
APPLICATION**

- A.** Some people who retire and own their own home finance their retirement by selling their house for an annuity: The buyer agrees to pay $\$x$ per year for n years in exchange for becoming the owner of the house after n years.
- Suppose you have your eye on a house down the street someone who recently retired owns. You approach the owner and offer to pay her \$100,000 each year (starting next year) for

- five years in exchange for getting the house in five years. What is the value of the annuity you are offering her assuming the interest rate is 10%?
- What if the interest rate is 5%?
 - The house's estimated current value is \$400,000 (and your real estate agent assures you that homes are appreciating at the same rate as the interest rate). Should the owner accept your deal if the interest rate is 10%? What if it is 5%?
 - True/False:* The value of an annuity increases as the interest rate increases.
 - Suppose that, after making the second payment on the annuity, you fall in love with someone from a distant place and decide to move there. The house has appreciated in value (from its starting value of \$400,000) by 10% each of the past two years. You no longer want the house and therefore would like to sell your right to the house in three years in exchange for having someone else make the last 3 annuity payments. How much will you be able to get paid to transfer this contract to someone else if the annual interest rate is always 10%?
- B.** In some countries, retirees are able to make contracts similar to those in part A except that they are entitled to annuity payments until they die and the house only transfers to the new owner after the retiree dies.
- Suppose you offer someone whose house is valued at \$400,000 an annual annuity payment (beginning next year) of \$50,000. Suppose the interest rate is 10% and housing appreciates in value at the interest rate. This will turn from a good deal to a bad deal for you when the person lives n number of years. What's n ? (This might be easiest to answer if you open a spreadsheet and you program it to calculate the value of annuity payments into the future.)
 - Recalling that the sum of the infinite series $1/(1+x) + 1/(1+x)^2 + 1/(1+x)^3 + \dots$ is $1/x$, what is the most you would be willing to pay in an annual annuity if you want to be absolutely certain that you are not making a bad deal?

**BUSINESS
APPLICATION**

3.14 Business Application:** *A Trick for Calculating the Value of Annuities:* In several of the previous exercises, we have indicated that an infinite series $1/(1+r) + 1/(1+r)^2 + 1/(1+r)^3 + \dots$ sums to $1/r$. This can be (and has been, in some of the B-parts of exercises) used to calculate the value of an annuity that pays x per year starting next year and continuing every year eternally as x/r .

- A.** Knowing this information, we can use a trick to calculate the value of annuities that do not go on forever. For this example, consider an annuity that pays \$10,000 per year for 10 years beginning next year, and assume $r = 0.1$.
- First, calculate the value of an annuity that begins paying \$10,000 next year and then every year thereafter (without end).
 - Next, suppose you are given such an annuity in 10 years; that is, suppose you know that the first payment will come 11 years from now. What is the consumption value of such an annuity today?
 - Now consider this: Think of the 10-year annuity as the difference between an infinitely lasting annuity that starts making payments next year and an infinitely lasting annuity that starts 11 years from now. What is the 10-year annuity worth when you think of it in these terms?
 - Calculate the value of the same 10-year annuity without using the trick mentioned in part (c). Do you get the same answer?
- B.** Now consider more generally an annuity that pays x every year beginning next year for a period of n years when the interest rate is r . Denote the value of such an annuity as $y(x, n, r)$.
- Derive the general formula for valuing such an annuity by using the trick described in part A.
 - Apply the formula to the following example: You are about to retire and have \$2,500,000 in your retirement fund. You can take it all out as a lump sum, or you can choose to take an annuity that will pay you (and your heirs if you pass away) $\$x$ per year (starting next year) for the next 30 years. What is the least x has to be in order for you to choose the annuity over the lump sum payment assuming an interest rate of 6%?
 - Apply the formula to another example: You can think of banks as accepting annuities when they give you a mortgage. Suppose you determine you would be able to pay at most \$10,000 per year in mortgage payments. Assuming an interest rate of 10%, what is the most the bank

will lend you on a 30-year mortgage (where the mortgage payments are made annually beginning one year from now)?

- d. How does your answer change when the interest rate is 5%?
- e. Can this explain how people in the late 1990s and early 2000s were able to finance increased current consumption as interest rates fell?

3.15[†] Policy Application: *Wage Taxes and Budget Constraints:* Suppose you have 60 hours of leisure that you could devote to work per week, and suppose that you can earn an hourly wage of \$25.

- A.** Suppose the government imposes a 20% tax on all wage income.
 - a. Illustrate your weekly budget constraint before and after the tax on a graph with weekly leisure hours on the horizontal and weekly consumption (measured in dollars) on the vertical axis. Carefully label all intercepts and slopes.
 - b. Suppose you decide to work 40 hours per week after the tax is imposed. How much wage tax do you pay per week? Can you illustrate this as a vertical distance in your graph? (*Hint:* Follow a method similar to that developed in end-of-chapter exercise 2.15.)
 - c. Suppose that instead of leisure hours on the horizontal axis, you put labor hours on this axis. Illustrate your budget constraints that have the same information as the ones you drew in (a).
- B.** Suppose the government imposes a tax rate t (expressed as a rate between 0 and 1) on all wage income.
 - a. Write down the mathematical equations for the budget constraints and describe how they relate to the constraints you drew in A(a). Assume again that the leisure endowment is 60 per week.
 - b. Use your equation to verify your answer to part A(b).
 - c. Write down the mathematical equations for the budget constraints you derived in B(a) but now make consumption a function of labor, not leisure hours. Relate this to your graph in A(c).

3.16 Policy Application: *Proportional versus Progressive Wage Taxes:* The tax analyzed in exercise 3.15 is a *proportional* wage tax. The U.S. federal income tax, however, is *progressive*. This means that the *average* tax rate one pays increases the more wage income is earned.

- A.** For instance, suppose the government exempts the first \$500 of weekly earnings from taxation, then taxes the next \$500 at 20% and any earnings beyond that at 40%. Suppose that you again have 60 hours of leisure per week and can earn \$25 per hour.
 - a. Graph your weekly budget constraint illustrating the trade-offs between leisure and consumption.
 - b. The *marginal tax rate* is defined as the tax rate you pay for the next dollar you earn, while the *average tax rate* is defined as your total tax payment divided by your before-tax income. What is your average and marginal tax rate if you choose to work 20 hours per week?
 - c. How does your answer change if you work 30 hours? What if you work 40 hours?
 - d. On a graph with before-tax weekly income on the horizontal axis and tax rates on the vertical, illustrate how average and marginal tax rates change as income goes up. Will the average tax rate ever reach the top marginal tax rate of 0.4?
 - e. Some have proposed that the United States should switch to a “flat tax,” a tax with one single marginal tax rate. Proponents of this tax reform typically also want some initial portion of income exempt from taxation. The flat tax therefore imposes two different marginal tax rates: a tax rate of zero for income up to some amount x per year, and a single rate t applied to any income earned above x per year. Is such a tax progressive?
- B.** Suppose more generally that the government does not tax income below x per week; that it taxes income at t for anything above x and below $2x$, and it taxes additional income (beyond $2x$) at $2t$. Let I denote income per week.
 - a. Derive the average tax rate as a function of income and denote that function $a(I, t, x)$, where I represents weekly income.
 - b. Derive the marginal tax rate function $m(I, t, x)$.

3.17[†] Policy Application: *Social Security (or Payroll) Taxes:* Social Security is funded through a payroll tax that is separate from the federal income tax. It works in a way similar to the following example: For the first \$1,800 in weekly earnings, the government charges a 15% wage tax but then charges no payroll tax for all earnings above \$1,800 per week.

- A.** Suppose that a worker has 60 hours of leisure time per week and can earn \$50 per hour.
- Draw this worker's budget constraint with weekly leisure hours on the horizontal axis and weekly consumption (in dollars) on the vertical.
 - Using the definitions given in exercise 3.16, what is the marginal and average tax rate for this worker assuming he works 30 hours per week? What if he works 40 hours per week? What if he works 50 hours per week?
 - A wage tax is called *regressive* if the average tax rate falls as earnings increase. On a graph with weekly before-tax income on the horizontal axis and tax rates on the vertical, illustrate the marginal and average tax rates as income increases. Is this tax regressive?
 - True or False:* Budget constraints illustrating the trade-offs between leisure and consumption will have no kinks if a wage tax is proportional. However, if the tax system is designed with different tax brackets for different incomes, budget constraints will have kinks that point inward when a wage tax is regressive and kinks that point outward when a wage tax is progressive.
- B.** Consider the more general case of a tax that imposes a rate t on income immediately but then falls to zero for income larger than x .
- Derive the average tax rate function $a(I, t, x)$ (where I represents weekly income).
 - Derive the marginal tax rate function $m(I, t, x)$.
 - Does the average tax rate reach the marginal tax rate for high enough income?

3.18* Policy Application: *AFDC versus a Negative Income Tax:* Until the late 1990s, one of the primary federal welfare programs was Aid to Families with Dependent Children (AFDC). The program was structured similarly to the following example: Suppose you can work any number of hours you choose at \$5 per hour and you have no income other than that which you earn by working. If you have zero overall income, the government pays you a welfare payment of \$25 per day. You can furthermore receive your full welfare benefits so long as you make no more than a total income of \$5 per day. For every dollar you earn beyond \$5, the government reduces your welfare benefits by exactly a dollar until your welfare benefits go to zero.

- A.** Suppose you have up to 8 hours of leisure per day that you can dedicate to work.
- Draw your budget constraint between daily leisure and daily consumption (measured in dollars).
 - If you define marginal tax rates in this example as the fraction of additional dollars earned in the labor market that a worker does not get to keep, what is the marginal tax rate faced by this worker when she is working 1 hour per day? What if she is working 5 hours per day? What if she is working 6 hours a day?
 - Without knowing anything about tastes, how many hours are you likely to work under these trade-offs?
 - The late Milton Friedman was critical of the incentives in the AFDC program and proposed a different mechanism for supporting the poor. He suggested a program, known as the *negative income tax*, that works something like this: Everyone is guaranteed \$25 per day that he or she receives regardless of how much he or she works. Every dollar from working, starting with the first one earned, is then taxed at $t = 0.2$. Illustrate our worker's budget constraint assuming AFDC is replaced with such a negative income tax.
 - Which of these systems will almost certainly cost the government more for this worker: the AFDC system or the negative income tax? Which does the worker most likely prefer? Explain.
 - What part of your negative income tax graph would be different for a worker who earns \$10 per hour?

- g. Do marginal tax rates for an individual differ under the negative income tax depending on how much leisure he or she consumes? Do they differ across individuals?
- B.** Consider a more general version of the negative income tax, one that provides a guaranteed income y and then reduces this by some fraction t for every dollar earned, resulting eventually in individuals with sufficiently high income paying taxes.
- Derive a general expression for the budget constraint under a negative income tax, a constraint relating daily consumption c (in dollars) to daily leisure hours ℓ assuming that at most 8 hours of leisure are available.
 - Derive an expression for how much the government will spend (or receive) for a given individual depending on how much leisure he or she takes.
 - Derive expressions for marginal and average tax rates as a function of daily income I , the guaranteed income level y , and the tax rate t . (*Hint:* Average tax rates can be negative.)
 - On a graph with daily before-tax income on the horizontal axis and tax rates on the vertical, illustrate how marginal and average tax rates change as income rises.
 - Is the negative income tax progressive?

3.19*† Policy Application: The Earned Income Tax Credit: During the Clinton administration, the Earned Income Tax Credit (EITC) was expanded considerably. The program provides a wage subsidy to low-income families through the tax code in a way similar to this example: Suppose, as in the previous exercise, that you can earn \$5 per hour. Under the EITC, the government supplements your first \$20 of daily earnings by 100% and the next \$15 in daily earnings by 50%. For any daily income above \$35, the government imposes a 20% tax.

- A.** Suppose you have at most 8 hours of leisure time per day.
- Illustrate your budget constraint (with daily leisure on the horizontal and daily consumption on the vertical axis) under this EITC.
 - Suppose the government ends up paying a total of \$25 per day to a particular worker under this program and collects no tax revenue. Identify the point on the budget constraint this worker has chosen. How much is he or she working per day?
 - Return to your graph of the same worker's budget constraint under the AFDC program in exercise 3.18. Suppose that the government paid a total of \$25 in daily AFDC benefits to this worker. How much is he or she working?
 - Discuss how the difference in trade-offs implicit in the EITC and AFDC programs could cause the same individual to make radically different choices in the labor market.
- B.** More generally, consider an EITC program in which the first x dollars of income are subsidized at a rate $2s$; the next x dollars are subsidized at a rate s ; and any earnings above $2x$ are taxed at a rate t .
- Derive the marginal tax rate function $m(I, x, s, t)$ where I stands for labor market income.
 - Derive the average tax rate function $a(I, x, s, t)$ where I again stands for labor market income.
 - Graph the average and marginal tax functions on a graph with before-tax income on the horizontal axis and tax rates on the vertical. Is the EITC progressive?

3.20* Policy Application: Three Proposals to Deal with the Social Security Shortfall: It is widely recognized that the Social Security systems in many Western democracies will face substantial shortfalls between anticipated revenues and promised benefits over the coming decades.

- A.** Various ideas have emerged on how we should prepare for this upcoming shortfall.
- In order to analyze the impact of different proposals, begin with a graph that has “consumption now” on the horizontal and “retirement consumption” on the vertical axes. For simplicity, suppose we can ignore periods between now and retirement. Consider a worker and his or her choice set over these two “goods.” This worker earns some current income I and is currently promised a retirement income R from the government. Illustrate how this establishes an “endowment point” in your graph. Then, assuming an interest rate r over the period between now and retirement, draw this worker's choice set.

- b. Some have proposed that we need to cut expected retirement benefits for younger workers; that is, we need to cut R to $R' < R$. Illustrate the impact this has on our worker's choice set.
 - c. Others have argued that we should instead raise Social Security taxes; that is, reduce I to $I' < I$ in order to prepare for the upcoming shortfall. Illustrate how this would impact our worker's budget constraint.
 - d. Assuming that r is not impacted differently by these two policies, could you argue that they are essentially the same policy?
 - e. Yet others have argued that we should lower future retirement benefits R but at the same time subsidize private savings; that is, increase r through policies like expanding tax deferred savings accounts. Illustrate the impact of lowering R and raising r .
 - f. Which of these policies is the only one that has a chance (although by no means a guarantee) of making some individuals better off?
- B.** Define I , R , and r as before.
- a. Write down the mathematical description of the current intertemporal budget for our worker in terms of I , R , and r . Let c_1 denote current consumption and let c_2 denote retirement consumption.
 - b. In your equation, show which parts correspond to the vertical intercept and slope in your graphs from part A.
 - c. Relate your equation to the changes that you identified in the graph from each of the policies.

Tastes and Indifference Curves

CHAPTER

4

Individuals try to do the *best* they can given their circumstances.¹ This was our starting point when we introduced the topic of microeconomics in Chapter 1, and we have devoted the intervening chapters to the question of how to model individual circumstances, what we called choice or budget sets. Choice sets do not tell us what individuals *will* do, only all the possible actions they *could* take. Put differently, knowing what our choice sets are is a *necessary* first step to finding what choices are best, but it is not *sufficient*. To determine what an individual will actually do when presented with a given choice set, we need to know more about the individual and about his or her tastes. This is tricky, both because tastes differ enormously across people and because they are difficult to observe.

I hate peanut butter, but my wife loves it; she hates fish, which I cannot get enough of. Clearly, we will make very different choices when faced with exactly the same choice set over fish and peanut butter, but it is difficult for an economist to look at us and know how much we like different goods without observing our behavior under different circumstances.² The good news is that there are some regularities in tastes that we can reasonably assume are shared across most people, and these regularities will lead us to be able to make predictions about behavior that will be independent of what exact tastes an individual has. Furthermore, economists have developed ways of observing choices that individuals make and then inferring from these choices what kinds of tastes they have. We will therefore be able to say a great deal about behavior and how behavior changes as different aspects of an economy change. First, however, we have to get comfortable with what it is that economists mean when we talk about tastes.

4A

THE ECONOMIC MODEL OF TASTES

In the previous two chapters, we described a choice set as a subset of all possible combinations of goods and services, the subset that is affordable given an individual's particular circumstances. In our example of me going to Walmart to buy shirts and pants, for instance, we used the information we had on the money I had available and the prices for shirts and pants to delineate

¹No prior chapter required as background for this chapter.

²OK, maybe I eat so much fish that I smell a lot like fish, but we probably don't want to build a model about tastes by smelling people.

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

the budget line in the larger space of all combinations of shirts and pants. While I was unable to *afford* bundles of shirts and pants outside the choice set, I may nevertheless dream about bundles outside that set; or put differently, I may nevertheless have tastes for bundles outside the choice set. For instance, I get deeply annoyed at the cramped conditions on commercial airplanes and have long dreamed of getting myself a private plane modeled after Air Force One. Unless Oprah invites me on her show and then tells everyone to buy this textbook, I doubt I will ever be in a position to be able to afford such a plane and will thus be confined to commercial airlines for the rest of my life. Still, one can dream. Tastes are therefore defined not only over bundles of goods that fall in our choice sets but also over bundles that we may never be able to attain.

4A.1 Two Fundamental Rationality Assumptions about Tastes

While individuals vary widely in how they would rank different bundles of goods, we will argue in this section that there are two basic properties of tastes that must be satisfied in order for us to be able to analyze rational choice behavior. There is some controversy within the broader social sciences regarding these basic properties, but they are nevertheless quite fundamental to much of what we will have to say in the rest of this book.

4A.1.1 Complete Tastes First, economists assume that individuals are able to compare any two bundles to one another, and this represents our most fundamental assumption about tastes. Put precisely, we assume that economic actors—whether they are workers, consumers, or financial planners—are able to look at any two choice bundles and tell us which they prefer or whether they are indifferent between them. When an economic actor can do this, we say that he or she has *complete tastes (or preferences)*, complete in the sense that the actor is always able to make comparisons between bundles. A statement such as one recently uttered by my wife in a clothing store—“It is impossible for me to compare these two outfits because they are so different”—moves economists like me to despair because they directly violate this assumption of complete preferences. We suspect that such statements are rarely true; human beings indeed do seem to have the ability to make comparisons when confronted with options.

Complete-ness implies a person can rank any two bundles.

4A.1.2 Transitive Tastes A second fundamental assumption economists make about tastes is that there is an internal consistency to tastes that makes choosing a *best* bundle possible. Consider, for instance, bundles *A*, *B*, and *C*, each containing different quantities of pants and shirts. If tastes are complete, I should be able to compare any two of these bundles and tell you which I prefer (or whether I am indifferent). But suppose that I tell you that I like *A* better than *B*, that I like *B* better than *C*, and that I like *C* better than *A*. Although my tastes may be complete—I could after all compare each set of two bundles and tell you which is better—there is no *best* alternative. You could present me with a sequence of choices, first *A* and *B*, then *B* and *C*, then *C* and *A*, and so on, and we could forever cycle between the three alternatives, never finding one that is best of all (or at least not worse than any other bundle). To rule out this possibility and thus form the foundations of a model of choice, we assume the following: *Whenever an individual likes A at least as much as B and B at least as much as C, it must be the case that she also likes A at least as much as C.*³ When this holds for all consumption bundles, we say that a person’s tastes are *transitive*.

Transitivity implies there is always a “best” bundle.

To be honest, it is not clear that people’s tastes are indeed always transitive. A friend of mine told me of his experience at a car dealership where he ordered a new car to be custom made. The sales person started with a stripped-down version of the car model he had selected and then

³Similarly, when the individual likes *A* strictly more than *B* and *B* strictly more than *C*, it must be the case that the individual likes *A* strictly more than *C*.

offered various special features. For instance, he would offer a choice as to whether to put a CD player into the car for an additional \$300, or air conditioning for an additional \$1,000, and so on. Each time, my friend found himself agreeing to the additional feature. At the end, however, he saw the price tag of the car with all the features and decided he liked the stripped-down version better. This certainly seems like a violation of transitivity, although I suspect that my friend in the end had simply not thought carefully along the way whether the various features were really worth the decrease in his other consumption that they implied. After all, in the end he *did* make a decision.⁴ Nevertheless, psychologists have sometimes been critical of the economist's transitivity assumption based on experiments in which people seemed to violate the assumption. Economists, however, continue to find the assumption useful in the sense that it permits us to make predictions about people's choice behavior, predictions that seem consistent with the data most of the time (even if there are instances, such as my "friend's" initial behavior in the car dealership, when the assumption might appear to be violated, at least briefly).

4A.1.3 "Rational" Tastes When an economic actor's tastes satisfy both completeness and transitivity, we will say that the individual has "rational" tastes or preferences. The term *rational* here does not imply any grand philosophical value judgments. Individuals might have tastes that most of us would consider entirely self-destructive (and "irrational," as the term is commonly used), but such individuals might still be able to compare any pair of alternatives and always choose the best one (or one where none of the other alternatives is worse). In that case, we could refer to such individuals as rational when we speak as economists although we may turn around and call them fools behind their backs when we step outside our role as economists. To the economist, rationality simply means the ability to make consistent choices, and economic actors whose tastes violate the two rationality assumptions are incapable of making choices when faced with some types of choice sets.

Rational tastes are complete and transitive.

4A.2 Three More Assumptions

While much of what economists have modeled depends critically only on the validity of the two rationality assumptions discussed in the previous section, some additional assumptions about tastes can simplify our models while remaining true to most real-world applications. One such additional assumption is that, for most goods, "more is better than less" (or, in some instances, "more is no worse than less"). A second additional assumption is that "averages are better than extremes" (or, in some instances, "averages are no worse than extremes"). Finally, we often assume that there are "no sudden jumps" in tastes, that happiness changes gradually as the basket of goods we consume changes only slightly. In what follows, we will explain in more detail what exactly we mean by each of these, and in Section 4A.3 it will become clear how these assumptions simplify our models of tastes in a way that makes our models workable.

4A.2.1 "More Is Better, or at Least Not Worse" (Monotonicity) In most economic applications, we are interested in situations where individuals make choices involving aspects of life that involve scarcity, whether this involves current consumption, future consumption, or leisure. If individuals did not in fact think "more is better" in such choices, scarcity would not be a problem. Everyone would simply be content with what he or she has, and there would be little need for economics as a discipline. The idea of a world in which individuals are just happy with what they have is appealing to many of us, but it is not the world we actually occupy. For better or worse, we always seem to want more, and our choices are often aimed at getting more. The

⁴All right, I'll confess: The "friend" at the car dealership was actually me, and it took my wife, a noneconomist, to point out the apparent evidence of an intransitivity in my tastes!

economist's recognition of this is not an endorsement of a philosophy of life focused on materialism or consumerism; rather, it is a simple starting point for better understanding human behavior in a world characterized by scarcity. If an individual has tastes for goods such that “more is better” (or at least that “more is not worse”), we will sometimes call such tastes *monotonic*, or we will say that such tastes satisfy the *monotonicity assumption*.

Consider the five bundles of pants and shirts depicted in Graph 4.1. The monotonicity assumption allows us to conclude that *E* must be better than *C* because *E* contains more pants and shirts than *C*. In cases where we compare two bundles that are the same in terms of one of the goods but differ in terms of the other, we will interpret “more is better” as meaning “more is at least as good.” For instance, bundle *C* contains just as many shirts as *D*, but it also contains more pants. Thus, “more is better” implies that *C* is at least as good as *D*. But the “more is better” assumption does *not* make it clear how *A* and *C* relate to each other because neither contains clearly “more”; *A* has more shirts than *C*, but *C* has more pants than *A*. Similarly, the assumption does not clarify how the pairs *A* and *B*, *C* and *B*, or *B* and *D* are ranked.

The monotonicity assumption allows us to rank some but not all pairs of bundles.

EXERCISE 4A.1 Do we know from the monotonicity assumption how *E* relates to *D*, *A*, and *B*? Do we know how *A* relates to *D*?

It is worth noting at this point that monotonicity may hold even in cases where it seems at first glance that it does not hold if we conceptualize the model appropriately. For instance, we might think that we would prefer less work over more and thus cite “labor” as a good that violates the “more is better” assumption. But we could equivalently model our choices over how much labor to provide as a choice of how much leisure we choose not to consume (as we did when we constructed choice sets for workers in Chapter 3). By reconceptualizing labor as the amount of leisure we do not consume, we have redefined the choice as one between leisure and

GRAPH 4.1 Ranking Consumption Bundles

consumption rather than between labor and consumption, and leisure is certainly a good that we would like to have more of rather than less. Similarly, consider someone who does not like more consumption beyond some basic subsistence level. For such a person, more consumption may not be better than less. At the same time, such an individual might care about the well-being of others whose consumption has not reached subsistence levels. The economic scarcity problem such a person faces then involves choices over what to do with money in excess of his or her own subsistence needs, perhaps what charitable causes to support. Once the problem has been reconceptualized in this way, more (charity) is once again better than less. Thus, in many cases we can reconceptualize a choice involving goods we would prefer to have fewer of as a choice involving goods that satisfy the “more is better” assumption.

What other goods are such that we would prefer to have fewer of them than many? How can we reconceptualize choices over such goods so that it becomes reasonable to assume “more is better”?

EXERCISE 4A.2

4A.2.2 “Averages Are Better than Extremes, or at Least No Worse” (Convexity)

While it may be obvious that the very nature of economic problems arises from the reality that people believe “more is better than less,” it is less obvious what we mean by “averages are better than extremes” or why this should be an assumption that is at all reasonable. Consider, for instance, two baskets of goods: The first contains 9 apples and 1 orange while the second contains 9 oranges and 1 apple. If we mixed the two baskets together and then divided them into two identical “average” baskets, we would get baskets with 5 apples and 5 oranges. It certainly seems plausible that this average basket might be preferred to the more extreme baskets we started with, but one could imagine someone who really likes apples and only sort of likes oranges preferring the more extreme basket with 9 apples. Thankfully, the economist’s assumption that “averages are better than extremes,” when properly defined, does not actually rule out this scenario. Rather, it gives expression to a general tendency by human beings to like variety in consumption choices.

Let’s begin by stating what we mean more precisely. We will say that your tastes satisfy the assumption that “averages are better than extremes” whenever it is the case that the average between two baskets *that you are indifferent between* is at least as good as the original two baskets. Thus, *if* you are indifferent between the 9 apples/1 orange basket and the 9 oranges/1 apple basket, *then* you would be willing to trade either of these extreme baskets for a basket with 5 apples and 5 oranges. If someone really likes apples and only sort of likes oranges, he or she would of course not be indifferent between the two extreme baskets. But if you *are* indifferent between the more extreme baskets, it is reasonable to assume that you would be willing to give up some of the good that you have a lot of for some of the good that you have only a little of, and that you would therefore prefer the 5 apples/5 oranges basket or at least not mind taking such a basket instead of one of the extremes. This assumption of “averages being better than extremes” is often called the *convexity assumption*, and tastes that satisfy it are referred to as *convex tastes*.

Consider again the five bundles graphed in Graph 4.1. There is nothing immediate the convexity assumption allows us to say in addition to what we could conclude from applying the monotonicity assumption in the previous section. However, suppose we find out that I am indifferent between bundles *A* and *B*. Then the convexity assumption lets us know that I would be at least as happy with an average between *A* and *B*. Bundle *C* is just that; it contains 5 shirts and 6 pants, which is exactly half of bundles *A* and *B* added together. (Note that such an average bundle lies halfway between the more extreme bundles on the line segment connecting those bundles.) Thus, convexity implies that *C* is at least as good as *A* and *B*.

EXERCISE 4A.3 Combining the convexity and monotonicity assumptions, can you now conclude something about the relationship between the pairs E and A and E and B if you do not know how A and B are related? What if you know that I am indifferent between A and B ?

EXERCISE 4A.4 Knowing that I am indifferent between A and B , can you now conclude something about how I rank B and D ? To reach this conclusion, do you have to invoke the convexity assumption?

In essence, the “averages are better than extremes” or convexity assumption gives expression to the general human tendency to seek diversity in consumption. No matter how much we like steak, few of us sit down to a meal of only steak, or only salad, only potatoes, only coffee, only dessert, or only wine. We might in fact be able to create all sorts of single-item meals that we are indifferent between: a certain quantity of steak, a certain quantity of salad, a certain quantity of potatoes, and so on. However, most of us would prefer a meal with some of each of these, or an average of single-item meals. The “meal” here is of course just an analogy that we don’t want to push too far; certain sets of single-item meals (perhaps pancakes and caviar) would, after all, not average well into one meal. Over the course of a week, however, even single-item meals that we may not want to mix in one meal might create welcome variety. Similarly, I may be indifferent between a basket containing 10 blue shirts with matched pants and another containing 10 red shirts with matched pants. My wife would not let me leave the house with mismatched clothes, so she would never let me mix one of the red shirts with one of the pants that matches only blue shirts. But, unless I like wearing the same outfit every day, I probably would prefer to have 5 of each, the average of the more extreme baskets, and then alternate which matched pair I wear on any given day.

These analogies give a sense of what it is that we mean intuitively when we say that often, averages in life are indeed better than extremes. In more life-changing decisions, the same seems to be true. Suppose I am indifferent between, on the one hand, consuming \$100,000 a year before retirement and living in poverty afterward and, on the other hand, living in poverty now and consuming \$150,000 a year after retirement. It seems reasonable that most of us would prefer an average between these scenarios, one that permits us a comfortable standard of living both before and after retirement. Or suppose that I am equally happy consuming a lot while working almost all the time and consuming very little while working very little. Most of us probably would prefer an average between these two bundles, to work without becoming a workaholic and consume less than we could if we did work all the time.

Convexity of tastes implies a tendency to like variety in consumption.

4A.2.3 “No Sudden Jumps” (or Continuity) Finally, we will usually assume that a consumer’s happiness does not change dramatically if the basket he or she consumes changes only slightly. Perhaps you are currently enjoying a nice cup of coffee so that you can stay awake as you read this chapter. If you like milk in your coffee, our “no sudden jumps” assumption implies that you will become neither dramatically better off nor dramatically worse off if I add one more drop of milk to the coffee. Starting out with coffee that is black, you may become gradually happier as I add milk and, at some point, gradually worse off as even more milk is added,⁵ but you will never switch from agony to ecstasy from just one more drop. Tastes that satisfy this assumption are often called *continuous*, and the “no sudden jumps” assumption is referred to as the *continuity assumption*.

The continuity assumption is most appealing for goods that can easily be divided into smaller and smaller units (such as milk) and less appealing for goods that come in very discrete

⁵Note that in this example, your tastes violate the “more is better” assumption if it is indeed the case that you become worse off as I add milk at some stage. Of course this is true only when the situation is viewed very narrowly as one instant in time; you would certainly continue to become better off if, instead of adding the additional milk to your coffee, I put it in the refrigerator for later use.

units (such as, perhaps, pants and shirts, or larger goods like cars). For purposes of our models, however, we will treat these other types of goods just as we treat milk: We will assume that you can in fact consume fractions of pants and shirts and cars. We do this not because it is realistic but rather because it simplifies our models in ways that ultimately are not all that critical for any of the analysis we will do with our models. If, for instance, we conclude from our analysis that a 10% drop in the price of pants will result in an increase of your consumption of pants by 3.2, we can simply round this off and know that you will probably end up buying 3 more pants.

Furthermore, in cases where the assumption of continuity becomes particularly problematic, there are often other ways of modeling the behavior such that the assumption once again is reasonable. For instance, we might think of cars or houses as very discrete units; it is, after all, not easy to consume three-quarters of a car or house. At the same time, we could model cars as bundled goods, goods that provide you with varying degrees of speed, safety, comfort, and so on. What you are really trying to buy is not a car but rather speed, safety, and comfort on the road, and your tastes over these attributes are probably quite immune to sudden jumps. Similarly, in the case of housing, we can think of your choice as one involving square footage, the age of the house, the quality of the neighborhood, features of the floorplan, and so on, and once again it is likely that your tastes over these attributes of housing are not subject to sudden jumps. (We explore this concept of modeling discrete goods as bundles of “attributes” further in the end-of-chapter exercises 4.9.⁶)

4A.3 Graphing Tastes

In Chapters 2 and 3, we found ways of graphically representing the constraints on people’s choices, or what we called the choice sets from which people can choose given their circumstances. Armed with the assumptions we just introduced, we will now do the same for people’s tastes before demonstrating in Chapter 6 how tastes and constraints combine to result in human behavior we can then observe. More precisely, we will find that it is impossible to graph fully the tastes of any individual, but we will develop ways of graphing the particular portions of individual tastes that are most relevant for the choices that confront us at different times.

4A.3.1 An Indifference Curve The basic building block of our graphs of tastes is what we will call an *indifference curve*. Suppose, for instance, that we are back to choosing between pants and shirts, and suppose that I currently have 8 shirts and 4 pants in my shopping basket. This is represented as point *A* in Graph 4.2a. *The indifference curve containing point A* is defined as the set of all other consumption bundles (i.e., the set of all other pairs of shirts and pants) that would make me exactly as happy as bundle *A*. While it is difficult to know exactly where such bundles lie, our assumptions about tastes allow us to derive the approximate location of this indifference curve.

We can begin by noting some places that could not possibly contain bundles that lie on the indifference curve which contains bundle *A*. Consider, for instance, the shaded magenta area to the northeast of *A*. All bundles in this area contain more pants and more shirts. If “more is better,” then bundles that contain more pants and shirts *must be* better than *A* and thus could not be indifferent to *A*. Similarly, consider bundles to the southwest of bundle *A*. All bundles represented by this shaded blue area contain fewer pants and shirts than bundle *A* and must therefore be worse. Thus, the monotonicity assumption allows us to rule out the shaded areas in Graph 4.2a as bundles that could lie on the indifference curve containing bundle *A*. Bundles that lie in non-shaded areas, on the other hand, are not ruled out by the monotonicity assumption. Those to

Monotonicity implies indifference curves slope down.

⁶The most common example of tastes that violate the continuity assumption is known as *lexicographic tastes*. An example of such tastes is given in end-of-chapter exercise 4.8.

GRAPH 4.2 Tastes and Indifference Curves

Go to MindTap to interact with this graph.

the northwest of *A*, for instance, all have fewer pants but more shirts, while those to the southeast have more pants and fewer shirts than bundle *A*. You therefore know from the monotonicity assumption that my indifference curve containing bundle *A* must be downward sloping through bundle *A*, but you can glean nothing further without knowing more about me.

Now suppose that I tell you I am indifferent between the bundles represented by points *A* (4 pants, 8 shirts) and *B* (2 shirts, 8 pants) in Graph 4.2b. This means that you of course immediately know that bundle *B* lies on the indifference curve that contains bundle *A*. You can also now draw some additional shaded areas (to the northeast and southwest of point *B*) that you know could not possibly include further indifferent bundles based on the “more is better” or monotonicity assumption. More importantly, however, you can now employ the “averages are better than extremes” or convexity assumption to come to some additional conclusions about the shape of the indifference curve that contains bundles *A* and *B*.

The convexity assumption simply states that whenever someone is indifferent between two bundles of goods and services, the average bundle (that is created by mixing the two original bundles and dividing them into two equal ones) is judged to be at least as good as the extreme bundles. In our case, the average bundle would be 5 shirts and 6 pants. Graphically, this average bundle is simply the midpoint of the line segment connecting points *A* and *B*, labeled *C* in Graph 4.2b.

Now notice that any bundle to the southwest of *C* has fewer pants and fewer shirts and is thus worse than *C*. Suppose we start at *C* and move a little to the southwest by taking just a tiny bit of each good away (assuming for the moment that it is possible to take away bits of shirts and pants). Then, given our “no sudden jumps” or continuity assumption, the new bundle is just a little worse than *C*. Suppose we keep doing this, each time creating yet another bundle that’s just a little worse and moving a little further southwest. If *C* is strictly better than *A* (and *B*), it should be the case that, as we inch our way southwest from *C*, we at some point hit a bundle *F* that is indifferent to *A* and *B*. Without knowing more about me, you can’t tell exactly how far southwest of *C* the new indifferent point *F* will lie. All we know is that it lies to the southwest.

Illustrate the area in Graph 4.2b in which F must lie, keeping in mind the monotonicity assumption.

EXERCISE
4A.5

Suppose our tastes satisfy weak convexity in the sense that averages are just as good (rather than strictly better than) extremes. Where does F lie in relation to C in that case?

EXERCISE
4A.6

We now have three bundles between which I am indifferent: A , B , and F . We could repeat what we just did for the average between A and F and the average between B and F . The intuition that should be emerging already, however, is that the *indifference curve containing bundles A and B must not only be downward sloping (because “more is better”) but also must be continuous (because of “no sudden jumps”) and bend toward the origin (because “averages are better than extremes”)*. For someone with tastes like this, all bundles that lie above the indifference curve (in the shaded region) must be better than any of the bundles on the indifference curve because these contain more of everything relative to *some* bundle that lies on the indifference curve. Similarly, all bundles that lie below this indifference curve (in the nonshaded region) are worse because they contain less of everything compared to some bundle that lies on the indifference curve.

Convexity implies indifference curves bend toward the origin.

4A.3.2 Marginal Rates of Substitution We have just demonstrated how our five assumptions about tastes result in a particular shape of indifference curves. One way of describing this shape is to say that *the slope of indifference curves is negative and becomes smaller in absolute value as one moves to the right in the graph*. The slope of the indifference curve at any given point is, however, more than a mere description of what the indifference curve looks like. It has real economic content and is called the *marginal rate of substitution*.

Consider, for instance, the slope of -3 at point A in Graph 4.3. This slope tells us that we could go down by 3 shirts and over to the right by 1 pair of pants and end up roughly on the same

GRAPH 4.3 Diminishing Marginal Rate of Substitution

indifference curve as the one that contains bundle A .⁷ Put differently, when I am consuming bundle A , I would be *willing to* trade in 3 of my shirts to get 1 more pair of pants because that would leave me roughly as well off as I currently am. Thus, the slope of the indifference curve at point A gives us an indication of how much I value 1 more pair of pants in terms of shirts. This *marginal rate of substitution* is therefore *my willingness to trade shirts for 1 more additional (or marginal) pair of pants given what I am currently consuming*.

Since the slope of the indifference curve typically changes as one moves along the indifference curve, the marginal rate of substitution—or how much value we place on an additional good on the horizontal axis in terms of the good on the vertical axis—also changes. Consider, for example, the shallower slope of $-1/2$ at point B (in Graph 4.3). This slope tells us that I would be willing to give up only half a shirt for 1 more pair of pants (or 1 shirt for 2 additional pants) when I am already consuming bundle B . This makes sense given our discussion about the “averages are better than extremes” assumption. At bundle A , I had relatively few pants and relatively many shirts, and I thus placed a high value on additional pants because that would get me to a less extreme bundle (and keep me from having to wash pants all the time or else go without pants). At bundle B , on the other hand, I have relatively many pants and few shirts, and thus I would not be willing to give up more shirts very easily given that this would get me to even more extreme bundles (causing me to have to wash shirts all the time or else go shirtless).

In fact, we concluded in the previous section that the shape of the indifference curve pictured in Graph 4.3 is due to the “averages are better than extremes” assumption. This shape implies that marginal rates of substitution begin as large numbers in absolute value and decline (in absolute value) as we move down an indifference curve. This is known as the concept of *diminishing marginal rates of substitution*, and it arises only when averages are indeed better than extremes.

Convexity
implies
diminishing
MRS.

EXERCISE 4A.7 Suppose extremes are better than averages. What would an indifference curve look like? Would it still imply diminishing marginal rates of substitution?

EXERCISE 4A.8 Suppose averages are just as good as extremes? What would an indifference curve look like? Would it still imply diminishing marginal rates of substitution?

4A.3.3 “Maps” of Indifference Curves In deriving our first indifference curve, we defined it *with respect to one bundle*. Put differently, we mapped out the indifference curve that contains one arbitrarily selected bundle: bundle A in Graph 4.2b. But of course we could have begun with some other arbitrary bundle, for instance bundle E in Graph 4.4a. Just as there is an indifference curve that runs through bundle A , there is an indifference curve that runs through bundle E . Notice that E lies to the northeast of the highlighted segment of the indifference curve that contains A in Graph 4.4a. This means that E contains more shirts and pants than any of the highlighted bundles, which means that it must be the case that E is better than those bundles (because of our “more is better” assumption). But this also means that E is better than *all* bundles on the indifference curve that contains bundle A .

EXERCISE 4A.9 Show how you can prove the last sentence in the previous paragraph by appealing to the transitivity of tastes.

⁷We would in fact end up slightly below the indifference curve unless we measured shirts and pants in very small units.

GRAPH 4.4 Parallel and Converging Indifference Curves

An important logical consequence of this is that the indifference curve that goes through point *A* can never cross the indifference curve that goes through point *E*. If the two indifference curves did cross, they would share one point in common. This intersection point would be indifferent to *A* (because it lies on the indifference curve that contains *A*), and it would also be indifferent to *E* (since it lies on the indifference curve that contains *E*). Since *E* is preferred to *A*, transitivity implies that the intersection point cannot be indifferent to both *E* and *A* simultaneously. Thus, *as long as tastes are rational (i.e., they satisfy completeness and transitivity), indifference curves cannot cross.* They can be parallel like those in Graph 4.4a, or they can converge like those in Graph 4.4b, or they can relate to each other in any number of other ways, but they can never touch.

Transitivity implies indifference curves cannot cross.

Furthermore, if tastes are complete, then *some* indifference curve runs through every bundle. As we showed earlier, the monotonicity assumption implies that indifference curves will be downward sloping; the convexity and continuity assumptions imply that they will bend toward the origin; and the transitivity assumption implies that no two indifference curves can ever cross. Graph 4.5 then illustrates an example of a whole map of indifference curves that represent the tastes over pants and shirts for an individual whose tastes satisfy the rationality assumptions as well as the three additional assumptions outlined in Section 4A.2. This is, of course, only one possible configuration of an indifference “map” that satisfies all these assumptions. While the assumptions we have made about tastes result in particular general shapes for indifference curves, we will see in Chapter 5 that there exist many different types of indifference maps (and thus many different tastes) that can be modeled using these assumptions.

Finally, to indicate that indifference curves to the northeast of Graph 4.5 represent bundles that yield greater happiness than indifference curves to the southwest of the graph, each indifference curve is accompanied by a number that indicates how bundles on that particular curve compare with bundles on other curves. For instance, when we compare bundle *A* with bundle *E*, we can read off the number 2 on the indifference curve containing point *A* and the number 4 on the indifference curve containing point *E*, and we can infer from this that bundle *E* is preferred to bundle *A*. If less is better than more, then the ordering of the numbers attached to these indifference curves would be reversed.

GRAPH 4.5 Map of Indifference Curves

EXERCISE 4A.10 Suppose less is better than more and averages are better than extremes. Draw three indifference curves (with numerical labels) that would be consistent with this.

We *cannot*, however, infer from these two numbers that bundles on one indifference curve yield “twice as much happiness” as bundles on the other indifference curve. *Happiness is simply not something that is objectively quantifiable.* While economists in the past had indeed hoped to measure happiness or “utility” in units they called “utils,” modern economists have abandoned any such attempts as misguided. To see just how silly the notion of objectively measuring happiness is, try asking a friend the following when you see him or her for the first time after he or she went on a date: “So, how many utils did you get out of that date?”

We *can* say that all bundles on a particular indifference curve yield the same level of utility (and thus must have the same numerical label), and that different utility numbers associated with different indifference curves tell us which are more preferred and which less. But we could change all the numbers in Graph 4.5 by multiplying them by 2 or dividing them by 5 or adding 13 to them because in each case, the *ordering* of indifference curves would remain unchanged. Thus, *so long as the shape of indifference curves and the ordering of the numbers that accompany the curves are unchanged between two graphs, we will say that the maps of indifference curves in the two graphs represent the same tastes.* By changing the numerical labels on indifference curves without changing their order, all we are in effect doing is changing the ruler we use to measure happiness, and since there isn’t an agreed upon ruler, any ruler that preserves the ordering of indifference curves will do.

This becomes somewhat clearer if you think of the following analogy (which we expand on in more detail in part B). Consider a two-dimensional map of a mountain (such as that depicted in Graph 4.10), a map in which different heights of the mountain are represented by outlines of the shape of the mountain at that height accompanied by a number that indicates the elevation of that outline. In essence, such maps are depictions of horizontal slices of the mountain at different heights drawn on a single two-dimensional surface. Indifference curves are very much like this. Longitude and latitude are replaced with pants and shirts, and the height of the mountain

is replaced with the level of happiness. While real-world mountains have peaks, our happiness mountains generally do not have peaks because of our “more is better” assumption. Indifference curves are then simply horizontal slices of our happiness mountain (such as the one depicted in Graph 4.8), with numbers indicating the height of happiness attained at that slice. And just as the outlines of the different elevations of a real-world mountain don’t change whether we measure the height of the elevation in feet or meters, the outlines of the slices of our happiness mountain, that is the indifference curves, do not change shapes if we use a different ruler to measure happiness.

We will have much more to say in Chapter 5 about how to interpret different types of indifference maps, what they imply about whether goods are relatively more complementary or substitutable, how to think of the relationship of indifference curves to one another, and so on. But first, we develop some of the underlying mathematics of the “utility mountains” through the concept of utility *functions*.

4B

TASTES AND UTILITY FUNCTIONS

We have shown in Section 4A how certain basic assumptions about our tastes can enable us to generate graphical ways of representing tastes with the tool of indifference curves. As was true for choice sets in Chapters 2 and 3, these graphical tools are mere representations of more general mathematical formulations of the same economic concepts. And the assumptions we introduced in Section 4A.1 and 4A.2 will translate directly into mathematical properties of functions that we can use to represent tastes.

4B.1 Two Fundamental Rationality Assumptions

When we speak of “bundles” or “baskets” of two goods, we have already defined these as points with two components, each representing the quantity of one of the goods in the basket. The point labeled *A* in Graph 4.1, for instance, can be expressed as $(x_1^A, x_2^A) = (4, 8)$, representing a basket with 4 units of good 1 (pants) and 8 units of good 2 (shirts). In general, we can then express a basket that contains two types of goods as

$$(x_1, x_2) \in \mathbb{R}_+^2, \quad (4.1)$$

where “ \in ” is read as “is an element of” and “ \mathbb{R}_+^2 ” denotes the set of all points with two non-negative (real number) components. Almost all of our graphs of choice sets consist of some subset of points in \mathbb{R}_+^2 , as do our graphs of indifference curves in Section 4A. When a larger number of different types of goods is included in a basket—shirts, pants, *and* socks, for instance—we can further generalize this by simply denoting a basket with n different types of goods by

$$(x_1, x_2, \dots, x_n) \in \mathbb{R}_+^n, \quad (4.2)$$

where \mathbb{R}_+^n now represents the set of all points with n non-negative components. In the case of shirts, pants, and socks, $n = 3$.⁸

Tastes, or preferences, involve subjective comparisons of different baskets or different points as denoted in (4.1) and (4.2). We will use the following shorthand notation

$$(x_1^A, x_2^A, \dots, x_n^A) \succeq (x_1^B, x_2^B, \dots, x_n^B) \quad (4.3)$$

whenever we want to say that “the basket $(x_1^A, x_2^A, \dots, x_n^A)$ is at least as good as the basket $(x_1^B, x_2^B, \dots, x_n^B)$.” Similarly, we read

$$(x_1^A, x_2^A, \dots, x_n^A) > (x_1^B, x_2^B, \dots, x_n^B) \quad (4.4)$$

⁸You may recall from your math classes that points with such multiple components are referred to as vectors.

as “basket $(x_1^A, x_2^A, \dots, x_n^A)$ is strictly better than basket $(x_1^B, x_2^B, \dots, x_n^B)$,” and we will read

$$(x_1^A, x_2^A, \dots, x_n^A) \sim (x_1^B, x_2^B, \dots, x_n^B) \quad (4.5)$$

as a person being *indifferent* between these two baskets. The objects “ \succeq ,” “ $>$,” and “ \sim ” are called *binary relations* because they relate two points to each other.

4B.1.1 Complete Tastes In Section 4A, we defined tastes as *complete* whenever a person with those tastes can unequivocally compare any two baskets, indicating whether one basket is better than the other or whether he or she is indifferent between the two baskets. We can now write this definition formally as follows: *A person has complete tastes over all baskets with n goods if and only if it is true that for all $(x_1^A, x_2^A, \dots, x_n^A) \in \mathbb{R}_+^n$ and for all $(x_1^B, x_2^B, \dots, x_n^B) \in \mathbb{R}_+^n$,*

$$\begin{aligned} (x_1^A, x_2^A, \dots, x_n^A) \succeq (x_1^B, x_2^B, \dots, x_n^B) \text{ or} \\ (x_1^B, x_2^B, \dots, x_n^B) \succeq (x_1^A, x_2^A, \dots, x_n^A) \text{ or both.} \end{aligned} \quad (4.6)$$

All we are saying is that a person can compare any two bundles in \mathbb{R}_+^n . Note that logically it has to be the case that if both of the statements in (4.6) are true for a given set of two bundles, then

$$(x_1^A, x_2^A, \dots, x_n^A) \sim (x_1^B, x_2^B, \dots, x_n^B). \quad (4.7)$$

EXERCISE 4B.1 True or False: If only one of the statements in (4.6) is true for a given set of bundles, then that statement's “ \succeq ” can be replaced with “ $>$ ”.

4B.1.2 Transitive Tastes While we certainly need tastes in our models to be complete in order for individuals within the models to be able to make choices, we argued in Section 4A that this is not enough: In order for an individual to be able to settle on a “best” choice, there needs to be a certain internal consistency to the tastes that guide the person's choices. We called this internal consistency “transitivity” and said that a person's tastes are *transitive* if, whenever the person likes a bundle A at least as much as a bundle B and he or she likes B at least as much as C , it must be the case that the person likes A at least as much as C . We can now define this more formally using the notation we just developed.

In particular, we will say that *a person's tastes are transitive if and only if it is true that whenever three bundles are evaluated by the person such that*

$$(x_1^A, x_2^A, \dots, x_n^A) \succeq (x_1^B, x_2^B, \dots, x_n^B) \text{ and } (x_1^B, x_2^B, \dots, x_n^B) \succeq (x_1^C, x_2^C, \dots, x_n^C), \quad (4.8)$$

we can conclude that

$$(x_1^A, x_2^A, \dots, x_n^A) \succeq (x_1^C, x_2^C, \dots, x_n^C). \quad (4.9)$$

EXERCISE 4B.2 Does transitivity also imply that (4.8) implies (4.9) when “ \succeq ” is replaced with “ $>$ ”?

4B.1.3 “Rational Tastes” The assumptions of completeness and transitivity of tastes are, as already noted in Section 4A, so fundamental to the economist's modeling of tastes that together they define what we mean by *rational* tastes. An individual's tastes over a particular set of bundles are then said to be rational if they are both complete and transitive.

4B.2 Three More Assumptions

While the two rationality assumptions are quite fundamental for the construction of a model of tastes that can result in individuals choosing “best” alternatives given their circumstances, they do

not by themselves tell us very much about what kinds of choices individuals are likely to make. For this reason, we introduced in Section 4A.2.3 additional assumptions that we informally called “more is better,” “averages are better than extremes,” and “no sudden jumps.” In more formal language, these same assumptions were referred to as *monotonicity*, *convexity*, and *continuity*.

4B.2.1 Monotonicity (or “More Is Better or at Least Not Worse”) We argued at length in Section 4A.2.1 that the fundamental scarcity that underlies economic decision making implies that more is indeed considered better by most individuals in most economic contexts. Given that bundles of goods and services by definition contain many different types of goods, we have to be clear about what we mean by “more.” In Graph 4.1, for instance, bundle *E* clearly has more of everything than bundle *C*, but it has more of some and less of other goods when compared with bundles *A* and *B*. By “more” we can mean either “more of all goods” or “more of at least some goods and no less of any of the other goods.” When a bundle contains “more of all goods” than a second bundle, we will generally assume that a consumer strictly prefers that bundle. When a bundle contains “more of at least some goods and no less of any of the other goods” than a second bundle, on the other hand, we will typically assume that a consumer thinks of this bundle as *at least as good as* the second bundle, thus leaving open the possibility that the consumer might be indifferent between the bundles.

Formally we can then define “more is better,” or what we will call monotonic tastes, as follows: *A consumer’s tastes are monotonic if and only if*

$$\begin{aligned} (x_1^A, x_2^A, \dots, x_n^A) \succeq (x_1^B, x_2^B, \dots, x_n^B) & \text{ whenever } x_i^A \geq x_i^B \text{ for all } i = 1, 2, \dots, n; \text{ and} \\ (x_1^A, x_2^A, \dots, x_n^A) > (x_1^B, x_2^B, \dots, x_n^B) & \text{ whenever } x_i^A > x_i^B \text{ for all } i = 1, 2, \dots, n. \end{aligned} \quad (4.10)$$

The first line of this definition allows for the possibility that some of the goods in the *A* and *B* bundles are the same while others are larger for the *A* bundle than for the *B* bundle, whereas the second line applies only to pairs of bundles where one contains more of every good than the other. In Graph 4.1, for instance, bundle *A* contains more shirts but the same number of pants as bundle *D*, and our definition of monotonic tastes therefore implies that $A \succeq D$, or “*A* is at least as good as *D*.” Bundle *E*, on the other hand, contains more of all goods than bundle *D*, implying that $E > D$, or “*E* is strictly better than *D*.”⁹

4B.2.2 Convexity (“Averages Are Better than (or at Least as Good as) Extremes”)

Next we argued in Section 4A.2.2 that it is often reasonable for us to assume that “averages are better than extremes” whenever an individual is indifferent between “extreme” bundles. By an “average” bundle we simply meant the bundle that emerges if we mix 2 more extreme bundles (like bundles *A* and *B* in Graph 4.2) and divide them into 2 identical bundles.¹⁰ We could translate this into a more formal statement by saying that

$$\begin{aligned} (x_1^A, x_2^A, \dots, x_n^A) \sim (x_1^B, x_2^B, \dots, x_n^B) & \text{ implies} \\ \left(\frac{1}{2}\right)(x_1^A, x_2^A, \dots, x_n^A) + \left(\frac{1}{2}\right)(x_1^B, x_2^B, \dots, x_n^B) & \succeq (x_1^A, x_2^A, \dots, x_n^A) \text{ and} \\ \left(\frac{1}{2}\right)(x_1^A, x_2^A, \dots, x_n^A) + \left(\frac{1}{2}\right)(x_1^B, x_2^B, \dots, x_n^B) & \succeq (x_1^B, x_2^B, \dots, x_n^B). \end{aligned} \quad (4.11)$$

⁹ Monotonicity assumptions are sometimes divided into *weak* and *strong* monotonicity, where weak monotonicity requires that each element of a bundle *A* must be larger than each corresponding element of *B* for us to be sure that *A* is strictly preferred to *B*, while a stronger form of monotonicity would require only some elements of *A* to be larger than the corresponding elements in *B* (with all remaining elements the same). Our definition corresponds to the weaker of these definitions of monotonicity. Finally, although we will generally maintain our assumption of monotonicity throughout the text, many of the results that we derive actually hold for a much weaker assumption called *local non-satiation*. This assumption simply requires that there exists no bundle of goods for which there isn’t another bundle close by that is strictly better. These concepts are clarified further in the end-of-chapter exercise 4.13.

¹⁰ As in the case of monotonicity, there exist several stronger and weaker versions of the convexity assumption. *Strict convexity* is usually defined as “averages are strictly preferred to extremes” while *weak convexity* is defined as “averages are at least as good as extremes.” Note that we will define our convexity notion in line with the latter, although you will see in the coming chapters that most of the tastes we work with actually satisfy the stronger definition of convexity.

EXERCISE 4B.3 True or False: Assuming tastes are transitive, the third line in expression (4.11) is logically implied by the first and second lines.

More generally, if the literal “average” (as opposed to a weighted average with weights different from 0.5) of two more extreme bundles is better than the extremes, the same logic would suggest that *any weighted average* that emerges from mixing two extremes is preferable to the extremes so long as it is not even more extreme. For instance, suppose again that I am indifferent between bundle A and B in Graph 4.2, where bundle A contains 4 pants and 8 shirts while bundle B contains 8 pairs of pants and 2 shirts. But now, instead of strictly averaging the bundles to yield a bundle with 6 pants and 5 shirts, suppose that we create one bundle that consists of $1/4$ of bundle A and $3/4$ of bundle B , and a second bundle that consists of $3/4$ of A and $1/4$ of B . An individual who likes averages better than extremes will then also prefer these two bundles to the more extreme original ones, and these bundles would also lie on the line segment connecting A and B .

Convex combinations are weighted averages of bundles.

Bundles that are created as a weighted average of extremes are called *convex combinations* of the extreme bundles. Put more precisely, any bundle that is created by weighting bundle A by α and bundle B by $(1 - \alpha)$ is a convex combination of A and B so long as α lies between 0 and 1. Our “averages are better than extremes,” or convexity, assumption from Section 4A can then be restated in the following way: *Tastes are convex if and only if convex combinations of indifferent bundles are at least as good as the bundles used to create the convex combination.* Or, in terms of the notation we have developed, *tastes over bundles of n goods are convex if and only if, for any α such that $0 \leq \alpha \leq 1$,*

$$\begin{aligned} (x_1^A, x_2^A, \dots, x_n^A) \sim (x_1^B, x_2^B, \dots, x_n^B) \text{ implies} \\ \alpha(x_1^A, x_2^A, \dots, x_n^A) + (1 - \alpha)(x_1^B, x_2^B, \dots, x_n^B) \succeq (x_1^A, x_2^A, \dots, x_n^A). \end{aligned} \quad (4.12)$$

4B.2.3 Continuity (“No Sudden Jumps”) Finally, we introduced the assumption that tastes generally do not have “sudden jumps” in Section 4A.2.3. We can now formalize this assumption by introducing a mathematical concept called a *converging sequence of points*. This concept is quite intuitive, but it consists of several parts. First, a *sequence of points in \mathbb{R}_+^n* is simply a list of points, each with n different non-negative components. This sequence is *infinite* if and only if the list has an infinite number of points in it. An infinite sequence of points then is said to *converge* to a single point in \mathbb{R}_+^n if and only if the distance between the points in the sequence and that single point becomes smaller and smaller (beginning at some point in the sequence).

Suppose for instance that we start in Graph 4.6 at a point B in \mathbb{R}_+^2 . Then suppose that point B is the first point in an infinite sequence that continues with B^1 lying halfway between point B and some other point A , with B^2 lying halfway between point B^1 and A , with B^3 lying halfway between B^2 and A , and so forth. An example of the first four points of such a sequence is graphed in Graph 4.6. If we now imagine this sequence of points continuing forever, no point in the sequence will ever quite reach point A , but it will get ever closer. In the language of calculus, the *limit of the sequence* is point A , and the sequence itself *converges* to point A .

Now suppose we have two infinite sequences of points: one denoted $\{B^1, B^2, B^3, \dots\}$ and the other denoted $\{C^1, C^2, C^3, \dots\}$, with the first sequence converging to point A and the second sequence converging to point D . *If it is the case that $B^i \succ C^i$ for all i 's, then the continuity assumption requires that $A \succeq D$.* Thus, if the B bundles are always preferred to the C bundles as we move along the two sequences and if this continues to hold as we get closer and closer to

GRAPH 4.6 Continuity: Converging Sequence of Points

the bundles A and D to which the two sequences converge, we can't suddenly have a “jump” at the end of the sequences that reverses the preference relation and causes D to be preferred to A.

4B.3 Representing Tastes with Utility Functions

In Section 4A.3, we demonstrated how the assumptions we have made about people's tastes allow us to graph different types of tastes using indifference curves. We will now see that these indifference curves can be interpreted as parts of mathematical functions that summarize tastes more fully. These functions are called *utility functions*, and utility functions are simply mathematical rules that assign numbers to bundles of goods in such a way that more preferred bundles are assigned higher numbers.

Recall from your math classes that a *mathematical function* is just a formula that assigns numbers to points. For instance, the function $f(x) = x^2$ is simply a way of assigning numbers to different points in the space \mathbb{R}^1 (the real line), the space consisting of points with only a single component. To the point $x = 1/2$, the function assigns a value of $1/4$; to the point $x = 1$, the function assigns a value of 1; and to the point $x = 2$, the function assigns the value 4. The full function is depicted in Graph 4.7.

In mathematical notation, we would indicate by $f: \mathbb{R}^1 \rightarrow \mathbb{R}^1$ that such a function f is a formula that assigns a real number to each point on the real line. We would then read this notation as “the function f takes points on the real line \mathbb{R}^1 and assigns to them a value from the real line \mathbb{R}^1 .” Such functions are not, however, of particular use to us as we think about representing tastes because we are generally considering bundles that consist of more than one good, bundles such as those consisting of combinations of shirts and pants. Thus, we might be more interested in a function $f: \mathbb{R}_+^2 \rightarrow \mathbb{R}^1$ that assigns to each point made up of two real numbers (i.e., points that lie in \mathbb{R}_+^2) a single real number (i.e., a number in \mathbb{R}^1). One example of such a function would be $f(x_1, x_2) = x_1 x_2$, a function that assigns the value 1 to the bundle (1, 1), the value 4 to the bundle (2, 2), and the value 2 to the bundle (2, 1).

GRAPH 4.7 An Example of a Function $f: \mathbb{R}^1 \rightarrow \mathbb{R}^1$ 

Utility functions assign numbers to all consumption bundles.

Suppose, for instance, that we are back to choosing between bundles composed of shirts and pants. If I have rational tastes, I can compare any two bundles and tell you which I prefer or whether I am indifferent between them. If I can find a function $f: \mathbb{R}_+^2 \rightarrow \mathbb{R}^1$ that assigns to each bundle of shirts and pants (represented by points in \mathbb{R}_+^2) a value in such a way that more preferred bundles are assigned higher numbers (and indifferent bundles are assigned the same number), we will say that I have found a utility function that represents my tastes. More formally, a function $f: \mathbb{R}_+^2 \rightarrow \mathbb{R}^1$ represents my tastes over pants (x_1) and shirts (x_2) if and only if,

$$\begin{aligned} (x_1^A, x_2^A) > (x_1^B, x_2^B) &\text{ implies } f(x_1^A, x_2^A) > f(x_1^B, x_2^B) \text{ and} \\ (x_1^A, x_2^A) \sim (x_1^B, x_2^B) &\text{ implies } f(x_1^A, x_2^A) = f(x_1^B, x_2^B). \end{aligned} \quad (4.13)$$

We will typically use u instead of f to denote such utility functions.

For the more general case of tastes over bundles with n different goods, we can now define a utility function as follows: $u: \mathbb{R}_+^n \rightarrow \mathbb{R}^1$ represents tastes \succeq over bundles of n goods if and only if, for any $(x_1^A, x_2^A, \dots, x_n^A)$ and $(x_1^B, x_2^B, \dots, x_n^B)$ in \mathbb{R}_+^n

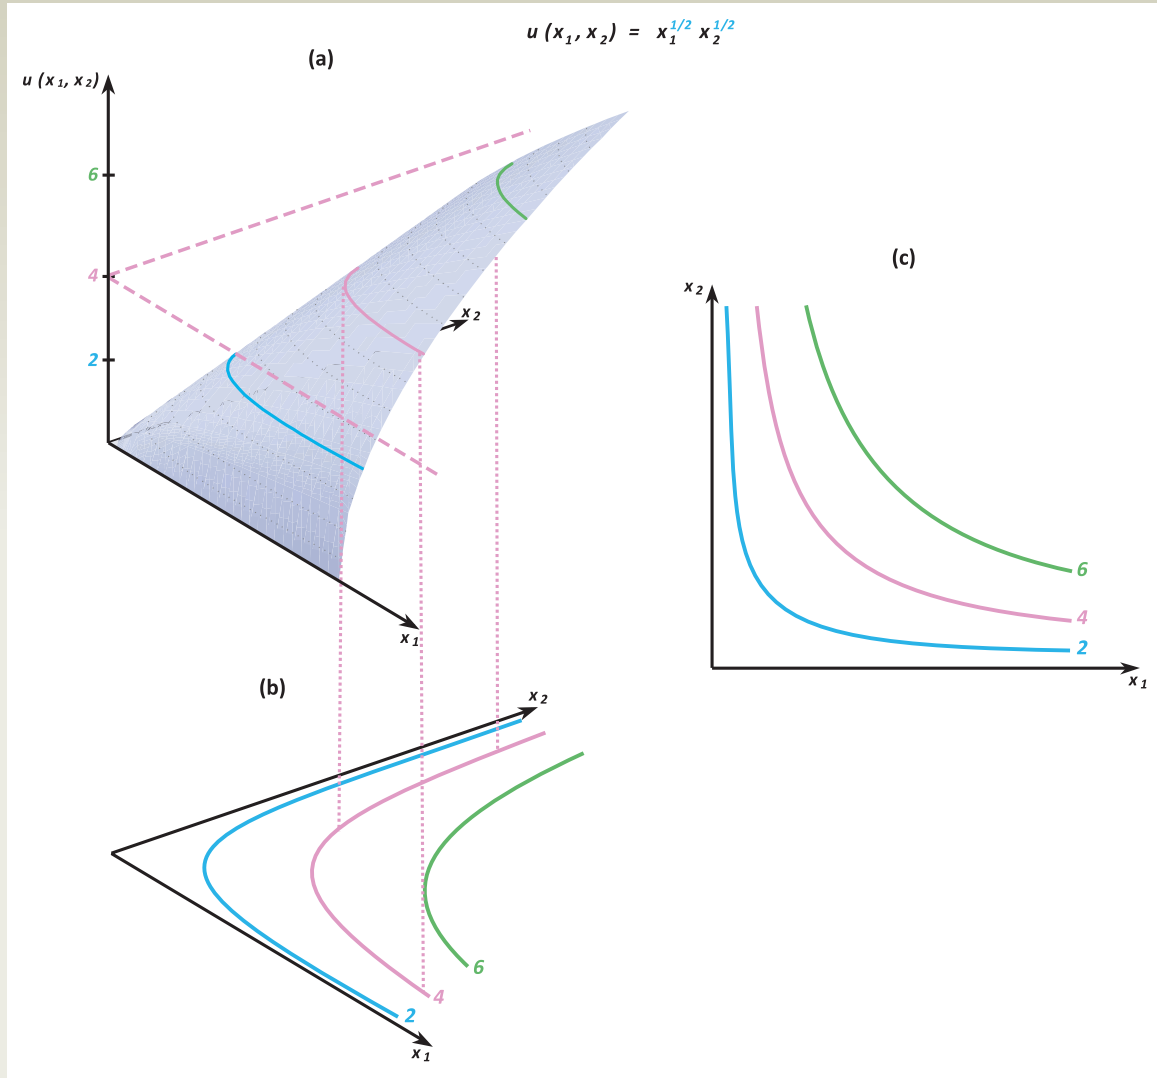

$$\begin{aligned} (x_1^A, x_2^A, \dots, x_n^A) > (x_1^B, x_2^B, \dots, x_n^B) &\text{ implies } u(x_1^A, x_2^A, \dots, x_n^A) > u(x_1^B, x_2^B, \dots, x_n^B) \text{ and} \\ (x_1^A, x_2^A, \dots, x_n^A) \sim (x_1^B, x_2^B, \dots, x_n^B) &\text{ implies } u(x_1^A, x_2^A, \dots, x_n^A) = u(x_1^B, x_2^B, \dots, x_n^B). \end{aligned} \quad (4.14)$$

You might notice right away how important our rationality assumptions about tastes are in ensuring that we can indeed represent tastes with utility functions. Functions assign values to all points in the space over which they are defined. Thus, we could not use functions to represent tastes unless we indeed were able to evaluate each bundle in relation to others; that is unless our tastes were complete. Similarly, mathematical functions *have to be* logically consistent in the sense that whenever point A is assigned a value greater than point B and point B is assigned a value greater than point C , point A *must be* assigned a value greater than point C . Thus, if tastes

were not also logically consistent as required by our transitivity assumption, we could not use mathematical functions to represent them.¹¹

4B.3.1 Utility Functions and Indifference Curves Let's return to my tastes over bundles of pants and shirts, with pants represented by x_1 and shirts by x_2 , and suppose that my tastes can be captured fully by the function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$. Graph 4.8a illustrates this

GRAPH 4.8 Indifference Curves and Utility Functions

Go to MindTap to interact with this graph.

¹¹ One can formally prove that any tastes that satisfy the rationality and continuity assumptions can be represented by utility functions. See A. Mas-Colell, M. Whinston, and J. Greene, *Microeconomic Theory* (New York, Oxford University Press, 2002). You can also construct a simplified version of this proof in end-of-chapter exercise 4.14.

function graphically, with shirts and pants measured on the lower axes and the values $u(x_1, x_2)$ plotted on the vertical axis. Now suppose that I wanted to plot only those bundles that are assigned a value of precisely 4. I would then focus on one horizontal (magenta) slice of this function that occurs at a height of 4 and could plot that slice in a two-dimensional picture with just pants and shirts on the axes, as in panels (b) and (c) of Graph 4.8. Since bundles that are assigned the same number are, by the definition of a utility function, valued exactly the same by me, these bundles represent one indifference curve, all those bundles of goods that give me “utility” of exactly 4 as measured by the utility function u . Similarly, I could focus on all bundles that are assigned a value of 2 by the utility function, thus creating a second indifference curve. And of course I could do this for all possible values on the vertical axis in Graph 4.8a, thus creating an entire map of indifference curves that is represented by this particular utility function.

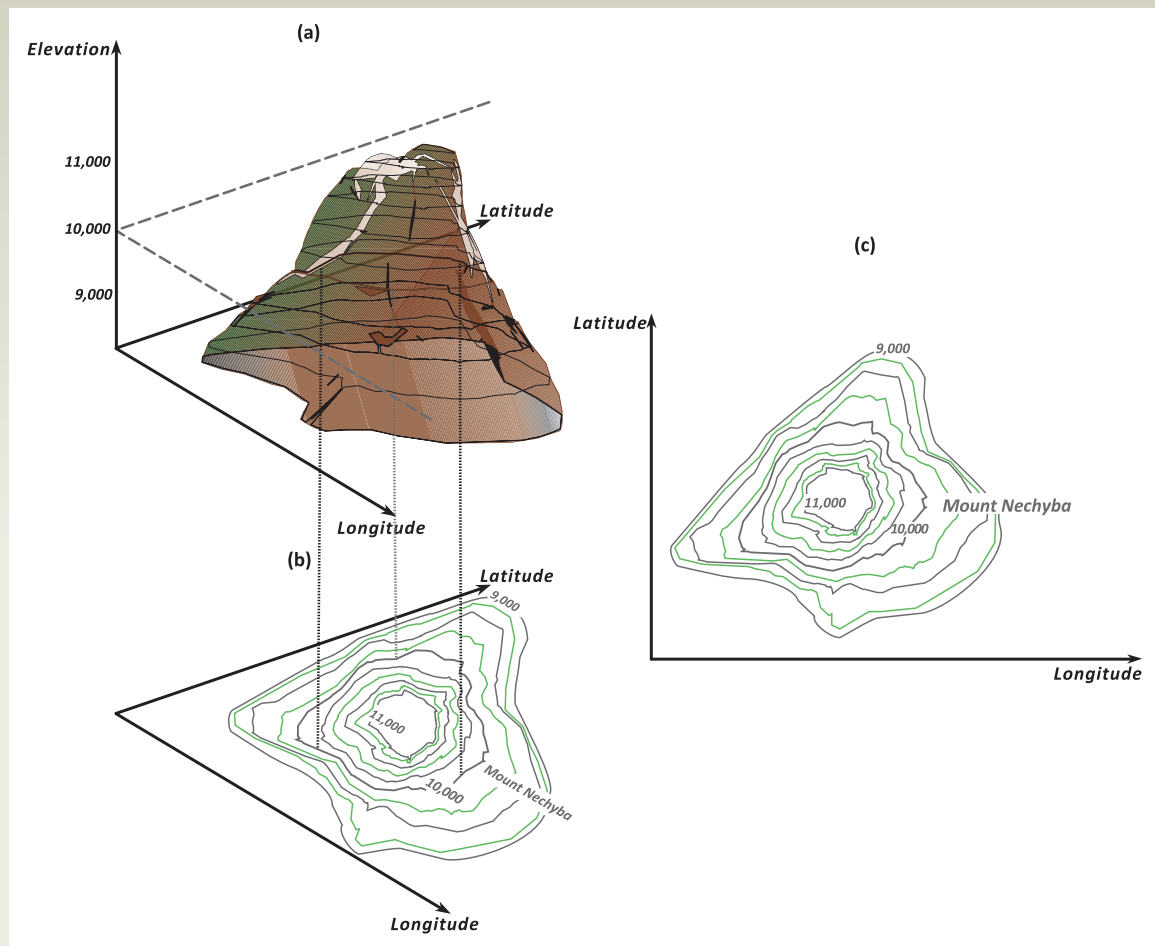

As already suggested in part A of the chapter, this relationship between utility functions and indifference curves becomes more intuitive when we relate it to something that most of us have no trouble with: The reading of maps of the geography of a particular region of a country. Graph 4.9 is an example of the kind of map I have in mind. The map itself is two-dimensional; it fits nicely on a single page of this book. But the map actually represents a three-dimensional mountain. It does so by indicating different elevations of the mountain with numbers next to quasi-circular lines that together tell us how far above sea level the points on those lines are. This is a clever way of illustrating a three-dimensional object in a two-dimensional picture. In Graph 4.10a and 4.10b, we illustrate exactly how this is done, with Graph 4.10a plotting the three-dimensional mountain’s height on the vertical axis, and Graph 4.10b plotting two-dimensional slices of this mountain and indicating the appropriate elevation next to it.

EXERCISE 4B.4 If you were searching for the steepest possible straight route up the last 2,000 feet of Mount Nechyba (in Graph 4.9), from what direction would you approach the mountain?

Indifference curves are exactly analogous to these levels of a three-dimensional mountain plotted in two dimensions. Instead of representing the geographical terrain of an area, they

GRAPH 4.9 “Mount Nechyba” Graphed in Two Dimensions

GRAPH 4.10 Going from Three to Two Dimensions for “Mount Nechyba”

illustrate the height of a “utility mountain” that rises as more goods enter a bundle. But unlike real mountains, the utility mountain generally has no peak because our “more is better” assumption implies that we can always climb higher by going to bundles of goods that have more of everything in them. Thus, the slices of our utility mountain are not closed circles like those of mountains with peaks but rather are open ended.

In political science models, politicians are sometimes assumed to choose between bundles of spending on various issues, say military and domestic spending. Since they have to impose taxes to fund this spending, more is not necessarily better than less, and thus most politicians have some ideal bundle of domestic and military spending. How would such tastes over domestic and military spending be similar to the geographic mountain analogy?

EXERCISE 4B.5

4B.3.2 Marginal Rates of Substitution In Section 4A.3.2, we defined the slope of the indifference curve as the marginal rate of substitution, or how much one is willing to give up in terms of one good (the good on the vertical axis) to get 1 more unit of another (the good on the

horizontal axis). This slope is a mathematical concept, and one that can be derived from a utility function that gives rise to particular kinds of indifference curves.

One way to express the definition of a marginal rate of substitution in terms of the mathematical language we have been developing is to say that it is the change in x_2 divided by the change in x_1 such that utility remains unchanged, or

$$\frac{\Delta x_2}{\Delta x_1} \text{ such that } \Delta u = 0. \quad (4.15)$$

Actually, what we mean by a marginal rate of substitution is somewhat more precise; we are not looking for just *any* combination of changes in x_2 and x_1 (such that $\Delta u = 0$). Rather, we are looking for small changes that define the slope around a particular point. Such small changes are denoted in calculus by using “*d*” instead of “ Δ .” Thus, we can rewrite (4.15) as

$$\frac{dx_2}{dx_1} \text{ such that } du = 0. \quad (4.16)$$

The following step now requires some knowledge of multivariable calculus. If you have only had single variable calculus, you will need to read this chapter’s appendix on total and partial differentiation before proceeding.

Changes in utility arise from the combined change in x_2 and x_1 consumption, and this is expressed as the total differential (du)

$$du = \frac{\partial u}{\partial x_1} dx_1 + \frac{\partial u}{\partial x_2} dx_2. \quad (4.17)$$

Since we are interested in changes in consumption that result in no change in utility (thus leaving us on the same indifference curve), we can set expression (4.17) to zero

$$\frac{\partial u}{\partial x_1} dx_1 + \frac{\partial u}{\partial x_2} dx_2 = 0 \quad (4.18)$$

and then solve out for dx_2/dx_1 to get

$$\frac{dx_2}{dx_1} = -\frac{(\partial u/\partial x_1)}{(\partial u/\partial x_2)}. \quad (4.19)$$

Since this expression for dx_2/dx_1 was derived from the expression $du = 0$, it gives us the equation for small changes in x_2 divided by small changes in x_1 such that utility remains unchanged, which is precisely our definition of a marginal rate substitution. Thus, if we know that a particular utility function u gives rise to an indifference map that accurately represents someone’s tastes, we now know how to calculate the marginal rate of substitution for that person at any consumption bundle (x_1, x_2) with

$$MRS(x_1, x_2) = -\frac{(\partial u/\partial x_1)}{(\partial u/\partial x_2)}. \quad (4.20)$$

Suppose, for instance, your tastes for pants (x_1) and shirts (x_2) can be summarized by the utility function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$ (which is graphed in Graph 4.8a), and suppose that we would like to determine the marginal rate of substitution when you are consuming 4 pants and 3 shirts. We can begin by finding the general expression for your marginal rate of substitution given that you have tastes summarized by this utility function. To do this, we have to take the partial derivative of u with respect to each of the two goods,

$$\frac{\partial u}{\partial x_1} = \left(\frac{1}{2}\right)(x_1^{-1/2}x_2^{1/2}) \text{ and } \frac{\partial u}{\partial x_2} = \left(\frac{1}{2}\right)(x_1^{1/2}x_2^{-1/2}) \quad (4.21)$$

and plug the results into the formula for MRS in equation (4.20) to get:

$$MRS = - \frac{(1/2)(x_1^{-1/2}x_2^{1/2})}{(1/2)(x_1^{1/2}x_2^{-1/2})} = - \frac{x_2}{x_1}. \quad (4.22)$$

This simplified expression, $MRS = -x_2/x_1$, then gives us the formula for the slope of all your indifference curves at every possible bundle in \mathbb{R}_+^2 assuming that these indifference curves can indeed be represented by the utility function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$. For instance, if you are currently consuming 4 pants (x_1) and 3 shirts (x_2), your marginal rate of substitution is equal to $-3/4$. If you are consuming 10 pants and 1 shirt, your marginal rate of substitution is $-1/10$, and if you are consuming 1 pair of pants and 10 shirts, it is -10 .

How does the expression for the marginal rate of substitution change if tastes could instead be summarized by the utility function $u(x_1, x_2) = x_1^{1/4}x_2^{3/4}$?

EXERCISE 4B.6

4B.3.3 Interpreting Values Assigned to Indifference Curves by Utility Functions

At this point, you may have gotten a little suspicious. After all, we made a big deal in Section 4A.3.3 about the fact that happiness or “utility” cannot be measured objectively and yet we seem to be measuring utility here with utility functions. When discussing the numbers next to indifference curves in Graph 4.5, we indicated that the numbers themselves were not important; it was the ordering of the numbers that mattered because we were simply using the numbers to indicate which indifference curves yield more happiness and which yield less. And we mentioned that we could just as easily have multiplied the numbers in Graph 4.5 by 2 or divided them by 5 or added 13 to them because in each case, the *ordering* of indifference curves would remain unchanged. We concluded that, *so long as the shape of indifference curves and the ordering of the numbers that accompany the curves are unchanged between two graphs, the maps of indifference curves in the two graphs represent the same tastes.*

The same is true of utility functions. You can think of these functions as rulers that use some scale to measure utility. We can adjust the scale: *As long as two functions give rise to the same shapes of indifference curves and as long as the ordering of the numbers assigned to these indifference curves is the same, the two functions represent the same underlying tastes.* All we are doing is using a different ruler. Again, it might be easy to see exactly what we mean here by returning to the mountain analogy. In Graph 4.10a, we used a “ruler” with “feet from sea level” to measure the height of a mountain, and we then translated slices of this mountain into two dimensions, placing the appropriate height of that slice (measured in feet) next to each slice in Graph 4.10b. Suppose that we had instead used a “ruler” with “meters from sea level” in Graph 4.10a. The height of the mountain might now be scaled differently, but the slices of the mountain would continue to exhibit the same shapes in Graph 4.10b, except that they would be accompanied by a different number indicating height since it would be expressed in meters instead of feet. Nothing fundamental changes when we change the units of measurement on our ruler.

A person's tastes can be represented by many different utility functions.

Consider the utility function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$ that we graphed in Graph 4.8a and that is replicated in Graph 4.11a. Now consider the same function squared, that is, $v(x_1, x_2) = (x_1^{1/2}x_2^{1/2})^2 = x_1x_2$, which is graphed in Graph 4.11c. The functions certainly look different, but it turns out that they give rise to exactly the same indifference curves in panels (b) and (d) just like the two differently measured versions of the same mountain give rise to the same two-dimensional picture of its levels. To prove this mathematically, all we have to do is check whether the two utility functions give rise to the same expression for the marginal rate of substitution because if the slopes of the indifference curves are the same at all points, the shapes of the

GRAPH 4.11 Rescaling Graph 4.8a

indifference curves must be the same. First, we find the partial derivatives of v with respect to each good (as we did for u in (4.21)):

$$\frac{\partial v}{\partial x_1} = x_2 \quad \text{and} \quad \frac{\partial v}{\partial x_2} = x_1. \quad (4.23)$$

These expressions certainly differ from the analogous derivatives for u in equation (4.21). They represent the additional (or marginal) utility you would obtain from 1 more unit of consumption of each of the two goods, and this additional utility differs depending on what ruler we use to measure utility. It therefore makes sense that the two different utility functions, u and v , have different partial derivatives with respect to each of the two goods. (For this reason, we do not think that there is any real content in the concept of “marginal utility.”) But when we then plug the results in equation (4.23) into our formula for a marginal rate of substitution in equation (4.20), we get that the marginal rate of substitution implied by the utility function v is again

equal to $-x_2/x_1$, just as it was when we calculated the marginal rate of substitution for the utility function u in equation (4.22).

Can you verify that squaring the utility function in exercise 4B.6 also does not change the underlying indifference curves?

EXERCISE 4B.7

You can see the intuition for what happened by comparing the partial derivatives in equation (4.21) and (4.23). While they are different, they are different only in ways that cancel out when we divide one partial derivative by the other as we calculate the marginal rate of substitution. Put differently, the units that measure marginal utility drop out of the equation when we divide two marginal utilities by each other. Thus, *the concept of a marginal rate of substitution is independent of what scale we use to measure utility*, and is thus meaningful even though we do not think utility itself can be objectively quantified.

MRS does not depend on how utility is measured.

Illustrate that the same conclusion we reached with respect to u and v representing the same indifference curves also holds when we take the square root of u ; that is when we consider the function $w(x_1, x_2) = (x_1^{1/2}x_2^{1/2})^{1/2} = x_1^{1/4}x_2^{1/4}$.

EXERCISE 4B.8

The idea that a rescaling of a utility function cancels out when we calculate marginal rates of substitution can be seen to hold more generally. Consider a function $f: \mathbb{R}^1 \rightarrow \mathbb{R}^1$ that is applied to a utility function $u(x_1, x_2)$ to create a new utility function $v(x_1, x_2) = f(u(x_1, x_2))$. (In our previous example, for instance, we applied the function $f(x) = x^2$ to get $v(x_1, x_2) = f(u(x_1, x_2)) = f(x_1^{1/2}x_2^{1/2}) = (x_1^{1/2}x_2^{1/2})^2 = x_1x_2$.) The partial derivatives of v with respect to the two goods are then

$$\frac{\partial v}{\partial x_1} = \frac{\partial f}{\partial u} \frac{\partial u}{\partial x_1} \quad \text{and} \quad \frac{\partial v}{\partial x_2} = \frac{\partial f}{\partial u} \frac{\partial u}{\partial x_2}. \quad (4.24)$$

When we divide these two terms by each other as we calculate the marginal rate of substitution, the $(\partial f/\partial u)$ terms cancel and we get

$$-\frac{(\partial v/\partial x_1)}{(\partial v/\partial x_2)} = -\frac{(\partial u/\partial x_1)}{(\partial u/\partial x_2)}. \quad (4.25)$$

Applying a transformation f to a utility function u therefore does not change the shapes of indifference curves since it does not change their marginal rates of substitutions; it simply relabels indifference curves with different numbers. So long as the ordering of the numbers assigned to indifference curves remains the same, the transformed utility function then represents the same tastes. Such transformations are sometimes called *order preserving* or *positive monotone* functions. Multiplying a utility function by 5, for instance, simply results in a number 5 times as high associated with each indifference curve. Multiplying the same utility function by -5 , on the other hand, results in the label of each indifference curve being -5 times what it was before; as a result, the ordering of the indifference curves is reversed, suggesting that indifference curves previously judged better than a particular bundle are now worse than that bundle. The former transformation (multiplying by 5) is therefore order preserving while the latter (multiplying by -5) is not even though both transformations preserve the shapes of the indifference curves. In end-of-chapter exercise 4.5, you will investigate some other possible transformations

of utility functions, but it should be clear from our discussion that *once we have found one utility function that represents a particular set of tastes (or indifference curves), we can find a large number of other utility functions that also represent those tastes* by subjecting the original utility function to a variety of different transformations.

EXERCISE 4B.9 Consider the utility function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$. Take natural logs of this function and calculate the MRS of the new function. Can the natural log transformation be applied to utility functions such that the new utility function represents the same underlying tastes?

EXERCISE 4B.10 Consider the utility function $u(x_1, x_2, x_3) = x_1^{1/2}x_2^{1/2}x_3^{1/2}$. Take natural logs of this function and calculate the marginal rates of substitution of each pair of goods. Can the natural log transformation be applied to utility functions of three goods such that the new utility function represents the same underlying tastes?

CONCLUSION

In this chapter, we have begun our investigation of how economists can model tastes, sometimes also called *preferences*. By making some basic rationality assumptions that ensure an individual is able to make choices (completeness and transitivity), we are able to graph tastes by illustrating bundles of goods over which an individual is indifferent. By making some additional assumptions that make sense in many economic settings (continuity, convexity, monotonicity), these indifference curves were shown to take on particular shapes. Maps of “indifference curves,” accompanied by numbers indicating which bundles are preferred to others, then provide complete descriptions of tastes. These maps can be represented mathematically as levels of utility functions, much as rings on geographic maps are levels of a more general function that represents the height of mountains. Because we do not think that there are objective measures of “utility,” we also showed that there are many different utility functions that can represent the same indifference map. While the actual number assigned to each indifference curve by a utility function thus has little meaning, the slope of indifference curves, known as the *marginal rate of substitution*, does carry real economic meaning because it tells us how easily an individual is willing to trade one good for another (depending on how many of each he or she currently has). As in previous chapters, the mathematical analog to our graphical tools permits us to expand our analysis to more than two goods.

In Chapter 6, we will begin our analysis of how tastes (as represented by indifference curves and utility functions) combine with our economic circumstances (as represented by budget constraints) to lead us to make optimal economic *choices*. Before taking this step, however, we will step back in Chapter 5 to investigate the different types of tastes that can be represented within the model we have introduced here.

APPENDIX: SOME BASICS OF MULTIVARIABLE CALCULUS

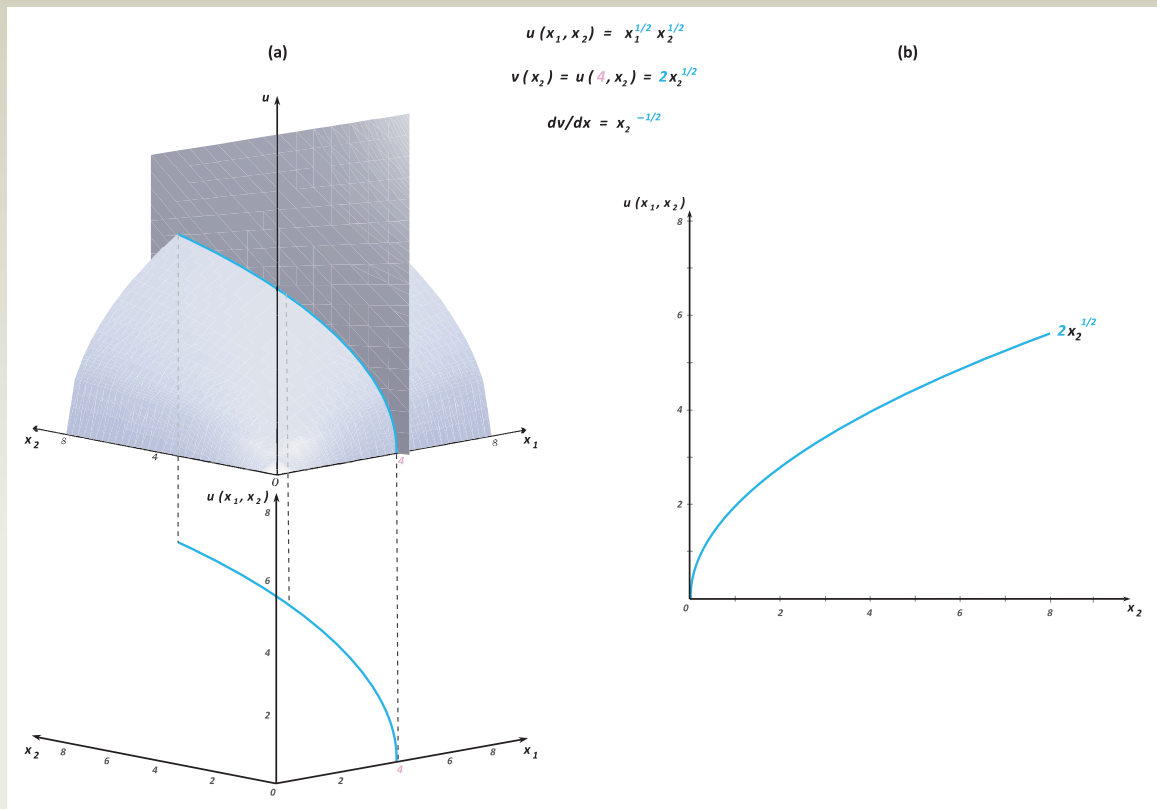

Some colleges and universities require a full three-semester calculus sequence for economics majors. If you have taken such a sequence, you will already have covered all the required calculus concepts used in this book and many calculus concepts that are not necessary for what we are trying to do. Often, however, economics majors are required to take only a single semester of calculus. Typically, this means that you will have covered *single-variable differentiation* but not differentiation involving functions of multiple variables. This appendix is intended to cover the basics of extending single-variable differentiation to functions of multiple variables without going into the level of detail that you would encounter in a full calculus sequence.

Single-variable functions take the form $y = f(x)$ such as the function graphed in Graph 4.7, which graphs $y = f(x) = x^2$. As you know from your first calculus course, the derivative (or slope) of this function is $df/dx = 2x$. Utility functions, however, are typically multivariable functions because we are interested in the trade-offs consumers make between different goods. For instance, we graphed in Graph 4.8a the function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$. The difference between a single-variable function and a function of multiple variables is simply that the former assigns a number to points on the real line \mathbb{R}^1 while the latter assigns numbers to points in a higher dimensional space. A single-variable function is therefore denoted as a rule that assigns a real number to elements of the real line, or $f: \mathbb{R}^1 \rightarrow \mathbb{R}^1$. A multivariable function $y = f(x_1, x_2, \dots, x_n)$, on the other hand, is a formula that assigns a real number to points with n components and is therefore denoted $f: \mathbb{R}^n \rightarrow \mathbb{R}^1$.

Partial Derivatives

Any multivariable function becomes a single-variable function if we hold all but “one” variable fixed. Consider, for instance, the utility function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$ and suppose that we want to ask how utility (as measured by this function) changes when x_2 changes while $x_1 = 4$. In that case, we are holding the x_1 variable fixed at 4 and are operating on a “slice” of the three-dimensional function depicted in Graph 4.12a. This slice is just a single-variable function $v(x_2) = u(4, x_2) = 2x_2^{1/2}$ (since the square root of 4 is 2) and is depicted in panel (a) of the graph and separately in panel (b).

GRAPH 4.12 A Single-Variable “Slice” of a Multivariable Function

From your single-variable calculus background, you already know how to take the *derivative* of the function $v(x_2)$ in panel (b) of the graph. This derivative $dv/dx = x_2^{-1/2}$ is then simply the slope of the slice of the two-variable function $u(x_1, x_2)$ depicted in panel (a). It is also called the *partial derivative of u with respect to x_2 when $x_1 = 4$* .

More generally, we can take the partial derivative of u with respect to x_2 by simply treating the x_1 variable as a constant. This partial derivative is denoted $\partial u/\partial x_2$ and is calculated exactly the same way you would calculate a derivative of a single-variable function in which x_1 is just a constant; that is,

$$\frac{\partial u}{\partial x_2} = \left(\frac{1}{2}\right) x_1^{1/2} x_2^{-1/2}. \quad (4.26)$$

This then gives us the derivative of a slice of the utility function $u(x_1, x_2)$ that holds x_1 constant at some value. For instance, when $x_1 = 4$ (as we assumed before), the expression reduces to $x_2^{-1/2}$ and represents the slope of the slice in Graph 4.12 at different values of x_2 .

EXERCISE 4B.11 What would be the expression of the slope of the slice of the utility function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$ when x_1 is fixed at 9? What is the slope of that slice when $x_2 = 4$?

Such partial derivatives of a utility function give us the *marginal utility* of an additional unit of a consumption good when the quantity of all other consumption goods is held fixed. As we discuss extensively in the main part of the chapter, this concept in and of itself is not economically meaningful because it is expressed in “units of happiness” that we do not believe can be measured objectively. Nevertheless, as we see in Section 4B.3.3, the economically meaningful concept of a marginal rate of substitution is composed of 2 marginal utility values divided by each other (thus canceling out the “units of happiness”). When we get to producer theory where “units of output” are economically meaningful concepts, these partial derivatives themselves will also become economically meaningful.

EXERCISE 4B.12 Calculate $\partial u/\partial x_1$ for $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$. What does this reduce to when x_2 is fixed at 4? Where in Graph 4.12 does the slice along which this partial derivative represents the slope lie?

EXERCISE 4B.13 Calculate $\partial u/\partial x_1$ for the function $u(x_1, x_2) = 10 \ln x_1 + 5 \ln x_2$.

EXERCISE 4B.14 Calculate $\partial u/\partial x_1$ for the function $u(x_1, x_2) = (2x_1 + 3x_2)^3$. (Remember to use the Chain Rule.)

Total Differential of Multivariable Functions

While a partial derivative of a function like $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$ tells us the rate at which utility will change if the quantity of one of the two goods in a consumption bundle is increased by a small amount (as the quantity of the other consumption good stays fixed), we might also be interested in how the utility changes when the quantity of both consumption goods changes by small amounts. The *total differential* of the function u then measures the change in utility resulting from small changes in both x_1 and

x_2 .¹² Letting dx_1 and dx_2 represent such small changes, the total differential du is expressed mathematically as

$$du = \frac{\partial u}{\partial x_1} dx_1 + \frac{\partial u}{\partial x_2} dx_2 \quad (4.27)$$

which, for the utility function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$, is

$$du = \frac{x_2^{1/2}}{2x_1^{1/2}} dx_1 + \frac{x_1^{1/2}}{2x_2^{1/2}} dx_2. \quad (4.28)$$

Verify that equation (4.28) is correct.

EXERCISE
4B.15

Notice that if $dx_1 = 0$, that is, if x_1 does not change and only x_2 changes, equation (4.27) reduces to

$$du = \frac{\partial u}{\partial x_2} dx_2, \quad (4.29)$$

which is called the *partial differential* of u with respect to x_2 .

Calculate the total differential du of $u(x_1, x_2) = 10 \ln x_1 + 5 \ln x_2$.

EXERCISE
4B.16

END-OF-CHAPTER EXERCISES

- 4.1[†]** I hate grits so much that the very idea of owning grits repulses me. I do, on the other hand, enjoy a good breakfast of Cocoa Puffs cereal.
- A.** In each of the following, put “boxes of grits” on the horizontal axis and “boxes of cereal” on the vertical. Then graph three indifference curves and number them.
- Assume that my tastes satisfy the convexity and continuity assumptions and otherwise satisfy the previous description.
 - How would your answer change if my tastes were “non-convex”; that is, if averages were worse than extremes?
 - How would your answer to (a) change if I hated both Cocoa Puffs and grits but we again assumed my tastes satisfy the convexity assumption?
 - What if I hated both goods and my tastes were non-convex?

¹² There is a distinction between the total *differential* and the total *derivative* of a multivariable function. For now, we are concerned only with the total differential (which is used in the main part of this chapter).

*conceptually challenging

**computationally challenging

[†]solutions in Study Guide

- B.** Now suppose you like both grits and Cocoa Puffs, that your tastes satisfy our five basic assumptions, and that they can be represented by the utility function $u(x_1, x_2) = x_1x_2$.
- Consider two bundles, $A = (1,20)$ and $B = (10,2)$. Which one do you prefer?
 - Use bundles A and B to illustrate that these tastes are in fact convex.
 - What is the *MRS* at bundle A ? What is it at bundle B ?
 - What is the simplest possible transformation of this function that would represent tastes consistent with those described in A(d)?
 - Now consider tastes that are instead defined by the function $u(x_1, x_2) = x_1^2 + x_2^2$. What is the *MRS* of this function?
 - Do these tastes have diminishing marginal rates of substitution? Are they convex?
 - How could you most easily turn this utility function into one that represents tastes like those described in A(c)?

4.2 Consider my wife's tastes for grits and cereal.

- A.** Unlike me, my wife likes both grits and cereal, but for her, averages (between equally preferred bundles) are worse than extremes.
- On a graph with "boxes of grits" on the horizontal and "boxes of cereal" on the vertical, illustrate three indifference curves that would be consistent with my description of my wife's tastes.
 - Suppose we ignored labels on indifference curves and simply looked at shapes of the curves that make up our indifference map. Could my indifference map look the same as my wife's if I hate both cereal and grits? If so, would my tastes be convex?
- B.** Consider the utility function $u(x_1, x_2) = x_1^2 + 4x_2^2$.
- Could this utility function represent the tastes you graphed in part A(a)?
 - How could you transform this utility function to be consistent with my tastes as described in A(b)?

4.3[†] Consider my tastes for consumption and leisure.

- A.** Begin by assuming that my tastes over consumption and leisure satisfy our five basic assumptions.
- On a graph with leisure hours per week on the horizontal axis and consumption dollars per week on the vertical, give an example of 3 indifference curves (with associated utility numbers) from an indifference map that satisfies our assumptions.
 - Now redefine the good on the horizontal axis as "labor hours" rather than "leisure hours." How would the same tastes look in this graph?
 - How would both of your graphs change if tastes over leisure and consumption were non-convex, that is, if averages were worse than extremes?
- B.** Suppose your tastes over consumption and leisure could be described by the utility function $u(\ell, c) = \ell^{1/2}c^{1/2}$.
- Do these tastes satisfy our five basic assumptions?
 - Can you find a utility function that would describe the same tastes when the second good is defined as labor hours instead of leisure hours? (*Hint:* Suppose your weekly endowment of leisure time is 60 hours. How does that relate to the sign of the slopes of indifference curves you graphed in part A(b)?)
 - What is the marginal rate of substitution for the function you just derived? How does that relate to your graph from part A(b)?
 - Do the tastes represented by the utility function in part (b) satisfy our five basic assumptions?

4.4 Basket A contains 1 unit of x_1 and 5 units of x_2 . Basket B contains 5 units of x_1 and 1 unit of x_2 . Basket C contains 3 units of x_1 and 3 units of x_2 . Assume throughout that tastes are monotonic.

- A.** On Monday, you are offered a choice between basket A and C , and you choose A . On Tuesday you are offered a choice between basket B and C , and you choose B .

- Graph these baskets on a graph with x_1 on the horizontal and x_2 on the vertical axis.
- If I know your tastes on any given day satisfy a strict convexity assumption, by which I mean that averages are strictly better than extremes, can I conclude that your tastes have changed from Monday to Tuesday?
- Suppose I only know that your tastes satisfy a weak convexity assumption, by which I mean that averages are at least as good as extremes. Suppose also that I know your tastes have not changed from Monday to Tuesday. Can I conclude anything about the precise shape of one of your indifference curves?

B. Continue to assume that tastes satisfy the monotonicity assumption.

- State formally the assumption of “strict convexity” as defined in part A(b).
- Suppose your tastes over x_1 and x_2 were strictly non-convex—averages are strictly worse than extremes. State this assumption formally. Under this condition, would your answer to part A(b) change?
- Consider the utility function $u(x_1, x_2) = x_1 + x_2$. Demonstrate that this captures tastes that give rise to your conclusion about the shape of one of the indifference curves in part A(c).

4.5[†] In this exercise, we explore the concept of marginal rates of substitution (and, in part B, its relation to utility functions) further.

A. Suppose I own 3 bananas and 6 apples, and you own 5 bananas and 10 apples.

- With “bananas” on the horizontal axis and “apples” on the vertical, the slope of my indifference curve at my current bundle is -2 , and the slope of your indifference curve through your current bundle is -1 . Assume that our tastes satisfy our usual 5 assumptions. Can you suggest a trade to me that would make both of us better off? (Feel free to assume we can trade fractions of apples and bananas.)
- After we engage in the trade you suggested, will our *MRS*'s have gone up or down (in absolute value)?
- If the values for our *MRS*'s at our current consumption bundles were reversed, how would your answers to (a) and (b) change?
- What would have to be true about our *MRS*'s at our current bundles in order for you not to be able to come up with a mutually beneficial trade?
- True or False:* If we have different tastes, then we will always be able to trade with both of us benefiting.
- True or False:* If we have the same tastes, then we will never be able to trade with both of us benefiting.

B. Consider the following 5 utility functions and assume that α and β are positive real numbers:

$$\begin{aligned}
 1. \quad u^A(x_1, x_2) &= x_1^\alpha x_2^\beta \\
 2. \quad u^B(x_1, x_2) &= \alpha x_1 + \beta x_2 \\
 3. \quad u^C(x_1, x_2) &= \alpha x_1 + \beta \ln x_2 \\
 4. \quad u^D(x_1, x_2) &= \left(\frac{\alpha}{\beta}\right) \ln x_1 + \ln x_2 \\
 5. \quad u^E(x_1, x_2) &= -\alpha \ln x_1 - \beta \ln x_2
 \end{aligned} \tag{4.30}$$

- Calculate the formula for *MRS* for each of these utility functions.
- Which utility functions represent tastes that have linear indifference curves?
- Which of these utility functions represent the same underlying tastes?
- Which of these utility functions represent tastes that do not satisfy the monotonicity assumption?
- Which of these utility functions represent tastes that do not satisfy the convexity assumption?
- Which of these utility functions represent tastes that are not rational (i.e., that do not satisfy the completeness and transitivity assumptions)?

- g. Which of these utility functions represent tastes that are not continuous?
- h. Consider the following statement: “Benefits from trade emerge because we have different tastes. If individuals had the same tastes, they would not be able to benefit from trading with one another.” Is this statement ever true, and if so, are there any tastes represented by the utility functions in this problem for which the statement is true?

4.6 Everyday Application: Rating Movies on a Numerical Scale: My wife and I often go to movies and afterward assign a rating ranging from 0 to 10 to the movie we saw.

- A. Suppose we go to see a double feature, first *Terminator 2* with the great actor Arnold Schwarzenegger and then the adaptation of Jane Austin’s boring novel *Emma*. Afterward, you hear me say that I rated *Terminator 2* as an 8 and *Emma* as a 2, and you hear my wife comment that she rated *Terminator 2* a 5 and *Emma* a 4.
 - a. Do my wife and I agree on which movie is better?
 - b. How would your answer change if my wife’s ratings had been reversed?
 - c. Can you tell for sure whether I liked *Terminator 2* more than my wife did?
 - d. Often, my wife and I then argue about our rankings. *True or False:* It makes little sense for us to argue if we both rank one movie higher than the other even if we assign very different numbers.
- B. Suppose that the only thing I really care about in evaluating movies is the fraction of “action” time (as opposed to thoughtful conversation) and let the fraction of screen time devoted to action be denoted x_1 . Suppose that the only thing my wife cares about when evaluating movies is the fraction of time strong women appear on screen, and let that fraction be denoted x_2 . *Terminator 2* has $x_1 = 0.8$ and $x_2 = 0.5$ while *Emma* has $x_1 = 0.2$ and $x_2 = 0.4$.
 - a. Consider the functions $u(x_1) = 10x_1$ and $v(x_2) = 10x_2$ and suppose that I use the function u to determine my movie rating and my wife uses the function v . What ratings do we give to the two movies?
 - b. One day, I decide that I will assign ratings differently, using the function $\bar{u}(x_1) = 5.25x_1^{1/6}$. Will I rank any pair of movies differently using this function rather than my previous function u ? What approximate values do I now assign to *Terminator 2* and *Emma*?
 - c. My wife also decides to change her way of assigning ratings to movies. She will now use the function $\bar{v}(x_2) = 590x_2^{6.2}$. Will her rankings of any two movies change as a result? What approximate values does she now assign to the two movies?
 - d. Suppose my wife had instead chosen the function $\underline{v}(x_2) = 10(1 - x_2)$. Will she now rank movies differently?

4.7*† Everyday Application: Did 9/11 Change Tastes?: In another textbook, the argument is made that consumer tastes over “airline miles traveled” and “other goods” changed as a result of the tragic events of September 11, 2001.

- A. Here, we will see how you might think of that argument as true or false depending on how you model tastes.
 - a. To see the reasoning behind the argument that tastes changed, draw a graph with “airline miles traveled” on the horizontal axis and “other goods” (denominated in dollars) on the vertical. Draw an indifference curve from the map of indifference curves that represent a typical consumer’s tastes (and that satisfy our usual assumptions).
 - b. Pick a bundle on the indifference curve on your graph and denote it A . Given the perception of increased risk, what do you think happened to the typical consumer’s MRS at this point after September 11, 2001?
 - c. For a consumer who perceives a greater risk of air travel after September 11, 2001, what is likely to be the relationship of the indifference curves from the old indifference map to the indifference curves from the new indifference map at every bundle?
 - d. Within the context of the model we have developed so far, does this imply that the typical consumer’s tastes for air travel have changed?

- e. Now suppose that we thought more comprehensively about the tastes of our consumer. In particular, suppose we add a third good that consumers care about: “air safety.” Imagine a three-dimensional graph, with “air miles traveled” on the horizontal axis and “other goods” on the vertical (as before), and with “air safety” on the third axis coming out at you. Suppose “air safety” can be expressed as a value between 0 and 100, with 0 meaning certain death when one steps on an airplane and 100 meaning no risk at all. Suppose that before 9/11, consumers thought that air safety stood at 90. On the slice of your three-dimensional graph that holds air safety constant at 90, illustrate the pre-9/11 indifference curve that passes through (x_1^A, x_2^A) , the level of air miles traveled (x_1^A) and other goods consumed (x_2^A) before 9/11.
- f. Suppose the events of 9/11 cause air safety to fall to 80. Illustrate your post-9/11 indifference curve through (x_1^A, x_2^A) on the slice that holds air safety constant at 80 but draw that slice on top of the one you just drew in (e).
- g. Explain that while you could argue that our tastes changed in our original model, in a bigger sense you could also argue that our tastes did not change after 9/11, only our circumstances did.
- B.** Suppose an average traveler’s tastes can be described by the utility function $u(x_1, x_2, x_3) = x_1 x_3 + x_2$, where x_1 is miles traveled by air, x_2 is “other consumption,” and x_3 is an index of air safety that ranges from 0 to 100.
- Calculate the *MRS* of other goods for airline miles; that is, the *MRS* that represents the slope of the indifference curves when x_1 is on the horizontal and x_2 is on the vertical axis.
 - What happens to the *MRS* when air safety (x_3) falls from 90 to 80?
 - Is this consistent with your conclusions from part A? In the context of this model, have tastes changed?
 - Suppose that $u(x_1, x_2, x_3) = x_1 x_2 x_3$ instead. Does the *MRS* of other consumption for air miles traveled still change as air safety changes? Is this likely to be a good model of tastes for analyzing what happened to consumer demand after 9/11?
 - What if $u(x_1, x_2, x_3) = x_2 x_3 + x_2$?

4.8* Everyday Application: Tastes of a Cocaine Addict: Fred is addicted to cocaine. Suppose we want to model his tastes over cocaine and other goods.

- A.** I propose to model his tastes in the following way: For any two bundles A and B of “grams of cocaine” and “dollars of other consumption,” I will assume that Fred always prefers bundle A if it contains more grams of cocaine than bundle B . If bundles A and B contain the same amount of cocaine, then I will assume he prefers A to B if and only if A contains more other consumption than B .
- On a graph with “grams of cocaine” on the horizontal axis and “other consumption” (denominated in dollars) on the vertical, denote one arbitrary bundle as A . Then indicate all the bundles that are strictly preferred to A .
 - On a separate graph, indicate all bundles that are strictly less preferred than A .
 - Looking over your two graphs, is there any bundle that Fred would say gives him exactly as much happiness as A ? Are there any two bundles (not necessarily involving bundle A) that Fred is indifferent between?
 - In order for this to be a useful model for studying Fred’s behavior, how severe would Fred’s addiction have to be?
 - Are these tastes rational? In other words, are they complete and transitive?
 - Do these tastes satisfy the monotonicity property?
 - Do they satisfy the convexity property?
- B.** The tastes previously defined are called *lexicographic*. Formally, we can define them as follows: For any $A, B \in \mathbb{R}_+^2$, $A > B$ if either “ $x_1^A > x_1^B$ ” or “ $x_1^A = x_1^B$ and $x_2^A > x_2^B$.”
- In this formal definition, which good is cocaine, x_1 or x_2 ?
 - On a graph with x_1 on the horizontal axis and x_2 on the vertical, pick an arbitrary bundle $A = (x_1^A, x_2^A)$. Then pick a second bundle $D = (x_1^D, x_2^D)$ such that $x_1^A = x_1^D$ and $x_2^A > x_2^D$.

- c. On your graph, illustrate an infinite sequence of bundles (B^1, B^2, B^3, \dots) that converges to A from the left. Then illustrate an infinite sequence of bundles (C^1, C^2, C^3, \dots) that converges to D from the right.
- d. *True or False:* Every bundle in the C -sequence is strictly preferred to every bundle in the B -sequence.
- e. *True or False:* Bundle A is strictly preferred to bundle D .
- f. Based on the answers you just gave to (d) and (e), do lexicographic tastes satisfy the continuity property?
- g. Can these tastes be represented by a utility function?

4.9† Business Application: Tastes for Cars and Product Characteristics: People buy all sorts of different cars depending on their income levels as well as their tastes. Industrial organization economists who study product characteristic choices (and advise firms like car manufacturers) often model consumer tastes as tastes over product characteristics (rather than as tastes over different types of products). We explore this concept here.

- A. Suppose people cared about two different aspects of cars: the size of the interior passenger cabin and the quality of handling of the car on the road.
 - a. Putting $x_1 =$ “cubic feet of interior space” on the horizontal axis and $x_2 =$ “speed at which the car can handle a curved mountain road” on the vertical, where would you generally locate the following types of cars assuming that they will fall on one line in your graph: a Chevrolet minivan, a Porsche 944, and a Toyota Camry.
 - b. Suppose we considered three different individuals whose tastes satisfy our five basic assumptions, and suppose each person owns one of the three types of cars. Suppose further that each indifference curve from one person’s indifference map crosses any indifference curve from another person’s indifference map at most once. (When two indifference maps satisfy this condition, we often say that they satisfy the *single crossing property*.) Now suppose you know person A’s *MRS* at the Toyota Camry is larger (in absolute value) than person B’s, and person B’s *MRS* at the Toyota Camry is larger (in absolute value) than person C’s. Who owns which car?
 - c. Suppose we had not assumed the “single crossing property” in part (a). Would you have been able to answer the question “Who owns which car” assuming everything else remained the same?
 - d. Suppose you are currently person B and you just found out that your uncle has passed away and bequeathed to you his three children, aged 4, 6, and 8 (and nothing else). This results in a change in how you value space and maneuverability. Is your new *MRS* at the Toyota Camry now larger or smaller (in absolute value)?
 - e. What are some other features of cars that might matter to consumers but that you could not fit easily into a two-dimensional graphical model?
- B. Let x_1 denote cubic feet of interior space and let x_2 denote maneuverability as defined in part A. Suppose that the tastes of persons A, B, and C can be represented by the utility functions $u^A(x_1, x_2) = x_1^\alpha x_2$, $u^B(x_1, x_2) = x_1^\beta x_2$, and $u^C(x_1, x_2) = x_1^\gamma x_2$ respectively.
 - a. Calculate the *MRS* for each person.
 - b. Assuming α, β , and γ take on different values, is the “single crossing property” defined in part A(b) satisfied?
 - c. Given the description of the three people in part A(b), what is the relationship between α, β , and γ ?
 - d. How could you turn your graphical model into a mathematical model that includes factors you raised in part A(e)?

4.10* Business Application: Investor Tastes over Risk and Return: Suppose you are considering where to invest money for the future.

- A. Like most investors, you care about the expected return on your investment as well as the risk associated with the investment. But different investors are willing to make different kinds of trade-offs relative to risk and return.

- a. On a graph, put risk on the horizontal axis and expected return on the vertical. (For purposes of this exercise, don't worry about the precise units in which these are expressed.) Where in your graph would you locate "safe" investments like inflation indexed government bonds, investments for which you can predict the rate of return with certainty?
 - b. Pick one of these "safe" investment bundles of risk and return and label it A . Then pick a riskier investment bundle B that an investor could plausibly find equally attractive (given that risk is bad in the eyes of investors while expected returns are good).
 - c. If your tastes are convex and you only have investments A and B to choose from, would you prefer diversifying your investment portfolio by putting half of your investment in A and half in B ?
 - d. If your tastes are non-convex, would you find such diversification attractive?
- B.** Suppose an investor has utility function $u(x_1, x_2) = (R - x_1)x_2$ where x_1 represents the risk associated with an investment, x_2 is the expected return, and R is a constant.
- a. What is the MRS of risk for return for this investor?
 - b. Suppose A is a risk-free investment, with $x_1^A = 0$, and suppose that B is risky but our investor is indifferent between A and B . What must the return x_2^A on the risk-free investment be in terms of x_1^B and x_2^B ?
 - c. Do this investor's tastes satisfy convexity? Illustrate by considering whether this investor would be willing to switch from A or B in part (b) to putting half his investment in A and half in B .
 - d. Suppose $R = 10$ for our investor. Imagine he is offered the following three investment portfolios: (1) a no-risk portfolio of government bonds with expected return of 2 and 0 risk; (2) a high-risk portfolio of volatile stocks with expected return of 10 and risk of 8; (3) or a portfolio that consists half of government bonds and half of volatile stocks, with expected return of 6 and risk of 4. Which would he choose?
 - e. Suppose a second investor is offered the same three choices. This investor is identical to the first in every way, except that R in her utility function is equal to 20 instead of 10. Which portfolio will she choose?
 - f. *True or False:* The first investor's tastes are convex while the second one's are not.
 - g. What value of R would make the investor choose the no-risk portfolio?

4.11*† Policy Application: Ideology and Preferences of Politicians: Political scientists often assume that politicians have tastes that can be thought of in the following way: Suppose that the two issues a politician cares about are domestic spending and military spending. Put military spending on the horizontal axis and domestic spending on the vertical axis. Then each politician has some "ideal point," some combination of military and domestic spending that makes him or her happiest.

- A.** Suppose that a politician cares only about how far the actual policy bundle is from his or her ideal point, not the direction in which it deviates from his or her ideal point.
- a. On a graph, pick any arbitrary "ideal point" and illustrate what 3 indifference "curves" would look like for such a politician. Put numerical labels on these to indicate which represent more preferred policy bundles.
 - b. On a separate graph, illustrate how tastes would be different for a political conservative (who likes a lot of military spending but is not as keen on domestic spending), a liberal (who likes domestic spending but is not as interested in military spending), and a libertarian (who does not like government spending in any direction to get very large).
 - c. This way of graphing political preferences is a short cut because it incorporates directly into tastes the fact that there are taxes that have to pay for government spending. Most politicians would love to spend increasingly more on everything, but they don't because of the increasing political cost of having to raise taxes to fund spending. Thus, there are really three goods we could be modeling: military spending, domestic spending, and taxes, where a politician's tastes are monotone in the first two goods but not in the last. First, think of this as three goods over which tastes satisfy all our usual assumptions—including *monotonicity* and *convexity*—where we define the goods as spending on military, spending on domestic goods, and the "relative

absence of taxes.” What would indifference “curves” for a politician look like in a three-dimensional graph? Since it is difficult to draw this, can you describe it in words and show what a two-dimensional slice looks like if it holds one of the goods fixed?

- d. Now suppose you model the same tastes, but this time you let the third good be defined as “level of taxation” rather than “relative absence of taxes.” Now monotonicity no longer holds in one dimension. Can you now graph what a slice of this three-dimensional indifference surface would look like if it holds domestic spending fixed and has taxes on the horizontal and military spending on the vertical axis? What would a slice look like that holds taxes fixed and has domestic spending on the horizontal and military spending on the vertical axis?
 - e. Pick a point on the indifference curve you drew for the slice that holds taxes fixed. How does the *MRS* at that point differ for a conservative from that of a liberal?
 - f. Pick a point on the slice that holds domestic spending fixed. How would the *MRS* at that point differ for a libertarian compared to a conservative?
- B.** Consider the following equation $u(x_1, x_2) = P - ((x_1 - a)^2 + (x_2 - b)^2)$.
- a. Can you verify that this equation represents tastes such as those described in this problem (and graphed in part A(a))?
 - b. What would change in this equation as you model conservative, liberal, and libertarian politicians?
 - c. Do these tastes satisfy the convexity property?
 - d. Can you think of a way to write a utility function that represents the tastes you were asked to envision in A(c) and A(d)? Let t represent the tax rate with an upper bound of 1.

4.12 Policy Application: Subsistence Levels of Consumption: Suppose you are interested in modeling a policy issue involving poor households in an underdeveloped country.

- A.** The households we are trying to model are primarily worried about survival, with a minimum quantity of certain goods (like food and water) necessary for survival. Suppose that one cannot live without at least 4 liters of water per week and at least 7,500 calories of food per week. These quantities of water and food are then *subsistence levels* of water and food.
- a. Suppose you graph weekly liters of water on the horizontal axis and weekly intake of calories on the vertical. Indicate the bundle required for subsistence.
 - b. If life below the subsistence quantities is not sustainable, we might find it reasonable not to model tastes below the subsistence quantities. Illustrate a plausible map of indifference curves that takes this into account.
 - c. Subsistence levels are a biological reality for all of us, not just for the poor in developing countries. Why might we nevertheless not worry about explicitly modeling subsistence levels for policy analysis in richer countries?
- B.** The following utility function is known as the *Stone-Geary utility function*: $u(x_1, x_2) = (x_1 - \bar{x}_1)^\alpha (x_2 - \bar{x}_2)^{(1-\alpha)}$, where $0 < \alpha < 1$.
- a. When interpreted as a model of tastes such as those described in part A, what are the subsistence levels of x_1 and x_2 ?
 - b. How does this utility function treat tastes below subsistence levels?
 - c. What is the *MRS* when consumption is above subsistence levels?
 - d. Suppose that instead of water and food for someone poor in the developing world, we modeled calories from food (x_1) and dollars spent on vacations (x_2) for someone in the developed world (taking for granted that he or she is consuming his or her desired quantity of water). How would you modify the Stone-Geary utility function assuming that you still want to recognize the absence of tastes for food levels below subsistence?

4.13*† In this exercise, we will explore some logical relationships between families of tastes that satisfy different assumptions.

- A.** Suppose we define a strong and a weak version of convexity as follows: Tastes are said to be *strongly convex* if whenever a person with those tastes is indifferent between A and B , the person strictly prefers the average of A and B (to A and B). Tastes are said to be *weakly convex* if whenever a person

with those tastes is indifferent between A and B , the average of A and B is at least as good as A and B for that person.

- Let the set of all tastes that satisfy strong convexity be denoted as SC and the set of all tastes that satisfy weak convexity as WC . Which set is contained in the other? (We would, for instance, say that “ WC is contained in SC ” if any taste that satisfies weak convexity also automatically satisfies strong convexity.)
 - Consider the set of tastes that are contained in one and only one of the two sets defined previously. What must be true about some indifference curves on any indifference map from this newly defined set of tastes?
 - Suppose you are told the following about three people: Person 1 strictly prefers bundle A to bundle B whenever A contains more of each and every good than bundle B . If only some goods are represented in greater quantity in A than in B while the remaining goods are represented in equal quantity, then A is at least as good as B for this person. Such tastes are often said to be *weakly monotonic*. Person 2 likes bundle A strictly better than B whenever at least some goods are represented in greater quantity in A than in B while others may be represented in equal quantity. Such tastes are said to be *strongly monotonic*. Finally, person 3’s tastes are such that for every bundle A , there always exists a bundle B very close to A that is strictly better than A . Such tastes are said to satisfy *local nonsatiation*. Call the set of tastes that satisfy strict monotonicity SM , the set of tastes that satisfy weak monotonicity WM , and the set of tastes that satisfy local non-satiation L . Give an example of tastes that fall in one and only one of these three sets.
 - What is true about tastes that are in one and only one of these three sets?
 - What is true of tastes that are in one and only one of the sets SM and WM ?
- B.** Here, we will consider the logical implications of convexity for utility functions. For the following definitions, $0 \leq \alpha \leq 1$. A function $f: \mathbb{R}_+^2 \rightarrow \mathbb{R}^1$ is defined to be *quasiconcave* if and only if the following is true: Whenever $f(x_1^A, x_2^A) \leq f(x_1^B, x_2^B)$, then $f(x_1^A, x_2^A) \leq f(\alpha x_1^A + (1 - \alpha)x_1^B, \alpha x_2^A + (1 - \alpha)x_2^B)$. The same type of function is defined to be *concave* if and only if $f(\alpha x_1^A, x_2^A) + (1 - \alpha)f(x_1^B, x_2^B) \leq f(\alpha x_1^A + (1 - \alpha)x_1^B, \alpha x_2^A + (1 - \alpha)x_2^B)$.
- True or False:* All concave functions are quasiconcave, but not all quasiconcave functions are concave.
 - Demonstrate that, if u is a quasiconcave utility function, the tastes represented by u are convex.
 - Do your conclusions imply that if u is a concave utility function, the tastes represented by u are convex?
 - Demonstrate that if tastes over two goods are convex, any utility functions that represents those tastes must be quasiconcave.
 - Do your conclusions imply that if tastes over two goods are convex, any utility function that represents those tastes must be concave?
 - Do the previous conclusions imply that utility functions that are not quasiconcave represent tastes that are not convex?

4.14* In this exercise, you will prove that as long as tastes satisfy rationality, continuity, and monotonicity, there always exists a well-defined indifference map (and utility function) that can represent those tastes.¹³

- A.** Consider a two-good world, with goods x_1 and x_2 represented on the two axes in any graphs you draw.
- Draw your two axes and pick some arbitrary bundle $A = (x_1^A, x_2^A)$ that contains at least some of each good.
 - Draw the 45-degree line in your graph. This is a ray that represents all bundles that have equal amounts of x_1 and x_2 in them.
 - Pick a second bundle $B = (x_1^B, x_2^B)$ such that $x_1^B = x_2^B$ and $x_1^B > \max\{x_1^A, x_2^A\}$. In other words, pick B such that it has equal amounts of x_1 and x_2 and such that it has more of x_1 and x_2 than A .

¹³ It can actually be demonstrated that this is true as long as tastes satisfy rationality and continuity only, but it is easier to demonstrate the intuition if we also assume monotonicity.

- d. Is A more or less preferred than the bundle $(0,0)$? Is B more or less preferred than A ?
 - e. Now imagine moving along the 45-degree line from $(0,0)$ toward B . Can you use the continuity property of tastes we have assumed to conclude that there exists some bundle C between $(0,0)$ and B such that the consumer is indifferent between A and C ?
 - f. Does the same logic imply that there exists such an indifferent bundle along *any* ray from the origin and not just along the 45-degree line?
 - g. How does what you have just done demonstrate the existence of a well-defined indifference map?
- B.** Next, we show that the same logic implies that there exists a utility function that represents these tastes.
- a. If you have not already done so, illustrate A(a)–(e).
 - b. Denote the distance from $(0,0)$ to C on the 45-degree line as $t_A = t(x_1^A, x_2^A)$, and assign the value t_A to the bundle A .
 - c. Imagine the same procedure for labeling each bundle in your graph; that is, for each bundle, determine what bundle on the 45-degree line is indifferent and label the bundle with the distance on the 45-degree line from $(0,0)$ to the indifferent bundle. The result is a function $u(x_1, x_2)$ that assigns to every bundle a number. Can you explain how this function meets our definition of a utility function?
 - d. Can you see how the same method of proof would work to prove the existence of a utility function when there are more than two goods (and when tastes satisfy rationality, continuity and monotonicity)?
 - e. Could we have picked a ray other than the 45-degree line to construct the utility values associated with each bundle?

Different Types of Tastes

In Chapter 4, we demonstrated how tastes can be represented by maps of indifference curves and how five basic assumptions about tastes result in particular features of these indifference curves.¹ In addition, we illustrated how tastes can be more formally defined and how these can be mathematically represented as utility functions. We now proceed to analyzing how maps of indifference curves can differ in important ways while still satisfying our five basic assumptions. This will tell us much about how different types of tastes can be modeled using our simple graphical framework as well as the more general mathematical framework that builds on our graphically derived intuitions. For instance, if two goods are close substitutes for one another, the indifference map that represents a consumer's tastes for these goods will look very different from one representing tastes for goods that are close complements, even though both types of indifference maps will satisfy our five basic assumptions. Shapes of indifference curves then translate into specific types of functional forms of utility functions.

One of the important insights that should emerge from this chapter is that our basic model of tastes is enormously general and allows us to consider all sorts of tastes that individuals might have. You may like apples more than oranges, but I may like oranges more than apples; you may think peanut butter and jelly go together well, but I may think they can't touch each other; you may see little difference between French wine and California wine, but I may think one is barely drinkable. Often, students that are introduced to indifference curves get the impression that they all look pretty much the same, but we will find here that their shapes and relationships to one another can vary greatly, and that this variation produces a welcome diversity of possible tastes that is necessary to analyze a world as diverse as ours.

5A

DIFFERENT TYPES OF INDIFFERENCE MAPS

Understanding how different tastes can be graphed will therefore be important for understanding how consumer behavior differs depending on what the consumer's underlying tastes are. We will begin in Section 5A.1 by discussing the shape of *individual* indifference curves for different types of goods. This will give us a way of talking about the degree to which consumers feel

¹Chapter 4 is necessary as background reading for this chapter.

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

that different goods are substitutable for one another and the degree to which goods have their own distinct character. We then proceed in Section 5A.2 with a discussion of *how indifference curves from an indifference map relate to one another* depending on what kinds of goods we are modeling. This will tell us how a consumer's perception of the value of one good relative to others changes as happiness, or what we will later call "real income," increases. Finally, we conclude in Section 5A.3 by exploring the characteristic of indifference maps that determines how "essential" particular goods are to our perceived well-being, how some goods are the kinds of goods we just can't live without while others are not essential for our happiness.

5A.1 Substitutability along an Indifference Curve: Coke, Pepsi, and Iced Tea

The extent to which two goods are substitutes depends on the nature of the goods we are modeling as well as the types of tastes that individuals have. For instance, Coke and Pepsi are more similar to one another than many other goods. In fact, I personally have trouble telling the difference between Coke and Pepsi. As a result, when my wife and I go to a restaurant and I order Coke, I am not upset if the waiter informs me that the restaurant only serves Pepsi; I simply order a Pepsi instead. My wife, on the other hand, has a strong preference for Coke, and she will switch to iced tea if she finds out that a restaurant serves Pepsi instead of Coke. I think she is nuts for thinking Coke and Pepsi are so different and attribute it to still-unresolved childhood issues. She, on the other hand, thinks my family might have grown up near a nuclear test site whose radiation emissions have destroyed some vital taste buds. (She thinks it might explain some of my other oddities as well.) Be that as it may, it is clear that Coke and Pepsi are less substitutable for her than for me.

5A.1.1 Perfect Substitutes Suppose, then, that we want to model my tastes for Coke and Pepsi. We could begin by thinking about some arbitrary bundle that I might presently consume, say, 1 can of Coke and 1 can of Pepsi. We could then ask what other bundles might be of equal value to me given that I cannot tell the difference between the products. For instance, 2 cans of Coke and no cans of Pepsi should be just as good for me, as should 2 cans of Pepsi and no cans of Coke. Thus, each of these three bundles must lie on the same indifference curve for someone with my tastes, as must any other linear combination, such as 1.5 cans of Coke and 0.5 cans of Pepsi. In Graph 5.1, these bundles are plotted and connected by a (blue) line. Each point on this line represents some combination of Coke and Pepsi that adds up to 2 cans, which is after all the only thing that matters to someone who can't tell the difference between the products. We could of course construct other indifference curves as well, such as those representing quantities of Coke and Pepsi that add up to 1 can or 3 cans, as also depicted in Graph 5.1.

The tastes we have graphed represent tastes over goods that are *perfect substitutes*. Such tastes are unusual in the sense that one of our five basic assumptions is already "almost" violated. In particular, notice that averages are no longer *better than* extremes; rather, averages are valued *the same as* extremes when two goods are perfect substitutes. (1 can of Coke and 1 can of Pepsi is the average between the more extreme bundles of 2 Cokes or 2 Pepsis, but it is equally valued by a consumer with the tastes we have graphed here.) This also implies that the slope of each indifference curve is constant, giving us constant rather than diminishing marginal rates of substitution. Upon reflection, it should make intuitive sense that marginal rates of substitution are constant in this case. After all, no matter how much or how little Coke I have, I will always be willing to trade 1 Coke for 1 Pepsi.

Students often ask if it has to be true that one is willing to trade goods one-for-one (i.e., that the *MRS* equals -1) in order for goods to be perfect substitutes. Different textbooks give different answers to such questions, but the only answer that makes sense to me is to say no, the defining characteristic of perfect substitute is not that $MRS = -1$, but rather that the *MRS* is the same everywhere. Even when $MRS = -1$ (as in my Coke and Pepsi example), I could change

The *MRS* is the same everywhere if two goods are perfect substitutes.

GRAPH 5.1 Indifference Curves for Perfect Substitutes

Go to MindTap to interact with this graph.

the units with which I measure quantities of Coke and Pepsi and get a different *MRS* without changing a person's tastes. The next within-chapter-exercise demonstrates this, and the idea is extended in exercise 5A.2.

How would the graph of indifference curves change if Coke came in 8-ounce cans and Pepsi came in 4-ounce cans?

EXERCISE 5A.1

On a graph with "quarters" (that are worth 25 cents) on the horizontal axis and "dimes" (that are worth 10 cents) on the vertical, what might your indifference curves look like? Use the same method we just employed to graph my indifference curves for Coke and Pepsi by beginning with one arbitrary bundle of quarters and dimes (say 4 quarters and 5 dimes) and then asking which other bundles might be just as good.

EXERCISE 5A.2

5A.1.2 Perfect Complements When my wife orders an iced tea in restaurants (after learning that the restaurant serves Pepsi rather than Coke), I have observed that she adds exactly 1 packet of sugar to the tea before drinking it. If there is less than a packet of sugar available, she will leave the iced tea untouched, whereas if there is more than 1 packet of sugar available, the additional sugar will remain unused unless she gets more iced tea.² From this somewhat compulsive behavior, I have concluded that iced tea and sugar are *perfect complements* for my wife: They complement each other to the point that she gets no satisfaction from consuming 1 unit of one without also consuming 1 unit of the other.

We can model my wife's tastes for iced tea and sugar by again starting with an arbitrary point and then asking which other bundles will make her indifferent. Suppose we start with 1 pack of sugar and 1 glass of iced tea. Together, these two represent the ingredients for 1 acceptable

² Actually that's not quite right: I really like sugar, so when she is not looking, I usually pour the remaining sugar into my mouth. Unfortunately, my wife views such behavior as thoroughly antisocial rather than charmingly quaint, and I usually have to endure a speech about having been raised in a barn whenever she catches me.

beverage. Now suppose I gave my wife another pack of sugar without any additional iced tea, giving her a bundle of 2 sugar packs and 1 glass of iced tea. Since this would still only give her 1 acceptable beverage, she would be no better (and no worse) off; that is, she would be indifferent. The same is true for a bundle containing any number of sugar packs greater than 1 so long as the bundle included only 1 glass of iced tea, and it would be true for any number of additional glasses of iced tea if only 1 sugar pack were available. The blue indifference curve with a right angle at 1 iced tea and 1 sugar pack in Graph 5.2 then represents all bundles that, given my wife's tastes, result in 1 acceptable beverage for her. Similar indifference curves exist for bundles that add up to 2 or 3 acceptable beverages.

Notice that, as in the case of perfect substitutes, perfect complements represent an extreme case in the sense that some of our five basic assumptions about tastes are almost violated. In particular, more is no longer necessarily better in the case of perfect complements, only more of *both* goods is better. Similarly, averages are not always better than extremes, as for bundles of goods that lie on the linear portions of the indifference curves where averages are just as good as extremes.³

EXERCISE 5A.3 What would my wife's indifference curves for packs of sugar and glasses of iced tea look like if she required 2 packs of sugar instead of 1 for each glass of iced tea?

5A.1.3 Less Extreme Cases of Substitutability and Complementarity Rarely do goods fall into either of the two extreme cases of perfect complements or perfect substitutes. Rather, goods tend to be relatively more or less substitutable depending on their inherent

GRAPH 5.2 Indifference Curves for Perfect Complements

Go to MindTap to interact with this graph.

³ Tastes that do not allow for substitutability between goods are sometimes referred to as *Leontief* tastes after Wassily Leontief (1906–1999), who extensively used a similar notion in producer theory. Leontief was awarded the Nobel Prize in Economics in 1973.

GRAPH 5.3 Indifference Curves for Less Extreme Cases of Substitutability and Complementarity

characteristics and the underlying tastes for the person whose tastes we are modeling. Such less extreme examples will then have shapes falling between the two extremes in Graphs 5.1 and 5.2, as for instance the tastes for goods x_1 and x_2 graphed in Graph 5.3a through 5.3c. Here, unlike for the case of perfect complements, a person is indeed willing to substitute some of x_2 for some of x_1 , but not always in the same proportions as would be true for perfect substitutes. In particular, a person with such tastes would be willing to substitute x_2 for x_1 more easily if the current bundle has a lot of x_2 and little x_1 , and this willingness to substitute one for the other decreases as the person moves to bundles that contain relatively more x_1 than x_2 . This is of course true because of the embedded assumption that averages are better than extremes, an assumption that, as we showed in the previous chapter, leads to diminishing marginal rates of substitution.

For the tastes modeled in Graph 5.3a, this willingness to substitute x_1 for x_2 changes relatively little as the underlying bundle changes, thus giving rise to indifference curves that are relatively flat and close in shape to those of tastes representing perfect substitutes. Tastes modeled in Graph 5.3c, on the other hand, are such that the willingness to substitute x_1 for x_2 changes relatively quickly along at least a portion of each indifference curve, thus giving rise to indifference curves whose shape is closer to those of perfect complements. Keeping the extremes of perfect substitutes and perfect complements in mind, it then becomes relatively easy to look at particular maps of indifference curves and discern whether they contain a relatively high or a relatively low degree of substitutability. This degree of substitutability decreases as we move from panel (a) to panels (b) and (c) in Graph 5.3.

The degree of substitutability will play an important role in our discussion of consumer behavior and consumer welfare in the next several chapters. It may at first seem like a trivial concept when applied to simple examples like Coke and Pepsi, but it becomes one of the most crucial concepts in controversies surrounding such issues as tax and retirement policy. In such debates, the degree of substitutability between current and future consumption or between consumption and leisure takes center stage, as we will see in later chapters.

The degree of substitutability between goods is related to the curvature of indifference curves.

Suppose I told you that each of the indifference maps graphed in Graph 5.3 corresponded to my tastes for one of the following sets of goods, which pair would you think corresponds to which map? Pair 1: Levi Jeans and Wrangler Jeans; Pair 2: Pants and Shirts; Pair 3: Jeans and Dockers pants.

EXERCISE 5A.4

5A.2 Some Common Indifference Maps

In our discussions of the degree of substitutability between goods, our focus was solely on the shape of particular indifference curves, and in particular on the curvature of the indifference curves and the rate at which the marginal rates of substitution change as one moves along a single indifference curve. A second important feature of indifference maps centers on *the relationship of indifference curves to one another rather than the shape of individual indifference curves*. How, for instance, do marginal rates of substitution change along a linear ray from the origin? How do they change holding fixed one of the goods? Do indifference curves touch the axes? And what do such features of indifference maps tell us about the underlying tastes of individuals? In the following section, we will take each of these questions and define particular types of tastes that represent important special cases that may be relevant for modeling tastes over different kinds of goods.

5A.2.1 Homothetic Tastes Let's begin by assuming that I currently consume bundle A in Graph 5.4a: 3 pants and 3 shirts. And suppose that you know that the indifference curve that contains bundle A has a marginal rate of substitution of -1 at bundle A , which implies that I am willing to exchange 1 shirt for 1 pair of pants whenever I have 3 of each. Now suppose you give me 3 additional pants and 3 additional shirts, thus doubling what I had originally at bundle A . This will put me on a new indifference curve, one that contains the new bundle B . Would it now be reasonable for us to expect that my marginal rate of substitution is still -1 at B ?

Perhaps it would be reasonable for this particular example. After all, the reason my marginal rate of substitution might be -1 at point A is that I like to change pants and shirts roughly at the same intervals *when I have equal numbers of pants and shirts*. If so, the important determinant of my marginal rate of substitution is the number of pants I have *relative to* the number of shirts, which is unchanged between points A and B . Put differently, if I change pants and shirts at equal intervals when I have 3 of each, I am probably changing them at equal intervals when I have 6 of each and am thus willing to trade them off for one another (at the margin) one-for-one. (Remember, however, that when we say that the MRS is -1 at A , we mean that you are willing to trade

GRAPH 5.4 Homothetic Tastes, Marginal Rates of Substitution, and Indifference Curves

very small quantities of pants and shirts one-for-one, not necessarily 1 entire pair of pants for 1 entire shirt. This is what I mean when I say that I am willing to trade them one-for-one *on the margin*. As we noted earlier, while it is awkward to think of pants and shirts as divisible goods, it is a useful modeling simplification and one that usually is not overly restrictive when we talk about bigger examples that matter more than pants and shirts.)

A similar argument could hold for other bundles on the indifference curve that contains bundle A . For instance, bundle A' contains 4 shirts and 2 pants, and the indifference curve shows a marginal rate of substitution of -2 at A' . Thus, I would be willing to give up 2 shirts to get 1 more pair of pants if I were currently consuming bundle A' because shirts are not of as much value to me when I have so few pants relative to shirts. But then it sounds plausible for the marginal rate of substitution to remain the same if you doubled A' to B' : I still have relatively many shirts compared with pants and thus might still be willing to trade 2 shirts for 1 pair of pants at B' .

Whenever tastes exhibit the property that marginal rates of substitution at particular bundles depend only on how much of one good relative to the other is contained in that bundle, we will say that tastes are homothetic. This technical term means nothing more than what we have already described for my tastes for pants and shirts: Whenever you determine the marginal rate of substitution at one particular bundle, you know that the marginal rate of substitution at all other bundles that lie on a ray connecting the origin and the original bundle is exactly the same. This is true because the amount of one good *relative* to the other is unchanged along this ray. Graph 5.4b illustrates three indifference curves of such a homothetic indifference map.

In Chapter 6, we will see how consumers with homothetic tastes will choose to double their current consumption basket whenever their income doubles. Tastes for certain “big-ticket” consumption goods can thus be quite accurately modeled using homothetic tastes because they represent goods that we consume in rough proportion to our income. For many consumers, for instance, the square footage of housing consumed increases linearly with income. Similarly, as we think of modeling our tastes for consumption across different time periods, it may be reasonable to assume that our tastes are homothetic and that we will choose to increase our consumption this year and next year by the same proportion if our yearly income doubles.

In concluding our discussion of homothetic tastes, it is important to note that when we say that someone’s tastes are homothetic, we are making a statement about how different indifference curves relate to one another; we are *not* saying anything in particular about the shape of individual indifference curves. For instance, you should be able to convince yourself that homothetic tastes could incorporate many different degrees of substitutability by thinking about the following:

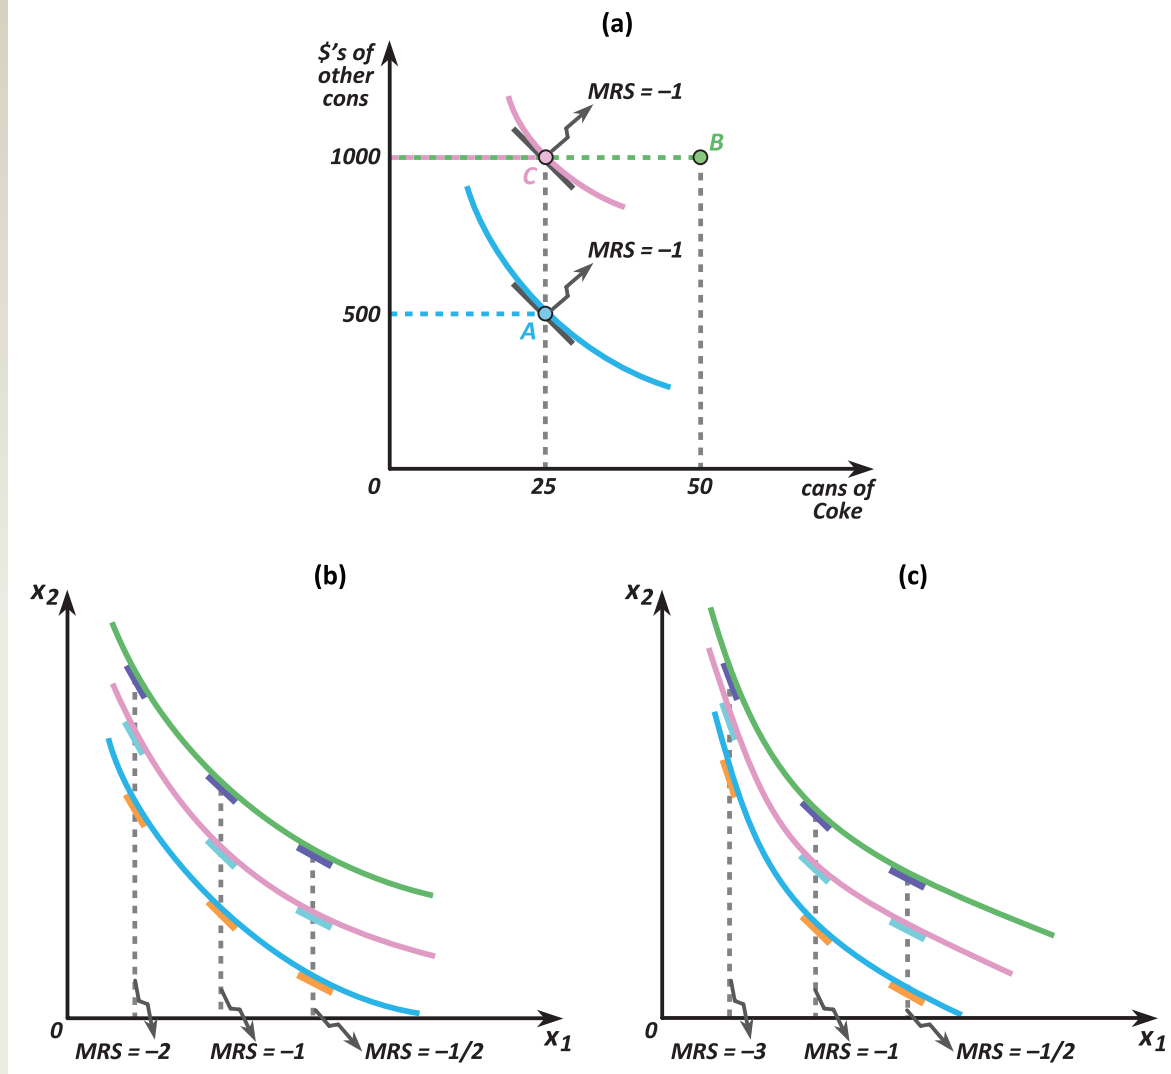

Homothetic indifference maps have constant MRS along all rays from the origin.

Are my tastes over Coke and Pepsi as described in Section 5A.1 homothetic? Are my wife’s tastes over iced tea and sugar homothetic? Why or why not?

EXERCISE
5A.5

5A.2.2 Quasilinear Tastes While the assumption that marginal rates of substitution at different consumption bundles depend only on the relative quantities of goods at those bundles is plausible for many applications, there are also many important instances when the assumption does not seem reasonable. Consider, for instance, my tastes for weekly soft drink consumption and a composite good representing my weekly consumption of all other goods in dollars.

Suppose we begin with a bundle A in Graph 5.5a, a bundle that contains 25 soft drinks and \$500 in other consumption. My indifference curve has a slope of -1 at that bundle, indicating that, given my current consumption bundle A , I am willing to give up \$1 in other consumption for 1 additional soft drink. Now suppose that you enabled me to consume at double my current consumption: point B with 50 soft drinks and \$1,000 in other consumption. Does it seem likely that I would value the 50th soft drink in bundle B the same as I valued the 25th soft drink in

GRAPH 5.5 Quasilinear Tastes, Marginal Rates of Substitution and Indifference Curves

bundle *A*? If so, my tastes would again be homothetic. But it is much more likely that there is room for only so many soft drinks in my stomach during any week, and even if you enable me to consume a lot more in other goods, I would still not value additional soft drinks very highly. In that case, my marginal rate of substitution at point *B* would be less than 1 in absolute value; that is, I would be willing to consume additional soft drinks at bundle *B* only if I had to give up less than \$1 in additional consumption.

In many examples like this, a more accurate description of tastes might be that my marginal rate of substitution depends *only* on how many soft drinks I am consuming, not on how much in other consumption I have during the same week. Consider, for instance, point *C* in Graph 5.5a—a bundle containing \$1,000 in other consumption and 25 soft drinks. It may well be that my willingness to trade dollars for additional soft drinks does not change at all between points *A* and

C ; whether I am consuming \$500 or \$1,000 in other goods, I will still only consume any soft drinks beyond 25 if I can get them for less than \$1 in other consumption. If this is the case, then my tastes will be such that my marginal rate of substitution is *the same along any vertical line* in Graph 5.5a. Two examples of indifference maps that satisfy this property are depicted in Graphs 5.5b and 5.5c.

Tastes for goods that are valued at the margin the same regardless of how much of the “other good” we are consuming are called *quasilinear* tastes. Goods that are likely to be modeled well using quasilinear tastes tend to be goods that represent a relatively small fraction of our income. They are goods that we tend to consume the same quantity of even if we get a big raise. Many goods that we consume probably fall into this category—milk, soft drinks, paper clips, and so on—but some clearly do not. For instance, we cited tastes for housing as an example better modeled as homothetic because housing is, at the margin, valued more highly as we become better off. More generally, it will become clearer in Chapter 6 that tastes for many big-ticket consumption items are not likely to be well modeled using the quasilinear specification of indifference maps.

The *MRS* for a quasilinear good depends only on the quantity consumed of that good.

Are my tastes over Coke and Pepsi as described in Section 5A.1 quasilinear? Are my wife’s tastes over iced tea and sugar quasilinear? Why or why not?

EXERCISE
5A.6

5A.2.3 Homothetic versus Quasilinear Tastes Tastes, then, are quasilinear in a particular good if the marginal rate of substitution between this and “the other” good depends only on the *absolute quantity* of the “quasilinear” good (and is thus independent of how much of “the other” good a consumer has in his or her consumption bundle). Graphically, this means that the marginal rate of substitution is the same along lines that are perpendicular to the axis on which we model the good that is “quasilinear.” Tastes are homothetic, on the other hand, if the marginal rate of substitution at any given bundle depends only on the quantity of one good *relative* to the quantity of the other. Graphically, this means that the marginal rates of substitution across indifference curves are the same along rays emanating from the origin of the graph. You will understand the difference between these if you feel comfortable with the following:

Can you explain why tastes for perfect substitutes are the only tastes that are both quasilinear and homothetic?⁴

EXERCISE
5A.7

5A.3 “Essential” Goods

There is one final dimension along which we can categorize indifference maps: whether or not the indifference curves intersect one or both of the axes in our graphs. Many of the indifference maps we have drawn so far have indifference curves that *converge* to the axes of the graphs without ever touching them. Some, such as those representing quasilinear tastes, however, intersect one or both of the axes. The distinction between indifference maps of the first and second kind will become important in the next chapter as we consider what we can say about the “best” bundle that individuals who are seeking to do the best they can given their circumstances will choose.

For now, we will say little more about this but simply indicate that the difference between these two types of tastes has something to do with how “essential” both goods are to the well-being of an individual. Take, for example, my tastes for Coke and Pepsi. When we model such

⁴In end-of-chapter exercise 5.1, you will work with limit cases of perfect substitutes, cases where the indifference curves become perfectly vertical or perfectly horizontal. For purposes of our discussions, we will treat such limiting cases as members of the family of perfect substitutes.

tastes, neither of the goods is in and of itself very essential since I am indifferent between bundles that contain both goods and bundles that contain only one of the two goods. This is not true for the case of perfect complements such as iced tea and sugar for my wife. For her, neither iced tea nor sugar is of any use unless she has both in her consumption bundle. In that sense, we could say both goods are “essential” for her well-being, at least so long as our model assumes she consumes only iced tea and sugar.

If both goods are essential, indifference curves do not cross either axis.

More generally, suppose we compare the indifference map in Graph 5.6a to that in Graph 5.6b. In the first graph, the indifference curves converge to the vertical axis (without touching it) while they *intersect* the horizontal axis. Therefore, there are bundles that contain no quantity of good x_2 (such as A and C) that are just as good as bundles that contain both x_1 and x_2 (such as B and D). In some sense, x_2 is therefore not as essential as x_1 . In the second graph (Graph 5.6b), on the other hand, bundles must always contain some of each good in order for the individual to be happier than he or she is without consuming anything at all at the origin. And, an individual is indifferent to any bundle that contains both goods (like bundle E) *only if* the second bundle (like F) also contains some of both goods. In that sense, both goods are quite essential to the well-being of the individual.

EXERCISE 5A.8

True or False: Quasilinear goods are never essential.

GRAPH 5.6 x_2 is “Essential” in (b) but not in (a)

5B

DIFFERENT TYPES OF UTILITY FUNCTIONS

The different types of tastes we have illustrated graphically so far can of course also be represented by utility functions, with particular classes of utility functions used to represent different degrees of substitutability as well as different relationships of indifference curves to one another. We therefore now take the opportunity to introduce some common types of utility functions that generalize precisely the kinds of intuitive concepts we illustrated graphically in Section 5A.

5B.1 Degrees of Substitutability and the “Elasticities of Substitution”

In Section 5A.1, we described different shapes of indifference curves that imply different levels of substitutability. For instance, my tastes for Coke and Pepsi were illustrated with linear indifference curves in Graph 5.1, a shape for indifference curves that indicates perfect substitutability between the two goods. The opposite extreme of no substitutability was illustrated using my wife’s tastes for sugar and iced tea with L-shaped indifference curves in Graph 5.2. And less extreme indifference curves ranging from those that implied a relatively large degree of substitutability to a relatively small degree of substitutability were illustrated in a sequence of graphs in Graph 5.3. From this discussion, one quickly walks away with the sense that *the degree of substitutability is directly related to the speed with which the slope of an indifference curve changes as one moves along the indifference curve*. The slope, for instance, changes relatively slowly in Graph 5.3a where two goods are relatively substitutable, and much more quickly in Graph 5.3c where goods are less substitutable.

What we referred to informally as the “degree of substitutability” in our discussion of these graphs is formalized mathematically through a concept known as the *elasticity of substitution*.⁵ As we will see again and again throughout this book, an *elasticity* is a measure of responsiveness. We will, for instance, discuss the responsiveness of a consumer’s demand for a good when that good’s price changes as the “price elasticity of demand” in Chapter 18. In the case of formalizing the notion of substitutability, we are attempting to formalize how quickly the bundle of goods on an indifference curve changes as the slope (or marginal rate of substitution) of that indifference curve changes; or, put differently, how “responsive” the bundle of goods along an indifference curve is to the changes in the marginal rate of substitution.

Consider, for instance, point A (with marginal rate of substitution of -2) on the indifference curve graphed in Graph 5.7a. In order for us to find a point B where the marginal rate of

GRAPH 5.7 Degrees of Substitutability and Marginal Rates of Substitution

⁵ This concept was introduced independently in the early 1930s by two of the major economists of the 20th century, Sir John Hicks (1904–1989) and Joan Robinson (1903–1983). Hicks was awarded the Nobel Prize in Economics in 1972.

substitution is -1 instead of -2 , we have to go from the initial bundle $(2,10)$ to the new bundle $(8,4)$. In Graph 5.7b, a similar change from an initial point A with marginal rate of substitution of -2 to a new point B with marginal rate of substitution of -1 implies a significantly smaller change in the bundle, taking us from $(2,10)$ to $(4,8)$. Put differently, the ratio of x_2 over x_1 declines quickly (from 5 to $1/2$) in panel (a) as the marginal rate of substitution falls (in absolute value from 2 to 1) while it declines less rapidly (from 5 to 2) in panel (b) for the same change in the marginal rate of substitution.

Economists have developed a mathematical way to give expression to the intuition that the degree of substitutability between two goods is related to the speed with which the ratio of the two goods along an indifference curve changes as the marginal rate of substitution changes. This is done by defining the *elasticity of substitution* (denoted σ) at a particular bundle of two consumption goods as *the percentage change in the ratio of those two goods that results from a 1% change in the marginal rate of substitution along the indifference curve that contains the bundle*, or, put mathematically,

$$\text{Elasticity of substitution} = \sigma = \left| \frac{\% \Delta(x_2/x_1)}{\% \Delta MRS} \right|. \quad (5.1)$$

The “percentage change” of a variable is simply the change of the variable divided by the original level of that variable. For instance, if the ratio of the two goods changes from 5 to $1/2$ (as it does in Graph 5.7a), the “percentage change” in the ratio is given by $-4.5/5$ or -0.9 . Similarly, the $\% \Delta MRS$ in Graph 5.7a is 0.5. Dividing -0.9 by 0.5 then gives a value of -1.8 , or 1.8 in absolute value. This is approximately the elasticity of substitution in Graph 5.7a. (It is only approximate because the formula in equation (5.1) evaluates the elasticity of substitution precisely at a point when the changes are very small. The calculus version of the elasticity formula is treated explicitly in the appendix to this chapter.)

EXERCISE 5B.1

Calculate the same approximate elasticity of substitution for the indifference curve in Graph 5.7b.

We will see that our definitions of perfect complements and perfect substitutes give rise to extreme values of zero and infinity for this elasticity of substitution, while tastes that lie in between these extremes are associated with values somewhere in between these extreme values.

5B.1.1 Perfect Substitutes The case of perfect substitutes—Coke and Pepsi for me in Section 5A.1.1—is one where an additional unit of x_1 (a can of Coke) always adds exactly the same amount to my happiness as an additional unit of x_2 (a can of Pepsi). A simple way of expressing such tastes in terms of a utility function is to write the utility function as

$$u(x_1, x_2) = x_1 + x_2. \quad (5.2)$$

In this case, you can always keep me indifferent by taking away 1 unit of x_1 and adding 1 unit of x_2 or vice versa. For instance, the bundles $(2,0)$, $(1,1)$, and $(0,2)$ all give “utility” of 2, implying all three bundles lie on the same indifference curve (as drawn in Graph 5.1).

EXERCISE 5B.2

What numerical labels would be attached to the three indifference curves in Graph 5.1 by the utility function in equation (5.2)?

Suppose you measured Coke in 8-ounce cans and Pepsi in 4-ounce cans. Draw indifference curves and find the simplest possible utility function that would give rise to those indifference curves.

EXERCISE
5B.3

Without doing the math explicitly, we can see intuitively that the elasticity of substitution in this case is infinity (∞). This is easiest to see if we think of an indifference map that is close to perfect substitutes, such as the indifference map in Graph 5.8a in which indifference curves are almost linear. Beginning at point *A*, even the very small percentage change in the *MRS* that gets us to point *B* is accompanied by a very large change in the ratio of the consumption goods. Considering this in light of equation (5.1), we get an elasticity of substitution that is determined by a large numerator divided by a very small denominator, giving a large value for the elasticity. The closer this indifference map comes to being linear, the larger will be the numerator and the smaller will be the denominator, thus causing the elasticity of substitution to approach ∞ as the indifference map approaches that of perfect substitutes.

Can you use similar reasoning to determine the elasticity of substitution for the utility function you derived in exercise 5B.3?

EXERCISE
5B.4

5B.1.2 Perfect Complements It is similarly easy to arrive at a utility function that represents the L-shaped indifference curves for goods that represent perfect complements (such as iced tea and sugar for my wife in Section 5A.1.2). Since the two goods are of use to you only when consumed together, your happiness from such goods is determined by whichever of the two goods you have less of. For instance, when my wife has 3 glasses of iced tea but only 2 packs of sugar, she is just as happy with any other combination of iced tea and sugar that

GRAPH 5.8 Degrees of Substitutability and the “Elasticities of Substitution”

contains exactly two units of one of the goods and at least two units of the other. For any bundle, happiness is therefore determined by the smaller quantity of the two goods in the bundle, or

$$u(x_1, x_2) = \min\{x_1, x_2\}. \quad (5.3)$$

EXERCISE 5B.5 Plug the bundles (3,1), (2,1), (1,1), (1,2), and (1,3) into this utility function and verify that each is shown to give the same utility, thus lying on the same indifference curve as plotted in Graph 5.2. What numerical labels does this indifference curve attach to each of the three indifference curves in Graph 5.2?

EXERCISE 5B.6 How would your graph and the corresponding utility function change if we measured iced tea in half glasses instead of glasses.

We can again see intuitively that the elasticity of substitution for goods that are perfect complements will be zero. As in the case of perfect substitutes, this is easiest to see if we begin by considering an indifference map that is close to one representing perfect complements, such as the indifference map drawn in Graph 5.8b. Beginning at point *A*, even the very large percentage change in the *MRS* that gets us to point *B* implies a small percentage change in the ratio of the inputs. Considering this in light of equation (5.1), this implies a small numerator divided by a large denominator, giving a small number for the elasticity of substitution. As this map comes closer and closer to one that represents perfect complements, the numerator becomes smaller and the denominator rises. This leads to an elasticity of substitution that approaches zero as the indifference map approaches that of perfect complements.

EXERCISE 5B.7 Can you determine intuitively what the elasticity of substitution is for the utility function you defined in exercise 5B.6?

5B.1.3 The Cobb–Douglas Function Probably the most widely used utility function in economics is one that gives rise to indifference curves that lie between the extremes of perfect substitutes and perfect complements and that, as we will see, exhibits an elasticity of substitution of 1. It is known as the *Cobb–Douglas* utility function and takes the form

$$u(x_1, x_2) = x_1^\gamma x_2^\delta \text{ where } \gamma > 0, \delta > 0. \quad (5.4)$$

While the exponents in the Cobb–Douglas function can in principle take any positive values, we often restrict ourselves to exponents that sum to 1. But since we know from Chapter 4 that we can transform utility functions without changing the underlying indifference map, restricting the exponents to sum to 1 turns out to be no restriction at all. We can, for instance, transform the function *u* by taking it to the power $1/(\gamma + \delta)$ to get

$$\begin{aligned} (u(x_1, x_2))^{1/(\gamma+\delta)} &= (x_1^\gamma x_2^\delta)^{1/(\gamma+\delta)} = x_1^{\gamma/(\gamma+\delta)} x_2^{\delta/(\gamma+\delta)} = \\ &= x_1^\alpha x_2^{(1-\alpha)} \text{ (where } \alpha = \gamma/(\gamma + \delta) \text{)} = \\ &= v(x_1, x_2). \end{aligned} \quad (5.5)$$

⁶This function was originally derived for producer theory where it is (as we will see in later chapters) still heavily used. It was first proposed by Knut Wicksell (1851–1926). It is named, however, for Paul Douglas (1892–1976), an economist, and Charles Cobb, a mathematician. They first used the function in empirical work (focused on producer theory) shortly after Wicksell's death. Paul Douglas went on to serve three terms as an influential U.S. senator from Illinois (1949–1967).

Demonstrate that the functions u and v both give rise to indifference curves that exhibit the same shape by showing that the MRS for each function is the same.

EXERCISE
5B.8

We can therefore simply write the utility function in Cobb–Douglas form as

$$u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)} \text{ where } 0 < \alpha < 1. \quad (5.6)$$

In the n -good case, the Cobb–Douglas form extends straightforwardly to

$$u(x_1, x_2, \dots, x_n) = x_1^{\alpha_1} x_2^{\alpha_2} \dots x_n^{\alpha_n} \text{ with } \alpha_1 + \alpha_2 + \dots + \alpha_n = 1. \quad (5.7)$$

We will show in the next section that this Cobb–Douglas function is just a special case of a more general functional form, the special case in which the elasticity of substitution is equal to 1 everywhere. Before doing so, however, we can get some intuition about the variety of tastes that can be represented through Cobb–Douglas functions by illustrating how these functions change as α changes in expression (5.6). The series of graphs in Graph 5.9 provide some examples.

While each of these graphs belongs to the family of Cobb–Douglas utility functions (and thus each represents tastes with elasticity of substitution of 1), you can see how Cobb–Douglas tastes can indeed cover many different types of indifference maps. When $\alpha = 0.5$ (as in panel (b) of the graph), the function places equal weight on x_1 and x_2 , resulting in an indifference map that is symmetric around the 45-degree line. Put differently, since the two goods enter the utility function symmetrically, the portions of indifference curves that lie below the 45-degree line are mirror images of the corresponding portions that lie above the 45-degree line (when you imagine putting a mirror along the 45-degree line). This implies that the MRS on the 45-degree line must be equal to -1 ; when individuals with such tastes have equal quantities of both goods, they are willing to trade them one-for-one.

When $\alpha \neq 0.5$, on the other hand, the two goods do not enter the utility function symmetrically, and so the symmetry around the 45-degree line is lost. If $\alpha > 0.5$ (as in panel (c) of the graph), relatively more weight is put on x_1 . Thus, if a consumer with such tastes has equal quantities of x_1 and x_2 , he or she is not willing to trade them one-for-one. Rather, since x_1 plays a more prominent role in the utility function, the consumer would demand more than 1 unit of x_2

Cobb–Douglas utility functions represent tastes with elasticity of substitution of -1 .

GRAPH 5.9 Different Cobb–Douglas Utility Functions

to give up 1 unit of x_1 when he or she starts with an equal number of each (i.e., on the 45-degree line), implying an MRS greater than 1 in absolute value along the 45-degree line. As α increases above 0.5, the points where $MRS = -1$ therefore fall below the 45-degree line. The reverse is, of course, true as α falls below 0.5 when more emphasis is placed on x_2 rather than x_1 (as in panel (a) of the graph).

EXERCISE 5B.9 Derive the MRS for the Cobb–Douglas utility function and use it to show what happens to the slope of indifference curves along the 45-degree line as α changes.

5B.1.4 A More General Model: Constant Elasticity of Substitution (CES)

Utility So far, we have explored the extremes of perfect substitutes (with elasticity of substitution of ∞) and perfect complements (with elasticity of substitution of 0), and we have identified the Cobb–Douglas case, which lies in between with an elasticity of substitution of 1. Of course there exist other in-between cases where the elasticity of substitution lies between 0 and 1 or between 1 and ∞ . And economists have identified a more general utility function that can capture all of these (including the cases of perfect substitutes, Cobb–Douglas tastes, and perfect complements). All utility functions that take this form have one thing in common: The elasticity of substitution is the same at all bundles, and it is for this reason that these functions are called *constant elasticity of substitution utility functions* or just *CES utility functions*.⁷

For bundles that contain two goods, these functions take on the following form:

$$u(x_1, x_2) = (\alpha x_1^{-\rho} + (1 - \alpha)x_2^{-\rho})^{-1/\rho}, \quad (5.8)$$

where $0 < \alpha < 1$ and $-1 \leq \rho \leq \infty$.⁸

It is mathematically intensive to derive explicitly the formula for an elasticity of substitution for utility functions that take this form; if you are curious, you can follow this derivation in the appendix. As it turns out, however, the elasticity of substitution σ takes on the following very simple form for this CES function:

$$\sigma = 1/(1 + \rho). \quad (5.10)$$

Thus, as ρ gets close to ∞ , the elasticity of substitution approaches 0, implying that the underlying indifference curves approach those of perfect complements. If, on the other hand, ρ gets close to -1 , the elasticity approaches ∞ , implying that the underlying indifference curves approach those of perfect substitutes. Thus, as the parameter ρ moves from -1 to ∞ , the underlying indifference map changes from that of perfect substitutes to perfect complements. This is illustrated graphically in Graph 5.10 for the case where α is set to 0.5. As we move left across the three panels of the graph, ρ increases, which implies the elasticity of substitution decreases and we move from tastes over goods that are relatively substitutable to tastes over goods that are more complementary.

⁷This function was first derived (and explored within the context of producer theory) in 1961 by Ken Arrow (1921–) and Robert Solow (1924–) together with H. B. Cherney and B. S. Minhas. Arrow went on to share the 1972 Nobel Prize in Economics with Sir John Hicks (who had originally developed the concept of an elasticity of substitution). Solow was awarded the Nobel Prize in 1987.

⁸The CES form can also be generalized to more than two goods, with the n -good CES function given by

$$u(x_1, x_2, \dots, x_n) = \left(\sum_{i=1}^n \alpha_i x_i^{-\rho} \right)^{-1/\rho} \quad \text{where } \sum_{i=1}^n \alpha_i = 1. \quad (5.9)$$

GRAPH 5.10 Different CES Utility Functions when $\alpha = 0.5$ and ρ Varies

What is the elasticity of substitution in each panel of Graph 5.10?

**EXERCISE
5B.10**

The best way to see how the CES function gives rise to different indifference maps is to derive its marginal rate of substitution; that is,

$$\begin{aligned}
 MRS &= -\frac{\partial u / \partial x_1}{\partial u / \partial x_2} \\
 &= -\frac{(\alpha x_1^{-\rho} + (1 - \alpha)x_2^{-\rho})^{-(\rho+1)/\rho} \alpha x_1^{-(\rho+1)}}{(\alpha x_1^{-\rho} + (1 - \alpha)x_2^{-\rho})^{-(\rho+1)/\rho} (1 - \alpha)x_2^{-(\rho+1)}} \\
 &= -\frac{\alpha x_1^{-(\rho+1)}}{(1 - \alpha)x_2^{-(\rho+1)}} = -\left(\frac{\alpha}{1 - \alpha}\right) \left(\frac{x_2}{x_1}\right)^{\rho+1}.
 \end{aligned} \tag{5.11}$$

Note, for instance, what happens when $\rho = -1$: The (absolute value of the) *MRS* simply becomes $\alpha/(1 - \alpha)$ and no longer depends on the bundle (x_1, x_2) . Put differently, when $\rho = -1$, the slopes of indifference curves are just straight parallel lines indicating that the consumer is willing to substitute perfectly $\alpha/(1 - \alpha)$ of x_2 for one more unit of x_1 regardless of how many of each of the two goods the consumer currently has.

We have also indicated that the Cobb–Douglas utility function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$ represents a special case of the CES utility function. To see this, consider the *MRS* for the Cobb–Douglas function, which is

$$MRS = -\frac{\partial u / \partial x_1}{\partial u / \partial x_2} = -\frac{\alpha x_1^{\alpha-1} x_2^{(1-\alpha)}}{(1 - \alpha) x_1^\alpha x_2^{-\alpha}} = -\left(\frac{\alpha}{1 - \alpha}\right) \left(\frac{x_2}{x_1}\right). \tag{5.12}$$

Note that the *MRS* from the CES function in equation (5.11) reduces to the *MRS* from the Cobb–Douglas function in equation (5.12) when $\rho = 0$. Thus, when $\rho = 0$, the indifference curves of the CES function take on the exact same shapes as the indifference curves of the Cobb–Douglas function, implying that the two functions represent exactly the same tastes. This is not easy to see by simply comparing the actual CES function to the Cobb–Douglas function because the CES function ceases to be well defined at $\rho = 0$ when the exponent $-1/\rho$ is undefined. But

by deriving the respective marginal rates of substitution for the two functions, we can see how the CES function in fact does *approach* the Cobb–Douglas function as ρ approaches zero.

Finally, since we know that the elasticity of substitution for the CES utility function is $\sigma = 1/(1 + \rho)$, we know that $\sigma = 1$ when $\rho = 0$. This, then, implies that the elasticity of substitution of the Cobb–Douglas utility function is in fact 1 as we had foreshadowed in our introduction of the Cobb–Douglas function.

EXERCISE 5B.11* Can you describe what happens to the slopes of the indifference curves on the 45-degree line, above the 45-degree line, and below the 45-degree line as ρ becomes large (and as the elasticity of substitution therefore becomes small)?

EXERCISE 5B.12 On the “Exploring Relationships” animation (access at <http://econ.duke.edu/ecoteach>) associated with Graph 5.10, develop an intuition for the role of the α parameter in CES utility functions and compare those with what emerges in Graph 5.9.

5B.2 Some Common Indifference Maps In Section 5A, we drew a logical distinction between *shapes* of individual indifference curves that define the degree of substitutability between goods and the *relation* of indifference curves to one another within a single indifference map. We have just formalized the degree of substitutability by exploring the concept of an elasticity of substitution and how tastes that have a constant elasticity of substitution at all consumption bundles can vary and be modeled using CES utility functions. We now turn toward exploring two special cases of indifference maps, those defined as “homothetic” and those defined as “quasi-linear” in Section 5A.2.

5B.2.1 Homothetic Tastes and Homogeneous Utility Functions Recall that we defined tastes as homothetic whenever the indifference map has the property that the marginal rate of substitution at a particular bundle depends only on how much of one good *relative* to the other is contained in that bundle. Put differently, the *MRS* of homothetic tastes is the same along any ray emanating from the origin of our graphs, implying that whenever we increase each of the goods in a particular bundle by the same proportion, the *MRS* will remain unchanged.

Consider, for instance, tastes that can be represented by the Cobb–Douglas utility function in equation (5.6). The *MRS* implied by this function is $-\alpha x_2/(1 - \alpha)x_1$. Suppose we begin at a particular bundle (x_1, x_2) and then increase the quantity of each of the goods in the bundle by a factor t to get to the bundle (tx_1, tx_2) that lies on a ray from the origin that also contains (x_1, x_2) . This implies that the new *MRS* is $-atx_2/(1 - \alpha)tx_1$, but this reduces to $-\alpha x_2/(1 - \alpha)x_1$ since the “ t ” appears in both the numerator and the denominator and thus cancels. Cobb–Douglas utility functions therefore represent homothetic tastes because the *MRS* is unchanged along a ray from the origin.

More generally, homothetic tastes can be represented by any utility function that has the mathematical property of being *homogeneous*. A function $f(x_1, x_2)$ is defined to be *homogeneous of degree k* if and only if

$$f(tx_1, tx_2) = t^k f(x_1, x_2). \quad (5.13)$$

For instance, the Cobb–Douglas function $u(x_1, x_2) = x_1^\gamma x_2^\delta$ is homogeneous of degree $(\gamma + \delta)$ because

$$u(tx_1, tx_2) = (tx_1)^\gamma (tx_2)^\delta = t^{(\gamma + \delta)} x_1^\gamma x_2^\delta = t^{(\gamma + \delta)} u(x_1, x_2). \quad (5.14)$$

Cobb–Douglas utility functions represent homothetic tastes.

Show that when we normalize the exponents of the Cobb–Douglas utility function to sum to 1, the function is homogeneous of degree 1.

**EXERCISE
5B.13**

Consider the following variant of the CES function that will play an important role in producer theory: $f(x_1, x_2) = (\alpha x_1^{-\rho} + (1 - \alpha)x_2^{-\rho})^{-\beta/\rho}$. Show that this function is homogeneous of degree β .

**EXERCISE
5B.14**

It is then easy to see how *homogeneous utility functions must represent homothetic tastes*. Suppose $u(x_1, x_2)$ is homogeneous of degree k . The *MRS* at a bundle (tx_1, tx_2) is

$$\begin{aligned} MRS(tx_1, tx_2) &= -\frac{\partial u(tx_1, tx_2)/\partial x_1}{\partial u(tx_1, tx_2)/\partial x_2} = -\frac{\partial(t^k u(x_1, x_2))/\partial x_1}{\partial(t^k u(x_1, x_2))/\partial x_2} = \\ &= -\frac{t^k \partial u(x_1, x_2)/\partial x_1}{t^k \partial u(x_1, x_2)/\partial x_2} = -\frac{\partial u(x_1, x_2)/\partial x_1}{\partial u(x_1, x_2)/\partial x_2} = \\ &= MRS(x_1, x_2). \end{aligned} \quad (5.15)$$

In this derivation, we use the definition of a homogeneous function in the first line in (5.15), are then able to take the t^k term outside the partial derivative (since it is not a function of x_1 or x_2), and finally can cancel the t^k that now appears in both the numerator and the denominator to end up at the definition of the *MRS* at bundle (x_1, x_2) . Thus, the *MRS* is the same when we increase each good in a bundle by the same proportion t , implying that the underlying tastes are homothetic.

Furthermore, *any function that is homogeneous of degree k can be transformed into a function that is homogeneous of degree 1 by simply taking that function to the power $(1/k)$* . We already showed in equation (5.5), for instance, that we can transform the Cobb–Douglas utility function $u(x_1, x_2) = x_1^\gamma x_2^\delta$ (which is homogeneous of degree $(\gamma + \delta)$) into a utility function that is homogeneous of degree 1 (taking the form $v(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$) by simply taking it to the power $1/(\gamma + \delta)$.

Can you demonstrate, using the definition of a homogeneous function, that it is generally possible to transform a function that is homogeneous of degree k to one that is homogeneous of degree 1 in the way we have suggested?

**EXERCISE
5B.15**

We can therefore conclude that homothetic tastes *can always be represented* by utility functions that are homogeneous, and since homogeneous functions can always be transformed into functions that are homogeneous of degree 1 without altering the underlying indifference curves, we can also conclude that *homothetic tastes can always be represented by utility functions that are homogeneous of degree 1*.⁹ Many commonly used utility functions are indeed homogeneous and thus represent homothetic tastes, including, as you can see from within-chapter exercise 5B.14, all CES functions we defined in the previous sections.

**CES utility
functions
represent
homothetic
tastes.**

⁹Even if a utility function is not homogeneous, however, it might still represent homothetic tastes because it is possible to transform a homogeneous function into a nonhomogeneous function by just, for instance, adding a constant term. The function $w(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)} + 5$, for example, has the same indifference curves as the utility function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$, but w is not homogeneous whereas u is. But given that utility functions are only tools we use to represent tastes (indifference curves), there is no reason to use nonhomogeneous utility functions when we want to model homothetic tastes because no economic content is lost if we simply use utility functions that are homogeneous of degree 1 to model such tastes.

5B.2.2 Quasilinear Tastes In Section 5A.2.2, we defined tastes as quasilinear in good x_1 whenever the indifference map has the property that the marginal rate of substitution at a particular bundle depends only on how much of x_1 that bundle contains (and thus *NOT* on how much of x_2 it contains). Formally, this means that the marginal rate of substitution is a function of only x_1 and not x_2 . This is generally not the case. For instance, we derived the *MRS* for a Cobb–Douglas utility function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$ to be $-\alpha x_2 / ((1 - \alpha)x_1)$. Thus, for tastes that can be represented by Cobb–Douglas utility functions, the marginal rate of substitution is a function of both x_1 and x_2 , which allows us to conclude immediately that such tastes are not quasilinear in either good.

Consider, however, the class of utility functions that can be written as

$$u(x_1, x_2) = v(x_1) + x_2, \quad (5.16)$$

where $v: \mathbb{R}_+ \rightarrow \mathbb{R}$ is a function of only the level of consumption of good x_1 .

The partial derivative of u with respect to x_1 is then equal to the derivative of v with respect to x_1 , and the partial derivative of u with respect to x_2 is equal to 1. Thus, the marginal rate of substitution implied by this utility function is

$$MRS = -\frac{\partial u / \partial x_1}{\partial u / \partial x_2} = -\frac{dv}{dx_1}, \quad (5.17)$$

which is a function of x_1 but *NOT* of x_2 . We will then refer to tastes that can be represented by utility functions of the form given in expression (5.16) as *quasilinear in x_1* . While some advanced textbooks refer to the good x_2 (that enters the utility function linearly) as the “quasilinear” good, note that I am using the term differently here; I am referring to the good x_1 as the quasilinear good. This convention will make it much easier for us to discuss economically important forces in later chapters.

The simplest possible form of equation (5.16) arises when $v(x_1) = x_1$. This implies $u(x_1, x_2) = x_1 + x_2$, the equation we derived in Section 5B.1.1 as representing perfect substitutes. The function v can, however, take on a variety of other forms, giving utility functions that represent quasilinear tastes that do not have linear indifference curves. The indifference curves in Graph 5.11, for instance, are derived from the function $u(x_1, x_2) = \alpha \ln x_1 + x_2$, and α varies as is indicated in the panels of the graph.

5B.2.3 Homothetic versus Quasilinear Tastes It can easily be seen from these graphs of quasilinear tastes that, *in general, quasilinear tastes are not homothetic* because the *MRS* is constant along any vertical line and thus generally not along a ray emanating from the origin. The same intuition arises from our mathematical formulation of utility functions that represent quasilinear tastes. In equation (5.17), we demonstrated that the *MRS* implied by (5.16) is $-(dv/dx_1)$. In order for tastes to be homothetic, the *MRS* evaluated at (tx_1, tx_2) would have to be the same as the *MRS* evaluated at (x_1, x_2) , which implies $dv(tx_1)/dx_1$ would have to be equal to $dv(x_1)/dx_1$. But the only way that can be true is if v is a linear function of x_1 where x_1 drops out when we take the derivative of v with respect to x_1 .

Thus, if $v(x_1) = \alpha x_1$ (where α is a real number), the marginal rate of substitution implied by (5.16) is just α , implying that the *MRS* is the same for all values of x_1 regardless of the value of x_2 . But this simply means that indifference curves are straight lines, as in the case of perfect substitutes. Perfect substitutes therefore represent the only quasilinear tastes that are also homothetic.

5B.3 “Essential” Goods A final distinction between indifference maps we made in Section 5A is between those that contain “essential” goods and those in which some goods are not essential. Put differently, we defined a good to be “essential” if some consumption of that

GRAPH 5.11 The Quasilinear Utility Functions $u(x_1, x_2) = \alpha \ln x_1 + x_2$ 

good was required in order for an individual to achieve greater utility than he or she does by consuming nothing at all, and we concluded that goods are essential so long as indifference curves do not intersect the axis on which those goods are measured. From our various graphs of CES utility functions, it can be seen that most of these functions implicitly assume that all goods are essential (with the exception of perfect substitutes). From our graphs of quasilinear utility functions, on the other hand, we can easily see that such functions implicitly assume that goods are not essential. This distinction will become important in our discussion in the next chapter.

Use the mathematical expression for quasilinear tastes to illustrate that neither good is essential if tastes are quasilinear in one of the goods.

**EXERCISE
5B.16**

Show that both goods are essential if tastes can be represented by Cobb–Douglas utility functions.

**EXERCISE
5B.17**

CONCLUSION

This chapter continued our treatment of tastes by focusing on particular features of tastes commonly used in economic analysis. We focused on three main features: First, the *shapes of indifference curves*, whether they are relatively flat or relatively L-shaped, has a lot to do with the degree to which goods are substitutable for the consumer we are analyzing. This degree of substitutability is formalized mathematically as the elasticity of substitution, which simply defines the speed with which the slope of indifference curves changes as one moves along them. Perfect substitutes and perfect complements represent polar opposites of perfect substitutability and no substitutability, with tastes over most goods falling somewhere in between. And a special class of tastes that give rise to indifference curves that have the same elasticity of substitution at every bundle can be represented by the family of constant elasticity of substitution utility

functions. Second, the *relationship of marginal rates of substitution across indifference curves* informs us about the way goods are evaluated as a consumer consumes more of all goods. Homothetic tastes have the feature that the marginal rates of substitution depend entirely on how much of one good *relative* to another is contained in the bundle, while quasilinear tastes have the feature that marginal rates of substitution depend only on the *absolute* level of one of the goods in the bundle. The former can be represented by utility functions that are homogeneous of degree 1, while the latter can be represented only by utility functions in which one of the goods enters linearly. Finally, *whether indifference curves intersect one (or more) axis* tells us whether goods are “essential.”

Each of these features of tastes will play a prominent role in the coming chapters as we investigate how consumers in our model “do the best they can given their circumstances.” The degree of substitutability will play a crucial role in defining what we will call “substitution effects” beginning in Chapter 7, effects that lie at the core of many public policy debates. The relationship of marginal rates of substitution across indifference curves will determine the size of what we will call “income effects” and “wealth effects” that, together with substitution effects, define how consumers change behavior as prices in an economy change. And whether a good is essential or not will be important (beginning in Chapter 6) in determining how easily we can identify “optimal” choices consumers make within our models. With both budgets and tastes explored in the previous chapters, we are now ready to proceed to analyze exactly what we mean when we say consumers “do the best they can given their circumstances.”

APPENDIX: THE CALCULUS OF ELASTICITIES OF SUBSTITUTION

As we indicated in the chapter, any elasticity is a measure of the responsiveness of one variable with respect to another. In the case of the elasticity of substitution, we are measuring the responsiveness of the ratio $r = (x_2/x_1)$ to the MRS along an indifference curve. Using r to denote the ratio of consumption goods and σ to denote the elasticity of substitution, the formula in equation (5.1) can then be written as

$$\sigma = \left| \frac{\% \Delta r}{\% \Delta MRS} \right| = \left| \frac{\Delta r/r}{\Delta MRS/MRS} \right|. \quad (5.18)$$

Expressing this for small changes in calculus notation, we can rewrite this as

$$\sigma = \left| \frac{dr/r}{dMRS/MRS} \right| = \left| \frac{MRS}{r} \frac{dr}{dMRS} \right|. \quad (5.19)$$

Calculating such elasticities is often easiest using the *logarithmic derivative*. To derive this, note that

$$\begin{aligned} d \ln r &= \frac{1}{r} dr \text{ and} \\ d \ln |MRS| &= \frac{1}{MRS} dMRS, \end{aligned} \quad (5.20)$$

where we have placed MRS in absolute values in order for the logarithm to exist. Dividing these by each other, we get

$$\frac{d \ln r}{d \ln |MRS|} = \frac{MRS}{r} \frac{dr}{dMRS}, \quad (5.21)$$

which (aside from the absolute values) is equivalent to the expression for σ in equation (5.19). Expanding out the r term, we can then write the elasticity of substitution as

$$\sigma = \frac{d \ln (x_2/x_1)}{d \ln |MRS|}. \quad (5.22)$$

You can now see more directly why the elasticity of substitution of the CES utility function is indeed $1/(1 + \rho)$. We already calculated in equation (5.11) that the *MRS* of the CES function is $-(\alpha/(1 - \alpha))(x_2/x_1)^{\rho+1}$. Taking absolute values and solving for (x_2/x_1) , we get

$$\frac{x_2}{x_1} = \left(\frac{(1 - \alpha)}{\alpha} |MRS| \right)^{\frac{1}{1+\rho}}, \quad (5.23)$$

and taking logs,

$$\ln \frac{x_2}{x_1} = \frac{1}{1 + \rho} \ln |MRS| + \frac{1}{1 + \rho} \ln \left(\frac{(1 - \alpha)}{\alpha} \right). \quad (5.24)$$

We can then just apply equation (5.22) to get

$$\sigma = \frac{1}{1 + \rho}. \quad (5.25)$$

Can you demonstrate similarly that $\sigma = 1$ for the Cobb–Douglas utility function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$?

**EXERCISE
5B.18***

END-OF-CHAPTER EXERCISES

5.1† Consider your tastes for right and left shoes.

- A.** Suppose you, like most of us, are the kind of person who is rather picky about having the shoes you wear on your right foot be designed for right feet and the shoes you wear on your left foot be designed for left feet. In fact you are so picky that you would never wear a left shoe on your right foot or a right shoe on your left foot, nor would you ever choose (if you can help it) not to wear shoes on one of your feet.
- In a graph with the number of right shoes on the horizontal axis and the number of left shoes on the vertical, illustrate three indifference curves that are part of your indifference map.
 - Now suppose you hurt your left leg and have to wear a cast (which means you cannot wear shoes on your left foot) for 6 months. Illustrate how the indifference curves you have drawn would change for this period. Can you think of why goods such as left shoes in this case are called *neutral goods*?
 - Suppose you hurt your right foot instead. How would this change your answer to part (b).
 - Are any of the tastes you have graphed homothetic? Are any quasilinear?
 - In the three different tastes that you graphed, are any of the goods ever “essential”? Are any not essential?
- B.** Continue with the description of your tastes given in part A and let x_1 represent right shoes and let x_2 represent left shoes.
- Write down a utility function that represents your tastes as illustrated in A(a). Can you think of a second utility function that also represents these tastes?
 - Write down a utility function that represents your tastes as graphed in A(b).
 - Write down a utility function that represents your tastes as drawn in A(c).

*conceptually challenging

**computationally challenging

†solutions in Study Guide

- d. Can any of the tastes you have graphed in part A be represented by a utility function that is homogeneous of degree 1? If so, can they also be represented by a utility function that is not homogeneous?
- e. Refer to end-of-chapter exercise 4.13 where the concepts of “strong monotonicity,” “weak monotonicity,” and “local non-satiation” were defined. Which of these are satisfied by the tastes you have graphed in this exercise?
- f. Refer again to end-of-chapter exercise 4.13 where the concepts of “strong convexity” and “weak convexity” were defined. Which of these are satisfied by the tastes you have graphed in this exercise?

5.2 Consider your tastes for \$5 bills and \$10 bills.

- A.** Suppose that all you care about is how much money you have, but you don’t care whether a particular amount comes in more or fewer bills (and suppose that you could have partial \$10 and \$5 bills).
 - a. With the number of \$5 bills on the horizontal axis and the number of \$10 bills on the vertical, illustrate 3 indifference curves from your indifference map.
 - b. What is your marginal rate of substitution of \$10 bills for \$5 bills?
 - c. What is the marginal rate of substitution of \$5 bills for \$10 bills?
 - d. Are averages strictly better than extremes? How does this relate to whether your tastes exhibit diminishing marginal rates of substitution?
 - e. Are these tastes homothetic? Are they quasilinear?
 - f. Are either of the goods on your axes “essential”?
- B.** Continue with the assumption that you care only about the total amount of money in your wallet, and let \$5 bills be denoted x_1 and \$10 bills be denoted x_2 .
 - a. Write down a utility function that represents the tastes you graphed in A(a). Can you think of a second utility function that also represents these tastes?
 - b. Calculate the marginal rate of substitution from the utility functions you wrote down in B(a) and compare it to your intuitive answer in A(b).
 - c. Can these tastes be represented by a utility function that is homogeneous of degree 1? If so, can they also be represented by a utility function that is not homogeneous?
 - d. Refer to end-of-chapter exercise 4.13 where the concepts of “strong monotonicity,” “weak monotonicity,” and “local non-satiation” were defined. Which of these are satisfied by the tastes you have graphed in this exercise?
 - e. Refer again to end-of-chapter exercise 4.13 where the concepts of “strong convexity” and “weak convexity” were defined. Which of these are satisfied by the tastes you have graphed in this exercise?

5.3[†] Beer comes in 6- and 12-packs. In this exercise, we will see how your model of tastes for beer and other consumption might be affected by the units in which we measure beer.

- A.** Suppose initially that your favorite beer is only sold in 6-packs.
 - a. On a graph with beer on the horizontal axis and other consumption (in dollars) on the vertical, depict three indifference curves that satisfy our usual five assumptions assuming that the units in which beer is measured is 6-packs.
 - b. Now suppose the beer company eliminates 6-packs and sells all its beer in 12-packs instead. What happens to the *MRS* at each bundle in your graph if 1 unit of beer now represents a 12-pack instead of a 6-pack.
 - c. In a second graph, illustrate one of the indifference curves you drew in part (a). Pick a bundle on that indifference curve and then draw the indifference curve through that bundle assuming we are measuring beer in 12-packs instead. Which indifference curve would you rather be on?
 - d. Does the fact that these indifference curves cross imply that tastes for beer change when the beer company switches from 6-packs to 12-packs?
- B.** Let x_1 represent beer and let x_2 represent dollars of other consumption. Suppose that, when x_1 is measured in units of 6-packs, your tastes are captured by the utility function $u(x_1, x_2) = x_1 x_2$.

- What is the *MRS* of other goods for beer?
- What does the *MRS* have to be if x_1 is measured in units of 12-packs?
- Give a utility function that represents your tastes when x_1 is measured in 12-packs and check to make sure it has the *MRS* you concluded it must have.
- Can you use this example to explain why it is useful to measure the substitutability between different goods using percentage terms (as in the equation for the elasticity of substitution) rather than basing it simply on the absolute value of slopes at different bundles?

5.4 Suppose two people want to see if they could benefit from trading with one another in a two-good world.

- A.** In each of the following cases, determine whether trade might benefit the individuals:
- As soon as they start talking with one another, they find that they own exactly the same amount of each good as the other does.
 - They discover that they are long-lost twins who have identical tastes.
 - The two goods are perfect substitutes for each of them, with the same *MRS* within and across their indifference maps.
 - They have the same tastes and own different bundles of goods but are currently located on the same indifference curve.
- B*.** Suppose that the two individuals have CES utility functions, with individual 1's utility given by $u(x_1, x_2) = (\alpha x_1^{-\rho} + (1 - \alpha)x_2^{-\rho})^{-1/\rho}$ and individual 2's by $v(x_1, x_2) = (\beta x_1^{-\rho} + (1 - \beta)x_2^{-\rho})^{-1/\rho}$.
- For what values of α , β , and ρ is it the case that owning the same bundle will always imply that there are no gains from trade for the two individuals?
 - Suppose $\alpha = \beta$ and the two individuals therefore share the same preferences. For what values of $\alpha = \beta$ and ρ is it the case that the two individuals are not able to gain from trade regardless of what current bundles they own?
 - Suppose that person 1 owns twice as much of all goods as person 2. What has to be true about α , β , and ρ for them not to be able to trade?

5.5[†] **Everyday Application:** *Personality and Tastes for Current and Future Consumption:* Consider brothers Eddy and Larry, who, despite growing up in the same household, have quite different personalities.

- A.** Eddy is known to his friends as “steady Eddy” because he likes predictability and wants to know that he’ll have what he has now again in the future. Larry, known to his friends as “crazy Larry,” adapts easily to changing circumstances. One year, he consumes everything around him like a drunken sailor; the next, he retreats to a Buddhist monastery and finds contentment in experiencing poverty.
- Take the characterization of Eddy and Larry to its extreme (within the assumptions about tastes that we introduced in Chapter 4) and draw two indifference maps with “current consumption” on the horizontal axis and “future consumption” on the vertical, one for steady Eddy and one for crazy Larry.
 - Eddy and Larry have another brother named Daryl, who everyone thinks is a weighted average between his brothers’ extremes. Suppose he is a lot more like steady Eddy than he is like crazy Larry; that is, he is a weighted average between the two but with more weight placed on the Eddy part of his personality. Pick a bundle *A* on the 45-degree line and draw a plausible indifference curve for Daryl through *A*. Could his tastes be homothetic?
 - One day, Daryl suffers a blow to his head, and suddenly it appears that he is more like crazy Larry than like steady Eddy; that is, the weights in his weighted average personality have flipped. (If you take this literally in a certain way, you would get a kink in Daryl’s indifference curve.) Can his tastes still be homothetic?
 - In end-of-chapter exercise 4.9, we defined what it means for two indifference maps to satisfy a “single crossing property.” Would you expect that Daryl’s preaccident and postaccident indifference maps satisfy that property?
 - If you were told that either Eddy or Larry saves every month for retirement and the other smokes a lot, which brother is doing what?

- B.** Suppose that one of the brothers' tastes can be captured by the utility function $u(x_1, x_2) = \min\{x_1, x_2\}$, where x_1 represents dollars of current consumption and x_2 represents dollars of future consumption.
- Which brother is it?
 - Suppose that when people say that Daryl is the weighted average of his brothers, what they mean is that his elasticity of substitution of current for future consumption lies in between those of his brothers. If Larry and Daryl have tastes that could be characterized by one (or more) of the utility functions from end-of-chapter exercise 4.5, which functions would apply to whom?
 - Which of the functions in end-of-chapter exercise 4.5 are homothetic? Which are quasilinear (and in which good)?
 - Despite being so different, is it possible that both steady Eddy and crazy Larry have tastes that can be represented by Cobb Douglas utility functions?
 - Is it possible that all their tastes could be represented by CES utility functions? Explain.

5.6 Everyday Application: Thinking About Old Age: Consider two individuals who each take a very different view of life, and consider how this shapes their tastes over intertemporal trade-offs.

- A.** Jim is a 25-year-old athlete who derives most of his pleasure in life from expensive and physically intense activities: mountain climbing in the Himalayas, kayaking in the Amazon, bungee jumping in New Zealand, lion safaris in Africa, and skiing in the Alps. He does not look forward to old age when he can no longer be as active and plans on getting as much fun in early on as he can. Ken is quite different; he shuns physical activity but enjoys reading in comfortable surroundings. The more he reads, the more he wants to read and the more he wants to retreat to luxurious libraries in the comfort of his home. He looks forward to quiet years of retirement when he can do what he loves most.
- Suppose both Jim and Ken are willing to perfectly substitute current for future consumption, but at different rates. Given the descriptions of them, draw two different indifference maps and indicate which is more likely to be Jim's and which is more likely to be Ken's.
 - Now suppose neither Jim nor Ken is willing to substitute at all across time periods. How would their indifference maps differ now given the descriptions of them provided?
 - Finally, suppose they both allowed for some substitutability across time periods but not as extreme as what you considered in part (a). Again, draw two indifference maps and indicate which refers to Jim and which to Ken.
 - Which of the indifference maps you have drawn could be homothetic?
 - Can you say for sure if the indifference maps of Jim and Ken in part (c) satisfy the single-crossing property (as defined in end-of-chapter exercise 4.9)?
- B.** Continue with the descriptions of Jim and Ken as given in part A and let c_1 represent consumption now and let c_2 represent consumption in retirement.
- Suppose that Jim's and Ken's tastes can be represented by $u^J(c_1, c_2) = \alpha c_1 + c_2$ and $u^K(c_1, c_2) = \beta c_1 + c_2$, respectively. How does α compare with β ; that is, which is larger?
 - How would you similarly differentiate, using a constant α for Jim and β for Ken, two utility functions that give rise to tastes as described in A(b)?
 - Now consider the case described in A(c), with their tastes now described by the Cobb–Douglas utility functions $u^J(c_1, c_2) = c_1^\alpha c_2^{(1-\alpha)}$ and $u^K(c_1, c_2) = c_1^\beta c_2^{(1-\beta)}$. How would α and β in those functions be related to one another?
 - Are all the tastes described by the given utility functions homothetic? Are any of them quasilinear?
 - Can you show that the tastes in B(c) satisfy the single-crossing property (as defined in end-of-chapter exercise 4.9)?
 - Are all the functions in B(a)–(c) members of the family of CES utility functions?

- 5.7*† Everyday Application:** *Tastes for Paper Clips:* Consider my tastes for paper clips and “all other goods” (denominated in dollar units).
- A.** Suppose that my willingness to trade paper clips for other goods does *not* depend on how many other goods I am also currently consuming.
- Does this imply that “other goods” are “essential” for me?
 - Suppose that, in addition, my willingness to trade paper clips for other goods does not depend on how many paper clips I am currently consuming. On two graphs, each with paper clips on the horizontal axis and “dollars of other goods” on the vertical, give two examples of what my indifference curves might look like.
 - How much can the *MRS* vary *within* an indifference map that satisfies the conditions in part (b)? How much can it vary *between* two indifference maps that both satisfy the conditions in part (b)?
 - Now suppose that the statement in (a) holds for my tastes but the statement in part (b) does not. Illustrate an indifference map that is consistent with this.
 - How much can the *MRS* vary *within* an indifference map that satisfies the conditions of part (d)?
 - Which condition do you think is more likely to be satisfied in someone’s tastes: that the willingness to trade paper clips for other goods is independent of the level of paper clip consumption or that it is independent of the level of other goods consumption?
 - Are any of the previous indifference maps homothetic? Are any of them quasilinear?
- B.** Let paper clips be denoted by x_1 and other goods by x_2 .
- Write down two utility functions, one for each of the indifference maps from which you graphed indifference curves in A(b).
 - Are the utility functions you wrote down homogeneous? If the answer is no, could you find utility functions that represent those same tastes and are homogeneous? If the answer is yes, could you find utility functions that are not homogeneous but still represent the same tastes?
 - Are the functions you wrote down homogeneous of degree 1? If the answer is no, could you find utility functions that are homogeneous of degree 1 and represent the same tastes? If the answer is yes, could you find utility functions that are not homogeneous of degree k and still represent the same tastes?
 - Is there any indifference map you could have drawn when answering A(d) that can be represented by a utility function that is homogeneous? Why or why not?

- 5.8 Everyday Application:** *Inferring Tastes for “Mozartkugeln”:* I love the Austrian candy Mozartkugeln. They are a small part of my budget, and the only factor determining my willingness to pay for additional Mozartkugeln is how many I already have.

- A.** Suppose you know that I am willing to give up \$1 of “other consumption” to get one more Mozartkugeln when I consume bundle *A*: 100 Mozartkugeln and \$500 in other goods per month.
- What is my *MRS* when my Mozartkugeln consumption remains unchanged from bundle *A* but I only consume \$200 per month in other goods?
 - Are my tastes quasilinear? Could they be homothetic?
 - You notice that this month I am consuming bundle *B*: \$600 in other goods and only 25 Mozartkugeln. When questioning me about my change in behavior (from bundle *A*), I tell you that I am just as happy as I was before. The following month, you observe that I consume bundle *C*: 400 Mozartkugeln and \$300 in other goods, and I once gain tell you my happiness remains unchanged. Does the new information about *B* and *C* change your answer in (b)?
 - Is consumption (other than of Mozartkugeln) essential for me?
- B.** Suppose my tastes could be modeled with the utility function $u(x_1, x_2) = 20x_1^{0.5} + x_2$, where x_1 refers to Mozartkugeln and x_2 refers to other consumption.
- Calculate the *MRS* for these tastes and use your answer to prove that my tastes are quasilinear in x_1 .

- b. Consider the bundles A , B , and C as defined in part A. Verify that they lie on one indifference curve when tastes are described by the previously defined utility function.
- c. Verify that the MRS at bundle A is as described in part A and derive the MRS at bundles B and C .
- d. Verify that the MRS at the bundle $(100,200)$ corresponds to your answer to A(a).
- e. How much “other goods” consumption occurs on the indifference curve that contains $(100,200)$ when my Mozartkugeln consumption falls to 25 per month? What about when it rises to 400 per month?
- f. Are Mozartkugeln essential for me?

5.9*† Everyday Application: Syllabi-Induced Tastes over Exam Grades: Suppose you are taking two classes, economics and physics. In each class, only two exams are given during the semester.

- A. Since economists are nice people, your economics professor drops the lower exam grade and bases your entire grade on the higher of the two grades. Physicists are another story. Your physics professor will do the opposite by dropping your highest grade and basing your entire class grade on your lower score.
 - a. With the first exam grade (ranging from 0 to 100) on the horizontal axis and the second exam grade (also ranging from 0 to 100) on the vertical, illustrate your indifference curves for your physics class.
 - b. Repeat this for your economics class.
 - c. Suppose all you care about is your final grade in a class and you otherwise value all classes equally. Consider a pair of exam scores (x_1, x_2) and suppose you knew before registering for a class what that pair will be, and that it will be the same for the economics and the physics class. What must be true about this pair in order for you to be indifferent between registering for economics and registering for physics?
- B. Consider the same scenario as the one described in part A.
 - a. Give a utility function that could be used to represent your tastes as you described them with the indifference curves you plotted in A(a).
 - b. Repeat for the tastes as you described them with the indifference curves you plotted in A(b).

5.10* Consider again the family of homothetic tastes.

- A. Recall that essential goods are goods that have to be present in positive quantities in a consumption bundle in order for the individual to get utility above what he or she would get by not consuming anything at all.
 - a. Aside from the case of perfect substitutes, is it possible for neither good to be essential but tastes nevertheless to be homothetic? If so, can you give an example?
 - b. Can there be homothetic tastes where one of the two goods is essential and the other is not? If so, give an example.
 - c. Is it possible for tastes to be nonmonotonic (less is better than more) but still homothetic?
 - d. Is it possible for tastes to be monotonic (more is better), homothetic but strictly non-convex (i.e., averages are worse than extremes)?
- B. Now relate the homotheticity property of indifference maps to utility functions.
 - a. Aside from the case of perfect substitutes, are there any CES utility functions that represent tastes for goods that are not essential?
 - b. All CES utility functions represent tastes that are homothetic. Is it also true that all homothetic indifference maps can be represented by a CES utility function? (*Hint:* Consider your answer to A(a) and ask yourself, in light of your answer to B(a), if it can be represented by a CES function.)
 - c. *True or False:* The elasticity of substitution can be the same at all bundles only if the underlying tastes are homothetic.

- d. *True or False:* If tastes are homothetic, then the elasticity of substitution is the same at all bundles.
- e. What is the simplest possible transformation of the CES utility function that can generate tastes that are homothetic but nonmonotonic?
- f. Are the tastes represented by this transformed CES utility function convex?
- g. So far, we have always assumed that the parameter ρ in the CES utility function falls between -1 and ∞ . Can you determine what indifference curves would look like when ρ is less than -1 ?
- h. Are such tastes convex? Are they monotonic?
- i. What is the simplest possible transformation of this utility function that would change both your answers to the previous question?

5.11*† In this exercise, we are working with the concept of an elasticity of substitution. This concept was introduced in part B of the chapter. Thus, this entire question relates to material from part B, but the A part of the question can be done simply by knowing the formula for an elasticity of substitution while the B part of the question requires further material from part B of the chapter. In Section 5B.1, we defined the elasticity of substitution as

$$\sigma = \left| \frac{\% \Delta(x_2/x_1)}{\% \Delta MRS} \right|. \quad (5.26)$$

- A. Suppose you consume only apples and oranges. Last month, you consumed bundle $A = (100, 25)$ 100 apples and 25 oranges, and you were willing to trade at most 4 apples for every orange. Two months ago, oranges were in season and you consumed $B = (25, 100)$ and were willing to trade at most 4 oranges for 1 apple. Suppose your happiness was unchanged over the past two months.
 - a. On a graph with apples on the horizontal axis and oranges on the vertical, illustrate the indifference curve on which you have been operating these past two months and label the *MRS* where you know it.
 - b. Using the formula for elasticity of substitution, estimate your elasticity of substitution of apples for oranges.
 - c. Suppose we know that the elasticity of substitution is in fact the same at every bundle for you and is equal to what you calculated in (b). Suppose the bundle $C = (50, 50)$ is another bundle that makes you just as happy as bundles A and B . What is the *MRS* at bundle C ?
 - d. Consider a bundle $D = (25, 25)$. If your tastes are homothetic, what is the *MRS* at bundle D ?
 - e. Suppose you are consuming 50 apples, you are willing to trade 4 apples for 1 orange, and you are just as happy as you were when you consumed at bundle D . How many oranges are you consuming (assuming the same elasticity of substitution)?
 - f. Call the bundle you derived in part (e) E . If the elasticity is as it was before, at what bundle would you be just as happy as at E but would be willing to trade 4 oranges for 1 apple?
- B. Suppose your tastes can be summarized by the utility function $u(x_1, x_2) = (\alpha x_1^{-\rho} + (1 - \alpha)x_2^{-\rho})^{-1/\rho}$.
 - a. In order for these tastes to contain an indifference curve such as the one containing bundle A that you graphed in A(a), what must be the value of ρ ? What about α ?
 - b. Suppose you were told that the same tastes can be represented by $u(x_1, x_2) = x_1^\gamma x_2^\delta$. In light of your answer, is this possible? If so, what has to be true about γ and δ given the symmetry of the indifference curves on the two sides of the 45-degree line?
 - c. What exact value(s) do the exponents γ and δ take if the label on the indifference curve containing bundle A is 50? What if that label is 2,500? What if the label is 6,250,000?
 - d. Verify that bundles A , B , and C (as defined in part A) indeed lie on the same indifference curve when tastes are represented by the three different utility functions you implicitly derived in B(c). Which of these utility functions is homogeneous of degree 1? Which is homogeneous of degree 2? Is the third utility function also homogeneous?
 - e. What values do each of these utility functions assign to the indifference curve that contains bundle D ?

- f. *True or False:* Homogeneity of degree 1 implies that a doubling of goods in a consumption basket leads to twice the utility as measured by the homogeneous function, whereas homogeneity greater than 1 implies that a doubling of goods in a consumption bundle leads to more than twice the utility.
- g. Demonstrate that the *MRS* is unchanged regardless of which of the three utility functions derived in B(c) is used.
- h. Can you think of representing these tastes with a utility function that assigns the value of 100 to the indifference curve containing bundle *A* and 75 to the indifference curve containing bundle *D*? Is the utility function you derived homogeneous?
- i. *True or False:* Homothetic tastes can always be represented by functions that are homogeneous of degree k (where k is greater than zero), but even functions that are not homogeneous can represent tastes that are homothetic.
- j. *True or False:* The marginal rate of substitution is homogeneous of degree 0 if and only if the underlying tastes are homothetic.

Doing the “Best” We Can

We began our introduction of microeconomics with the simple premise that economic actors try to do the best they can given their circumstances.¹ For three types of economic actors—consumers, workers, and individuals planning for the future—we showed in Chapters 2 and 3 how choice sets can be used to illustrate the *circumstances* these economic actors face when making choices. We then illustrated in Chapters 4 and 5 how we can model individual tastes, giving us a way of now addressing how individuals will judge which of their available choices is indeed the “best.” Chapters 2 through 5 therefore developed our basic *model* of individual choice sets and tastes, the first step in our economic analysis of choice. We now begin the second step, the analysis of how individuals in our basic model *optimize*; that is, how they would behave if they are indeed doing the best they can.

6A

CHOICE: COMBINING ECONOMIC CIRCUMSTANCES WITH TASTES

We begin by building some intuition about how tastes and choice sets interact to determine optimal choices. This means that we will essentially combine the graphs of Chapters 2 and 3 with those of Chapters 4 and 5 as we return to some of the examples we raised in those chapters. In the process, we’ll begin to get our first glimpse at the important role market prices play in helping us exploit all the potential *gains from trade* that would be difficult to realize in the absence of such prices. Then, in Section 6A.2, we consider scenarios under which individuals may choose not to purchase any quantity of a particular good, scenarios we will refer to as *corner solutions*. And, in Section 6A.3, we will uncover scenarios under which individuals may discover that more than one choice is optimal for them, scenarios that arise when either choice sets or tastes exhibit *non-convexities*.

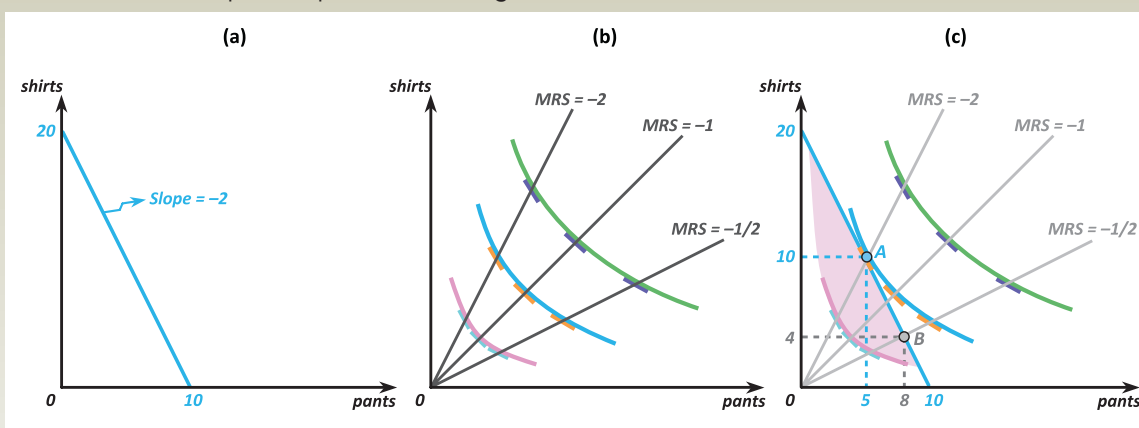

6A.1 The “Best” Bundle of Shirts and Pants

Suppose we return to my story of me going to Walmart with \$200 to spend on shirts and pants, with shirts costing \$10 each and pants costing \$20 per pair. We know from our work in Chapter 2

¹Chapters 2, 4, and 5 are required as reading for this chapter. Chapter 3 is not necessary.

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

GRAPH 6.1 Graphical Optimization: Budget Constraint & Indifference Curves

Go to MindTap to interact with this graph.

that in a graph with “pants” on the horizontal axis and “shirts” on the vertical, my budget constraint intersects at 20 on the vertical and at 10 on the horizontal. Its slope, which gives expression to the opportunity cost of one more pair of pants in terms of how many shirts I have to give up, is -2 . Suppose further that the marginal rate of substitution is equal to -2 at all bundles where I have twice as many shirts as pants, that it is equal to -1 at bundles where I have an equal number of shirts and pants, and that it is equal to $-1/2$ at bundles where I have twice as many pants as shirts. (This is an example of what we called “homothetic” tastes in Chapter 5.) My budget constraint and choice set are then graphed in Graph 6.1a, and some of the indifference curves from the indifference map that represents my tastes are graphed in Graph 6.1b. To determine which of the available choices is “best” given my circumstances, we now have to combine the information from Graphs 6.1a and 6.1b.

This is done in Graph 6.1c where panel (b) is simply laid on top of panel (a). Of the three indifference curves that are graphed, the green curve contains only bundles that are in fact not available to me given my circumstances because the entire curve lies outside my choice set. The magenta indifference curve has many bundles that fall within my choice set, but none of these is “best” for me because there are bundles in the shaded area to the northeast that all lie within my choice set and above this indifference curve, bundles that are “better” for someone with my tastes. We could now imagine me starting at some low indifference curve like this one and pushing northeast to get to higher and higher indifference curves without leaving the choice set. This process would end at the blue indifference curve in Graph 6.1c, an indifference curve that contains 1 bundle that lies in the choice set (bundle A) with no bundles above the indifference curve that also lie in the choice set. Bundle A, then, is the bundle I would choose if indeed I am trying to do the best I can given my circumstances. More precisely, I would consume 5 pair of pants and 10 shirts at my optimal bundle A.²

Choices emerge when tastes confront choice sets.

EXERCISE 6A.1 In Chapter 2, we discussed a scenario under which my wife gives me a coupon that reduces the effective price of pants to \$10 per pair. Assuming the same tastes, what would be my best bundle?

²This optimal bundle lies at the intersection of the budget line ($x_2 = 20 - 2x_1$) and the ray $x_2 = 2x_1$ representing all the points with MRS of -2 . Solving these by substituting the second equation into the first gives us the answer that $x_1 = 5$, and putting that into either of the two equations gives us that $x_2 = 10$.

6A.1.1 Opportunity Cost = Marginal Rate of Substitution At bundle A in Graph 6.1c, a very particular relationship exists between the slope of the budget constraint and the slope of the indifference curve that contains bundle A : *The two slopes are equal.* This is no accident, and it should make intuitive sense why this is true. The slope of the budget constraint represents the opportunity cost of pants in terms of shirts, which is the number of shirts I *have* to give up to get one more pair of pants (given the prices Walmart charges for pants and shirts). Put differently, the slope of the budget constraint represents the rate at which Walmart is allowing me to change pants into shirts. The slope of the indifference curve, in contrast, represents the marginal rate of substitution, which is the number of shirts I *am willing* to give up to get one more pair of pants. If I have a bundle in my shopping basket at which the value I place on pants (in terms of shirts) differs from the rate at which Walmart is allowing me to change pants into shirts, I can make myself better off by choosing a different bundle. Thus, at the optimal bundle, the rate at which I am *willing* to trade pants for shirt and the rate at which I *have* to trade them must be equal.

For goods we choose,
 $MRS = -p_1/p_2$.

Suppose, for instance, that I have B from Graph 6.1c (8 pants, 4 shirts) in my shopping basket. The marginal rate of substitution at B is $-1/2$. This means that I am *willing* to trade 1 pair of pants for half a shirt, but Walmart will give me 2 shirts for every pair of pants that I put back on the rack. If I am willing to trade a pair of pants for just half a shirt and Walmart will give me 2 shirts for a pair of pants, then I can clearly make myself better off by trading pants for more shirts. Put differently, when I have B in my basket, the marginal value I place on pants is lower than the marginal value Walmart is placing on those pants, and Walmart is therefore willing to give me more for pants (in terms of shirts) than I think they are worth. B therefore cannot possibly be a “best” bundle because I can make myself better off by exchanging pants for shirts.

Suppose you and I each have a bundle of 6 pants and 6 shirts, and suppose that my MRS of shirts for pants is -1 and yours is -2 . Suppose further that neither one of us has access to Walmart. Propose a trade that would make both of us better off.

EXERCISE
6A.2

6A.1.2 How Walmart Makes Us All the Same at the Margin I am not the only one who rushes to buy shirts and pants right before the school year starts; lots of others do the same. Some of those consumers have tastes very different than mine, so their indifference maps look very different. Others will have more generous wives (and thus more generous budgets); yet others may be poorer and may only be able to spend a fraction of what my wife is permitting me to spend. Imagine all of us—rich and poor, some in more need of pants and some in more need of shirts—all coming to Walmart to do the best we can. Coming into Walmart, we will be very different; but coming out of Walmart, it turns out that we will be quite the same in one important respect: *Our marginal rates of substitution of pants for shirts given what we have just purchased will all be the same.*

Consider, for instance, the two consumers whose choice sets and tastes are graphed in Graph 6.2a and 6.2b. Consumer 1 is rich (and thus has a large choice set) whereas consumer 2 is poor (and thus has a small choice set). Consumer 1 and consumer 2 also have very different indifference maps. In the end, however, they both choose an optimal bundle of shirts and pants at which their marginal rate of substitution is equal to the slope of their budget constraint. Since the slope of each consumer’s budget constraint is determined by the ratio of prices for shirts and pants at Walmart, and since Walmart charges the same prices to anyone who enters the store, the marginal rates of substitution for both people is thus equal once they have chosen their best bundle. Put differently, *while the two consumers enter the store with very different incomes and tastes, they leave the store with the same tastes for pants and shirts at the margin* (i.e., around the bundle they purchase).

GRAPH 6.2 Different Choice Sets, Different Tastes: But Same Tastes “at the Margin”

6A.1.3 How Walmart Eliminates Any Need for Us to Trade An important and unintended side effect of Walmart’s policy to charge everyone the same price is that *all gains from trade in pants and shirts occur inside Walmart*, eliminating any need for us to trade with one another once we leave the store. As we all enter the store, we may have different quantities of pants and shirts at home, and we could probably benefit from trading shirts and pants among us given that some of us might be willing to trade shirts for pants more easily than others. But once we leave Walmart, we value pants and shirts exactly the same at the margin; that is, we all have the same marginal rate of substitution of pants for shirts. There is therefore no more possibility for us to trade and become better off because we became as well off as we could by simply doing the best we can inside Walmart.

This is an important initial insight into a more general result we will develop later on in this book. Whenever two people have bundles of goods at which they value the goods in the bundle differently on the margin, there is the *potential for gains from trade*, the potential for trade to make both people better off. We already illustrated this in the end-of-chapter exercise 4.5 in Chapter 4 as well as in within-chapter exercise 6A.2, but here is another example. Suppose I am willing to trade 1 can of Coke for 1 can of Pepsi (i.e., my marginal rate of substitution is -1), but my wife is willing to trade 1 can of Coke for 2 cans of Pepsi (i.e., her marginal rate of substitution is -2). Then we can gain from trading with one another so long as we each have both Coke and Pepsi in our bundles. In particular, I could offer my wife 2 Cokes for 3 Pepsis. This will make me better off because I would have been willing to take only 2 Pepsis for 2 Cokes, and it will make my wife better off because she would have been willing to give me as many as 4 Pepsis for 2 Cokes. The fact that our marginal rates of substitution are different, the fact that we value goods differently at the margin, makes it possible for us to trade in a way that makes both of us better off.

*Economists say that a situation is efficient if there is no way to change the situation so as to make some people better off without making anyone worse off.*³ A situation is therefore

When *MRS* differs across people, they can gain from trading.

³Sometimes economists refer to this as *Pareto efficient* or *Pareto optimal* after Vilfredo Pareto (1848–1923). Pareto was among the first economists in the late 19th century to realize that economic analysis did not require utility to be objectively measurable, that all that was required was for individuals to be able rank different alternatives. This led him to his definition of efficiency, which stands in contrast to earlier “utilitarian” theories that relied on adding up people’s “utils.” We will return to some of this in Chapter 29.

inefficient if we can think of a way to change the situation and make some people better off without making anyone else worse off. If we find ourselves in a situation where people value goods that they possess differently at the margin, we know there is a way to make everyone better off through trade. Thus, situations where people have different marginal rates of substitution for goods that they possess are inefficient. Since Walmart’s policy of charging the same prices to everyone results in a situation where everyone leaves the store with marginal rates of substitution between goods in their baskets identical, *Walmart ensures that the distribution of pants and shirts is efficient among those that purchase pants and shirts at Walmart.*

Efficiency implies that all gains from trade have been exhausted.

We keep using the phrase “at the margin” as, for example, when we say that tastes for those leaving Walmart will be the “same at the margin.” What do economists mean by this “at the margin” phrase?

EXERCISE
6A.3

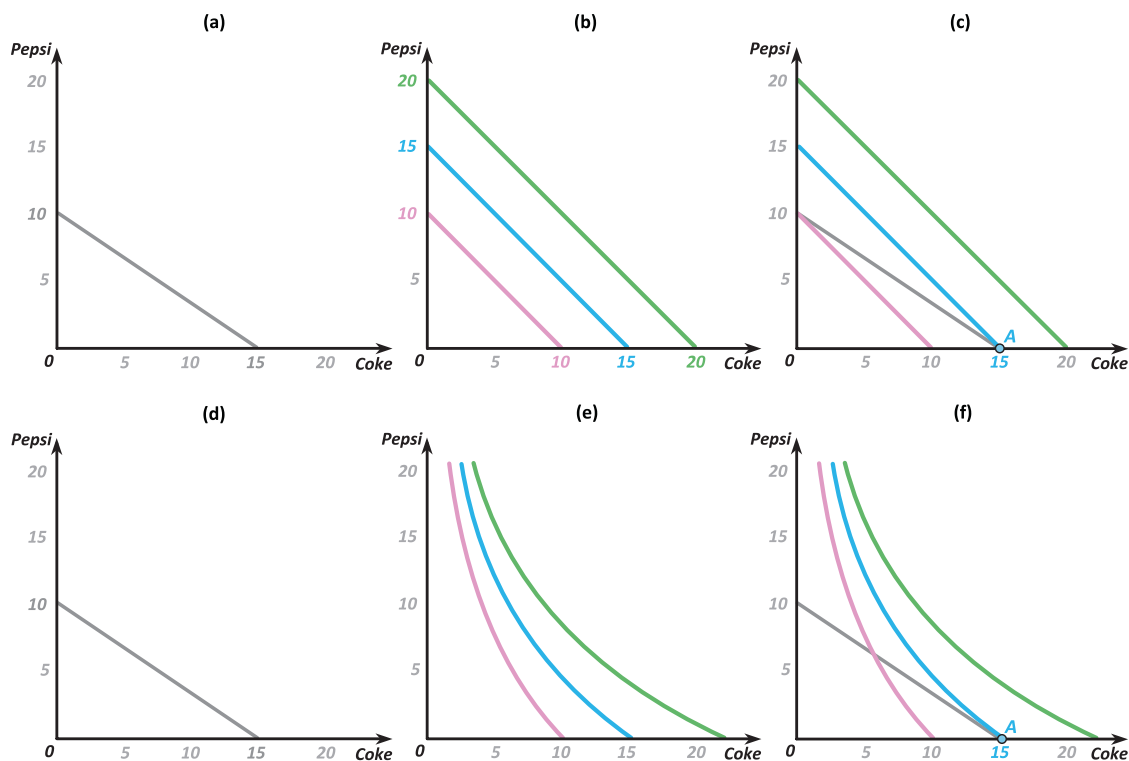

I doubt you have ever thought of approaching someone in the Walmart parking lot to propose a trade of goods in your shopping basket with goods you see in his or her basket. It turns out, there is a very good reason for this: It would be an exercise in futility because all gains from trade have been exhausted within Walmart, and the distribution of goods is already efficient. Put differently, once we leave Walmart, any trade that I propose to you will either leave us just as well off as we would be without trading or would make one of us worse off. So we don’t need to bother trying.

6A.2 To Buy or Not to Buy

With the indifference maps and budget sets used above, “doing the best I can” led me to purchase *both* pants and shirts at Walmart. But sometimes our tastes and circumstances are such that doing the best we can implies we will choose *not* to consume any of a particular good. This certainly happens for goods that we consider “bads,” goods of which we would prefer less rather than more. Peanut butter is such a good for me. I simply cannot imagine why anyone would ever consume any unless there was an immediate need to induce vomiting. Ketchup is another such good for me. I will never buy peanut butter or ketchup. But there are also goods that I like of which I will consume none. For instance, I like both Coke and Pepsi equally (and in fact cannot tell the difference between the two), but whenever Pepsi is more expensive than Coke, I will buy no Pepsi. My tastes for goods that I like combine, in this case, with my economic circumstances to lead to my “best” choice at a “corner” of my budget constraint.

6A.2.1 Corner Solutions Let’s consider the case of me choosing between Coke and Pepsi in the context of our model of tastes and circumstances. Suppose that I get sent to the store with \$15 to spend on soft drinks, and suppose that the store sells only Coke and Pepsi. Suppose further that the price of Coke is \$1 per can and the price of Pepsi is \$1.50 per can. Graph 6.3a then illustrates my choice set and budget constraint. In Chapter 5, we further illustrated my tastes for Coke and Pepsi with an indifference map containing indifference curves that all have a marginal rate of substitution equal to -1 everywhere. Such indifference curves, illustrated again in Graph 6.3b, give expression to the fact that I cannot tell the difference between Coke and Pepsi and therefore am always willing to trade them one for one.

In panel (c) of Graph 6.3, we again overlay my choice set (from panel (a)) and my indifference map (from panel (b)). My goal is to reach the highest indifference curve that contains at least one bundle in the choice set. I could start with the lowest (magenta) indifference curve, note that all bundles on that indifference curve lie in my choice set, then move to the northeast to higher indifference curves. Eventually, I will reach the blue indifference curve in Graph 6.3c,

GRAPH 6.3 Corner Solutions

which contains one bundle (bundle A) that lies both on the indifference curve and within my choice set. Since any bundle on an indifference curve higher than this lies outside my choice set, bundle A is my “best” bundle. It contains 15 Cokes and no Pepsi and is called a “corner solution” because it lies on one corner of my choice set.

EXERCISE 6A.4

In the previous section, we argued that Walmart’s policy of charging the same price to all consumers ensures that there are no further gains from trade for goods contained in the shopping baskets of individuals who leave Walmart. The argument assumed that all consumers end up at an interior solution, not a corner solution. Can you see why the conclusion still stands when some people optimize at corner solutions where their *MRS* may be quite different from the *MRS*’s of those who optimize at interior solutions?

EXERCISE 6A.5

Suppose the prices of Coke and Pepsi were the same. Illustrate that now there are many optimal bundles for someone with my kind of tastes. What would be my “best” bundle if Pepsi is cheaper than Coke?

Of course, tastes do not have to be as extreme as those for perfect substitutes in order for corner solutions to arise. Panels (d), (e), and (f) of Graph 6.3, for instance, illustrate a less extreme

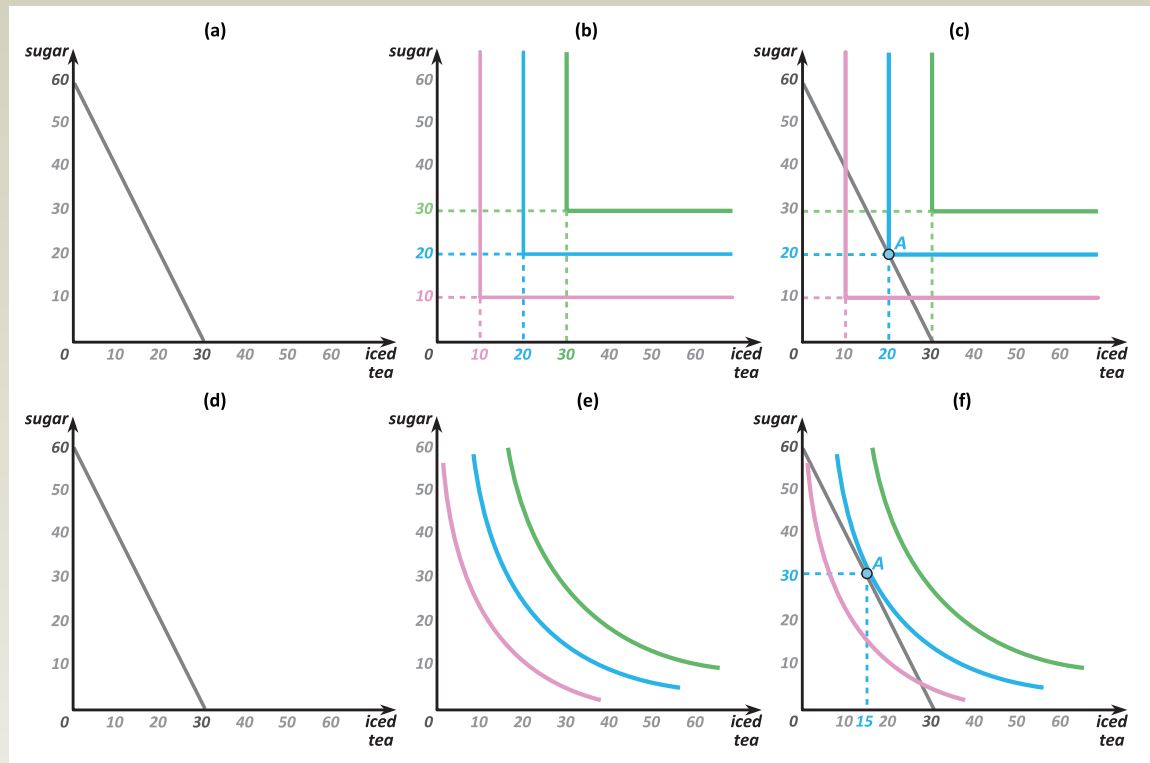

set of indifference curves that nevertheless results in corner solutions for certain economic circumstances.

6A.2.2 Ruling Out Corner Solutions In Chapter 5, we discussed how a good is “essential” if indifference curves do not intersect the axes on which the other good is measured, essential in the sense that no utility above that of consuming at the origin of the graph can be attained without at least some consumption of such “essential” goods. If all goods in a particular model of a consumer’s tastes are “essential,” then corner solutions are not possible; it can never be optimal to choose a bundle with zero quantity of one of the goods because that would be the same as choosing zero quantity of all goods. *Whenever indifference curves intersect an axis, however, some goods are not essential, and there is thus a potential for a corner solution to be the optimal choice under some economic circumstances.*

Essential goods cannot give rise to corner solutions.

Consider, for instance, my wife’s tastes for iced tea and sugar as described in Chapter 5. Suppose that sugar costs \$0.25 per packet and iced tea costs \$0.50 per glass, and suppose that my wife has budgeted \$15 for her weekly iced tea drinking. Her weekly choice set is illustrated in Graph 6.4a, and her tastes for iced tea and sugar packets are illustrated with three indifference curves in Graph 6.4b (given that these are perfect complements for her). Panel (c) of Graph 6.4 then illustrates her optimal choice as bundle A, with equal numbers of glasses of iced tea and sugar packets.

GRAPH 6.4 Ruling Out Corner Solutions

We could now think of changing the prices of iced tea and sugar packets, of making sugar packets really cheap and making iced tea really expensive, for instance. While the total quantity of iced tea and sugar packets that is optimal will be different, it will always be true that my wife will consume equal numbers of iced tea glasses and sugar packets, and never a corner solution.

The case of perfect complements is an extreme case that ensures that no corner solutions will ever be optimal. But the same logic holds for any map of indifference curves that do not intersect either axis, or, put differently, for any set of goods that are all essential. Panels (d) through (f) of Graph 6.4, for instance, model my wife's tastes for iced tea and sugar as less extreme, with some willingness to trade off some sugar for more iced tea and vice versa. Still, the indifference map in panel (e) of the graph is such that no indifference curve ever intersects either axis, ensuring an *interior solution* where the marginal rate of substitution is exactly equal to the slope of the budget constraint.

6A.2.3 Is It Realistic to Rule Out Corner Solutions? In many of our applications throughout this book, we will assume tastes with indifference maps that rule out corner solutions by assuming that all goods are essential. Our first reaction to this might be that this is highly unrealistic. After all, we are all at corner solutions because there are many goods at Walmart that never end up in our shopping baskets. This is certainly true, but remember that we are not trying to model everything that happens in the world when we write down an economic model. Rather, we try to isolate the aspects of the world that are essential for a proper analysis of particular questions, and so it may often make sense simply to abstract away from the existence of all those goods that we never purchase.

For instance, I might be interested in analyzing how your housing choices change as your circumstances change. I might therefore abstract away from your tastes over Coke and Pepsi and pants and shirts, and simply model your tastes for square feet of housing and “other consumption.” In that case, of course, it makes perfect sense to assume indifference maps that exclude the possibility of corner solutions because you will almost certainly choose to consume some housing and some other goods regardless of how much your circumstances change. Similarly, when I am interested in analyzing your choice of leisure and consumption, it is likely that you will always choose some leisure and some consumption. The same is probably the case when I model your choice of how much to consume this year versus next year: Few people will consciously plan to consume only today or only next year regardless of how much individual circumstances change. Thus, while we certainly are at corner solutions almost all the time in the sense that we do not consume many types of goods, economic modeling of the relevant choices often makes it quite reasonable to assume tastes that prohibit corner solutions by assuming that the goods relevant to our analysis are all essential.

Most interesting economic models do not give rise to corner solutions.

6A.3 More than One “Best” Bundle? Non-Convexities of Choice Sets and Tastes

Thus far, almost all our examples have made it appear as if a consumer will always be able to reach a unique optimal decision.⁴ It turns out that this “uniqueness” occurs in most of our models because of two assumptions that have held throughout the earlier portions of this chapter: First, all budget constraints were lines, and second, all tastes were assumed to satisfy the “averages are better than extremes” assumption. More generally, we will find next that the “uniqueness” of the “best” choice may disappear as “non-convexities” in choice sets or tastes enter the problem we are modeling.

⁴The one exception to this has been the case of indifference curves with linear components such as those for perfect substitutes, where a whole set of bundles may be optimal when the ratio of prices is exactly equal to the slope of the linear component of the budget line (see the within-chapter exercise 6A.5 in Section 6A.2.1).

6A.3.1 Optimizing with Kinked Budgets As we illustrated in Chapters 2 and 3, there are two basic types of kinks in budget constraints that may arise under various circumstances: those that point “outward” and those that point “inward.” We introduced these in Chapter 2 with two types of coupons for pants. First we considered a coupon that gave a consumer 50% off for the first 6 pairs of pants (Graph 2.4a) and then turned toward thinking about a coupon that gave 50% off for any pair of pants a consumer purchases after buying 6 at regular price. We will demonstrate now that multiple “best” bundles may arise only in the second case but not in the first (assuming for now that our tastes satisfy the basic five assumptions laid out in Chapter 4).

Graph 6.5 considers how three different types of tastes may result in three different optimal bundles on the same “outwardly” kinked budget constraint derived from the first type of coupon (see Section 2A.2). In each case, the general shape of our standard indifference curves guarantees only a single “best” choice because there is no way to draw our usual shapes for indifference curves and get more than one tangency to the outwardly kinked budget constraint.

Graph 6.6, in contrast, considers the “inwardly” kinked budget that arises under the second type of coupon (see also Section 2A.2) and particularly models tastes that lead to two “best” bundles: bundles *A* and *B*. You can immediately see how this is possible: Since indifference curves begin steep and become shallower as we move toward the right in the graph, the only way we can have two bundles at which the budget constraint has the same slope at the best indifference curve is for the budget constraint itself also to become shallower as we move to the right. This can happen with an “inward” kink in the budget, but it cannot happen with an “outward” kink such as that in Graph 6.5.

6A.3.2 Non-Convexities in Choice Sets In fact, a “kink” in the budget is, strictly speaking, not necessary for the possibility of multiple “best” bundles when indifference maps satisfy the “averages better than extremes” assumption. Rather, what is necessary is a property known as “non-convexity” of the choice set.

A set of points is said to be *convex* whenever the line connecting any two points in the set is itself contained within the set. Conversely, a set of points is said to be *non-convex* whenever some part of a line connecting two points in the set lies outside the set. No such non-convexity exists in the choice set of Graph 6.5. Regardless of which two points in the set we pick, the line connecting them always also lies within the set. But in the choice set of Graph 6.6, it is easy to find pairs of points where the line connecting those points lies outside the set. For instance, both

GRAPH 6.5 Optimizing along Budget with an “Outward” Kink

GRAPH 6.6 Example of 2 Optimal Bundles When the Choice Set Is Kinked “Inward”

points *A* and *B* in Graph 6.6 lie in the choice set, but the line connecting the two points lies outside the set. Thus, the choice set in Graph 6.6 is non-convex.

EXERCISE 6A.6 Consider a set of points that compose a solid sphere. Is this set convex? What about the set of points contained in a donut?

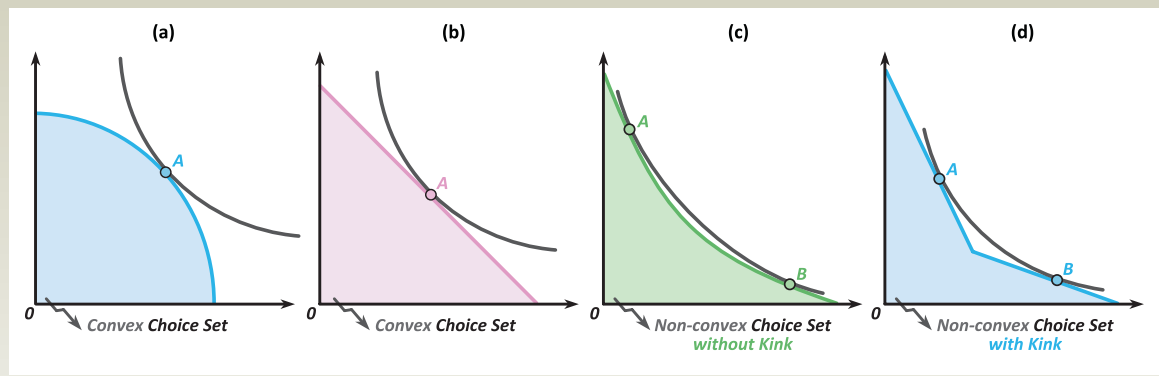

EXERCISE 6A.7 We have just defined what it means for a set of points to be convex—it must be the case that any line connecting two points in the set is fully contained in the set as well. In Chapter 4, we defined tastes to be convex when “averages are better than (or at least as good as) extremes.” The reason such tastes are called “convex” is because the set of bundles that is better than any given bundle is a convex set. Illustrate that this is the case with an indifference curve from an indifference map of convex tastes.

Now, notice that a regularly shaped indifference curve can be tangent to the boundary of a choice set more than once *only if* the choice set is non-convex. The series of graphs in Graph 6.7 attempts to show this intuitively by beginning with a convex choice set (in panel (a)), continuing with a linear budget that is still convex (in panel (b)), and then proceeding to two non-convex choice sets in panels (c) and (d). *The important characteristic of a choice set to produce multiple “best bundles” is therefore not the existence of a kink but rather the existence of a non-convexity* (which may or may not involve a kink). While we can think of examples of non-convex choice sets, we will see that convex choice sets are most common in most of the economic applications we will discuss in the remainder of this book.

EXERCISE 6A.8 *True/False:* If a choice set is non-convex, there are definitely multiple “best” bundles for a consumer whose tastes satisfy the usual assumptions.

EXERCISE 6A.9 *True/False:* If a choice set is convex, then there will be a unique “best” bundle, assuming consumer tastes satisfy our usual assumptions and averages are strictly better than extremes.

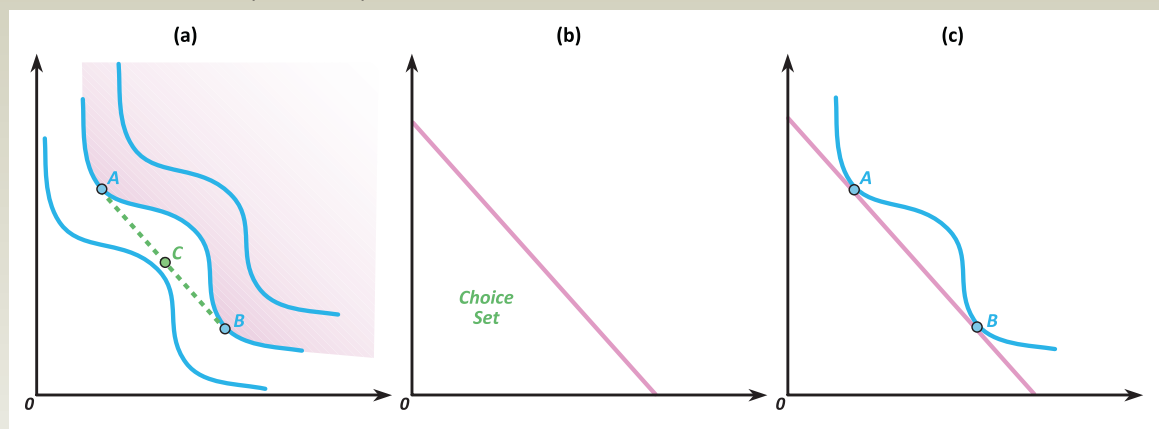

GRAPH 6.7 The Role of Convexity of Choice Sets in Insuring Unique Optimal Bundles

6A.3.3 Non-Convexities in Tastes Suppose next that an indifference map had indifference curves that looked like those graphed in Graph 6.8a. You can demonstrate that such indifference curves violate the “averages are better than extremes” (or convexity) assumption by considering bundles *A* and *B* together with the average between those bundles, labeled *C* in the graph. Since *C* falls below the indifference curve that contains *A* and *B*, it is worse than *A* and *B*; thus the average bundle is not as good as the more extreme bundles. As already suggested in exercise 6A.7, the reason we call such tastes non-convex is that the set of bundles that is better than a given bundle is a non-convex set. In our example, bundle *C* lies on the line connecting bundles *A* and *B* but is worse, not better, than bundles *A* and *B*. Thus, the set of bundles that are better than those on the indifference curve containing bundle *A* (the shaded area in Graph 6.8a) is non-convex.

Now suppose we consider an individual with tastes that can be represented by the indifference map in Graph 6.8a trying to do the best he or she can on the linear (and thus convex) budget in Graph 6.8b. This can then result in both *A* and *B* in Graph 6.8c being optimal.

GRAPH 6.8 Example of 2 Optimal Bundles When Tastes Are Non-Convex

are better than extremes” assumption rules this scenario out by explicitly ruling out non-convexities in tastes. We have argued in Chapter 4 that assuming “averages are better than extremes” is reasonable for most economic models. It makes sense that people are more willing to trade shirts for pants if they have lots of shirts and relatively few pants. In most economic models, we therefore feel comfortable ruling out “non-convex” tastes, and thus ruling out multiple optimal bundles due to non-convexities in tastes.

EXERCISE 6A.10* Suppose that the choice set is defined by linear budget constraint and tastes satisfy the usual assumptions but contain indifference curves with linear components (or “flat spots”). *True/False:* There might then be multiple “best” bundles, but we can be sure that the set of “best” bundles is a convex set.

EXERCISE 6A.11* *True/False:* When there are multiple “best” bundles due to non-convexities in tastes, the set of “best” bundles is also non-convex (assuming convex choice sets).

Non-convexities in budgets or tastes can result in multiple “best” bundles.

There are instances, however, when we might think that tastes should be modeled as non-convex, and should thus permit multiple optimal solutions. Suppose, for instance, we modeled our tastes for steak dinners versus chicken dinners, and suppose we considered a model in which we are trying to predict whether someone will choose a steak or a chicken dinner, or some combination of the two. It may well be reasonable for someone to have non-convex tastes that allow for both a steak dinner and a chicken dinner to be optimal, with a half steak and half chicken dinner being worse. At the same time, if we instead modeled someone’s weekly tastes for steak and chicken dinners (rather than just his or her tastes at a single meal), the non-convexity is less reasonable because, over the course of a week, someone is much more likely to be willing to have some steak and some chicken dinners.

Putting the insights from this and the previous section together, we can conclude that *we can be sure that an individual has a single, unique “best” choice given a particular set of economic circumstances only if neither his or her choice set nor his or her tastes exhibit non-convexities.* More precisely, we need tastes to be *strictly convex*—averages to be strictly better than (and not just as good as) extremes, because, as we saw in exercise 6A.10, multiple optimal bundles are possible when indifference curves contain linear segments or “flat spots.”

6A.4 Learning about Tastes by Observing Choices in Supermarkets or Laboratories

It is impossible for you to look at me and know whether or not I like Coke and Pepsi, whether I enjoy peanut butter or would rather have more shirts than pants or the other way around. We do not carry our tastes around on our sleeves for all the world to see. Thus, you may think all this “theory” about tastes is a little pie in the sky, that it wrecks of the cluttered mind of an academic who has lost his marbles and his connection to the real world. Not so! *Despite the fact that tastes are not directly observable, we are able to observe people’s choices under different economic circumstances, and from those choices we can conclude something about their tastes.* In fact, if we observe enough real-world choices under enough different economic circumstances, we can pretty much determine what a person’s indifference map looks like. Economists and neuroscientists are also beginning to map tastes directly to features of our brain through the use of sophisticated brain scanning equipment in laboratories.

6A.4.1 Estimating Tastes from Real-World Choices It is not difficult to see how we can estimate tastes by observing people’s choices in the real world (even though the statistical methods required for an economist actually to determine a consumer’s underlying tastes are quite sophisticated and beyond the scope of this text). Take our example of me shopping for pants and shirts at Walmart, for instance, and suppose that you observe that I purchase 10 shirts and 5 pants with my \$200 budget when the prices of shirts and pants are \$10 and \$20, respectively. This tells you that my *MRS* at the bundle (5, 10) is equal to the slope of my budget (−2). Then suppose that my economic circumstances change because Walmart changes the price of pants to \$10 and the price of shirts to \$20, and suppose you now see me purchasing 10 pants and 5 shirts. You now know that my *MRS* at the bundle (10, 5) is $-1/2$. If you continue to see changes in my economic circumstances and my response to those changes in terms of my choices, you can keep collecting information about the *MRS* at each of the bundles that I purchase under each scenario. The more such choices you observe, the easier it is for you to estimate what my underlying indifference map must look like.

By observing choice, we can infer *MRSs* at different bundles.

Thus, economists have developed ways to estimate underlying tastes by observing choices under different economic circumstances. Many supermarkets, for instance, provide consumers with cards that can be scanned at the check-out counter and that give consumers some discounts on certain products. Every time I shop in our local supermarket, I give the check-out clerk my card so that I get the discounts on advertised items. The supermarket then automatically collects data on my consumption patterns. It knows what I buy when I shop and how my consumption patterns change with the supermarket’s discounts and price changes. Economists can then analyze such data to recover underlying tastes for particular consumers or the “average consumer.”

6A.4.2 Learning about the Link from the Brain to Tastes Over the last few years, a new area has emerged within economics known as *neuroeconomics*. Many neuroeconomists are actually neuroscientists who specialized in understanding how our brain makes decisions, and a small but increasing number have been trained as economists who collaborate with neuroscientists. Their aim is, in part, to unravel the “black box” of tastes: to understand what determines our tastes and how they change over time, to what extent tastes are “hard-wired” into our brain, and how our brain uses tastes to make decisions. In doing their work, neuroeconomists rely on both the economic theory of choice as well as experimental evidence gathered from observing individuals make choices within a laboratory where various aspects of their physiology can be closely monitored. Neuroeconomists can, for instance, see which parts of the brain are active—and how active they are—when individuals confront a variety of choices, and through this they are beginning to be able to infer something about the mapping of features of tastes (such as marginal rates of substitution) to the structure of the brain. They are also able to see how the decision-making process is altered when the brain is altered by such factors as substance abuse. This is fascinating research, but it is beyond the scope of this book. However, within a relatively short period, it is likely that you will be able to take course work in neuroeconomics and should consider doing so if the intersection between economics and neuroscience seems interesting to you.

6B

OPTIMIZING WITHIN THE MATHEMATICAL MODEL

In part 6A, we found ways of depicting mathematical optimization problems in intuitive graphs, and we now turn toward an exposition of the mathematics that underlies this intuition. Specifically, we will see that consumers face what mathematicians call a *constrained optimization problem*, a problem where some variables (the goods in the consumption bundle) are *chosen* so as to *optimize* a function (the utility function), subject to the fact that there are *constraints* (the choice set).

6B.1 Optimizing by Choosing Pants and Shirts

Letting x_1 and x_2 denote pants and shirts, consider once again the example of me choosing a consumption bundle (x_1, x_2) in Walmart given that the price for a pair of pants is \$20 and the price for a shirt is \$10, and given that my wife gave me a total of \$200 to spend. Suppose further that my tastes can be represented by the Cobb–Douglas utility function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$, which gives rise to the indifference curves drawn in Graph 6.1 of Section 2A.1. Then the mathematical problem I face is that I would like to choose the quantities of x_1 and x_2 so that they are affordable (i.e., they lie within the choice set) and so that they attain for me the highest possible utility as evaluated by the utility function u . That is, of course, exactly the same problem we were solving graphically in Graph 6.1, where we were finding the “best” bundle by finding the highest indifference curve (and thus the highest level of utility) that contains at least one point in the budget set.

Put differently, I would like to *choose* (x_1, x_2) so as to *maximize* the function $u(x_1, x_2)$ *subject to the constraint* that my expenditures on good x_1 plus my expenditures on good x_2 are no larger than \$200. Formally, we write this as

$$\max_{x_1, x_2} u(x_1, x_2) = x_1^{1/2}x_2^{1/2} \quad \text{subject to } 20x_1 + 10x_2 \leq 200. \quad (6.1)$$

The “max” notation at the beginning of the expression signifies that we are attempting to *maximize* or “get to the highest possible value” of a function. The variables that appear immediately below the “max” notation as subscripts signify those variables that we are choosing, or the *choice variables* in the optimization problem. I am able to choose the quantities of the two goods, but I am not able to choose the prices at which I purchase them or, since my wife determined it, my money budget. Thus, x_1 and x_2 are the only choice variables in this optimization problem. This is then followed by the function that we are maximizing, called the *objective function* of the optimization problem. Finally, if there is a constraint to the optimization problem, it appears as the last item of the formal statement of the problem following the words “subject to.” We will follow this general format for stating optimization problems throughout this text.

Since we know that Cobb–Douglas utility functions represent tastes that satisfy our “more is better” assumption, we can furthermore rewrite expression (6.1) with the certainty that the bundle (x_1, x_2) that solves the optimization problem is one that lies *on* the budget line, *not inside* the choice set. When such an inequality constraint holds with equality in an optimization problem, we say that the constraint is *binding*. In other words, we know that I will end up spending all of my allocated money budget, so we might as well write that constraint as an equality rather than as an inequality. Expression (6.1) then becomes

$$\max_{x_1, x_2} u(x_1, x_2) = x_1^{1/2}x_2^{1/2} \quad \text{subject to } 20x_1 + 10x_2 = 200. \quad (6.2)$$

6B.1.1 Two Ways of Approaching the Problem Mathematically We begin by viewing the problem strictly through the eyes of a mathematician, and we illustrate two equivalent methods to solving the problem defined in equation (6.2).

Method 1: Converting the Constrained Optimization Problem into an Unconstrained Optimization Problem

One way is to turn the problem from a constrained optimization to an *unconstrained* optimization problem by inserting the constraint into the objective function. For example, we can solve the constraint for x_2 by subtracting $20x_1$ from both sides and dividing both sides by 10 to get $x_2 = 20 - 2x_1$. When we insert this into the utility function for x_2 , we get a new function that is simply a function of the variable x_1 . We can call this function $f(x_1)$ and rewrite the problem defined in (6.2) as

$$\max_{x_1} f(x_1) = x_1^{1/2}(20 - 2x_1)^{1/2}. \quad (6.3)$$

GRAPH 6.9 Unconstrained Optimization: Derivative Is 0 at the Optimum

Graph 6.9 plots this function, and this graph illustrates that the function f attains a maximum at $x_1 = 5$, which is exactly the same answer we derived graphically in Graph 6.1. Furthermore, the f function attains a value of zero at $x_1 = 10$. Thinking back to the underlying economics, when x_1 (the number of pants) is 10, I have no money left over for shirts. Since the tastes are such that both shirts and pants are “essential,” it makes sense that the function returns back to zero when I purchase no shirts.

Rather than plotting the whole function and finding the maximum graphically, we can of course use calculus to find the maximum. More precisely, since the function has a slope of zero when it attains its maximum, all we have to do to find this maximum mathematically is find where the slope (or derivative) of the function is zero. Taking the derivative of f with respect to x_1 , we get

$$\frac{df}{dx_1} = \frac{1}{2}x_1^{-1/2}(20 - 2x_1)^{1/2} - x_1^{1/2}(20 - 2x_1)^{-1/2}. \quad (6.4)$$

When we then set this expression to zero and solve for x_1 , we get $x_1 = 5$ as the maximum of the function, just as Graph 6.9 illustrated. Thus, we know that I will purchase 5 pairs of pants (costing a total of \$100), leaving \$100 to purchase 10 shirts (at a price of \$10 each). We have found mathematically what we found graphically in Graph 6.1: the “best” choice for me “given my circumstances.”

Method 2: The Lagrange Method for Solving the Constrained Optimization Problem

A second (and more general) way to solve problems of the type expressed in (6.2) is to use a method that is known as the *Lagrange Method*. If you have taken a full calculus sequence, you have probably covered this in your last calculus course, but the method is not very complicated and does not require all the material usually covered in the entire calculus sequence. The method does essentially what we did in Method 1: It defines a new function and sets derivatives equal to zero to find the maximum of that new function. The function that we define is called the *Lagrange function*, and it is always constructed as a combination of the objective function in the optimization problem plus a term λ multiplied by the constraint (where the terms in the constraint are all collected to one side, with the other side equal to zero). For instance, expression (6.2) results in the *Lagrange function* \mathcal{L} given by

$$\mathcal{L}(x_1, x_2, \lambda) = x_1^{1/2}x_2^{1/2} + \lambda(200 - 20x_1 - 10x_2). \quad (6.5)$$

Notice that the function \mathcal{L} is a function of three variables: the two choice variables (x_1, x_2) and λ , which is called the *Lagrange multiplier*. Without explaining exactly why the following solution method works, Lagrange problems of this type are solved by solving the system of three equations that arises when we take the partial derivatives of \mathcal{L} with respect to each of the three variables and set these derivatives to zero; that is we solve the following system of equations known jointly as the *first order conditions* of the constrained optimization problem:

$$\begin{aligned}\frac{\partial \mathcal{L}}{\partial x_1} &= \frac{1}{2} x_1^{-1/2} x_2^{1/2} - 20\lambda = 0, \\ \frac{\partial \mathcal{L}}{\partial x_2} &= \frac{1}{2} x_1^{1/2} x_2^{-1/2} - 10\lambda = 0, \\ \frac{\partial \mathcal{L}}{\partial \lambda} &= 200 - 20x_1 - 10x_2 = 0.\end{aligned}\tag{6.6}$$

One easy way to solve this system of equations is to rewrite the first two by adding the λ terms to both sides, thus getting

$$\begin{aligned}\frac{1}{2} x_1^{-1/2} x_2^{1/2} &= 20\lambda \\ \frac{1}{2} x_1^{1/2} x_2^{-1/2} &= 10\lambda\end{aligned}\tag{6.7}$$

and then dividing these two equations by each other to get

$$\frac{x_2}{x_1} = 2.\tag{6.8}$$

Multiplying both sides of (6.8) by x_1 then gives us

$$x_2 = 2x_1,\tag{6.9}$$

which we can insert into the third equation in expression (6.6) to get

$$200 - 20x_1 - 10(2x_1) = 0.\tag{6.10}$$

Solving this expression for x_1 then gives the same answer we calculated using our first method: $x_1 = 5$, and substituting that into expression (6.9) gives us $x_2 = 10$. Doing the “best” I can “given my circumstances” in Walmart again means that I will purchase 5 pants and 10 shirts. Intuitively, condition (6.9) tells us that, for the type of tastes we are modeling and the prices that we are facing at Walmart (20 and 10), it will be optimal for me to consume twice as many shirts (x_2) as pants (x_1); that is it will be optimal for me to consume on the ray emanating from the origin that contains bundles with twice as many shirts as pants. That is exactly the ray containing point *A* in Graph 6.1c, where we modeled the same homothetic tastes graphically. In fact, steps (6.9) and (6.10) above are exactly the same as the steps we used to solve for the optimal solutions when all we had to go on was the graphical information in Section 6A.1!

The Lagrange Method of solving constrained optimization problems is the preferred method for economists because it generalizes most easily to cases where we are choosing more than two goods. For instance, suppose that I was at Walmart choosing bundles of pants (x_1), shirts (x_2), and socks (x_3) with the price of socks being equal to 5 (and all other prices the same as before), and suppose one utility function that can represent my tastes is the Cobb–Douglas function $u(x_1, x_2, x_3) = x_1^{1/2} x_2^{1/2} x_3^{1/2}$. Then my constrained optimization problem would be written as

$$\max_{x_1, x_2, x_3} u(x_1, x_2, x_3) = x_1^{1/2} x_2^{1/2} x_3^{1/2} \text{ subject to } 20x_1 + 10x_2 + 5x_3 = 200,\tag{6.11}$$

and the Lagrange function would be written as

$$\mathcal{L}(x_1, x_2, x_3, \lambda) = x_1^{1/2} x_2^{1/2} x_3^{1/2} + \lambda(200 - 20x_1 - 10x_2 - 5x_3). \quad (6.12)$$

We would then solve a system of 4 equations made up of the partial derivatives of \mathcal{L} with respect to each of the choice variables (x_1, x_2, x_3) and λ .

Solve for the optimal quantities of x_1 , x_2 , and x_3 in the problem defined in equation 6.11. (*Hint:* The problem will be considerably easier to solve if you take the logarithm of the utility function (which you can do since logarithms are order-preserving transformations that do not alter the shapes of indifference curves.))

EXERCISE
6B.1

6B.1.2 Opportunity Cost = Marginal Rate of Substitution: Solving the Problem by Combining Intuition and Math When we solved my Walmart consumer problem graphically in Graph 6.1, we discovered that once I made my “best” choice “given my circumstances,” my *MRS* of shirts for pants (the slope of my indifference curve at the optimal bundle) was exactly equal to the opportunity cost of pants (given by the slope of the budget constraint), at least as long as my tastes are such that I end up buying at least some of each good. The Lagrange Method we have just learned implicitly confirms this.

Specifically, suppose we just write the general constrained optimization problem for a consumer who chooses a bundle (x_1, x_2) given prices (p_1, p_2) , an exogenous income I and tastes that can be summarized by a utility function $u(x_1, x_2)$:

$$\max_{x_1, x_2} u(x_1, x_2) \text{ subject to } p_1 x_1 + p_2 x_2 = I. \quad (6.13)$$

We then write the Lagrange function $\mathcal{L}(x_1, x_2, \lambda)$ as

$$\mathcal{L}(x_1, x_2, \lambda) = u(x_1, x_2) + \lambda(I - p_1 x_1 - p_2 x_2), \quad (6.14)$$

and we know that, at the optimal bundle, the partial derivatives of \mathcal{L} with respect to each of the three variables is equal to zero. Thus,

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial x_1} &= \frac{\partial u(x_1, x_2)}{\partial x_1} - \lambda p_1 = 0, \\ \frac{\partial \mathcal{L}}{\partial x_2} &= \frac{\partial u(x_1, x_2)}{\partial x_2} - \lambda p_2 = 0. \end{aligned} \quad (6.15)$$

These first order conditions can then be rewritten as

$$\begin{aligned} \frac{\partial u(x_1, x_2)}{\partial x_1} &= \lambda p_1, \\ \frac{\partial u(x_1, x_2)}{\partial x_2} &= \lambda p_2 \end{aligned} \quad (6.16)$$

and the two equations can be divided by one another and multiplied by -1 to give us

$$-\left(\frac{\partial u(x_1, x_2) / \partial x_1}{\partial u(x_1, x_2) / \partial x_2} \right) = -\frac{p_1}{p_2}. \quad (6.17)$$

Notice that the left-hand side of equation (6.17) is the definition of the *MRS* whereas the right-hand side is the definition of the slope of the budget line. Thus, at the optimal bundle,

$$MRS = -\frac{p_1}{p_2} = \text{opportunity cost of } x_1 \text{ (in terms of } x_2\text{)}. \quad (6.18)$$

Knowing that this condition *has to* hold at the optimum, we can now illustrate a third method for solving the constrained optimization problem defined in (6.2):

Method 3 Using $MRS = -p_1/p_2$ to Solve the Constrained Optimization Problem

Returning to the case of my Walmart problem, we arrived in the previous section at two equivalent methods of solving for my “best” bundle (as evaluated by the utility function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$) given my circumstances of facing prices of \$20 for pants and \$10 for shirts as well as a budget of \$200. In each case, the best option for me was to purchase 5 pants and 10 shirts. We could also, however, simply use the fact that we know expression (6.17) must hold at the optimum to get the same solution.

In particular, the left-hand side of equation (6.17) for the utility function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$ is simply equal to $-x_2/x_1$ (which we previously derived in Chapter 4 when we derived the MRS for such a function). Thus, the full equation (6.17) reduces to

$$-\frac{x_2}{x_1} = -\frac{p_1}{p_2} = -2, \quad (6.19)$$

which can also be written as

$$x_2 = 2x_1. \quad (6.20)$$

The budget constraint must also hold at the optimum, so we can plug (6.20) into the budget constraint $20x_1 + 10x_2 = 200$ to get

$$20x_1 + 10(2x_1) = 200. \quad (6.21)$$

Solving for x_1 , we then get $x_1 = 5$, and plugging this back into (6.20) we get $x_2 = 10$; that is 5 pants and 10 shirts are once again optimal.

Notice that expressions (6.9) and (6.10) are exactly equivalent to equations (6.20) and (6.21). This is no accident. Method 3 of solving the constrained optimization problem simply substitutes some of our intuition (i.e., $MRS = -p_1/p_2$) to take a shortcut that is implicitly a part of the Lagrange Method (Method 2). Put differently, the two methods are rooted in the same underlying logic, with one using only mathematics and the other using the intuition that $MRS = -p_1/p_2$, an intuition that is based on the graphical logic of Graph 6.1.

This also confirms our intuition from Section 6A.1.2 that when all consumers face the same prices (as they do at Walmart), their tastes are the same *at the margin* after they optimize. This is because the equality $MRS = -p_1/p_2$ holds for *all* consumers who consume both goods, regardless of how different their underlying tastes or money budgets are. Thus, tastes can differ even if tastes *at the margin* are the same after consumers choose their optimal bundles. Our discussion of gains from trade and efficiency in Section 6A.1.3 then follows from this.

6B.2 To Buy or Not to Buy: How to Find Corner Solutions

Although we have assumed throughout our mathematical discussion in this chapter that optimal choices always involve consumption of each of the goods, we had demonstrated in Section 6A.2 that, for certain types of tastes and certain economic circumstances, it is optimal to choose zero consumption of some goods, or, put differently, to choose a *corner solution*. This is important for the three mathematical optimization approaches we have discussed so far because *each of them assumes an interior, not a corner, solution*. We will see in this section what goes wrong with the mathematical approach when there are corner solutions and what assumptions we can make to be certain that the mathematical approach in Section 6B.1 does not run into problems due to the possible existence of corner solutions.

6B.2.1 Corner Solutions and First Order Conditions Consider, for instance, our example of me shopping in Walmart for pants (x_1) and shirts (x_2) when the prices are \$20 and \$10 and my money budget is \$200. Now, however, suppose that my tastes are properly summarized by the quasilinear utility function

$$u(x_1, x_2) = \alpha \ln x_1 + x_2, \quad (6.22)$$

where “ln” stands for the natural logarithm. Notice that tastes that can be represented by this utility function are such that x_2 is not essential and the indifference curves thus cross the x_1 axis. The *MRS* of good x_1 for x_2 for this function is $-\alpha/x_1$. Using our optimization Method 3, this implies that the optimal bundle must be such that $-\alpha/x_1 = -p_1/p_2 = -2$, which implies $x_1 = \alpha/2$. Plugging this into the budget constraint and solving for x_2 , we get

$$x_2 = \frac{(200 - 10\alpha)}{10}. \quad (6.23)$$

Set up the Lagrange function for this problem and solve it to see whether you get the same solution.

EXERCISE 6B.2

Now suppose that $\alpha = 25$ in the utility function (6.22). Then our solution for how much of x_2 is “best” in equation (6.23) would suggest that I should consume a negative quantity of shirts (x_2), negative 5 shirts to be specific! This is of course nonsense, and we can see what went wrong with the mathematics by illustrating the problem graphically.

More specifically, in Graph 6.10a we illustrate the shape of the optimal indifference curve derived from the utility function (6.22) (when $\alpha = 25$) as well as the budget constraint. The optimal bundle, bundle A, contains no shirts and 10 pants. Our mathematical optimization missed this point because we did not explicitly add the constraint that consumption of neither good can be negative and simply assumed an interior solution where $MRS = -p_1/p_2$. At the actual optimum A, however, $MRS \neq -p_1/p_2$.

Our mathematical solution method (without the constraint that consumption cannot be negative) pictured the problem as extending into a quadrant of the graph that we usually do not picture, the quadrant in which consumption of x_2 is negative. This is illustrated in panel (b) of Graph 6.10, where indifference curves represented by the utility function (6.22) are allowed to cross into this new quadrant of the graph, as is the budget constraint. The “solution” found by solving first order conditions is illustrated as the tangency of the higher (magenta) indifference curve with the extended budget line, where $MRS = -p_1/p_2$ as would be the case if the optimum was an interior solution.

The bottom line you should take from this example is that the mathematical methods of optimization we introduced in this chapter *assume that the actual optimum is an interior solution and thus involves a positive level of consumption of all goods*. When this is not the case, the math will give us the nonsensical answer unless we employ a more complicated method that explicitly introduces nonnegativity constraints for all consumption goods.⁵ Instead of resorting to more complex methods, however, we can just use common sense to conclude that the true optimum is a corner solution whenever our solution method suggests a negative level of consumption as optimal.

When we get a negative quantity as an answer, the true optimum involves a corner solution.

Demonstrate how the Lagrange Method (or one of the related methods we introduced earlier in this chapter) fails even more dramatically in the case of perfect substitutes. Can you explain what the Lagrange Method is doing in this case?

EXERCISE 6B.3

⁵ This more complicated method is a generalization of the Lagrange Method known as the “Kuhn Tucker method,” but it goes beyond the scope of this chapter. You can find it developed in graduate texts such as that by Mas-Colell, et al. (1992).

GRAPH 6.10 A Clear Corner Solution (a) with an Economically Nonsensical “Interior Solution” (b)

6B.2.2 Ruling Out Corner Solutions We have already concluded intuitively in Section 6A.2.2 what assumptions on tastes are required in order for us to be sure that the optimum is an *interior* rather than a *corner* solution. Specifically, we argued that all goods that are modeled must be “essential” in the sense we defined in Chapter 5; that is indifference curves can converge to each axis but can never cross any axis. This should be even clearer now that we have seen how the mathematics of the Lagrange or related methods fails when indifference curves *do* cross an axis. Since our mathematical solution methods are guaranteed to work only in cases when we assume utility functions that represent tastes for goods that are all essential, the easiest way to model economic circumstances and use only the solution methods we have introduced is to assume only such utility functions. This does, however, rule out the important class of quasilinear tastes unless we simply modify our solution to be zero whenever the Lagrange (or a related) Method indicates a negative optimal consumption level.

The good news is that we will certainly know when we use the Lagrange (or a related) Method and we miss a corner solution because we will get the nonsensical solution of a negative optimal consumption level. *But if we use these methods in models where not all goods are essential and we obtain solutions in which all consumption levels are positive, the methods are still giving us the correct answer.* For instance, if α in equation (6.22) is 10 instead of 25, the answer from equation (6.23) is that I should optimally consume 10 shirts (and five pants with the remainder of my budget). This solution is illustrated graphically in Graph 6.11 where, despite the fact that pants are not essential (and thus my indifference curves cross the shirt axis), my optimal choice is to purchase both shirts and pants under the economic circumstances I am facing at Walmart.

GRAPH 6.11 The Presence of Nonessential Goods Does Not *Have* to Result in a Corner Solution

At what value for α will the Lagrange Method correctly indicate an optimal consumption of zero shirts? Which of the panels of Graph 6.10 illustrates this?

EXERCISE 6B.4

6B.3 Non-Convexities and First Order Conditions

When all goods in our optimization problem are essential—that is when indifference curves do not cross the axes—we have shown that any optimum of the problem must satisfy the first order conditions of the Lagrange problem. In other words, when all goods are essential, the first order conditions are *necessary conditions* for a point to be optimal. Unless non-convexities are absent from the optimization problem, however, the system of first order conditions may have multiple “solutions” (as we demonstrated in Section 6A.3 of the chapter), and not all of these are true optima (as we will show later). Put differently, in the presence of non-convexities, the first order conditions of the constrained optimization problem are necessary but not *sufficient* for a point to be a true optimum.

For this reason, we can simply solve for the solution of the first order condition equations and know for sure that the solution will be optimal *only if* we know that the problem has an interior solution *and* that the model has no non-convexities in choice sets or tastes. In the following section, we briefly explore the intuition of how such non-convexities can in fact result in nonoptimal solutions to the first order conditions of the Lagrange problem.

First order conditions are guaranteed to give the right answer if budgets and tastes are convex and all goods are essential.

In the previous section, we concluded that the first order conditions of the Lagrange problem may be misleading when goods are not essential. Are these conditions either necessary or sufficient in that case?

EXERCISE 6B.5

6B.3.1 Non-Convexities in Choice Sets In Section 6A.3 of the chapter, we motivated the potential for non-convex choice sets by appealing to one of our coupon examples from an earlier chapter, an example in which a kink in the budget constraint emerges. Solving optimization problems with kinked budgets is a little involved, and so we leave it to be explored in the appendix to this chapter where a problem with an “outward” kink is solved. The same logic can be used to solve a problem with a non-convex kinked budget, one with an “inward kink.”

The mathematics of solving for the optimum when a budget is non-convex *without the presence of a kink* is somewhat different. We rarely encounter such budget constraints in microeconomic analysis, so we will not spend much time discussing them here. A problem of this type could be formally written as

$$\max_{x_1, x_2} u(x_1, x_2) \text{ subject to } f(x_1, x_2) = 0 \quad (6.24)$$

where the function f represents the nonlinear budget constraint. Such a problem could be set up exactly as we set up problems with linear budget constraints using a Lagrange function. The intuition of how just using first order conditions might yield misleading answers is seen relatively clearly with graphical examples. Consider, for instance, the shaded choice set in Graph 6.12 and the indifference curves that are tangent at points A and B . At both points, the MRS is equal to the slope of the budget constraint, and thus both points would be solutions to the system of first derivative equations of the Lagrange function. But it is clear from the picture that only point B is truly optimal since it lies on a higher indifference curve than point A . Whenever we solve a problem of this kind, we would therefore have to be careful to identify the true optimum from the possible optima that are produced through the Lagrange Method. Put differently, first order conditions are now necessary but not sufficient for identifying an optimal bundle.⁶

6B.3.2 Non-Convexities in Tastes In Section 6A.3.3, we discussed an example in which non-convex tastes result in multiple optimal solutions to an optimization problem (Graph 6.8). In the presence of such non-convexities in tastes, the Lagrange Method will still identify these optimal bundles, but it will once again also identify non optimal bundles. This is again because when non-convexities appear in constrained optimization problems, the first order conditions we use to solve for optimal solutions are necessary but not sufficient.

Graph 6.13 expands Graph 6.8 by adding another indifference curve to the picture, thus giving three points at which the MRS is equal to the ratio of prices. We can see immediately in this

GRAPH 6.12 Non-Convex Budgets: “First Order Conditions” Can Hold at a Bundle (A) that Is Not an Optimum

⁶You may have learned in your calculus classes about *second order conditions*. These conditions, involving second derivatives, ensure that points identified by first order conditions are indeed optimal. For an exploration of the mathematics of second order conditions, the reader is referred to E. Silberberg and W. Suen, *The Structure of Economics: A Mathematical Analysis*, 3d ed. (Boston: McGraw-Hill, 2001) or other mathematical economics texts.

GRAPH 6.13 Non-Convex Tastes: “First Order Conditions” Can Hold at a Bundle (C) That Is Not an Optimum

picture, however, that, while bundles *A* and *B* are optimal, bundle *C* is not (since it lies on an indifference curve below that which contains bundles *A* and *B*). The Lagrange Method will offer all three of these points as solutions to the system of first order conditions, which implies that, when we know that the underlying tastes are non-convex, we must check to see which of the points the Lagrange Method suggests are actually optimal. One way to do this is simply to plug the bundles the Lagrange method identifies back into the utility function to see which gives the highest utility. In the example of Graph 6.13, bundles *A* and *B* will give the same utility, but bundle *C* will give less. Thus, we could immediately conclude that only *A* and *B* are optimal.

While this method of plugging in the “candidate” optimal points (identified by the first order conditions) back into the utility function works, there exists a more general method by which to ensure that the Lagrange Method only yields truly optimal points. This method involves checking second derivative conditions, known in mathematics as *second order conditions*. Since we will rarely find a need to model tastes as non-convex, we will not focus on developing this method here. In general, you should simply be aware that we introduce greater complexity to the mathematical approach when we model situations in which non-convexities are important, complexities we do not need to worry about when the optimization problem is convex.

6B.4 Estimating Tastes from Observed Choices

In Section 6A.4, we acknowledged explicitly that tastes in themselves are not observable but also suggested that economists have developed ways of estimating the underlying tastes that are implied by choice behavior that we can observe. Essentially, we saw that the more choices we observe under different economic circumstances, the more information we can gain regarding the marginal rates of substitutions at different bundles that individuals are choosing. One interesting implication of this, however, is that the tastes that choice behavior implies are *always* going to satisfy our convexity assumption *even when the true underlying tastes of a consumer are non-convex*.

To see the intuition behind this, consider the case of a consumer whose indifference map contains the indifference curves drawn in Graph 6.13. We may observe such a consumer choosing bundles *A* and *B*, but we will never observe her choosing a bundle that lies on the non-convex

Non-convexities in tastes are typically impossible to infer from observed choices.

portion of the indifference curve between A and B (unless the budget sets take on very odd shapes). The reason for this is that tangencies with budget lines that lie on the non-convex portion of an indifference curve are not true optimal choices because they are like the bundle C in Graph 6.13. Thus, since we never observe choice behavior on non-convex portions of indifference maps, we can rarely infer the existence of non-convexities in tastes from choice behavior. An economist who observes the types of choices an individual makes with indifference curves like the ones in Graph 6.13 could simply conclude that there might be a “flat spot” in the indifference curve between A and B , but such an indifference curve would not contain the underlying non-convexity. The economist might suspect that there is a non-convexity in the indifference curve, but there is no way to identify it from observing consumption behavior easily.

CONCLUSION

We have now begun our analysis of optimizing behavior, of economic actors “doing the best they can” given their economic circumstances. In the end, all we are doing is combining our model of economic circumstances (budget constraints and choice sets from Chapters 2 and 3) with our model of tastes (indifference curves and utility functions from Chapters 4 and 5). But, even though we are just at the beginning of exploring all the implications of optimizing behavior, we are already gaining some insights relevant to the real world. We have defined in this chapter what it means for a situation to be economically efficient and have shown that optimizing consumer behavior in markets leads to an efficient allocation of goods across consumers. Put differently, market prices organize optimizing consumers so as to ensure that, once they have optimized in the market, they all have the same tastes on the margin for the goods that they have purchased. And with the same tastes on the margin, there is no way for consumers to find trades among each other that would make both parties better off; there are no gains from trade that have not already occurred in the market.

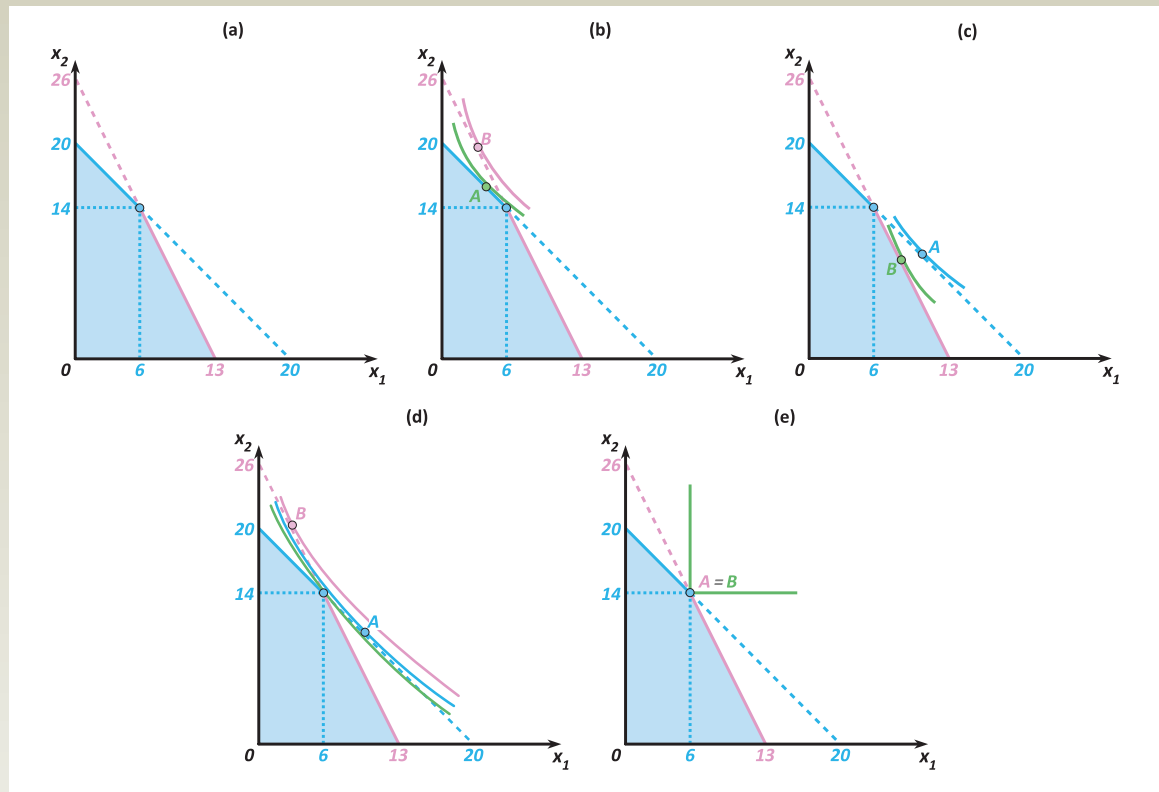

Along the way, we have also explored some technical details of optimization. Interior solutions are guaranteed only when tastes are defined such that all goods are “essential,” and corner solutions may arise when some goods are not essential. The consumer optimization problem will furthermore have a single unique solution if the optimization problem is in every way convex, with convex choice sets and (strictly) convex tastes (where averages are strictly better than extremes). This “uniqueness” of the solution may disappear, however, when tastes are defined such that averages can be just as good as extremes, or when tastes are non-convex. In the former case, a convex set of bundles may emerge as the solution (tangent to a “flat spot” on an indifference curve), whereas in the latter case a non-convex set of multiple solutions may emerge. Furthermore, when non-convexities in budgets or tastes are part of the consumer choice problem, the Lagrange Method (or derivatives of it) will identify as solutions bundles that are in fact not optimal.

We are not, however, done with our building of conceptual tools in our optimization model. Rather, we now move to Chapter 7 in which we begin to explore how optimizing behavior changes as economic circumstances (income and prices) in the economy change. Chapter 8 will extend this analysis to labor and financial markets, and Chapter 9 will demonstrate how the individual optimizing behavior results in demand curves for goods and supply curves for labor and capital. Finally, we will conclude our analysis of consumer optimization in Chapter 10, where we explore the concept of consumer surplus.

APPENDIX: OPTIMIZATION PROBLEMS WITH KINKED BUDGETS

The mathematics of solving for optimal bundles when budget constraints have kinks is more complicated because the optimization problem contains a constraint that cannot be captured in a single equation.

GRAPH 6.14 Mathematical Optimization on Kinky Budgets

Consider the shaded kinked (but convex) choice set in Graph 6.14a, which replicates the coupon example graphed initially in Graph 6.5. The budget constraint of this choice set consists of two line segments, with the dotted extension of each line segment indicating the intercepts. The constrained optimization problem can now be written in two parts as

$$\begin{aligned} \max_{x_1, x_2} u(x_1, x_2) \text{ subject to } x_2 &= 20 - x_1 \text{ for } 0 \leq x_1 \leq 6 \text{ and} \\ \max_{x_1, x_2} u(x_1, x_2) \text{ subject to } x_2 &= 26 - 2x_1 \text{ for } 6 \leq x_1, \end{aligned} \tag{6.25}$$

with the true optimum represented by the solution that achieves greater utility.

The easiest way to solve such a problem is to solve two separate optimization problems with the extended line segments in Graph 6.14a representing the budget constraints in those problems; that is

$$\begin{aligned} \max_{x_1, x_2} u(x_1, x_2) \text{ subject to } x_2 &= 20 - x_1 \text{ and} \\ \max_{x_1, x_2} u(x_1, x_2) \text{ subject to } x_2 &= 26 - 2x_1. \end{aligned} \tag{6.26}$$

For the convex budget in Graph 6.14a, the true optimal point will occur either *to the left* of the kink (as in Graph 6.5b), *to the right* of the kink (as in Graph 6.5c), or *on the kink* (as in Graph 6.5d). When solving the two separate optimization problems in expression (6.26), we may get one of several corresponding sets

of solutions. First, both optimization problems could result in an optimum with $x_1 < 6$, in which case the true optimum is the one resulting from the first optimization problem that is relevant for $x_1 < 6$ represented by A in Graph 6.14b. Second, both optimization problems could result in a solution with $x_1 > 6$, in which case the true optimum is the one resulting from the second optimization problem that is relevant when $x_1 > 6$ represented by point B in Graph 6.14c. Third, the first optimization problem could result in $x_1 > 6$ while the second optimization problem results in $x_1 < 6$, as represented in Graph 6.14d. In this case, both problems give a solution on the dotted extensions of the linear segments of the true budget constraint, with both A and B lying outside the shaded choice set. In this case, the true optimal point is the kink point (on the green indifference curve). Finally, both optimization problems could result in $x_1 = 6$, thus again indicating that the kink point is optimal (as depicted in Graph 6.14e).

EXERCISE 6B.6 Is it necessary for the indifference curve at the kink of the budget constraint to have a kink in order for both problems in (6.26) to result in $x_1 = 6$?

When solving mathematically for optimal bundles when budget constraints are kinked, it is then best to combine the mathematics described with the intuition we gain from the graphical analysis. While we have illustrated this here with an “outwardly” kinked budget, the same is true for “inwardly” kinked (and thus non-convex) budgets, which we leave here to the following exercise.

EXERCISE 6B.7* Using the intuitions from graphical analysis similar to that in Graph 6.14, illustrate how you might go about solving for the true optimum when a choice set is non-convex due to an “inward” kink.

END-OF-CHAPTER EXERCISES

- 6.1[†]** I have two 5-year-old girls, Ellie and Jenny, at home. Suppose I begin the day by giving each girl 10 toy cars and 10 princess toys. I then ask them to plot their indifference curves that contain these endowment bundles on a graph with “cars” on the horizontal and “princess toys” on the vertical axis.
- A.** Ellie’s indifference curve appears to have a marginal rate of substitution of -1 at her endowment bundle, whereas Jenny’s appears to have a marginal rate of substitution of -2 at the same bundle.
- Can you propose a trade that would make both girls better off?
 - Suppose the girls cannot figure out a trade on their own. So I open a store where they can buy and sell any toy for \$1. Illustrate the budget constraint for each girl.
 - Will either of the girls shop at my store? If so, what will they buy?
 - Suppose I do not actually have any toys in my store and simply want my store to help the girls make trades between themselves. Suppose I fix the price at which princess toys are bought and sold to \$1. Without being specific about what the price of toy cars would have to be, illustrate, using final indifference curves for both girls on the same graph, a situation where the prices in my store result in an efficient allocation of toys.
 - What values might the price for toy cars take to achieve the efficient trades you described in your answer to (d)?

*conceptually challenging

**computationally challenging

[†]solutions in Study Guide

- B.** Now suppose that my girls’ tastes could be described by the utility function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$, where x_1 represents toy cars, x_2 represents princess toys, and $0 < \alpha < 1$.
- What must be the value of α for Ellie (given the information in part A)? What must the value be for Jenny?
 - When I set all toy prices to \$1, what exactly will Ellie do? What will Jenny do?
 - Given that I am fixing the price of princess toys at \$1, do I have to raise or lower the price of car toys in order for me to operate a store in which I don’t keep inventory but simply facilitate trades between the girls?
 - Suppose I raise the price of car toys to \$1.40, and assume that it is possible to sell fractions of toys. Have I found a set of prices that allow me to keep no inventory?

6.2 Suppose Coke and Pepsi are perfect substitutes for me, and right and left shoes are perfect complements.

- A.** Suppose my income allocated to Coke/Pepsi consumption is \$100 per month, and my income allocated to right/left shoe consumption is similarly \$100 per month.
- Suppose Coke currently costs \$0.50 per can and Pepsi costs \$0.75 per can. Then the price of Coke goes up to \$1 per can. Illustrate my original and my new optimal bundle with “Coke” on the horizontal and “Pepsi” on the vertical axis.
 - Suppose right and left shoes are sold separately. If right and left shoes are originally both priced at \$1, illustrate (on a graph with “right shoes” on the horizontal and “left shoes” on the vertical) my original and my new optimal bundle when the price of left shoes increases to \$2.
 - True or False:* Perfect complements represent a unique special case of homothetic tastes in the following sense: Whether income goes up or whether the price of one of the goods falls, the optimal bundle will always lie on a the same ray emerging from the origin.
- B.** Continue with the assumptions about tastes from part A.
- Write down two utility functions: one representing my tastes over Coke and Pepsi, another representing my tastes over right and left shoes.
 - Using the appropriate equation derived in B(a), label the two indifference curves you drew in A(a).
 - Using the appropriate equation derived in B(a), label the two indifference curves you drew in A(b).
 - Consider two different equations representing indifference curves for perfect complements: $u^1(x_1, x_2) = \min\{x_1, x_2\}$ and $u^2(x_1, x_2) = \min\{x_1, 2x_2\}$. By inspecting two of the indifference curves for each of these utility functions, determine the equation for the ray along which all optimal bundles will lie for individuals whose tastes these equations can represent.
 - Explain why the Lagrange Method does not seem to work for calculating the optimal consumption bundle when the goods are perfect substitutes.
 - Explain why the Lagrange Method cannot be applied to calculate the optimal bundle when the goods are perfect complements.

6.3[†] *Pizza and Beer:* Sometimes we can infer something about tastes from observing only two choices under two different economic circumstances.

- A.** Suppose we consume only beer and pizza (sold at prices p_1 and p_2 , respectively) with an exogenously set income I .
- With the “number of beers” on the horizontal axis and the “number of pizzas” on the vertical, illustrate a budget constraint (clearly labeling intercepts and the slope) and some initial optimal (interior) bundle A .
 - When your income goes up, I notice that you consume more beer and the same amount of pizza. Can you tell whether my tastes might be homothetic? Can you tell whether they might be quasilinear in either pizza or beer?
 - How would your answers change if I had observed you decreasing your beer consumption when income goes up?
 - How would your answers change if both beer and pizza consumption increased by the same proportion as income?

- B.** Suppose your tastes over beer (x_1) and pizza (x_2) can be summarized by the utility function $u(x_1, x_2) = x_1^2 x_2$ and that $p_1 = 2$, $p_2 = 10$ and weekly income $I = 180$.
- Calculate your optimal bundle A of weekly beer and pizza consumption by simply using the fact that, at any interior solution, $MRS = -p_1/p_2$.
 - What numerical label does this utility function assign to the indifference curve that contains your optimal bundle?
 - Set up the more general optimization problem where, instead of using the prices and income given earlier, you simply use p_1 , p_2 , and I . Then, derive your optimal consumption of x_1 and x_2 as a function of p_1 , p_2 , and I .
 - Plug the values $p_1 = 2$, $p_2 = 10$, and $I = 180$ into your answer to B(c) and verify that you get the same result you originally calculated in B(a).
 - Using your answer to part B(c), verify that your tastes are homothetic.
 - Which of the scenarios in A(b) through (d) could be generated by the utility function $u(x_1, x_2) = x_1^2 x_2$?

6.4 *Inferring Tastes for Roses (and Love) from Behavior:* I express my undying love for my wife through weekly purchases of roses that cost \$5 each.

- A.** Suppose you have known me for a long time and you have seen my economic circumstances change with time. For instance, you knew me in graduate school when I managed to have \$125 per week in disposable income that I could choose to allocate between purchases of roses and “other consumption” denominated in dollars. Every week, I brought 25 roses home to my wife.
- Illustrate my budget as a graduate student, with “roses” on the horizontal and “dollars of other consumption” on the vertical axis. Indicate my optimal bundle on that budget as A . Can you conclude whether either good is not “essential”?
 - When I became an assistant professor, my disposable income rose to \$500 per week, and the roses I bought for my wife continued to sell for \$5 each. You observed that I still bought 25 roses each week. Illustrate my new budget constraint and optimal bundle B on your graph. From this information, can you conclude whether my tastes might be quasilinear in roses? Might they not be quasilinear?
 - Suppose for the rest of the problem that my tastes in fact are quasilinear in roses. One day while I was an assistant professor, the price of roses suddenly dropped to \$2.50. Can you predict whether I then purchased more or fewer roses?
 - Suppose I had not gotten tenure, and the best I could do was rely on a weekly allowance of \$50 from my wife. Suppose further that the price of roses goes back up to \$5. How many roses will I buy for my wife per week?
 - True or False:* Consumption of quasilinear goods always stays the same as income changes.
 - True or False:* Over the range of prices and incomes where corner solutions are not involved, a decrease in price will result in increased consumption of quasilinear goods but an increase in income will not.
- B.** Suppose my tastes for roses (x_1) and other goods (x_2) can be represented by utility function $u(x_1, x_2) = \beta x_1^\alpha + x_2$.
- Letting the price of roses be denoted by p_1 , the price of other goods by 1, and my weekly income by I , determine my optimal weekly consumption of roses and other goods as a function of p_1 and I .
 - Suppose $\beta = 50$ and $\alpha = 0.5$. How many roses do I purchase when $I = 125$ and $p_1 = 5$? What if my income rises to \$500?
 - Comparing your answers with your graph from part A, could the actions observed in part A(b) be rationalized by tastes represented by the utility function $u(x_1, x_2)$? Give an example of another utility function that can rationalize the behavior described in part A(b).

- d. What happens when the price of roses falls to \$2.50? Is this consistent with your answer to part A(c)?
- e. What happens when my income falls to \$50 and the price of roses increases back to \$5? Is this consistent with your answer to part A(d)? Can you illustrate in a graph how the math is giving an answer that is incorrect?

6.5[†] Assume you have an income of \$100 to spend on goods x_1 and x_2 .

A. Suppose that you have homothetic tastes that happen to have the special property that indifference curves on one side of the 45-degree line are mirror images of indifference curves on the other side of the 45-degree line.

- a. Illustrate your optimal consumption bundle graphically when $p_1 = 1 = p_2$.
- b. Now suppose the price of the first 75 units of x_1 you buy is 1/3 while the price for any additional units beyond that is 3. The price of x_2 remains at 1 throughout. Illustrate your new budget and optimal bundle.
- c. Suppose instead that the price for the first 25 units of x_1 is 3 but then falls to 1/3 for all units beyond 25 (with the price of x_2 still at 1). Illustrate this budget constraint and indicate what would be optimal.
- d. If the homothetic tastes did not have the symmetry property, which of your answers might not change?

B.* Suppose that your tastes can be summarized by the Cobb–Douglas utility function $u(x_1, x_2) = x_1^{1/2}x_2^{1/2}$.

- a. Does this utility function represent tastes that have the symmetry property described in part A?
- b. Calculate the optimal consumption bundle when $p_1 = 1 = p_2$.
- c. Derive the two equations that make up the budget constraint you drew in part A(b) and use the method described in the appendix to this chapter to calculate the optimal bundle under that budget constraint.
- d. Repeat for the budget constraint you drew in A(c).
- e. Repeat (b) through (d) assuming instead $u(x_1, x_2) = x_1^{3/4}x_2^{1/4}$ and illustrate your answers in graphs.

6.6* *Coffee, Coke, and Pepsi:* Suppose there are three different goods: cans of Coke (x_1), cups of coffee (x_2), and cans of Pepsi (x_3).

A. Suppose each of these goods costs the same price, p , and you have an exogenous income, I .

- a. Illustrate your budget constraint in three dimensions and carefully label all intercepts and slopes.
- b. Suppose each of the three drinks has the same caffeine content, and suppose caffeine is the only characteristic of a drink you care about. What do “indifference curves” look like?
- c. What bundles on your budget constraint would be optimal?
- d. Suppose that Coke and Pepsi become more expensive. How does your answer change? Are you now better or worse off than you were before the price change?

B. Assume again that the three goods cost the same price, p .

- a. Write down the equation of the budget constraint you drew in part A(a).
- b. Write down a utility function that represents the tastes described in A(b).
- c. Can you extend our notion of homotheticity to tastes over three goods? Are the tastes represented by the utility function you derived in (b) homothetic?

6.7*[†] *Coffee, Milk, and Sugar:* Suppose there are three different goods: cups of coffee (x_1), ounces of milk (x_2), and packets of sugar (x_3).

A. Suppose each of these goods costs \$0.25 and you have an exogenous income of \$15.

- a. Illustrate your budget constraint in three dimensions and carefully label all intercepts.

- b. Suppose that the only way you get enjoyment from a cup of coffee is to have at least 1 ounce of milk and 1 packet of sugar in the coffee, the only way you get enjoyment from an ounce of milk is to have at least 1 cup of coffee and 1 packet of sugar, and the only way you get enjoyment from a packet of sugar is to have at least 1 cup of coffee and 1 ounce of milk. What is the optimal consumption bundle on your budget constraint?
- c. What does your optimal indifference curve look like?
- d. If your income falls to \$10, what will be your optimal consumption bundle?
- e. If instead of a drop in income the price of coffee goes to \$0.50, how does your optimal bundle change?
- f. Suppose your tastes are less extreme and you are willing to substitute some coffee for milk, some milk for sugar, and some sugar for coffee. Suppose that the optimal consumption bundle you identified in (b) is still optimal under these less extreme tastes. Can you picture what the optimal indifference curve might look like in your picture of the budget constraint?
- g. If tastes are still homothetic (but of the less extreme variety discussed in (f)), would your answers to (d) or (e) change?

- B.** Continue with the assumption of an income of \$15 and prices for coffee, milk, and sugar of \$0.25 each.
- a. Write down the budget constraint.
 - b. Write down a utility function that represents the tastes described in A(b).
 - c. Suppose that instead your tastes are less extreme and can be represented by the utility function $u(x_1, x_2, x_3) = x_1^\alpha x_2^\beta x_3$. Calculate your optimal consumption of x_1, x_2 , and x_3 when your economic circumstances are described by the prices p_1, p_2 , and p_3 and income is given by I .
 - d. What values must α and β take in order for the optimum you identified in A(b) to remain the optimum under these less extreme tastes?
 - e. Suppose α and β are as you concluded in part B(d). How does your optimal consumption bundle under these less extreme tastes change if income falls to \$10 or if the price of coffee increases to \$0.50? Compare your answers with your answer for the more extreme tastes in A(d) and (e).
 - f. *True or False:* Just as the usual shapes of indifference curves represent two-dimensional “slices” of a three-dimensional utility function, three-dimensional “indifference bowls” emerge when there are three goods, and these “bowls” represent slices of a four-dimensional utility function.

6.8 *Grits and Cereal:* In end-of-chapter exercise 4.1, I described my dislike for grits and my fondness for Coco Puffs Cereal.

- A.** In part A of exercise 4.1, you were asked to assume that my tastes satisfy convexity and continuity and then to illustrate indifference curves on a graph with “grits” on the horizontal axis and “cereal” on the vertical.
- a. Now add a budget constraint (with some positive prices for grits and cereal and some exogenous income, I , for me). Illustrate my optimal choice given my tastes.
 - b. Does your answer change if my tastes are non-convex (as in part (b) of exercise 4.1A)?
 - c. In part (c) of exercise 4.1A, you were asked to imagine that I hate cereal as well and that my tastes are again convex. Illustrate my optimal choice under this assumption.
 - d. Does your answer change when my tastes are not convex (as in part (d) of exercise 4.1A)?
- B.** In part B of exercise 4.1, you derived a utility function that was consistent with my dislike for grits.
- a. Can you explain why the Lagrange Method will not work if you used it to try to solve the optimization problem using this utility function?
 - b. What would the Lagrange Method offer as the optimal solution if you used a utility function that captured a dislike for both grits and cereal when tastes are non-convex? Illustrate your answer using $u(x_1, x_2) = -x_1 x_2$ and graph your insights.

- c. What would the Lagrange Method offer as a solution if a utility function that captures a dislike for both grits and cereal represented convex tastes? Illustrate your answer using the function $u(x_1, x_2) = -x_1^2 - x_2^2$ and show what happens graphically.

6.9† **Everyday Application: Price Fluctuations in the Housing Market:** Suppose you have \$400,000 to spend on a house and “other goods” (denominated in dollars).

- A.** The price of 1 square foot of housing is \$100, and you choose to purchase your optimally sized house at 2,000 square feet. Assume throughout that you spend money on housing solely for its consumption value (and not as part of your investment strategy).
- On a graph with “square feet of housing” on the horizontal axis and “other goods” on the vertical, illustrate your budget constraint and your optimal bundle *A*.
 - After you bought the house, the price of housing falls to \$50 per square foot. Given that you can sell your house from bundle *A* if you want to, are you better or worse off?
 - Assuming you can easily buy and sell houses, will you now buy a different house? If so, is your new house smaller or larger than your initial house?
 - Does your answer to (c) differ depending on whether you assume tastes are quasilinear in housing or homothetic?
 - How does your answer to (c) change if the price of housing went up to \$200 per square foot rather than down to \$50.
 - What form would tastes have to take in order for you not to sell your 2,000-square-foot house when the price per square foot goes up or down?
 - True or False:* So long as housing and other consumption is at least somewhat substitutable, any change in the price per square foot of housing makes homeowners better off (assuming it is easy to buy and sell houses).
 - True or False:* Renters are always better off when the rental price of housing goes down and worse off when it goes up.
- B.** Suppose your tastes for “square feet of housing” (x_1) and “other goods” (x_2) can be represented by the utility function $u(x_1, x_2) = x_1x_2$.
- Calculate your optimal housing consumption as a function of the price of housing (p_1) and your exogenous income I (assuming of course that p_2 is by definition equal to 1).
 - Using your answer, verify that you will purchase a 2,000-square-foot house when your income is \$400,000 and the price per square foot is \$100.
 - Now suppose the price of housing falls to \$50 per square foot and you choose to sell your 2,000-square-foot house. How big a house would you now buy?
 - Calculate your utility (as measured by your utility function) at your initial 2,000-square-foot house and your new utility after you bought your new house. Did the price decline make you better off?
 - How would your answers to B(c) and B(d) change if, instead of falling, the price of housing had increased to \$200 per square foot?

6.10 **Everyday Application: Different Interest Rates for Borrowing and Lending:** You first analyzed intertemporal budget constraints with different interest rates for borrowing and saving (or lending) in end-of-chapter exercise 3.8.

- A.** Suppose that you have an income of \$100,000 now and you expect to have a \$300,000 income 10 years from now, and suppose that the interest rate for borrowing from the bank is twice as high as the interest rate the bank offers for savings.
- Begin by drawing your budget constraint with “consumption now” and “consumption in 10 years” on the horizontal and vertical axes. (Assume for purposes of this problem that your consumption in the intervening years is covered and not part of the analysis.)
 - Can you explain why, for a wide class of tastes, it is rational for someone in this position not to save or borrow?

- c. Now suppose that the interest rate for borrowing was half the interest rate for saving. Draw this new budget constraint.
 - d. Illustrate a case where it might be rational for a consumer to flip a coin to determine whether to borrow a lot or to save a lot.
- B.** Suppose that your incomes are as described in part A and that the *annual* interest rate for borrowing is 20% and the *annual* interest rate for saving is 10%. Also, suppose that your tastes over current consumption, c_1 , and consumption 10 years from now, c_2 , can be captured by the utility function $u(c_1, c_2) = c_1^\alpha c_2^{(1-\alpha)}$.
- a. Assuming that interest compounds annually, what are the slopes of the different segments of the budget constraint that you drew in A(a)? What are the intercepts?
 - b. For what ranges of α is it rational to neither borrow nor save?

6.11*† Business Application: Quantity Discounts and Optimal Choices: In end-of-chapter exercise 2.9, you illustrated my department's budget constraint between "pages copied in units of 100" and "dollars spent on other goods" given the quantity discounts our local copy service gives the department. Assume the same budget constraint as the one described in 2.9A.

- A.** In this exercise, assume that my department's tastes do not change with time (or with who happens to be department chair). When we ask whether someone is "respecting the department's tastes," we mean whether that person is using the department's tastes to make optimal decisions for the department given the circumstances the department faces. Assume throughout that my department's tastes are convex.
- a. *True or False:* If copies and other expenditures are very substitutable for my department, then you should observe either very little or a great deal of photocopying by our department at the local copy shop.
 - b. Suppose that I was department chair last year and had approximately 5,000 copies per month made. This year, I am on leave and an interim chair has taken my place. He has chosen to make 150,000 copies per month. Given that our department's tastes are not changing over time, can you say that either I or the current interim chair is not respecting the department's tastes?
 - c. Now the interim chair has decided to go on vacation for a month, and an interim interim chair has been named for that month. He has decided to purchase 75,000 copies per month. If I was respecting the department's tastes, is this interim interim chair necessarily violating them?
 - d. If both the initial interim chair and I were respecting the department's tastes, is the new interim interim chair necessarily violating them?
- B.** Consider the decisions made by the three chairs as previously described.
- a. If the second interim chair (i.e., the interim interim chair) and I both respected the department's tastes, can you approximate the elasticity of substitution of the department's tastes?
 - b. If the first and second interim chairs both respected the department's tastes, can you approximate the elasticity of substitution for the department?
 - c. Could the underlying tastes under which all three chairs respect the department's tastes be represented by a CES utility function?

6.12* Business Application: Retail Industry Lobbying for Daylight Savings Time: In 2005, the U.S. Congress passed a bill to extend daylight savings time earlier into the spring and later into the fall (beginning in 2007). The change was made as part of an Energy Bill, with some claiming that daylight savings time reduces energy use by extending sunlight to later in the day (which means fewer hours of artificial light). Among the biggest advocates for daylight savings time, however, was the retail and restaurant industry that believes consumers will spend more time shopping and eating in malls for reasons explored here.

- A.** Consider a consumer who returns home from work at 6 p.m. and goes to sleep at 10 p.m. In the month of March, the sun sets by 7 p.m. in the absence of daylight savings time, but with daylight savings time, the sun does not set until 8 p.m. When the consumer comes home from work, she can either spend time (1) at home eating food from her refrigerator while e-mailing friends and surfing/shopping on the Internet or (2) at the local mall meeting friends for a bite to eat and strolling through stores to

- shop. Suppose this consumer gets utility from (1) and (2) (as defined here) but she also cares about x_3 , which is defined as the fraction of daylight hours after work.
- On a graph with “weekly hours at the mall” on the horizontal axis and “weekly hours at home” on the vertical, illustrate this consumer’s typical weekly after-work time constraint (with a total of 20 hours per week available, 4 hours on each of the 5 workdays). (For purposes of this problem, assume the consumer gets as much enjoyment from driving to the mall as she does being at the mall.)
 - Consider first the scenario of no daylight savings time in March. This implies only 1 hour of daylight in the 4 hours after work and before going to sleep; that is the fraction x_3 of daylight hours after work is $1/4$. Pick a bundle A on the budget constraint from (a) as the optimum for this consumer given this fraction of after-work of daylight hours.
 - Now suppose daylight savings time is moved into March, thus raising the number of after-work daylight hours to 2 per day. Suppose this changes the *MRS* at every bundle. If the retail and restaurant industry is right, which way does it change the *MRS*?
 - Illustrate how if the retail and restaurant industry is right, this results in more shopping and eating at malls every week.
 - Explain the following statement: “While it appears in our two-dimensional indifference maps that tastes have changed as a result of a change in daylight savings time, tastes really haven’t changed at all because we are simply graphing two-dimensional slices of the same three-dimensional indifference surfaces.”
 - Businesses can lobby Congress to change the *circumstances* under which we make decisions, but Congress has no power to change our *tastes*. Explain how the change in daylight savings time illustrates this in light of your answer to (e).
 - Some have argued that consumers must be irrational for shopping more just because daylight savings is introduced. Do you agree?
 - If we consider not just energy required to produce light but also energy required to power cars that take people to shopping malls, is it still clear that the change in daylight savings time is necessarily energy saving?
- B.** Suppose a consumer’s tastes can be represented by the utility function $u(x_1, x_2, x_3) = 12x_3 \ln x_1 + x_2$, where x_1 represents weekly hours spent at the mall, x_2 represents weekly after-work hours spent at home (not sleeping), and x_3 represents the fraction of after-work (before-sleep) time that has daylight.
- Calculate the *MRS* of x_2 for x_1 for this utility function and check to see whether it has the property that retail and restaurant owners hypothesize.
 - Which of the three things the consumer cares about— x_1 , x_2 , and x_3 —are choice variables for the consumer?
 - Given the overall number of weekly after-work hours our consumer has (i.e., 20), calculate the number of hours per week this consumer will spend in malls and restaurants as a function of x_3 .
 - How much time per week will she spend in malls and restaurants in the absence of daily savings time? How does this change when daylight savings time is introduced?

6.13[†] Policy Application: Food Stamps versus Food Subsidies: In exercise 2.13, you considered the food stamp programs in the United States. Under this program, poor households receive a certain quantity of “food stamps,” stamps that contain a dollar value that is accepted like cash for food purchases at grocery stores.

- A.** Consider a household with monthly income of \$1,500 and suppose that this household qualifies for food stamps in the amount of \$500.
- Illustrate this household’s budget, both with and without the food stamp program, with “dollars spent on food” on the horizontal axis and “dollars spent on other goods” on the vertical. What has to be true for the household to be just as well off under this food stamp program as it would be if the government simply gave \$500 in cash to the household (instead of food stamps)?
 - Consider the following alternate policy: Instead of food stamps, the government tells this household that it will reimburse 50% of the household’s food bills. On a separate graph,

POLICY APPLICATION

illustrate the household's budget (in the absence of food stamps) with and without this alternate program.

- Choose an optimal bundle A on the alternate program budget line and determine how much the government is paying to this household (as a vertical distance in your graph). Call this amount S .
- Now suppose the government decided to abolish the program and instead gives the same amount S in food stamps. How does this change the household's budget?
- Will this household be happy about the change from the first alternate program to the food stamp program?
- If some politicians want to increase food consumption by the poor and others just want to make the poor happier, will they differ on what policy is best?
- True or False:* The less substitutable food is for other goods, the greater the difference in food consumption between equally funded cash and food subsidy programs.
- Consider a third possible alternative: giving cash instead of food stamps. *True or False:* As the food stamp program becomes more generous, the household will at some point prefer a pure cash transfer over an equally costly food stamp program.

B.** Suppose this household's tastes for spending on food (x_1) and spending on other goods (x_2) can be characterized by the utility function $u(x_1, x_2) = \alpha \ln x_1 + \ln x_2$.

- Calculate the level of food and other good purchases as a function of I and the price of food p_1 (leaving the price of dollars on other goods as just 1).
- For the household described in part A, what is the range of α that makes the \$500 food stamp program equivalent to a cash gift of \$500?
- Suppose for the remainder of the problem that $\alpha = 0.5$. How much food will this household buy under the alternate policy described in A(b)?
- How much does this alternate policy cost the government for this household? Call this amount S .
- How much food will the household buy if the government gives S as a cash payment and abolishes the alternate food subsidy program?
- Determine which policy—the price subsidy that leads to an amount S being given to the household or the equally costly cash payment in part (e)—the household prefers.
- Now suppose the government considered subsidizing food more heavily. Calculate the utility that the household will receive from three *equally funded* policies: a 75% food price subsidy (i.e., a subsidy where the government pays 75% of food bills), a food stamp program, and a cash gift program.

POLICY
APPLICATION

6.14 Policy Application: Gasoline Taxes and Tax Rebates: Given the concerns about environmental damage from car pollution, many have proposed increasing the tax on gasoline. We will consider the social benefits of such legislation later on in the text when we introduce externalities. For now, however, we can look at the impact on a single consumer.

- Suppose a consumer has annual income of \$50,000 and suppose the price of a gallon of gasoline is currently \$2.50.
 - Illustrate the consumer's budget constraint with "gallons of gasoline" per year on the horizontal axis and "dollars spent on other goods" on the vertical. Then illustrate how this changes if the government imposes a tax on gasoline that raises the price per gallon to \$5.00.
 - Pick some bundle A on the after tax budget constraint and assume that bundle is the optimal bundle for our consumer. Illustrate in your graph how much in gasoline taxes this consumer is paying, and call this amount T .
 - One of the concerns about using gasoline taxes to combat pollution is that it will impose hardship on consumers (and, perhaps more importantly, voters). Some have therefore suggested that the government simply rebate all revenues from a gasoline tax to taxpayers. Suppose that our consumer receives a rebate of exactly T . Illustrate how this alters the budget of our consumer.
 - Suppose our consumer's tastes are quasilinear in gasoline. How much gasoline will he consume after getting the rebate?

- e. Can you tell whether the tax/rebate policy is successful at getting our consumer to consume less gasoline than he would were there neither the tax nor the rebate?
- f. *True or False:* Since the government is giving back in the form of a rebate exactly the same amount as it collected in gasoline taxes from our consumer, the consumer is made no better or worse off from the tax/rebate policy.
- B.** Suppose our consumer’s tastes can be captured by the quasilinear utility function $u(x_1, x_2) = 200x_1^{0.5} + x_2$, where x_1 denotes gallons of gasoline and x_2 denotes dollars of other goods.
- Calculate how much gasoline this consumer consumes as a function of the price of gasoline (p_1) and income I . Since other consumption is denominated in dollars, you can simply set its price (p_2) to 1.
 - After the tax raises the price of gasoline to \$5, how much gasoline does our consumer purchase this year?
 - How much of a tax does he pay?
 - Can you verify that his gasoline consumption will not change when the government sends him a rebate check equal to the tax payments he has made?
 - How does annual gasoline consumption for our consumer differ under the tax/rebate program from what it would be in the absence of either a tax or rebate?
 - Illustrate that our consumer would prefer no tax/rebate program but, if there is to be a tax on gasoline, he would prefer to have the rebate rather than no rebate.

6.15*† Policy Application: AFDC and Work Disincentives: Consider the AFDC program for an individual as described in end-of-chapter exercise 3.18.

- A.** Consider again an individual who can work up to 8 hours per day at a wage of \$5 per hour.
- Replicate the budget constraint you were asked to illustrate in 3.18A.
 - True or False:* If this person’s tastes are homothetic, then he/she will work no more than 1 hour per day.
 - For purposes of defining a 45-degree line for this part of the question, assume that you have drawn hours on the horizontal axis 10 times as large as dollars on the vertical. This implies that the 45-degree line contains bundles like (1, 10), (2, 20), and so on. How much would this person work if his tastes are homothetic and symmetric across this 45-degree line? (By “symmetric across the 45-degree line,” I mean that the portions of the indifference curves to one side of the 45-degree line are mirror images to the portions of the indifference curves to the other side of the 45-degree line.)
 - Suppose you knew that the individual’s indifference curves were linear but you did not know the *MRS*. Which bundles on the budget constraint could in principle be optimal and for what ranges of the *MRS*?
 - Suppose you knew that, for a particular person facing this budget constraint, there are two optimal solutions. How much in AFDC payments does this person collect at each of these optimal bundles (assuming the person’s tastes satisfy our usual assumptions)?
- B.** Suppose this worker’s tastes can be summarized by the Cobb–Douglas utility function $u(c, \ell) = c^\alpha \ell^{1-\alpha}$, where ℓ stands for leisure and c for consumption.
- Forget for a moment the AFDC program and suppose that the budget constraint for our worker could simply be written as $c = I - 5\ell$. Calculate the optimal amount of consumption and leisure as a function of α and I .
 - On your graph of the AFDC budget constraint for this worker, there are two line segments with slope -5 : one for 0–2 hours of leisure and another for 7–8 hours of leisure. Each of these lies on a line defined by $c = I - 5\ell$ except that I is different for the two equations that contain these line segments. What are the relevant I s to identify the right equations on which these budget constraint segments lie?
 - Suppose $\alpha = 0.25$. If this worker were to optimize using the two budget constraints you have identified with the two different I s, how much leisure would he choose under each constraint?

POLICY
APPLICATION

Can you illustrate what you find in a graph and tell from this where on the real AFDC budget constraint this worker will optimize?

- d. As α increases, what happens to the MRS at each bundle?
- e. Repeat B(c) for $\alpha = 0.3846$ and for $\alpha = 0.4615$. What can you now say about this worker's choice for any $0 < \alpha < 0.3846$? What can you say about this worker's leisure choice if $0.3846 < \alpha < 0.4615$?
- f. Repeat B(c) for $\alpha = 0.9214$ and calculate the utility associated with the resulting choice. Compare this to the utility of consuming at the kink point (7, 30) and illustrate what you have found on a graph. What can you conclude about this worker's choice if $0.4615 < \alpha < 0.9214$?
- g. How much leisure will the worker take if $0.9214 < \alpha < 1$?
- h. Describe in words what this tells you about what it would take for a worker to overcome the work disincentives under the AFDC program.

6.16 Policy Application: *Cost of Living Adjustments of Social Security Benefits:* Social Security payments to the elderly are adjusted every year in the following way: The government has in the past determined some average bundle of goods consumed by an average elderly person. Each year, the government then takes a look at changes in the prices of all the goods in that bundle and raises Social Security payments by the percentage required to allow the hypothetical elderly person to continue consuming that same bundle. This is referred to as a cost of living adjustment or COLA.

- A. Consider the impact on an average senior's budget constraint as cost of living adjustments are put in place. Analyze this in a two-good model where the goods are simply x_1 and x_2 .
 - a. Begin by drawing such a budget constraint in a graph where you indicate the "average bundle" the government has identified as A and assume that initially this average bundle is indeed the one our average senior would have chosen from his budget.
 - b. Suppose the prices of both goods went up by exactly the same proportion. After the government implements the COLA, has anything changed for the average senior? Is behavior likely to change?
 - c. Now suppose that the price of x_1 went up but the price of x_2 stayed the same. Illustrate how the government will change the average senior's budget constraint when it calculates and passes along the COLA. Will the senior alter his behavior? Is he better off, worse off, or unaffected?
 - d. How would your answers change if the price of x_2 increased and the price of x_1 stayed the same?
 - e. Suppose the government's goal in paying COLAs to senior citizens is to insure that seniors become neither better nor worse off from price changes. Is the current policy successful if all price changes come in the form of general "inflation"; that is, if all prices always change together by the same proportion? What if inflation hits some categories of goods more than others?
 - f. If you could "choose" your tastes under this system, would you choose tastes for which goods are highly substitutable, or would you choose tastes for which goods are highly complementary?
- B.** Suppose the average senior has tastes that can be captured by the utility function $u(x_1, x_2) = (x_1^{-\rho} + x_2^{-\rho})^{-1/\rho}$.
 - a. Suppose the average senior has income from all sources equal to \$40,000 per year, and suppose that prices are given by p_1 and p_2 . How much will our senior consume of x_1 and x_2 ? (*Hint:* It may be easiest simply to use what you know about the MRS of CES utility functions to solve this problem.)
 - b. If $p_1 = p_2 = 1$ initially, how much of each good will the senior consume? Does your answer depend on the elasticity of substitution?
 - c. Now suppose that the price of x_1 increases to $p_1 = 1.25$. How much does the government have to increase the senior's Social Security payment in order for the senior still to be able to purchase the same bundle as he purchased prior to the price change?

- d. Assuming the government adjusts the Social Security payment to allow the senior to continue to purchase the same bundle as before the price increase, how much x_1 and x_2 will the senior actually end up buying if $\rho = 0$?
- e. How does your answer change if $\rho = -0.5$ and if $\rho = -0.95$? What happens as ρ approaches -1 ?
- f. How does your answer change when $\rho = 1$ and when $\rho = 10$? What happens as ρ approaches infinity?
- g. Can you come to a conclusion about the relationship between how much a senior benefits from the way the government calculates COLAs and the elasticity of substitution that the senior’s tastes exhibit? Can you explain intuitively how this makes sense, particularly in light of your answer to A(f)?
- h. Finally, show how COLAs affect consumption decisions by seniors under general inflation that raises all prices simultaneously and in proportion to one another as, for instance, when both p_1 and p_2 increase from 1.00 to 1.25 simultaneously.

CHAPTER
7

Income and Substitution Effects in Consumer Goods Markets

We have just demonstrated in Chapter 6 how we can use our model of choice sets and tastes to illustrate optimal decision making by individuals such as consumers or workers.¹ We now turn to the question of how such optimal decisions change when economic circumstances change. Since economic circumstances in this model are fully captured by the choice set, we could put this differently by saying that we will now ask how optimal choices change when income, endowments, or prices change.

As we proceed, it is important for us to keep in mind the difference between *tastes* and *behavior*. Behavior, or what we have been calling *choice*, emerges when tastes confront circumstances as individuals try to do the “best” they can given those circumstances. If I buy less wine because the price of wine has increased, my *behavior* has changed but my *tastes* have not. Wine still tastes the same as it did before; it just costs more. In terms of the tools we have developed, my indifference map remains exactly as it was. I simply move to a different indifference curve as my circumstances (that is, the price of wine) change.

In the process of thinking about how *behavior* changes with economic circumstances, we will identify two conceptually distinct causes, known as *income* and *substitution* effects.² At first it will seem like the distinction between these effects is abstract and quite unrelated to real-world issues we care about. As you will see later, however, this could not be further from the truth. Answers to deep questions related to the efficiency of tax policy, the effectiveness of Social Security and health policy, and the desirability of different types of antipoverty programs are fundamentally rooted in an understanding of income and substitution effects. While we are still in the stage of building tools for economic analysis, I hope you will be patient and bear with me as we develop an understanding of these tools.

Still, it may be useful to at least give an initial example to motivate the effects we will develop in this chapter, an example that will already be familiar to you if you have done end-of-chapter exercise 6.14. As you know, there is increasing concern about carbon-based emissions

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

¹Chapters 2 and 4 through 6 are required reading for this chapter. Chapter 3 is not necessary.

²This distinction was fully introduced into neoclassical economics by Sir John Hicks in his influential book *Value and Capital* originally published in 1939. We had previously mentioned him in part B of Chapter 5 as the economist who first derived a way to measure substitutability through “elasticities of substitution.” Hicks was awarded the Nobel Prize in Economics in 1972 (together with Ken Arrow).

from automobiles, and an increased desire by policy makers to find ways of reducing such emissions. Many economists have long recommended the simple policy of taxing gasoline heavily in order to encourage consumers to find ways of conserving gasoline (by driving less and buying more fuel-efficient cars). The obvious concern with such a policy is that it imposes substantial hardship on households that rely heavily on their cars, particularly poorer households that would be hit pretty hard by such a tax. Some economists have therefore proposed simply sending all tax revenues from such a gasoline tax back to taxpayers in the form of a tax refund. This has led many editorial writers to conclude that economists must be nuts; after all, if we send the money back to the consumers, wouldn't they then just buy the same amount of gasoline as before since (at least on average) they would still be able to afford it? Economists may be nuts, but our analysis will tell us that they are also almost certainly right, and editorial writers are almost certainly wrong, when it comes to the prediction of how this policy proposal would change behavior. And the explanation lies fully in an understanding of substitution effects that economists understand and most noneconomists don't think about. We'll return to this in the conclusion to the chapter.

7A

GRAPHICAL EXPOSITION OF INCOME AND SUBSTITUTION EFFECTS

There are two primary ways in which choice sets (and thus our economic circumstances) can change: First, a change in our income or wealth might shift our budget constraints without changing their slopes, and thus without changing the opportunity costs of the various goods we consume. Second, individual prices in the economy—whether in the form of prices of goods, wages, or interest rates—may change and thus alter the slopes of our budget constraints and the opportunity costs we face. These two types of changes in choice sets result in different types of effects on behavior, and we will discuss them separately in what follows. First, we will look only at what happens to economic choices when income or wealth changes without a change in opportunity costs (Section 7A.1). Next, we will investigate how decisions are impacted when only opportunity costs change without a change in real wealth (Section 7A.2). Finally, we will turn to an analysis of what happens when changes in income and opportunity costs occur at the same time, which, as it turns out, is typically the case when relative prices in the economy change.

7A.1 The Impact of Changing Income on Behavior

What happens to our consumption when our income increases because of a pay raise at work or when our wealth endowment increases because of an unexpected inheritance or when our leisure endowment rises due to the invention of some time-saving technology? Would we consume more shirts, pants, Coke, housing, and jewelry? Would we consume more of some goods and fewer of others, work more or less, save more or less? Would our consumption of all goods go up by the same proportion as our income or wealth?

The answer depends entirely on the nature of our tastes, and the indifference map that represents our tastes. For most of us, it is likely that our consumption of some goods will go up by a lot while our consumption of other goods will increase by less, stay the same, or even decline. *The impact of changes in our income or wealth on our consumption decisions (in the absence of changes in opportunity costs) is known as the income or wealth effect.*

The economics “lingo” is not entirely settled on whether to call this kind of an effect a “wealth” or an “income” effect, and we will use the two terms in the following way: Whenever we are analyzing a model where the size of the choice set is determined by exogenously given income, as in Chapter 2 and for the remainder of this chapter, we will refer to the impact of a

Income effects
arise from
parallel shifts
in budgets.

change in income as an *income effect*. In models where the size of the choice set is determined by the value of an endowment, as in Chapter 3 and in the next chapter, we will refer to the impact of changes in that endowment as a *wealth effect*. What should be understood throughout, however, is that by both income and wealth effect we mean *an impact on consumer decisions that arises from a parallel shift in the budget constraint*, a shift that does *not* include a change in opportunity costs as captured by a change in the slope of the budget line.

7A.1.1 Normal and Inferior Goods During my first few years in graduate school, my wife and I made relatively little money. Often, our budget would permit few extravagances, with dinners heavily tilted toward relatively cheap foods such as potatoes and pasta. When my wife's business began to take off, our income increased considerably, and she observed one night over a nice steak dinner that we seemed to be eating a lot less pasta these days. Our consumption of pasta, it turned out, declined as our income went up, whereas our consumption of steak and other goods increased. How could this happen within the context of the general model that we have developed in the last few chapters?

Consider a simple model in which we put monthly consumption of boxes of pasta on the horizontal axis and the monthly consumption of pounds of steak on the vertical. My wife and I began with a relatively low income and experienced an increase in income as my wife's business succeeded. This is illustrated by the outward shift in our budget constraint (from blue to magenta) in each of the panels of Graph 7.1. As we then add the indifference curves that contain our optimal choices under the two budget constraints, we get less pasta consumption at the higher income only if the tangency on the budget line occurs to the left of our tangency on the lower budget line. This is illustrated in panel (a) of Graph 7.1. Panel (b), on the other hand, illustrates the relationship between the two indifference curves if pasta consumption had remained unchanged with the increase in our income, while panel (c) illustrates the case had our pasta consumption increased with our income. This change in consumer behavior as exogenous income changes is called the *income effect*.

Since my wife observed that our consumption of pasta *declined* with an increase in our income, our preferences must look more like those in panel (a), where increased income has a negative impact on pasta consumption. We will then say that *the income effect is negative whenever an increase in exogenous income (without a change in opportunity cost) results in less*

GRAPH 7.1 Income Effects for Inferior and Normal Goods

consumption, and goods whose consumption is characterized by negative income effects are called *inferior goods*. In contrast, we will say that *the income effect is positive whenever an increase in exogenous income (without a change in opportunity cost) results in more consumption*, and goods whose consumption is characterized by positive income effects are called *normal goods*. Panel (c) of Graph 7.1 illustrates an example of what our preferences could look like if pasta were in fact a normal good for us.

Finally, panel (b) of Graph 7.1 illustrates an indifference map that gives rise to *no* income effect on our pasta consumption. Notice the following defining characteristic of this indifference map: The marginal rate of substitution is constant along the vertical line that connects points *A* and *B*. In Chapter 5, we called tastes that are represented by indifference curves whose marginal rates of substitution are constant in this way *quasilinear (in pasta)*. The sequence of panels in Graph 7.1 then illustrates how *quasilinear tastes are the only kinds of tastes that do not give rise to income effects for some good, and as such they represent the borderline case between normal and inferior goods*.

It is worthwhile noting that *whenever we observe a negative income effect on our consumption of one good, there must be a positive income effect on our consumption of a different good*. After all, the increased income must be going somewhere, whether it is increased consumption of some good today or increased savings for consumption in the future. In Graph 7.1a, for instance, we observe a negative income effect on our consumption of pasta on the horizontal axis. At the same time, on the vertical axis we observe a positive income effect on our consumption of steak.

Income effects are positive for normal goods and negative for inferior goods.

Quasilinear goods are borderline between normal and inferior.

Is it also the case that whenever there is a positive income effect on our consumption of one good, there must be a negative income effect on our consumption of a different good?

EXERCISE
7A.1

Can a good be an inferior good at all income levels? (*Hint*: Consider the bundle $(0, 0)$.)

EXERCISE
7A.2

7A.1.2 Luxuries and Necessities As we have just seen, quasilinear tastes represent one special case that divides two types of goods: normal goods whose consumption increases with income and inferior goods whose consumption decreases with income. The defining difference between these two types of goods is how consumption changes in an *absolute* sense as our income changes. A different way of dividing goods into two sets is to ask how our *relative* consumption of different goods changes as income changes. Put differently, instead of asking whether *total* consumption of a particular good increases or decreases with an increase in income, we could ask whether the *fraction of our income spent* on a particular good increases or decreases as our income goes up, that is, whether our consumption increases *relative to our income*.

Consider, for instance, our consumption of housing. In each panel of Graph 7.2, we model choices between square footage of housing and “dollars of other goods.” As in the previous graph, we consider how choices will change as income doubles, with bundle *A* representing the optimal choice at the lower income and bundle *B* representing the optimal choice at the higher income. Suppose that in each panel, the individual spends 25% of her income on housing at bundle *A*. If housing remains a constant fraction of consumption as income increases, then the optimal consumption bundle *B* when income doubles would simply involve twice as much housing and twice as much “other good” consumption. This bundle would then lie on a ray emanating from the origin and passing through point *A*, as pictured in Graph 7.2b. If, on the other hand, the fraction of income allocated to housing declines as income rises, *B* would lie to the left of this ray (as in Graph 7.2a), and if the fraction of income allocated to housing increases

GRAPH 7.2 Income Effects for Necessities and Luxuries

as income rises, B would lie to the right of the ray (as in Graph 7.2c). It turns out that on average, people spend approximately 25% of their income on housing regardless of how much they make, which implies that tastes for housing typically look most like those in Graph 7.2b.

Economists have come to refer to goods whose consumption as a fraction of income declines with income as necessities while referring to goods whose consumption as a fraction of income increases with income as luxuries. The borderline tastes that divide these two classes of goods are tastes of the kind represented in Graph 7.2b, tastes that we defined as *homothetic* in Chapter 5. (Recall that we said tastes were homothetic if the marginal rates of substitution are constant along any ray emanating from the origin.) Thus, just as quasilinear tastes represent the borderline tastes between normal and inferior goods, *homothetic tastes represent the borderline tastes between necessary and luxury goods.*

Homothetic goods are borderline between luxuries and necessities.

EXERCISE 7A.3 Are all inferior goods necessities? Are all necessities inferior goods? (*Hint:* The answer to the first is yes; the answer to the second is no.) Explain.

EXERCISE 7A.4 At a particular consumption bundle, can both goods (in a two-good model) be luxuries? Can they both be necessities?

7A.2 The Impact of Changing Opportunity Costs on Behavior

Suppose my brother and I go off on a week-long vacation to the Cayman Islands during different weeks. He and I are identical in every way, same income, same tastes.³ Since there is no public transportation on the Cayman Islands, you only have two choices of what to do once you step off the airplane: You can either rent a car for the week, or you can take a taxi to your hotel and then

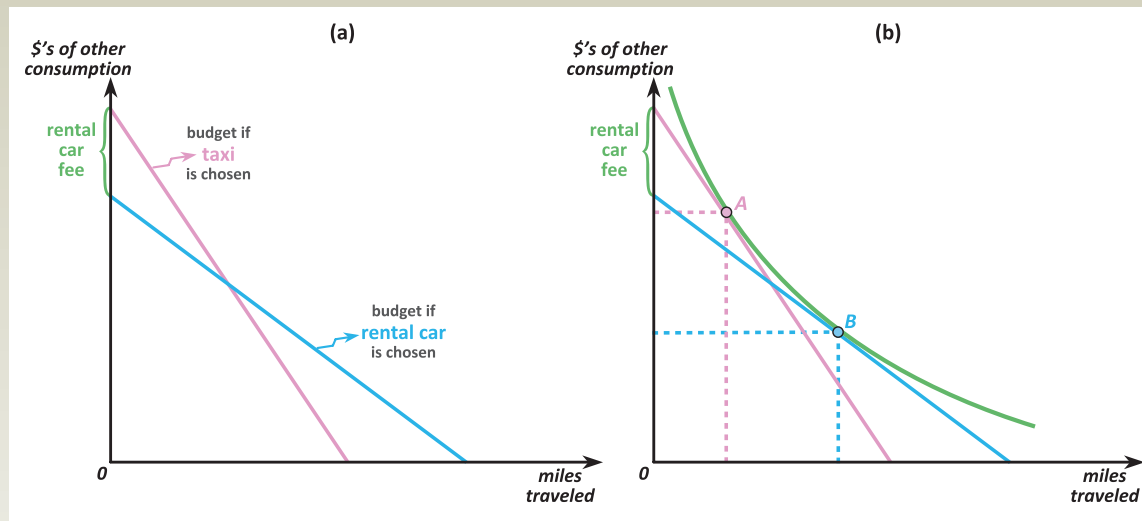

³This assumption is for illustration only. Both my brother and I are horrified at the idea of anyone thinking we are identical, and he asked for this clarification in this text.

rely on taxis for any additional transportation needs. After we returned home from our respective vacations, we compared notes and discovered that, although we had stayed at exactly the same hotel, I had rented a car whereas my brother had used only taxis. Which one of us do you think went on more trips away from our hotel? The difference between the number of car rides he and I took is what we will call a substitution effect.

7A.2.1 Renting a Car versus Taking Taxis on Vacation The answer jumps out straight away if we model the relevant aspects of the choice problem that my brother and I were facing when we arrived at the airport in the Cayman Islands. Basically, we were choosing the best way to travel by car during our vacation. We can model this choice by putting “miles traveled” on the horizontal axis and “dollars of other consumption” on the vertical. Depending on whether I rent a car or rely on taxis, I will face different budget constraints. If I rent a car, I end up paying a weekly rental fee that is the same regardless of how many miles I actually drive. I then have to pay only for the gas I use as I drive to different parts of the island. If I rely on taxis, on the other hand, I pay only for the miles I travel, but of course I pay a per mile cost that is higher than just the cost of gas. Translated into budget constraints with “miles driven” on the horizontal axis and “dollars of other consumption” on the vertical, this implies that my budget will have a higher intercept on the vertical axis if I choose to use taxis because I do not have to pay the fixed rental fee. At the same time, the slope of the budget constraint would be steeper if I chose to use taxis because each mile I travel has a higher opportunity cost.

The choice my brother and I faced when we arrived in the Cayman Islands is thus a choice between two different budget constraints, one with a higher intercept and steeper slope than the other, as depicted in Graph 7.3a. (If this looks familiar, it is because you may have done this in end-of-chapter exercise 2.6.) Since my brother and I are identical in every way and faced exactly the same choice, you can reasonably conclude that we were indifferent between these two modes of transportation (and thus between the two budget constraints). After all, if one choice was clearly better than the other, we should have ended up making the same choice.

GRAPH 7.3 Substitution Effects in the Cayman Islands

Go to MindTap to interact with this graph.

Thus, although we made different choices, we must have ended up on the same indifference curve. (This statement—that we ended up on the same indifference curve—makes sense only because we know that my brother and I have the same tastes and thus the same map of indifference curves, and we have the same exogenous income.) Graph 7.3b therefore fits a single indifference curve tangent to the two budget constraints, illustrating that our optimal choices on the two different budget constraints result in the same level of satisfaction. My brother's optimal choice *A* then indicates fewer miles traveled than my optimal choice *B*.

The intuition behind the model's prediction is straightforward. Once I sped off to my hotel in my rented car, I had already paid the rental fee and could not get it back no matter what else I did for the week. So, the opportunity cost or price of driving a mile (once I decided to rent a car) was only the cost of gasoline. My brother, on the other hand, faced a much higher opportunity cost since he had to pay taxi prices for every mile he traveled. Even though our choices made us equally well off, it is clear that my lower opportunity cost of driving led me to travel more miles and consume less of other goods than my brother.

EXERCISE 7A.5 If you knew only that my brother and I had the same income (but not necessarily the same tastes), could you tell which one of us drove more miles: the one that rented or the one that took taxis?

Economists will often say that the flat weekly rental fee becomes a *sunk cost* as soon as I have chosen to rent a car. Once I paid it at the airport, there is no way for me to get the fee back, and it stays the same no matter what I do thereafter. So, the rental fee is never an opportunity cost of anything I do once I have rented the car. Such sunk costs, once they have been incurred, therefore do not affect economic decisions because our economic decisions are shaped by the trade-offs inherent in opportunity costs. We will return to the concept of sunk costs more extensively when we discuss producer behavior, and we will note in Chapter 29 that some psychologists quarrel with the economist's conclusion that such costs should have no impact on behavior.

7A.2.2 Substitution Effects The difference in my brother's and my behavior in our Cayman Island example is what is known as a *substitution effect*. Substitution effects arise whenever opportunity costs or prices change. In our example, for instance, we analyzed the difference in consumer behavior when the price of driving changes, but the general intuition behind the substitution effect will be important for many more general applications throughout this book.

We will define a substitution effect more precisely as follows: *The substitution effect of a price change is the change in behavior that results purely from the change in opportunity costs and not from a change in real income.* By *real income*, we mean *real welfare*, so “no change in real income” should be taken to mean “no change in satisfaction” or “no change in indifference curves.” The Cayman Island example was constructed so that we could isolate a substitution effect clearly by focusing our attention on a single indifference curve or a single level of “real income.”⁴

Substitution effects arise from differently sloped budgets that are tangent to the same indifference curve.

⁴This definition of *real income* differs from another definition you may run into during your studies of economics (one that we also used in an earlier chapter on budget constraints). Macroeconomists who study inflation, or microeconomists who want to study behavior that is influenced by inflation, often define “real income” as “inflation adjusted income.” For instance, when comparing someone's income in 1990 to his or her income in 2000, an economist might adjust the 2000 income by the amount of inflation that occurred between 1990 and 2000, thus reporting 2000 “real income” expressed in 1990 dollars.

The fact that bundle B *must* lie to the right of bundle A is a simple matter of geometry: A steeper budget line fit tangent to an indifference curve *must* lie to the left of a shallower budget line that is tangent to the same indifference curve. *The direction of a substitution effect is therefore always toward more consumption of the good that has become relatively cheaper and away from the good that has become relatively more expensive.* Note that this differs from what we concluded about income effects whose direction depends on whether a good is normal or inferior.

7A.2.3 How Large Are Substitution Effects? While the *direction* of substitution effects is unambiguous, the *size* of the effect is dependent entirely on the kinds of underlying tastes a consumer has. The picture in Graph 7.3b suggests a pretty clear and sizable difference between the number of miles I drove and the number of miles my brother drove given that we faced different opportunity costs for driving while having the same level of satisfaction or welfare. But I could have equally well drawn the indifference curve with more curvature, and thus with less substitutability between miles driven and other consumption. *The less substitutability is built into a consumer's tastes, the smaller will be substitution effects arising from changes in opportunity costs.*

For instance, consider the indifference curve in Graph 7.4b, an indifference curve with more curvature than that in Graph 7.4a and thus less built-in substitutability along the portion on which my brother and I are making our choices. Notice that, although the substitution effect points in the same direction as before, the effect is considerably smaller. Graph 7.4c illustrates this even more clearly by focusing on the extreme case of perfect complements. Such tastes give rise to indifference curves that permit no substitutability between goods, leading to bundles A and B overlapping and a consequent disappearance of the substitution effect.

True or False: If you observed my brother and I consuming the same number of miles driven during our vacations, then our tastes must be those of perfect complements between miles driven and other consumption.

**EXERCISE
7A.6**

GRAPH 7.4 The Degree of Substitutability and the Size of Substitution Effects

7A.2.4 “Hicks” versus “Slutsky” Substitution We have now defined the substitution effect as the change in consumption that is due to a change in opportunity cost without a change in “real income,” that is, without a change in the indifference curve. This is sometimes called *Hicksian* substitution. A slightly different concept of a substitution effect arises when we ask how a change in opportunity costs alters a consumer’s behavior assuming that her ability to purchase the original bundle remains intact. This is called *Slutsky* substitution. It operates very similarly to Hicksian substitution, and we will therefore leave it to end-of-chapter exercise 7.11 to explore this further. We are also using the idea in exercise 7.6 (and its previous companion exercise 6.9) and have implicitly used it in exercise 6.16.

7A.3 Price Changes: Income and Substitution Effects Combined

As you were reading through the Cayman Island example, you may have wondered why I chose such an admittedly contrived story. The reason is that I wanted to follow our discussion of *pure* income effects (which occur in the absence of changes in opportunity costs) in Section 7A.1 with a discussion of *pure* substitution effects (which occur in the absence of any changes in real income or wealth) in Section 7A.2. Most real-world changes in opportunity costs, however, implicitly also give rise to changes in real income, causing the simultaneous operation of both income and substitution effects.

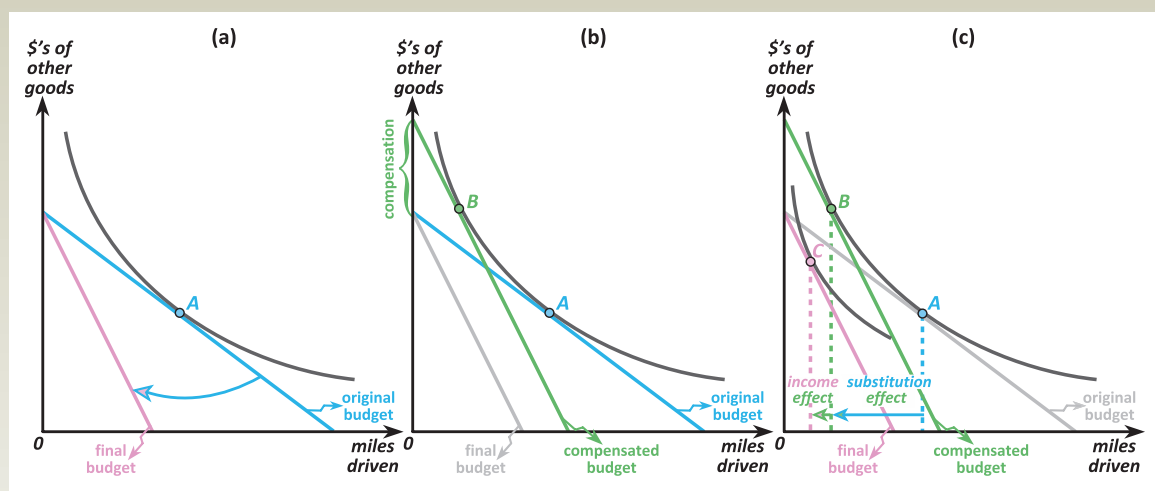

Let’s forget the Cayman Islands, then, and consider what happens when the price of a good that most of us consume goes up, as, for instance, the price of gasoline. When this happens, I can no longer afford to reach the same indifference curve as before if my exogenous income remains the same. Thus, not only do I face a different opportunity cost for gasoline but I also have to face the prospect of ending up with less satisfaction—or what we have called less “real” income—because I am doomed to operate on a lower indifference curve than before the price increase. Similarly, if the price of gasoline declines, I not only face a different opportunity cost for gasoline but will also end up on a higher indifference curve, and thus experience an increase in real income. *A price change therefore typically results in both an income effect and a substitution effect.* These can be conceptually disentangled even though they occur simultaneously, and it will become quite important for many policy applications to know the relative sizes of these conceptually different effects. You will see how this is important more clearly in later chapters. For now, we will simply focus on conceptually disentangling the two effects of price changes.

7A.3.1 An Increase in the Price of Gasoline To model the impact of an increase in the price of gasoline on my behavior, we can once again put “miles driven” on the horizontal axis and “dollars of other consumption” on the vertical. An increase in the price of gasoline then causes an inward rotation of the budget line around the vertical intercept, as illustrated in Graph 7.5a. My optimal bundle prior to the price increase is illustrated by the tangency of the indifference curve at point *A*.

We can now begin our disentangling of income and substitution effects by asking how my consumption bundle would have changed had I only experienced the change in opportunity costs without a change in my real income. Put differently, we can ask how my consumption decision would change if I faced a new budget that incorporated the steeper slope implied by the price change but was large enough to permit me to be as satisfied as I was before the price change, large enough to keep me on my original indifference curve. This budget is illustrated as the green budget tangent to the indifference curve containing bundle *A* in Graph 7.5b and is called the *compensated budget*. *A compensated budget for a price change is the budget that incorporates the new price but includes sufficient monetary compensation to make the consumer as well off as she was before the price change.* If income is exogenous (as it is in our example), the compensated budget requires positive compensation when prices increase and negative compensation when prices decrease.

Price changes typically give rise to both income and substitution effects.

Compensated budgets are used to isolate substitution effects of price changes.

GRAPH 7.5 Income and Substitution Effects When Gasoline Is a Normal Good

Go to MindTap to interact with this graph.

Graph 7.5b then looks very much like Graph 7.4b that illustrated a pure substitution effect for our Cayman Islands example. This is because we have imagined that I was provided sufficient compensation at the higher gasoline price to keep my real income constant in order to focus only on the change in my consumption that is due to the change in my opportunity costs along a single indifference curve. As in the Cayman example, we can then quickly see that consumption of gasoline is less at point *B* than at point *A*. When real income is unchanged, the substitution effect tells us that I will consume less gasoline because gasoline has become more expensive relative to other goods.

Rarely, however, will someone come to me and offer me compensation for a price change in real life. Rather, I will have to settle for a decrease in my real income when prices go up. In Graph 7.5c, we thus start with the compensated budget and ask how my actual consumption decision will differ from the hypothetical outcome *B*. Before answering this question, notice that the compensated budget and the final budget in Graph 7.5c have the same slope and thus differ only by the hypothetical compensation we have assumed when plotting the compensated budget. Thus when going from the compensated (green) to the final (magenta) budget, we are simply analyzing the impact of a change in my exogenous money income, or what we called a pure income effect in Section 7A.1.

Whether my optimal consumption of gasoline on my final budget line is larger or smaller than at point *B* then depends entirely on whether gasoline is a normal or an inferior good for me. We defined a normal good as one whose consumption moves in the same direction as changes in exogenous income, while we defined an inferior good as one whose consumption moved in the opposite direction of changes in exogenous income. Thus, the optimal bundle on the final budget might lie to the left of point *B* if gasoline is a normal good, and it might lie to the right of *B* if gasoline is an inferior good. In the latter case, it could lie in between *A* and *B* if the income effect is smaller than the substitution effect, or it might lie to the right of point *A* if the income effect is larger than the substitution effect. In Graph 7.5c, we illustrate the case where gasoline is a normal good, and the optimal final bundle *C* lies to the left of *B*. In this case, both income and substitution effects suggest that I will purchase less gasoline as the price of gasoline increases.

Income effects of price changes emerge when hypothetical compensation is removed.

7A.3.2 Regular Inferior and Giffen Goods Notice that we can conclude unambiguously that my consumption of gasoline will decline if its price increases whenever gasoline is a normal good (as is the case if bundle *C* in Graph 7.5c is my optimal final choice). This is because both the substitution and the income effect suggest declining consumption. If, on the other hand, gasoline is an inferior good for me, then my gasoline consumption could increase or decrease depending on whether my final consumption bundle lies between *A* and *B* as in Graph 7.6a or whether it lies to the right of *A* as in Graph 7.6b. We can therefore divide inferior goods into two subcategories: those whose consumption decreases with an increase in price and those whose consumption increases with an increase in price (when exogenous income remains constant). We will call the former *regular inferior goods* and the latter *Giffen goods*.

Notice what a strange kind of good a “Giffen good” is: A consumer would choose to *consume more of it when the price increases!* It is such a strange idea that, when initially introduced to it, students often misinterpret what economists mean by this. You might, for instance, already have thought of certain goods that carry a high level of prestige precisely because everyone knows they are expensive. Perhaps some consumers who care about the prestige value of a BMW will be more likely to purchase BMWs as the price (and thus the prestige value) increases. This is *not*, however, the kind of behavior we have in mind when we think of Giffen goods. The person who attaches a prestige value to the price of a BMW is really buying two different goods when he or she buys this car: the car itself *and* the prestige value of the car. As the price of the BMW goes up, the car remains the same but the quantity of prestige value rises. So, a consumer who is more likely to buy BMWs as the price increases is not buying more of a single good but is rather buying a different mix of goods when the price of the BMW goes up. When the same consumer’s income falls (and the price of BMWs remains the same), the consumer would almost

GRAPH 7.6 Income and Substitution Effects When Gasoline Is an Inferior Good

certainly be less likely to buy BMWs, which indicates that the car itself (with the prestige value held constant) is a normal good.⁵

Real Giffen goods are quite different, and we rarely observe them in the real world. Economists have struggled for literally centuries to find examples; this is how rare they are. At the end of the 19th century, Alfred Marshall (1842–1924), one of the great economists of that century, included a hypothetical example in his economics textbook and attributed it to Robert Giffen, a contemporary of his.⁶ Over the years, a variety of attempts to find credible historical examples that are not hypothetical have been discredited, although a recent paper demonstrates that rice in poor areas of China may indeed be a Giffen good there.⁷

A friend of mine in graduate school once told me a story that is the closest example I have ever personally heard of a real Giffen good. He came from a relatively poor family in the Midwest where winters get bitterly cold and where they heated their home with a form of gasoline. Every winter, they would spend a month over Christmas with relatives in Florida. One year during the 1973 energy crisis, the price of gasoline went up so much that they decided they could not afford to go on their annual vacation in Florida. So, they stayed in the Midwest and had to heat their home for one additional month. While they tried to conserve on gasoline all winter, they ended up using more than usual because of that extra month. Thus, their consumption of gasoline went up precisely because the price of gasoline went up and the income effect outweighed the substitution effect. This example, as well as the recent research on rice in China, both illustrate that, in order to find the “Giffen behavior” of increasing consumption with an increase in price, it must be that the good in question represents a large portion of a person’s income to begin with, with a change in price therefore causing a large income effect. It furthermore must be the case that there are no very good substitutes for the good in order for the substitution effect to remain small. Given the variety of substitutable goods in the modern world and the historically high standard of living, it therefore seems very unlikely that we will find much Giffen behavior in the part of the world that has risen above subsistence income levels.

Can you retell the Heating Gasoline-in-the-Midwest story in terms of income and substitution effects in a graph with “yearly gallons of gasoline consumption” on the horizontal axis and “yearly time on vacation in Florida” on the vertical?

EXERCISE
7A.7*

7A.3.3 Income and Substitution Effects for Pants and Shirts Now let’s return to our example from Chapter 2: My wife sends me to Walmart with a fixed budget to buy pants and shirts. Since I know how much Walmart charges for pants and shirts, I enter the store already

⁵While an increase in the price still causes an increase in the consumption of the physical good we observe, such goods are examples of what is known as *Veblen Goods* after Thorstein Veblen (1857–1929) who hypothesized that preferences for certain goods intensify as price increases, which can cause what appear to be increases in consumption as price goes up. You can think through this more carefully in end-of-chapter exercise 7.9, where you are asked to explain an increase in the consumption of Gucci accessories when the price increases. In Chapter 21, we revisit Veblen goods in end-of-chapter exercise 21.5 in the context of network externalities.

⁶To quote from his text: “As Mr. Giffen has pointed out, a rise in the price of bread makes so large a drain on the resources of the poorer labouring families . . . that they are forced to curtail their consumption of meat and the more expensive farinaceous foods: and bread being still the cheapest food which they can get and will take, they consume more, and not less of it.” A. Marshall, *Principles of Economics* (London: MacMillan, 1895), p. 208. While Robert Giffen (1837–1910) was a highly regarded economist and statistician, it appears no one has located a reference to the kinds of goods that are named after him in any of his own writings, only in Marshall’s.

⁷R. Jensen and N. Miller, (2007). “Giffen Behavior: Theory and Evidence,” National Bureau of Economic Research working paper 13243 (Cambridge, MA, 2007).

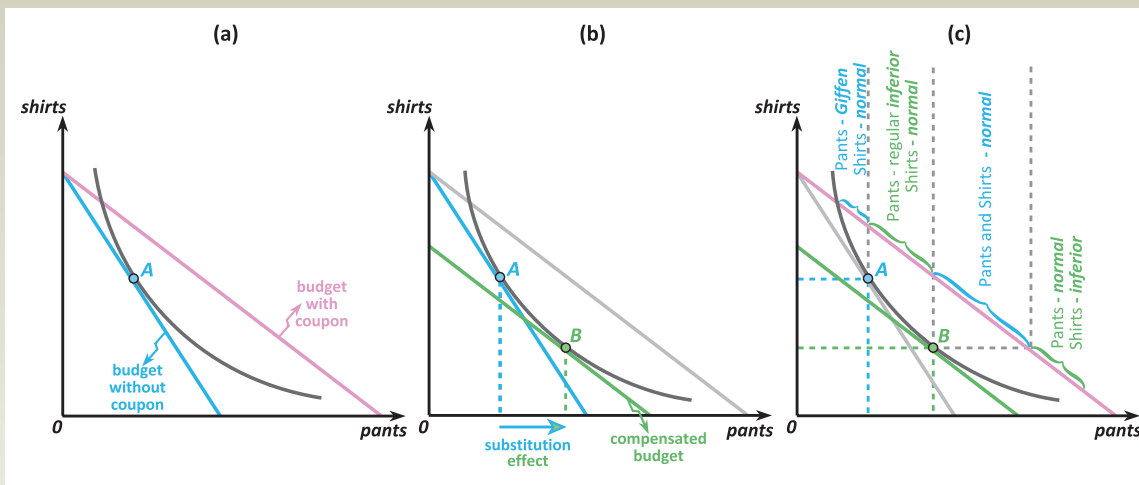

having solved for my optimal bundle. Now suppose that one of the greeters at Walmart hands me a 50% off coupon for pants, effectively decreasing the price of pants I face. We already know that this will lead to an outward rotation of my budget as shown in Graph 7.7a. Armed with the new information presented in this chapter, however, we can now predict how my consumption of pants and shirts will change depending on whether pants and shirts are normal, regular inferior, or Giffen goods.

First, we isolate once again the substitution effect by drawing my (green) compensated budget under the new price in Graph 7.7b. Notice that the “compensation” in this case is negative: In order to keep my “real income” (that is, my indifference curve) constant and concentrate only on the impact of the change in opportunity costs, you would have to take away some of the money my wife had given me. As always, the substitution effect, the shift from *A* to *B*, indicates that I will switch away from the good that has become relatively more expensive (shirts) and toward the good that has become relatively cheaper (pants).

In Graph 7.7c, we then focus on what happens when we switch from the hypothetical optimum on the compensated (green) budget to our new optimum on the final (magenta) budget. Since this involves no change in opportunity costs, we are left with a pure income effect as we jump from the optimal point *B* on the compensated budget line to the final optimum on the final budget constraint. Suppose we know that both shirts and pants are normal goods for me. This would tell me that, when I experience an increase in income from the compensated to the final budget, I will choose to consume more pants and shirts than I did at point *B*. If shirts are inferior and pants are normal, I will consume more pants and fewer shirts than at *B*; and if pants are inferior and shirts are normal, I will consume fewer pants and more shirts. Given that I am restricted in this example to consuming only shirts and pants, it cannot be the case that both goods are inferior because this would imply that I consume fewer pants and fewer shirts on my final budget than I did at point *B*, which would put me at a bundle to the southwest of *B*. Since “more is better,” I would not be at an optimum given that I can move to a higher indifference curve from there.

Now suppose that you know not only that pants are an inferior good but also that pants are a Giffen good. The definition of a Giffen good implies that I will consume less of the good as its price decreases when exogenous income remains unchanged. Thus, I would end up

GRAPH 7.7 Inferring the Type of Good from Observed Choices

Go to MindTap to interact with this graph.

consuming not just fewer pants than at point *B* but also fewer than at point *A*. Notice that this is the only scenario under which we would not even have to first find the substitution effect; if we know something is a Giffen good and we know its price has decreased, we immediately know that consumption will decrease as well. In each of the other scenarios, however, we needed to find the compensated optimum *B* before being able to apply the definition of normal or inferior goods.

In panel (c) of Graph 7.7, where would the final optimal bundle on the magenta budget lie if tastes were homothetic? What if they were quasilinear?

EXERCISE
7A.8

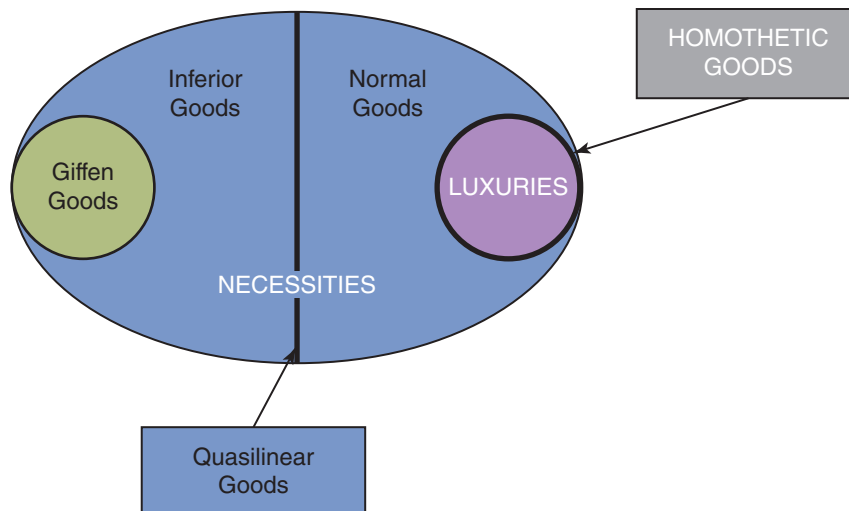

Finally, suppose you know that shirts rather than pants are a Giffen good. Remember that in order to observe a Giffen good, we must observe a price change for that good (with exogenous income constant) since Giffen goods are goods whose consumption moves in the same direction as *price* (when income is exogenous and unchanged). In this example, we did not observe a price change for shirts, which means that we cannot usefully apply the definition of a Giffen good to predict how consumption will change. Rather, we can simply note that, since all Giffen goods are also inferior goods, I will consume fewer shirts as my income increases from the compensated budget to the final budget. Thus, knowing that shirts are Giffen tells us nothing more in this example than knowing that shirts are inferior goods.

Replicate Graph 7.7 for an increase in the price of pants (rather than a decrease).

7B

THE MATHEMATICS OF INCOME AND SUBSTITUTION EFFECTS

In this section, we will now begin to explore income and substitution effects mathematically. I say that we will “begin” doing this because our exploration of these effects will become deeper as we move through the next few chapters. For now, we will try to illustrate how to relate the intuitions developed in part A of this chapter most directly to some specific mathematics, and in the process we will build the tools for a more general treatment later on. As you read through this section, you will undoubtedly get lost a bit unless you sit with pencil and paper and follow the calculations we undertake closely on your own. As you do this, you will begin to get a feel for how we can use the various mathematical concepts introduced thus far to identify precisely the points A , B , and C that appear in our graphs of this chapter. It might help you even more to then reread the chapter and construct simple spreadsheets in a program like Microsoft Excel, which is precisely how I kept track of the different numerical answers that are presented in the text as I wrote this section. Setting up such spreadsheets will give you a good feel for how the mathematics of consumer choice works for specific examples.

7B.1 The Impact of Changing Income on Behavior

In Chapter 6, we solved the consumer’s constrained optimization problem for specific economic circumstances, that is, for specific prices and incomes. In Section 7A.1, we became interested in how consumer behavior changes when exogenous income changes, and we discovered that the answer depends on the nature of the underlying map of indifference curves. We will now translate some of this analysis from Section 7A.1 into the mathematical optimization language we developed in Chapter 6.

7B.1.1 Inferior and Normal Goods Consider, for instance, the example of pasta and steak we introduced in Section 7A.1.1, and suppose my wife and I had discovered that our consumption of pasta remained unchanged as our income increased (as depicted in Graph 7.1b). Suppose that the price of a box of pasta is \$2 and the price of a pound of steak is \$10, and suppose we let boxes of pasta be denoted by x_1 and pounds of steak by x_2 . We know from our discussion in Section 7A.1.1 that pasta consumption can remain constant as income increases only if the underlying tastes are quasilinear in pasta, that is, when utility functions can be written as $u(x_1, x_2) = v(x_1) + x_2$. For an income level I and for tastes that can be described by a utility function $u(x_1, x_2) = v(x_1) + x_2$, the constrained optimization problem can then be written as

$$\max_{x_1, x_2} u(x_1, x_2) = v(x_1) + x_2 \quad \text{subject to} \quad 2x_1 + 10x_2 = I, \quad (7.1)$$

with a corresponding Lagrange function

$$\mathcal{L}(x_1, x_2, \lambda) = v(x_1) + x_2 + \lambda(I - 2x_1 - 10x_2). \quad (7.2)$$

Taking the first two first-order conditions, we get

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial x_1} &= \frac{dv(x_1)}{dx_1} - 2\lambda = 0, \\ \frac{\partial \mathcal{L}}{\partial x_2} &= 1 - 10\lambda = 0. \end{aligned} \quad (7.3)$$

The second of the expressions in (7.3) can then be rewritten as $\lambda = 1/10$, which, when substituted into the first expression in (7.3), gives

$$\frac{dv(x_1)}{dx_1} = \frac{1}{5}. \quad (7.4)$$

Notice that the left-hand side of expression (7.4) is just a function of x_1 , whereas the right-hand side is just a real number, which implies that, when we have a specific functional form for the function v , we can solve for x_1 as just a real number. For instance, if $u(x_1, x_2) = \ln x_1 + x_2$ (implying $v(x_1) = \ln x_1$), expression (7.4) becomes

$$\frac{1}{x_1} = \frac{1}{5} \text{ or } x_1 = 5. \quad (7.5)$$

When the underlying tastes are quasilinear, the optimal quantity of pasta (x_1) is therefore 5 (when prices of pasta and steak are \$2 and \$10) and is thus always the same regardless of what value the exogenous income I takes in the optimization problem (7.1). Put differently, the variable I simply drops out of the analysis as we solve for x_1 . Thus, quasilinear—or borderline normal/inferior—goods have no income effects.

Quasilinearity in good x implies no income effect for good x .

This is not true, of course, for tastes that cannot be represented by quasilinear utility functions. Consider, for instance, the same problem but with underlying tastes that can be represented by the Cobb–Douglas utility function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$. The Lagrange function is then

$$\mathcal{L}(x_1, x_2, \lambda) = x_1^\alpha x_2^{(1-\alpha)} + \lambda(I - 2x_1 - 10x_2), \quad (7.6)$$

and the first-order conditions for this problem are

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial x_1} &= \alpha x_1^{(\alpha-1)} x_2^{(1-\alpha)} - 2\lambda = 0, \\ \frac{\partial \mathcal{L}}{\partial x_2} &= (1 - \alpha) x_1^\alpha x_2^{-\alpha} - 10\lambda = 0, \\ \frac{\partial \mathcal{L}}{\partial \lambda} &= I - 2x_1 - 10x_2 = 0. \end{aligned} \quad (7.7)$$

Adding 2λ to both sides of the first equation and 10λ to both sides of the second equation, and then dividing these equations by each other, we get $\alpha x_2 / (1 - \alpha) x_1 = 1/5$ or $x_2 = (1 - \alpha) x_1 / 5\alpha$. Substituting this into the third equation of expression (7.7) and solving for x_1 , we get

$$x_1 = \frac{\alpha I}{2}. \quad (7.8)$$

Thus, for the underlying Cobb–Douglas tastes specified here, the optimal consumption of pasta (x_1) depends on income, with higher income leading to greater consumption of pasta. Cobb–Douglas tastes (as well as all other homothetic tastes) therefore represent tastes for normal goods as depicted in Graph 7.1c.

Finally, none of the utility functions we have discussed thus far represent tastes for inferior goods. This is because such tastes are difficult to capture in simple mathematical functions, in part because *there are no tastes such that a particular good is always an inferior good*. To see this, imagine beginning with zero income, thus consuming the origin $(0, 0)$ in our graphs. Now suppose I give you \$10. Since we cannot consume negative amounts of goods, it is not possible for you to consume less pasta than you did before I gave you \$10, and it is therefore not possible to have tastes that represent inferior goods around the origin of our graphs. *All goods are therefore normal or borderline normal/inferior goods at least around the bundle $(0, 0)$* . Goods can be

inferior only for some portion of an indifference map, and this logical conclusion makes it difficult to represent such tastes in simple utility functions.

7B.1.2 Luxury Goods and Necessities We also defined in Section 7A.1.2 the terms *luxury goods* and *necessities*, with borderline goods between the two represented by homothetic tastes. We know from our discussion of homothetic tastes in Chapter 5 that such tastes have the feature that the marginal rates of substitution stay constant along linear rays emanating from the origin, and it is this feature of such tastes that ensures that, when exogenous income is increased by $k\%$ (without a change in opportunity costs), our consumption of each good also increases by $k\%$, leaving the ratio of our consumption of one good relative to the other unchanged.

For instance, in equation (7.8), we discovered that my optimal consumption of pasta is equal to $\alpha I/2$ when my tastes are captured by the Cobb–Douglas function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$, when the price of pasta is \$2 and the price of steak is \$10 and when my income is given by I . When plugging this value into the budget constraint for x_1 and solving for x_2 , we can also determine that my optimal consumption of steak is $(1 - \alpha)I/10$. Thus, the ratio (x_1/x_2) of my pasta consumption to my steak consumption under these economic circumstances is $5\alpha/(1 - \alpha)$. Put differently, my consumption of pasta relative to steak is *independent of income*. Since we know that Cobb–Douglas utility functions represent homothetic tastes, this simply confirms what our intuition already tells us: Both pasta and steak are borderline luxury/necessity goods when the underlying tastes can be represented by Cobb–Douglas utility functions.

Again, this is not true for all types of tastes. If my tastes could be represented by the quasi-linear utility function $u(x_1, x_2) = \ln x_1 + x_2$, we concluded in expression (7.5) that my optimal consumption of pasta would be equal to 5 boxes *regardless of my income level* (assuming, of course, that I had at least enough income to cover that much pasta consumption). Plugging this into the budget constraint for x_1 and solving for x_2 , we also get that my optimal steak consumption is $(I - 10)/10$; that is, my optimal steak consumption is a function of my income whereas my optimal pasta consumption is not. Put differently, my consumption of pasta *relative* to my consumption of steak declines with income, making pasta a necessity (and steak a luxury good).

7B.2 The Impact of Changing Opportunity Costs on Behavior

We introduced the concept of a *substitution effect* in Section 7A.2 by focusing on a particular example in which my brother chose to use taxis for transportation on his Cayman Islands vacation whereas I rented a car. To really focus on the underlying ideas, we assumed that my brother and I were identical in every way, allowing us to infer from the fact that we made two different choices that he and I were indifferent between renting a car and using taxis when we arrived at the airport in Cayman. The choice we made was one of choosing one of two budget constraints between “miles driven” and “other consumption” on our vacation. Renting a car requires a large fixed payment (thus reducing the level of other consumption that is possible even if little or no driving occurs) but has the advantage of making additional miles cheap. Using taxis, on the other hand, involves no fixed payment but makes additional miles more expensive. Graph 7.3a illustrated the resulting choice sets, and Graph 7.3b illustrated a substitution effect from the different opportunity costs arising from those choice sets.

7B.2.1 Renting a Car versus Taking a Taxi Suppose you know that my brother and I came to the Cayman Islands with \$2,000 to spend on our vacations and that taxi rides cost \$1 per mile. Letting x_1 denote miles driven in Cayman and x_2 “dollars of other consumption in Cayman,” we know that my brother’s budget line is $2,000 = x_1 + x_2$ given that the price of “dollars of other consumption” is by definition also 1. Suppose we also know that my brother’s (and my own) tastes can be summarized by the Cobb–Douglas utility function $u(x_1, x_2) = x_1^{0.1} x_2^{0.9}$.

Doing our usual constrained optimization problem, we can then determine that my brother's optimal consumption bundle is $x_1 = 200$ and $x_2 = 1,800$.

Set up my brother's constrained optimization problem and solve it to check that his optimal consumption bundle is indeed equal to this.

**EXERCISE
7B.1**

Now suppose that I had lost my receipt for the rental car and no longer remember how much of a fixed fee I was charged to drive it for the week. All I do remember is that gasoline cost \$0.20 per mile. From the information we have, we can calculate what the fixed rental car fee must have been in order for me to be just as well off renting a car as my brother was using taxis.

Specifically, we can calculate the value associated with my brother's optimal indifference curve by simply plugging $x_1 = 200$ and $x_2 = 1,800$ into the utility function $u(x_1, x_2) = x_1^{0.1}x_2^{0.9}$ to get a value of approximately 1,445. While this number has no inherent meaning since we cannot quantify utility objectively, we do know from our analysis in Section 7A.2.1 (and Graph 7.3) that I ended up on the same indifference curve, and thus with the same utility level as measured by the utility function that my brother and I share. This gives us enough information to find bundle *B*—my optimal bundle of miles driven and other consumption in Graph 7.3b using a method that builds on the intuition that comes out of the graph. All we have to do is find the smallest possible choice set with a budget line that has the slope reflecting my lower opportunity cost for miles driven and is tangent to the indifference curve that my brother has achieved, that is, the indifference curve associated with the utility value 1,445.

This can be formulated mathematically as the following problem: We would like to find the minimum expenditure necessary for achieving a utility value of 1,445 (as measured by the utility function $u(x_1, x_2) = x_1^{0.1}x_2^{0.9}$) given that my price for miles driven is 0.2 (while my price for "other consumption" remains at 1). Letting E stand for expenditure, we can state this formally as a *constrained minimization problem*:

$$\min_{x_1, x_2} E = 0.2x_1 + x_2 \quad \text{subject to} \quad x_1^{0.1}x_2^{0.9} = 1,445. \quad (7.9)$$

Constrained minimization problems have the same basic structure as constrained maximization problems. The first part of (7.9) lets us know that we are trying to minimize a function by choosing the values for x_1 and x_2 . The function we are trying to minimize, or what we call our *objective function*, then follows and is simply the equation for the budget constraint that we will end up with, which reflects the new opportunity cost of driving miles given that I have paid a fixed fee for my rental car and now face a lower opportunity cost for driving each mile. Finally, the last part of (7.9) tells us the *constraint* of our minimization problem: We are trying to reach the indifference curve associated with the value 1,445.

Finding the solution to a minimization problem is quite similar to finding the solution to a maximization problem. The reason for this similarity is most easily seen within the economic examples with which we are working. In our utility maximization problem, for instance, we are taking the budget line as fixed and trying to find the indifference curve that is tangent to that line. This is illustrated graphically in Graph 7.8a where a consumer faces a fixed budget line and tries to get to the highest possible indifference curve that still contains a bundle within the choice set defined by the fixed budget line. In the expenditure minimization problem defined in expression (7.9), on the other hand, we are taking the indifference curve as fixed and trying to find the smallest possible choice set given the opportunity costs of the goods. This is illustrated in Graph 7.8b where we are trying to reach a fixed indifference curve with the smallest possible choice set. In both cases, we are therefore trying to find a solution, a combination of x_1 and x_2 ,

Expenditure minimization allows us to identify the smallest budget necessary to reach a particular indifference curve.

GRAPH 7.8 Maximizing Utility with Budgets Fixed (a) versus Minimizing Expenditure with Utility Fixed (b)

where an indifference curve is tangent to a budget line (assuming the problem does not have non-convexities or corner solutions).

For this reason, the same Lagrange Method that we have employed in solving maximization problems can be employed to solve our newly defined minimization problem. Again, we create the Lagrange function by combining the *objective function* with a second term that is equal to λ times the *constraint* set to zero, only now the objective function is the budget constraint and the constraint is the indifference curve. Thus,

$$\mathcal{L}(x_1, x_2, \lambda) = 0.2x_1 + x_2 + \lambda(1,445 - x_1^{0.1}x_2^{0.9}) \quad (7.10)$$

We then again take the first derivatives of \mathcal{L} with respect to the choice variables (x_1 and x_2) and λ to get the first-order conditions

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial x_1} &= 0.2 - 0.1\lambda x_1^{-0.9}x_2^{0.9} = 0, \\ \frac{\partial \mathcal{L}}{\partial x_2} &= 1 - 0.9\lambda x_1^{0.1}x_2^{-0.1} = 0, \\ 1,445 - x_1^{0.1}x_2^{0.9} &= 0. \end{aligned} \quad (7.11)$$

Solving the first two equations for x_2 we get

$$x_2 = \frac{0.9(0.2x_1)}{0.1} = 1.8x_1 \quad (7.12)$$

and plugging this into the third equation and solving for x_1 , we get $x_1 = 851.34$. Finally, plugging this back into expression (7.12), we get $x_2 = 1,532.41$. This is point *B* in Graph 7.3, which implies that I chose to drive approximately 851 miles in my rental car during my Cayman Island vacation while consuming approximately \$1,532 in other goods.

We can now see how much the bundle B costs by multiplying my optimal levels of x_1 and x_2 by the prices of those goods, 0.2 for x_1 and 1 for x_2 , and adding these expenditures together:

$$E = 0.2(851.34) + 1(1,532.41) = 1,702.68 \quad (7.13)$$

Thus, bundle B costs a total of \$1,702.68. Since you know that I arrived in Cayman with \$2,000, you know that the difference between my total money budget for my vacation and the total I spent on driving and other goods must be what I paid for the fixed rental car fee: \$297.32. This is equal to the vertical distance labeled “rental car fee” in Graph 7.3a.

7B.2.2 Substitution Effects Notice that, in the process of making these calculations, we have identified the size of the substitution effect we treated graphically in Graph 7.3. Put differently, assuming tastes that can be represented by the utility function $u(x_1, x_2) = x_1^{0.1} x_2^{0.9}$, an individual who chooses to drive 200 miles while consuming \$1,800 in other goods when the opportunity cost per mile is \$1 will reduce his other consumption and *substitute* toward 851 miles driven when we keep his real wealth—or his real well-being—fixed and change the opportunity cost for driving a mile to \$0.2.

7B.2.3 The Size of Substitution Effects By using a Cobb–Douglas utility function to represent tastes in the previous example, we have chosen a utility function that we know (from our discussion of Constant Elasticity of Substitution (CES) utility functions in Chapter 5) has an elasticity of substitution equal to 1. The answers we calculated relate directly to this property of Cobb–Douglas utility functions. In fact, we can verify that the function $u(x_1, x_2) = x_1^{0.1} x_2^{0.9}$ has an elasticity of substitution of 1 using our answers as we determined the bundles associated with points A and B in Graph 7.3. Recall the formula for an elasticity of substitution:

$$\text{Elasticity of substitution} = \left| \frac{\% \Delta(x_2/x_1)}{\% \Delta MRS} \right|. \quad (7.14)$$

Bundle A , my brother’s optimal bundle, is (200, 1800), while bundle B , my optimal bundle, is (851.34, 1532.41). My brother’s ratio of x_2/x_1 is therefore equal to 1,800/200, or 9, while my ratio of x_2/x_1 is 1,532.41/851.34 or 1.8. In going from A to B on the same indifference curve, the change in the ratio x_2/x_1 , $\Delta(x_2/x_1)$, is therefore equal to -7.2 . The $\% \Delta(x_2/x_1)$ is just the change in the ratio (x_2/x_1) divided by the original level of (x_2/x_1) at bundle A , that is,

$$\% \Delta \left(\frac{x_2}{x_1} \right) = \frac{\Delta(x_2/x_1)}{x_2^A/x_1^A} = \frac{-7.2}{9} = -0.8. \quad (7.15)$$

Similarly, the MRS at bundle A is equal to the slope of my brother’s budget line, which is equal to -1 given that he faces a cost per mile of \$1. My MRS at bundle B , on the other hand, is equal to the slope of my budget line, which is equal to -0.2 given that I face a cost per mile of only \$0.20. The $\% \Delta MRS$ as we go from A to B is therefore the change in the MRS divided by the original MRS at bundle A , that is,

$$\% \Delta MRS = \frac{\Delta MRS}{MRS^A} = 0.8. \quad (7.16)$$

Plugging (7.15) and (7.16) into the equation for an elasticity of substitution in expression (7.14), we get an elasticity of substitution equal to 1. Thus, when the marginal rate of substitution of the indifference curve in Graph 7.3 changed by 80% (from -1 to -0.2), the ratio of other consumption (x_2) to miles driven (x_1) also changed by 80% (from 9 to 1.8). *It is the elasticity of substitution in the utility function that determined the size of the substitution effect we calculated!*

Elasticities of substitution determine the size of substitution effects.

This relates directly to the intuition we built in Graph 7.4, where we showed how substitution effects get larger as the degree of substitutability, or the elasticity of substitution in our more mathematical language, changes. Were we to use utility functions with elasticities of substitution different from those in Cobb–Douglas utility functions, we would therefore calculate substitution effects that were larger or smaller depending on whether the elasticity of substitution embedded into those utility functions was greater or smaller.

Consider, for instance, the CES utility function with $\rho = -0.5$, which implies an elasticity of substitution of 2 (rather than 1 as in the Cobb–Douglas case where $\rho = 0$). More precisely, suppose that the utility function my brother and I share is

$$u(x_1, x_2) = (0.25x_1^{0.5} + 0.75x_2^{0.5})^2, \quad (7.17)$$

and suppose again that our money budget for our Cayman vacation is \$2,000 and the per mile cost is \$1 for taxis and \$0.20 for rental cars.⁸ My brother's optimization problem is then

$$\max_{x_1, x_2} (0.25x_1^{0.5} + 0.75x_2^{0.5})^2 \text{ subject to } x_1 + x_2 = 2,000, \quad (7.18)$$

the results of which you can verify in an optimal consumption bundle of $x_1 = 200$ and $x_2 = 1,800$ just as it did in our previous example. Thus, point *A* remains unchanged. The indifference curve on which point *A* lies, however, differs substantially from that in the previous example because of the different elasticity of substitution embedded in equation (7.17). When you plug the optimal bundle for my brother back into the utility function (7.17) you can calculate that he operates on an indifference curve giving him utility of 1,250 as measured by this utility function. We could then repeat our analysis of calculating bundle *B* by solving the problem analogous to the one we stated in expression (7.9) but adapted to the model we are now working with:

$$\min_{x_1, x_2} E = 0.2x_1 + x_2 \text{ subject to } (0.25x_1^{0.5} + 0.75x_2^{0.5})^2 = 1,250. \quad (7.19)$$

You can again verify on your own that this results in an optimal bundle *B* of $x_1 = 2,551.02$ and $x_2 = 918.37$, which implies a substitution effect much larger than the one we found with the Cobb–Douglas utility function. This is because we have built a greater elasticity of substitution into the utility function of equation (7.17) than we had in our previous Cobb–Douglas utility function. The difference between the two scenarios is illustrated graphically in Graph 7.9.

EXERCISE 7B.2 How much did I pay in a fixed rental car fee in order for me to be indifferent to taking taxis in this example? Why is this amount larger than in the Cobb–Douglas case we calculated earlier?

Table 7.1 summarizes the outcome of similar calculations for CES utility functions with different elasticities of substitution. In each case, the remaining parameters of the CES utility function are set to ensure that my brother's optimal choice remains the same: 200 miles driven and \$1,800 in other consumption.⁹

⁸The exponents in equation (7.17) are positive because ρ is negative and each exponent in the CES utility function has a negative sign in front of it.

⁹More precisely, the utility function $u(x_1, x_2) = (\alpha x_1^{-\rho} + (1 - \alpha)x_2^{-\rho})^{-1/\rho}$ was used for these calculations, with ρ set as indicated in the first column of the table and α adjusted to ensure that point *A* remains at (200, 1800).

GRAPH 7.9 Different Elasticities of Substitution

TABLE 7.1 $u(x_1, x_2) = (\alpha x_1^{-\rho} + (1 - \alpha)x_2^{-\rho})^{-1/\rho}$

Substitution Effects as Elasticity of Substitution Changes		
ρ	Elasticity of Substitution	Substitution Effect
-0.5	2	2,351.02 more miles driven at B than at A
0.0	1	651.34 more miles driven at B than at A
0.5	0.67	337.28 more miles driven at B than at A
1.0	0.50	222.53 more miles driven at B than at A
5.0	0.167	57.55 more miles driven at B than at A
10.0	0.091	29.67 more miles driven at B than at A
∞	0.000	0.00 more miles driven at B than at A

7B.3 Price Changes: Income and Substitution Effects Combined

Finally, we concluded in Section 7A.3 that most price changes involve both income and substitution effects because they involve both a change in our real wealth (or our optimal indifference curve) and a change in opportunity costs. We can then employ all the mathematical tools we have built thus far to identify income and substitution effects when prices change. In the following, we will consider once again the case of me shopping at Walmart for pants (x_1) and shirts (x_2), as we did in Section 7A.3.3, to demonstrate how we can identify these effects separately. Throughout, we will assume that I have \$200 to spend and that the price of shirts is \$10, and we will focus on what happens when the price of pants, p_1 , changes. We will assume (unrealistically) in

this section that it is possible to consume fractions of shirts and pants. If this bothers you, you may feel more comfortable thinking of more continuous goods, such as nuts and candy from the bulk food aisle where one can scoop as little or as much into a bag, instead of pants and shirts.

Suppose first that my tastes can once again be represented by a Cobb–Douglas utility function

$$u(x_1, x_2) = x_1^{0.5} x_2^{0.5}. \quad (7.20)$$

My constrained maximization problem at Walmart is then

$$\max_{x_1, x_2} x_1^{0.5} x_2^{0.5} \text{ subject to } p_1 x_1 + 10x_2 = 200. \quad (7.21)$$

Solving this in the usual way gives us the optimal bundle

$$x_1 = \frac{100}{p_1} \text{ and } x_2 = 10. \quad (7.22)$$

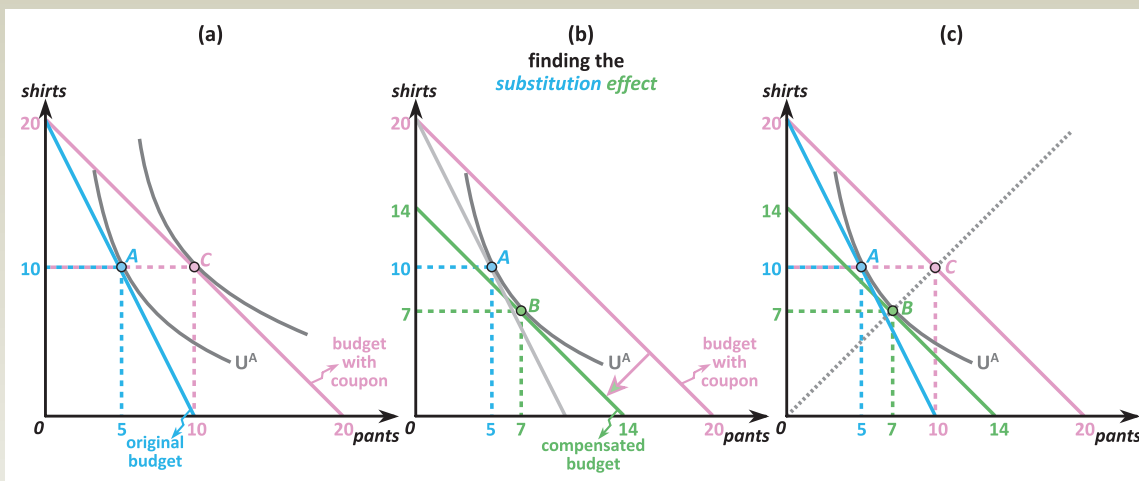

EXERCISE 7B.3

Check to see that this solution is correct.

Initially, I face a price of \$20 per pair of pants, which implies [according to equation (7.22)] that my optimal bundle is 5 pants and 10 shirts. Then I discover that my wife gave me a 50% off coupon for pants, effectively reducing the price of pants from \$20 to \$10. As a result of this decrease in the price of pants, my optimal consumption bundle changes from (5, 10) to (10, 10). This is illustrated in Graph 7.10a, with bundle A representing my original optimal bundle and bundle C representing my new optimal bundle.

In order to decompose this change in my behavior into income and substitution effects, we have to calculate how my consumption would have changed had I faced the same change in opportunity costs without experiencing an increase in real wealth, that is, without having shifted

GRAPH 7.10 Income and Substitution Effects When Tastes Are Cobb–Douglas

to a higher indifference curve. Thus, we need to employ the method we developed in the previous section to identify how much money I would have to give up when I received the coupon to be able to be just as well off as I was originally without the coupon. Notice that this is exactly analogous to our example involving my brother and I in the Cayman Islands where we wanted to identify how much the fixed rental car fee must have been in order for me to be just as well off as my brother was using taxis. In both cases, we have a fixed indifference curve, and we are trying to find the smallest possible choice set that will give me a fixed utility level when my opportunity costs change.

In Graph 7.10b, we illustrate the problem of finding the substitution effect graphically. We begin by drawing the indifference curve U^A that contains bundle A and the (magenta) budget line that I have with the coupon. Then we shift this budget line inward, keeping the slope and thus the new opportunity cost fixed, until only a single point on the indifference curve remains within the choice set. This process identifies bundle B on the compensated (green) budget, the bundle I would choose if I faced the opportunity costs under the coupon but had lost just enough of my money to be just as well off as I was originally when I consumed bundle A .

Mathematically, we state the process graphed in Graph 7.10b as a constrained minimization problem in which we are trying to minimize my total expenditures (or my money budget) subject to the constraint that I would like to consume on the indifference curve that contains bundle A .

We can write this as follows:

$$\min_{x_1, x_2} E = 10x_1 + 10x_2 \quad \text{subject to} \quad x_1^{0.5}x_2^{0.5} = U^A, \quad (7.23)$$

where U^A represents the level of utility I attained at bundle A . This level of utility can be calculated using the utility function $x_1^{0.5}x_2^{0.5}$ by simply plugging the bundle A ($x_1 = 5$, $x_2 = 10$) into the function, which gives us $U^A \approx 7.071$. Solving this *minimization* problem using the Lagrange Method illustrated in our Cayman example in the previous section, we get

$$x_1 = x_2 \approx 7.071 \quad (7.24)$$

Verify the solutions to the minimization problem.

EXERCISE 7B.4

The total expenditure required to consume this bundle at prices $p_1 = p_2 = 10$ is \$141.42, which implies that you could take \$58.58 out of my initial \$200 and give me a 50% off coupon and I would be just as well off as I was without the coupon and with my initial \$200. Put differently, my “real income” is \$58.58 higher when I get the coupon because that is how much you could take from me once I get the coupon without changing my well-being. The compensated budget (which keeps utility constant) is therefore \$141.42.

Combining Graphs 7.10a and 7.10b into a single graph, we then get Graph 7.10c showing bundles A , B , and C with the values we have calculated for each of these bundles. The substitution effect is the movement from A to B , while the income effect, reflecting the change in my behavior that is solely due to the fact that I am \$58.58 “richer” when I receive the coupon, is the movement from B to C .

Notice that the ratio of my pants to shirts consumption is the same ($=1$) at bundles B and C . What feature of Cobb–Douglas tastes is responsible for this result?

EXERCISE 7B.5

Just as was true for substitution effects we identified in the Cayman Islands example, the size of the substitution effect here once again arises from the degree of substitutability of the goods as captured by the shape of indifference curves and the form of the utility function. Similarly, the size of the income effect depends on the underlying nature of tastes and the degree to which pants and shirts represent normal or inferior goods.

Suppose, for instance, that my tastes could be represented by the quasilinear utility function

$$u(x_1, x_2) = 6x_1^{0.5} + x_2 \quad (7.25)$$

Setting up the maximization problem analogous to (7.21) gives

$$\max_{x_1, x_2} 6x_1^{0.5} + x_2 \quad \text{subject to} \quad p_1x_1 + 10x_2 = 200, \quad (7.26)$$

which you can verify solves to

$$x_1 = \frac{900}{p_1^2} \quad \text{and} \quad x_2 = \frac{20p_1 - 90}{p_1}. \quad (7.27)$$

Thus, when the price of pants is \$20, we get an optimal bundle (2.25, 15.5), and when the price falls to \$10 due to the coupon, we get an optimal bundle (9, 11). Total utility without the coupon is found by plugging $x_1 = 2.25$ and $x_2 = 15.5$ into equation (7.25), which gives utility equal to 24.5. This then permits us to find the substitution effect by solving the constrained minimization problem

$$\min_{x_1, x_2} E = 10x_1 + 10x_2 \quad \text{subject to} \quad 6x_1^{0.5} + x_2 = 24.5, \quad (7.28)$$

which gives $x_1 = 9$ and $x_2 = 6.5$. Thus (ignoring the fact that it is difficult to consume fractions of pants) the substitution effect changes my consumption of pants from my original 2.25 to 9, and the income effect causes no additional change in my consumption for pants. This lack of an income effect of course arises because tastes that are quasilinear in a particular good (in this case, pants) do not exhibit income effects for that good; such goods are borderline normal/inferior goods.¹⁰

EXERCISE 7B.6 Using the previous calculations, plot graphs similar to Graph 7.10 illustrating income and substitution effects when my tastes can be represented by the utility function $u(x_1, x_2) = 6x_1^{0.5} + x_2$.

CONCLUSION

We have begun in this chapter to discuss the important concepts of income and substitution effects in the context of consumer goods markets. In our mathematical section, we furthermore began to calculate income and substitution effects for some very specific examples in order to illustrate how the graphs of Section 7A related to the mathematical ideas we have dealt with thus far. A more general theory of consumer behavior will emerge from the building blocks of the optimization model we have laid out, but we will not have completed the building of this theory until Chapter 10. Before doing so, we will now first translate the concepts of income and substitution effects in consumer goods markets to similar ideas that emerge in labor and capital markets (Chapter 8). We will then illustrate in Chapters 9 and 10 how our notions of demand and consumer surplus relate directly to income and substitution effects as introduced here.

¹⁰A small caveat to this is that such tastes *do* exhibit income effects in the quasilinear good when there are corner solutions. This is explored in more detail in end-of-chapter exercise 7.5.

There is no particular reason why it should be fully apparent to you at this point why these concepts are important. The importance will become clearer as we apply them in exercises and as we turn to some real-world issues later on. We did, however, raise one example in the introduction, and we can now make a bit more sense of it. We imagined a policy in which the government would reduce consumption of gasoline by taxing it heavily, only to turn around and distribute the revenues from the tax in the form of rebate checks. For many, including some very smart columnists and politicians, such a combination of a gasoline tax and rebate makes no sense; on average, they argue, consumers would receive back as much as they paid in gasoline taxes, and as a result, they would not change their behavior.¹¹ Now that we have isolated income and substitution effects, however, we can see why economists think such a tax/rebate program will indeed curb gasoline consumption: The tax raises the price of gasoline and thus gives rise to income and substitution effects that (assuming gasoline is a normal good) both result in less consumption of gasoline. The rebate, on the other hand, does not change prices back; it simply causes incomes to rise above where they would otherwise have been after the tax. Thus, the rebate only causes an income effect in the opposite direction. The negative income effect from the increase in the price should be roughly offset by the positive income effect from the tax rebate, which leaves us with a substitution effect that unambiguously implies a decrease in gasoline consumption.

END-OF-CHAPTER EXERCISES

7.1[†] Here, we consider some logical relationships between preferences and types of goods.

- A.** Suppose you consider all the goods that you might potentially want to consume.
- Is it possible for all these goods to be luxury goods at every consumption bundle? Is it possible for all of them to be necessities?
 - Is it possible for all goods to be inferior goods at every consumption bundle? Is it possible for all of them to be normal goods?
 - True or False:* When tastes are homothetic, all goods are normal goods.
 - True or False:* When tastes are homothetic, some goods could be luxuries while others could be necessities.
 - True or False:* When tastes are quasilinear, one of the goods is a necessity.
 - True or False:* In a two-good model, if the two goods are perfect complements, they must both be normal goods.
 - * *True or False:* In a three-good model, if two of the goods are perfect complements, they must both be normal goods.
- B.** In each of the following cases, suppose that a person whose tastes can be characterized by the given utility function has income I and faces prices that are all equal to 1. Illustrate mathematically how his or her consumption of each good changes with income, and use your answer to determine whether the goods are normal or inferior, luxuries or necessities.
- $u(x_1, x_2) = x_1 x_2$
 - $u(x_1, x_2) = x_1 + \ln x_2$
 - $u(x_1, x_2) = \ln x_1 + \ln x_2$
 - $u(x_1, x_2, x_3) = 2 \ln x_1 + \ln x_2 + 4 \ln x_3$
 - * $u(x_1, x_2) = 2x_1^{0.5} + \ln x_2$

¹¹This argument was in fact advanced by opponents of such a policy advocated by the Carter administration in the late 1970s, a proposal that won only 35 votes (out of 435) in the U.S. House of Representatives. It is not the only argument against such policies. For instance, some have argued that a gasoline tax would be too narrow, and that the goals of such a tax would be better advanced by a broad-based carbon tax on all carbon-emitting activity.

*conceptually challenging

**computationally challenging

[†]solutions in Study Guide

- 7.2** Suppose you have an income of \$24 and the only two goods you consume are apples (x_1) and peaches (x_2). The price of apples is \$4 and the price of peaches is \$3.
- A.** Suppose that your optimal consumption is 4 peaches and 3 apples.
- Illustrate this in a graph using indifference curves and budget lines.
 - Now suppose that the price of apples falls to \$2 and I take enough money away from you to make you as happy as you were originally. Will you buy more or fewer peaches?
 - In reality, I do not actually take income away from you as described in (b), but your income stays at \$24 after the price of apples falls. I observe that, after the price of apples fell, you did not change your consumption of peaches. Can you conclude whether peaches are an inferior or normal good for you?
- B.** Suppose that your tastes can be characterized by the function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$.
- What value must α take in order for you to choose 3 apples and 4 peaches at the original prices?
 - What bundle would you consume under the scenario described in A(b)?
 - How much income can I take away from you and still keep you as happy as you were before the price change?
 - What will you actually consume after the price increase?
- 7.3[†]** Consider once again my tastes for Coke and Pepsi and my tastes for right and left shoes (as described in end-of-chapter exercise 6.2).
- A.** On two separate graphs—one with Coke and Pepsi on the axes, the other with right shoes and left shoes—replicate your answers to end-of-chapter exercise 6.2A(a) and (b). Label the original optimal bundles A and the new optimal bundles C .
- In your Coke/Pepsi graph, decompose the change in consumer behavior into income and substitution effects by drawing the compensated budget and indicating the optimal bundle B on that budget.
 - Repeat (a) for your right shoes/left shoes graph.
- B.** Now consider the following utility functions: $u(x_1, x_2) = \min\{x_1, x_2\}$ and $u(x_1, x_2) = x_1 + x_2$. Which of these could plausibly represent my tastes for Coke and Pepsi, and which could represent my tastes for right and left shoes?
- Use the appropriate function to assign utility levels to bundles A , B , and C in your graph from 7.3A(a).
 - Repeat this for bundles A , B , and C for your graph in 7.3A(b).
- 7.4** Return to the case of our beer and pizza consumption from end-of-chapter exercise 6.3.
- A.** Again, suppose you consume only beer and pizza (sold at prices p_1 and p_2 , respectively) with an exogenously set income I . Assume again some initial optimal (inferior) bundle A .
- In 6.3A(b), can you tell whether beer is normal or inferior? What about pizza?
 - When the price of beer goes up, I notice that you consume less beer. Can you tell whether beer is a normal or an inferior good?
 - When the price of beer goes down, I notice you buy less pizza. Can you tell whether pizza is a normal good?
 - When the price of pizza goes down, I notice you buy more beer. Is beer an inferior good for you? Is pizza?
 - Which of your conclusions in part (d) would change if you knew pizza and beer are very substitutable?
- B.** Suppose, as you did in end-of-chapter exercise 6.3B, that your tastes in beer (x_1) and pizza (x_2) can be summarized by the utility function $u(x_1, x_2) = x_1^2 x_2$. If you have not already done so, calculate the optimal quantity of beer and pizza consumption as a function of p_1 , p_2 , and I .
- Illustrate the optimal bundle A when $p_1 = 2$, $p_2 = 10$, and weekly income $I = 180$. What numerical label does this utility function assign to the indifference curve that contains bundle A ?

- b. Using your answer, show that both beer and pizza are normal goods when your tastes can be summarized by this utility function.
- c. Suppose the price of beer goes up to \$4. Illustrate your new optimal bundle and label it C .
- d. How much beer and pizza would you buy if you had received just enough of a raise to keep you just as happy after the increase in the price of beer as you were before (at your original income of \$180)? Illustrate this as bundle B .
- e. How large was your salary increase in (d)?
- f. Now suppose the price of pizza (p_2) falls to \$5 (and suppose the price of beer and your income are \$2 and \$180 as they were originally at bundle A). Illustrate your original budget, your new budget, the original optimum A , and the new optimum C in a graph.
- g. Calculate the income effect and the substitution effect for both pizza and beer consumption from this change in the price of pizza. Illustrate this in your graph.
- h. *True or False:* Since income and substitution effects point in opposite directions for beer, beer must be an inferior good.

7.5[†] Return to the analysis of my undying love for my wife expressed through weekly purchases of roses (as introduced in end-of-chapter exercise 6.4).

- A.** Recall that initially roses cost \$5 each and, with an income of \$125 per week, I bought 25 roses each week. Then, when my income increased to \$500 per week, I continued to buy 25 roses per week (at the same price).
 - a. From what you observed thus far, are roses a normal or an inferior good for me? Are they a luxury or a necessity?
 - b. On a graph with “weekly roses consumption” on the horizontal and “other goods” on the vertical, illustrate my budget constraint when my weekly income is \$125. Then illustrate the change in the budget constraint when income remains \$125 per week and the price of roses falls to \$2.50. Suppose that my optimal consumption of roses after this price change rises to 50 roses per week and illustrate this as bundle C .
 - c. Illustrate the compensated budget line and use it to illustrate the income and substitution effects.
 - d. Now consider the case where my income is \$500 and, when the price changes from \$5 to \$2.50, I end up consuming 100 roses per week (rather than 25). Assuming quasilinearity in roses, illustrate income and substitution effects.
 - e. *True or False:* Price changes of goods that are quasilinear give rise to no income effects for the quasilinear good unless corner solutions are involved.
- B.** Suppose again, as in 6.4B, that my tastes for roses (x_1) and other goods (x_2) can be represented by the utility function $u(x_1, x_2) = \beta x_1^\alpha + x_2$.
 - a. If you have not already done so, assume that p_2 is by definition equal to 1, let $\alpha = 0.5$, and $\beta = 50$, and calculate my optimal consumption of roses and other goods as a function of p_1 and I .
 - b. The original scenario you graphed in 7.5A(b) contains corner solutions when my income is \$125 and the price is initially \$5 and then \$2.50. Does your previous answer allow for this?
 - c. Verify that the scenario in your answer to 7.5A(d) is also consistent with tastes described by this utility function, that is, verify that A , B , and C are as you described in your answer.

7.6 **Everyday Application: Housing Price Fluctuations: Part 2:** Suppose, as in end-of-chapter exercise 6.9, you have \$400,000 to spend on “square feet of housing” and “all other goods.” Assume the same is true for me.

- A.** Suppose again that you initially face a \$100 per square foot price for housing, and you choose to buy a 2,000-square-foot house.
 - a. Illustrate this on a graph with “square footage of housing” on the horizontal axis and “other consumption” on the vertical. Then suppose, as you did in exercise 6.9, that the price of housing falls to \$50 per square foot after you bought your 2,000-square-foot house. Label the square footage of the house you would switch to h_B .

EVERYDAY
APPLICATION

- b. Is h_B smaller or larger than 2,000 square feet? Does your answer depend on whether housing is normal, regular inferior, or Giffen?
 - c. Now suppose that the price of housing had fallen to \$50 per square foot *before* you bought your initial 2,000-square-foot house. Denote the size of house you would have bought h_C and illustrate it in your graph.
 - d. Is h_C larger than h_B ? Is it larger than 2,000 square feet? Does your answer depend on whether housing is a normal, regular inferior, or Giffen good?
 - e. Now consider me. I did not buy a house until the price of housing was \$50 per square foot, at which time I bought a 4,000-square-foot house. Then the price of housing rises to \$100 per square foot. Would I sell my house and buy a new one? If so, is the new house size $h_{B'}$ larger or smaller than 4,000 square feet? Does your answer depend on whether housing is normal, regular inferior, or Giffen for me?
 - f. Am I better or worse off?
 - g. Suppose I had not purchased at the low price but rather purchased a house of size h_C after the price had risen to \$100 per square foot. Is h_C larger or smaller than $h_{B'}$? Is it larger or smaller than 4,000 square feet? Does your answer depend on whether housing is normal, regular inferior, or Giffen for me?
- B.** Suppose both you and I have tastes that can be represented by the utility function $u(x_1, x_2) = x_1^{0.5} x_2^{0.5}$, where x_1 is “square feet of housing” and x_2 is “dollars of other goods.”
- a. Calculate the optimal level of housing consumption x_1 as a function of per square foot housing prices p_1 and income I .
 - b. Verify that your initial choice of a 2,000-square-foot house and my initial choice of a 4,000-square-foot house were optimal under the circumstances we faced (assuming we both started with \$400,000).
 - c. Calculate the values of h_B and h_C as they are described in A(a) and (c).
 - d. Calculate $h_{B'}$ and h_C as they are described in A(e) and (g).
 - e. Verify your answer to A(f).

- 7.7†** **Everyday Application: Turkey and Thanksgiving:** Every Thanksgiving, my wife and I debate about how we should prepare the turkey we will serve (and will then have left over). On the one hand, my wife likes preparing turkeys the conventional way: roasted in the oven where it has to cook at 350 degrees for 4 hours or so. I, on the other hand, like to fry turkeys in a big pot of peanut oil heated over a powerful flame outdoors. The two methods have different costs and benefits. The conventional way of cooking turkeys has very little set-up cost (since the oven is already there and just has to be turned on) but a relatively large time cost from then on. (It takes hours to cook.) The frying method, on the other hand, takes some setup (dragging out the turkey fryer, pouring gallons of peanut oil, and so on, and then later the cleanup associated with it), but turkeys cook predictably quickly in just 3.5 minutes per pound.
- A.** As a household, we seem to be indifferent between doing it one way or another; sometimes we use the oven, sometimes we use the fryer. But we have noticed that we cook much more turkey, several turkeys, as a matter of fact, when we use the fryer than when we use the oven.
- a. Construct a graph with “pounds of cooked turkeys” on the horizontal and “other consumption” on the vertical. (“Other consumption” here is not denominated in dollars as it normally is but rather in some consumption index that takes into account the time it takes to engage in such consumption.) Think of the set-up cost for frying turkeys and the waiting cost for cooking them as the main costs that are relevant. Can you illustrate our family’s choice of whether to fry or roast turkeys at Thanksgiving as a choice between two “budget lines”?
 - b. Can you explain the fact that we seem to eat more turkey around Thanksgiving whenever we pull out the turkey fryer as opposed to roasting the turkey in the oven?
 - c. We have some friends who also struggle each Thanksgiving with the decision of whether to fry or roast, and they, too, seem to be indifferent between the two options. But we have noticed that they only cook a little more turkey when they fry than when they roast. What is different about them?

- B.**** Suppose that, if we did not cook turkeys, we could consume 100 units of “other consumption,” but the time it takes to cook turkeys takes away from that consumption. Setting up the turkey fryer costs c units of consumption and waiting 3.5 minutes (which is how long it takes to cook 1 pound of turkey) costs 1 unit of consumption. Roasting a turkey involves no set-up cost, but it takes 5 times as long to cook per pound. Suppose that tastes can be characterized by the CES utility function $u(x_1, x_2) = (0.5x_1^{-\rho} + 0.5x_2^{-\rho})^{-1/\rho}$ where x_1 is pounds of turkey and x_2 is “other consumption.”
- What are the two budget constraints I am facing?
 - Can you calculate how much turkey someone with these tastes will roast (as a function of ρ)? How much will the same person fry? (*Hint*: Rather than solving this using the Lagrange Method, use the fact that you know the *MRS* is equal to the slope of the budget line and recall from Chapter 5 that, for a CES utility function of this kind, $MRS = -(x_2/x_1)^{\rho+1}$.)
 - Suppose my family has tastes with $\rho = 0$ and my friend’s with $\rho = 1$. If each of us individually roasts turkeys this Thanksgiving, how much will we each roast?
 - How much utility will each of us get (as measured by the relevant utility function)? (*Hint*: In the case where $\rho = 0$, the exponent $1/\rho$ is undefined. Use the fact that you know that when $\rho = 0$ the CES utility function is Cobb–Douglas.)
 - Which family is happier?
 - If we are really indifferent between roasting and frying, what must c be for my family? What must it be for my friend’s family? (*Hint*: Rather than setting up the usual minimization problem, use your answer to (b) to determine c by setting utility equal to what it was for roasting.)
 - Given your answers so far, how much would we each have fried had we chosen to fry instead of roast (and we were truly indifferent between the two because of the different values of c we face)?
 - Compare the size of the substitution effect you have calculated for my family and that you calculated for my friend’s family and illustrate your answer in a graph with pounds of turkey on the horizontal and other consumption on the vertical. Relate the difference in the size of the substitution effect to the elasticity of substitution.

7.8* Business Application: Sam’s Club and the Marginal Consumer: Superstores like Costco and Sam’s Club serve as wholesalers to businesses but also target consumers who are willing to pay a fixed fee in order to get access to the lower wholesale prices offered in these stores. For purposes of this exercise, suppose that you can denote “goods sold at superstores” as x_1 and “dollars of other consumption” as x_2 .

- A.** Suppose all consumers have the same homothetic tastes over x_1 and x_2 , but they differ in their income. Every consumer is offered the same option of either shopping at stores with somewhat higher prices for x_1 or paying the fixed fee c to shop at a superstore at somewhat lower prices for x_1 .
- On a graph with x_1 on the horizontal axis and x_2 on the vertical, illustrate the regular budget (without a superstore membership) and the superstore budget for a consumer whose income is such that these two budgets cross on the 45-degree line. Indicate on your graph a vertical distance that is equal to the superstore membership fee c .
 - Now consider a consumer with twice that much income. Where will this consumer’s two budgets intersect relative to the 45-degree line?
 - Suppose consumer 1 [from part (a)] is just indifferent between buying and not buying the superstore membership. How will her behavior differ depending on whether or not she buys the membership?
 - If consumer 1 was indifferent between buying and not buying the superstore membership, can you tell whether consumer 2 [from part (b)] is also indifferent? (*Hint*: Given that tastes are homothetic and identical across consumers, what would have to be true about the intersection of the two budgets for the higher income consumer in order for the consumer also to be indifferent between them?)
 - True or False:* Assuming consumers have the same homothetic tastes, there exists a “marginal” consumer with income \bar{I} such that all consumers with income greater than \bar{I} will buy the superstore membership and no consumer with income below \bar{I} will buy that membership.

- f. *True or False:* By raising c and/or p_1 , the superstore will lose relatively lower-income customers and keep high-income customers.
- g. Suppose you are a superstore manager and you think your store is overcrowded. You'd like to reduce the number of customers while at the same time increasing the amount each customer purchases. How would you do this?
- B.** Suppose you manage a superstore and you are currently charging an annual membership fee of \$50. Since x_2 is denominated in dollar units, $p_2 = 1$. Suppose that $p_1 = 1$ for those shopping outside the superstore, but your store sells x_1 at 0.95. Your statisticians have estimated that your consumers have tastes that can be summarized by the utility function $u(x_1, x_2) = x_1^{0.15} \cdot x_2^{0.85}$.
- What is the annual discretionary income (that could be allocated to purchasing x_1 and x_2) of your “marginal” consumer?
 - Can you show that consumers with more income than the marginal consumer will definitely purchase the membership while consumers with less income will not? (*Hint:* Calculate the income of the marginal consumer as a function of c and show what happens to income that makes a consumer marginal as c changes.)
 - If the membership fee is increased from \$50 to \$100, how much could the superstore lower p_1 without increasing membership beyond what it was when the fee was \$50 and p_1 was 0.95?

BUSINESS
APPLICATION

7.9*† Business Application: *Are Gucci Products Giffen Goods?* We defined a Giffen good as a good that consumers (with exogenous incomes) buy more of when the price increases. When students first hear about such goods, they often think of luxury goods such as expensive Gucci purses and accessories. If the marketing departments for firms like Gucci are very successful, they may find a way of associating price with “prestige” in the minds of consumers, and this may allow them to raise the price *and* sell more products. But would that make Gucci products Giffen goods? The answer, as you will see in this exercise, is no.

- A.** Suppose we model a consumer who cares about the “practical value and style of Gucci products,” “dollars of other consumption,” and the “prestige value” of being seen with Gucci products. Denote these as x_1 , x_2 , and x_3 , respectively.
- The consumer only has to buy x_1 and x_2 —the prestige value x_3 comes with the Gucci products. Let p_1 denote the price of Gucci products and $p_2 = 1$ be the price of dollars of other consumption. Illustrate the consumer’s budget constraint (assuming an exogenous income I).
 - The prestige value of Gucci purchases, x_3 , is something an individual consumer has no control over. If x_3 is fixed at a particular level \bar{x}_3 , the consumer therefore operates on a two-dimensional slice of her three-dimensional indifference map over x_1 , x_2 , and x_3 . Draw such a slice for the indifference curve that contains the consumer’s optimal bundle A on the budget from part (a).
 - Now suppose that Gucci manages to raise the prestige value of its products and thus x_3 that comes with the purchase of Gucci products. For now, suppose they do this without changing p_1 . This implies you will shift to a different two-dimensional slice of your three-dimensional indifference map. Illustrate the new two-dimensional indifference curve that contains A . Is the new MRS at A greater or smaller in absolute value than it was before?
 - * Would the consumer consume more or fewer Gucci products after the increase in prestige value?
 - Now suppose that Gucci manages to convince consumers that Gucci products become more desirable the more expensive they are. Put differently, the prestige value x_3 is linked to p_1 , the price of the Gucci products. On a new graph, illustrate the change in the consumer’s budget as a result of an increase in p_1 .
 - Suppose that our consumer increases her purchases of Gucci products as a result of the increase in the price (p_1). Illustrate two indifference curves: one that gives rise to the original optimum A and another that gives rise to the new optimum C . Can these indifference curves cross?
 - Explain why, even though the behavior is consistent with what we would expect if Gucci products were a Giffen good, Gucci products are not a Giffen good in this case.
 - In a footnote in the chapter, we defined the following: A good is a *Veblen good* if preferences for the good change as price increases, with this change in preferences possibly leading to an increase in consumption as price increases. Are Gucci products a Veblen good in this exercise?

- B.** Consider the same definition of x_1 , x_2 , and x_3 as in part A. Suppose that the tastes for our consumer can be captured by the utility function $u(x_1, x_2, x_3) = \alpha x_3^2 \ln x_1 + x_2$.
- Set up the consumer's utility maximization problem, keeping in mind that x_3 is not a choice variable.
 - Solve for the optimal consumption of x_1 (which will be a function of the prestige value x_3).
 - Is x_1 normal or inferior? Is it Giffen?
 - Now suppose that prestige value is a function of p_1 . In particular, suppose that $x_3 = p_1$. Substitute this into your solution for x_1 . Will consumption increase or decrease as p_1 increases?
 - How would you explain that x_1 is not a Giffen good despite the fact that its consumption increases as p_1 goes up?

7.10 Policy Application: Tax Deductibility and Tax Credits: In end-of-chapter exercise 2.17, you were asked to think about the impact of tax deductibility on a household's budget constraint.

- A.** Suppose we begin in a system in which mortgage interest is not deductible and then tax deductibility of mortgage interest is introduced.
- Using a graph (as you did in exercise 2.17) with "square feet of housing" on the horizontal axis and "dollars of other consumption" on the vertical, illustrate the direction of the substitution effect.
 - What kind of good would housing have to be in order for the household to consume less housing as a result of the introduction of the tax deductibility program?
 - On a graph that contains both the before and after deductibility budget constraints, how would you illustrate the amount of subsidy the government provides to this household?
 - Suppose the government provided the same amount of money to this household but did so instead by simply giving it to the household as cash back on its taxes (without linking it to housing consumption). Will the household buy more or less housing?
 - Will the household be better or worse off?
 - Do your answers to (d) and (e) depend on whether housing is normal, regular inferior, or Giffen?
 - Under tax deductibility, will the household spend more on other consumption before or after tax deductibility is introduced? Discuss your answer in terms of income and substitution effects and assume that "other goods" is a normal good.
 - If you observed that a household consumes more in "other goods" after the introduction of tax deductibility, could that household's tastes be quasilinear in housing? Could they be homothetic?
- B.**** Households typically spend about a quarter of their after-tax income I on housing. Let x_1 denote square feet of housing and let x_2 denote other consumption.
- If we represent a household's tastes with the Cobb–Douglas function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$, what should α be?
 - Using your answer about the value of α , and letting the price per square foot of housing be denoted as p_1 , derive the optimal level of housing consumption (in terms of I , p_1 , and t) under a tax deductibility program that implicitly subsidizes a fraction t of a household's housing purchase.
 - What happens to housing consumption and other good consumption under tax deductibility as a household's tax bracket (i.e., their tax rate t) increases?
 - Determine the portion of changed housing consumption that is due to the income effect and the portion that is due to the substitution effect.
 - Calculate the amount of money the government is spending on subsidizing this household's mortgage interest.
 - Now suppose that, instead of a deductibility program, the government simply gives the amount you calculated in (e) to the household as cash. Calculate the amount of housing now consumed and compare it with your answer under tax deductibility.

7.11[†] Policy Application: *Substitution Effects and Social Security Cost of Living Adjustments:* In end-of-chapter exercise 6.16, you investigated the government’s practice for adjusting Social Security income for seniors by ensuring that the average senior can always afford to buy some average bundle of goods that remains fixed. To simplify the analysis, let us again assume that the average senior consumes only two different goods.

- A.** Suppose that last year our average senior optimized at the average bundle A identified by the government and begin by assuming that we denominate the units of x_1 and x_2 such that last year $p_1 = p_2 = 1$.
- Suppose that p_1 increases. On a graph with x_1 on the horizontal and x_2 on the vertical axis, illustrate the compensated budget and the bundle B that, given your senior’s tastes, would keep the senior just as well off at the new price.
 - In your graph, compare the level of income the senior requires to get to bundle B with the income required to get him back to bundle A .
 - What determines the size of the difference in the income necessary to keep the senior just as well off when the price of good 1 increases as opposed to the income necessary for the senior still to be able to afford bundle A ?
 - Under what condition will the two forms of compensation be identical?
 - You should recognize the move from A to B as a pure substitution effect as we have defined it in this chapter. Often this substitution effect is referred to as the *Hicksian substitution effect*, defined as the change in behavior when opportunity costs change but the consumer receives sufficient compensation to remain just as happy. Let B' be the consumption bundle the average senior would choose when compensated so as to be able to afford the original bundle A . The movement from A to B' is often called the *Slutsky substitution effect*, defined as the change in behavior when opportunity costs change but the consumer receives sufficient compensation to be able to afford to stay at the original consumption bundle. *True or False:* The government could save money by using Hicksian rather than Slutsky substitution principles to determine appropriate cost of living adjustments for Social Security recipients.
 - True or False:* Hicksian and Slutsky compensation get closer to one another the smaller the price changes.
- B.** Now suppose that the tastes of the average senior can be captured by the Cobb–Douglas utility function $u(x_1, x_2) = x_1 x_2$, where x_2 is a composite good (with price by definition equal to $p_2 = 1$). Suppose the average senior currently receives Social Security income I (and no other income) and with it purchases bundle (x_1^A, x_2^A) .
- Determine (x_1^A, x_2^A) in terms of I and p_1 .
 - Suppose that p_1 is currently \$1 and I is currently \$2,000. Then p_1 increases to \$2. How much will the government increase the Social Security check given how it is actually calculating cost of living adjustments? How will this change the senior’s behavior?
 - How much would the government increase the Social Security check if it used Hicksian rather than Slutsky compensation? How would the senior’s behavior change?
 - * Can you demonstrate mathematically that Hicksian and Slutsky compensation converge to one another as the price change gets small and diverge from each other as the price change gets large?
 - We know that Cobb–Douglas utility functions are part of the CES family of utility functions, with the elasticity of substitution equal to 1. Without doing any math, can you estimate the range of how much Slutsky compensation can exceed Hicksian compensation with tastes that lie within the CES family? (*Hint:* Consider the extreme cases of elasticities of substitution.)

7.12 Policy Application: *Fuel Efficiency, Gasoline Consumption, and Gas Prices:* Policy makers frequently search for ways to reduce consumption of gasoline. One straightforward option is to tax gasoline, thereby encouraging consumers to drive less and switch to more fuel-efficient cars.

- A.*** Suppose that you have tastes for driving and for other consumption, and assume throughout that your tastes are homothetic.
- On a graph with “monthly miles driven” on the horizontal and “monthly other consumption” on the vertical axis, illustrate two budget lines: one in which you own a gas-guzzling car, which has a low monthly payment (that has to be made regardless of how much the car is

driven) but high gasoline use per mile; the other in which you own a fuel-efficient car, which has a high monthly payment that has to be made regardless of how much the car is driven but uses less gasoline per mile. Draw this in such a way that it is possible for you to be indifferent between owning the gas-guzzling and the fuel-efficient car.

- b. Suppose you are indeed indifferent. With which car will you drive more?
 - c. Can you tell with which car you will use more gasoline? What does your answer depend on?
 - d. Now suppose that the government imposes a tax on gasoline, and this doubles the opportunity cost of driving both types of cars. If you were indifferent before the tax was imposed, can you now say whether you will definitively buy one car or the other (assuming you waited to buy a car until after the tax is imposed)? What does your answer depend on? (*Hint*: It may be helpful to consider the extreme cases of perfect substitutes and perfect complements before deriving your general conclusion to this question.)
 - e. The empirical evidence suggests that consumers shift toward more fuel-efficient cars when the price of gasoline increases. *True or False*: This would tend to suggest that driving and other good consumption are relatively complementary.
 - f. Suppose an increase in gasoline taxes raises the opportunity cost of driving a mile with a fuel-efficient car to the opportunity cost of driving a gas guzzler *before* the tax increase. Will someone who was previously indifferent between a fuel-efficient and a gas-guzzling car now drive more or less in a fuel-efficient car than he did in a gas guzzler prior to the tax increase? (Continue with the assumption that tastes are homothetic.)
- B.** Suppose your tastes were captured by the utility function $u(x_1, x_2) = x_1^{0.5} x_2^{0.5}$, where x_1 stands for miles driven and x_2 stands for other consumption. Suppose you have \$600 per month of discretionary income to devote to your transportation and other consumption needs and that the monthly payment on a gas guzzler is \$200. Furthermore, suppose the initial price of gasoline is \$0.10 per mile in the fuel-efficient car and \$0.20 per mile in the gas guzzler.
- a. Calculate the number of monthly miles driven if you own a gas guzzler.
 - b. Suppose you are indifferent between the gas guzzler and the fuel-efficient car. How much must the monthly payment for the fuel-efficient car be?
 - c. Now suppose that the government imposes a tax on gasoline that doubles the price per mile driven of each of the two cars. Calculate the optimal consumption bundle under each of the new budget constraints.
 - d. Do you now switch to the fuel-efficient car?
 - e. Consider the utility function you have worked with so far as a special case of the CES family $u(x_1, x_2) = (0.5x_1^{-\rho} + 0.5x_2^{-\rho})^{-1/\rho}$. Given what you concluded in A(d) of this question, how would your answer to B(d) change as ρ changes?

7.13[†] Policy Application: Public Housing and Housing Subsidies: In exercise 2.14, you considered two different public housing programs in parts (a) and (b), one where a family is simply offered a particular apartment for a below-market rent and another where the government provides a housing price subsidy that the family can use anywhere in the private rental market.

- A.** Suppose we consider a family that earns \$1,500 per month and either pays \$0.50 per square foot in monthly rent for an apartment in the private market or accepts a 1,500-square-foot government public housing unit at the government's price of \$500 per month.
- a. On a graph with "square feet of housing" and "dollars of other consumption," illustrate two cases where the family accepts the public housing unit, one where this leads them to consume less housing than they otherwise would and another where it leads them to consume more housing than they otherwise would.
 - b. If we use the members of the household's own judgment about the household's well-being, is it always the case that the option of public housing makes the participating households better off?
 - c. If the policy goal behind public housing is to increase the housing consumption of the poor, is it more or less likely to succeed the less substitutable housing and other goods are?

- d. What is the government's opportunity cost of owning a public housing unit of 1,500 square feet? How much does it therefore cost the government to provide the public housing unit to this family?
 - e. Now consider instead a housing price subsidy under which the government tells qualified families that it will pay some fraction of their rental bills in the private housing market. If this rental subsidy is set so as to make the household just as well off as it was under public housing, will it lead to more or less consumption of housing than if the household chooses public housing?
 - f. Will giving such a rental subsidy cost more or less than providing the public housing unit? What does your answer depend on?
 - g. Suppose instead that the government simply gave cash to the household. If it gave sufficient cash to make the household as well off as it is under the public housing program, would it cost the government more or less than \$250? Can you tell whether under such a subsidy the household consumes more or less housing than under public housing?
- B.** Suppose that household tastes over "square feet of housing" (x_1) and "dollars of other consumption" (x_2) can be represented by $u(x_1, x_2) = \alpha \ln x_1 + (1 - \alpha) \ln x_2$.
- a. Suppose that empirical studies show that we spend about a quarter of our income on housing. What does that imply about α ?
 - b. Consider a family with an income of \$1,500 per month facing a per square foot price of $p_1 = 0.50$. For what value of α would the family not change its housing consumption when offered the 1,500-square-foot public housing apartment for \$500?
 - c. Suppose that this family has α as derived in B(a). How much of a rental price subsidy would the government have to give to this family in order to make it as well off as the family is with the public housing unit?
 - d. How much housing will the family rent under this subsidy? How much will it cost the government to provide this subsidy?
 - e. Suppose the government instead gave the family cash (without changing the price of housing). How much cash would it have to give the family in order to make it as happy?
 - f. If you are a policy maker whose aim is to make this household happier at the least cost to the taxpayer, how would you rank the three policies? What if your goal was to increase the household's housing consumption?

Wealth and Substitution Effects in Labor and Capital Markets

CHAPTER

8

In Chapter 7, we introduced the concepts of income and substitution effects in models where income enters the consumer's optimization problem exogenously; that is, where consumers are choosing to allocate a fixed money budget across consumption goods.¹ We now turn to cases where income is endogenous; that is, where our consumption is funded not by a fixed money budget but rather by the sale of something that we own. This can happen in consumer goods markets if we own one of the goods that is part of the analysis. More important, as we illustrated in some detail in Chapter 3, it happens in labor markets where we sell our leisure time and in capital markets where we buy and sell financial assets as we plan for the future.

The analysis in this chapter in one sense is no different than that in Chapter 7. We will again look at changes in behavior that result from changes in opportunity costs (i.e., substitution effects) and changes that happen as a result of "real income" having changed. At the same time, some important differences emerge, differences in the analysis that are in the end quite intuitive. When the price of gasoline increases, we would always expect the substitution effect to indicate that we will consume less gasoline. But whether the price increase makes us better off (and thus increases our "real" income) or whether it makes us worse off (and thus decreases our "real" income) depends on whether we own an oil well. Most of us don't, and thus most of us become worse off when gasoline prices increase. In the language of Chapter 7, we experience a negative income effect (that will lead to a further decrease in our gasoline consumption if gasoline is a normal good). But if you own an oil well, the increase in gasoline prices probably makes you better off because what you own just became more valuable. Thus, you would experience a positive income effect, one that will lead you to increase your consumption of gasoline if gasoline is a normal good.

Wealth effects are income effects that are caused by changes in the value of endowments.

8A

WEALTH EFFECTS, SUBSTITUTION EFFECTS, AND ENDOWMENTS

In Chapter 7, we adopted the term "income effect" for the impact of parallel shifts in budget constraints on consumption behavior. Such effects occurred either because the fixed money income within the models we dealt with changed directly or because the "real" income changed

¹Chapters 2 through 7 are required reading for this chapter.

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

as a result of a price change. We now turn to the case where the change in the price of a good has a different effect because it changes the value of something we own and thus alters our budget constraint differently than it did in Chapter 7. We will call the new effect that emerges a “wealth effect” because it captures the change in wealth a consumer experiences when prices change and thus affects the value of what the consumer owns. As we will see, the substitution effect remains exactly the same for endogenous choice sets, but the wealth effect can point in different directions depending on what the consumer owns.

8A.1 An Increase in the Price of Gasoline for George Exxon

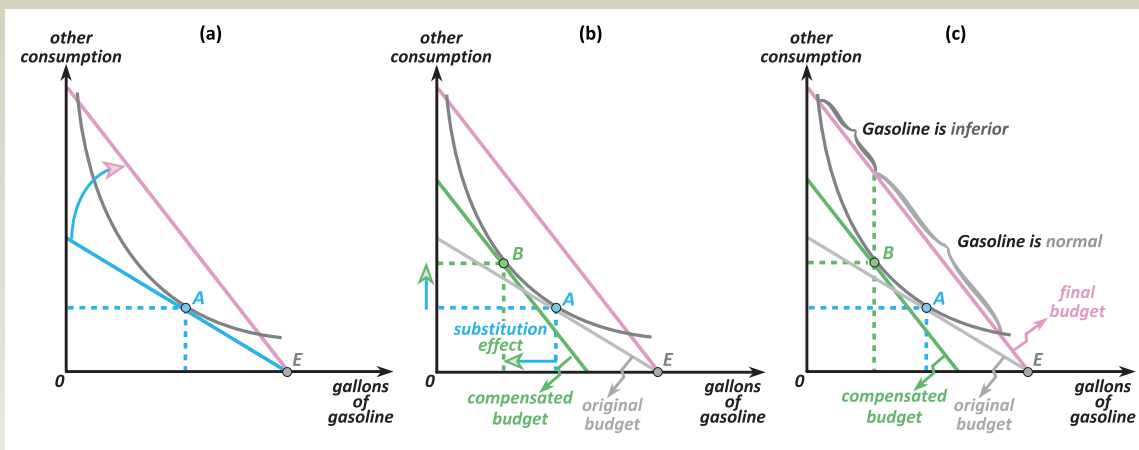

When we investigated in Chapter 7 the ways in which my consumption of gasoline might change when the price of gasoline increases, two effects emerged: the substitution effect due to the change in the opportunity cost of gasoline, and the income effect due to the fact that my real income (as measured by the indifference curve I am able to reach) declined as a result of the price change. The situation is somewhat different for my imaginary friend George Exxon. George and I are very different in many ways, not the least of which is that he owns large reserves of gasoline. In our following example, we suppose that he finances his entire consumption by selling gasoline. Unlike my income, which we modeled as exogenous, George’s income is then more appropriately modeled as arising *endogenously* from the value of his gasoline “endowment.”

8A.1.1 The Substitution Effect Revisited Graph 8.1a then illustrates the impact of an increase in the price of gasoline on George’s budget. Point *E* is George’s endowment point—the amount of gasoline he owns and can choose to consume if he would like to consume only gasoline and no other consumption. While an increase in the price of gasoline caused my budget constraint to rotate *inward* in Chapter 7, the same increase in price causes George’s budget to rotate *outward* around his endowment point until its slope reflects the new opportunity cost. Point *A* denotes George’s optimal consumption bundle prior to the increase in price.

We can now divide George’s behavioral response to the price change into two distinct parts just as we did for my response in the previous chapter. First, we ask how his behavior would have changed if his real income (as measured by the indifference curve he can reach) were held constant and he only faced a change in the opportunity cost reflected in the steeper slope. Graph 8.1b thus introduces the (green) compensated budget that has the new (magenta) budget’s

Substitution effects are the same regardless of whether budgets are exogenous or endogenous.

GRAPH 8.1 Substitution and Wealth Effects when Income Is Derived Endogenously from Selling Gasoline

slope and is tangent to the original indifference curve (reflecting no change in real welfare). As always, the resulting substitution effect from bundle *A* to bundle *B* indicates that George would reduce his consumption of the good that has become relatively more expensive (gasoline) in favor of other goods that have become relatively cheaper.

8A.1.2 The Wealth Effect, and How an Increase in the Price of One Good Can Look Like a Decrease in the Price of Another

In Graph 8.1c, we then determine where on the final (magenta) budget line George might consume relative to point *B*. Notice as always that the (green) compensated budget and the final budget are parallel; the only difference is that, in going from the compensated to the final budget, George receives additional income to spend. Unlike me, George is *richer* as a result of the price change because the value of his wealth goes up with an increased price of gasoline. If gasoline is a normal good, an increase in income from the compensated to the final budget should imply an increased level of gasoline consumption, causing the new optimal point on the final budget to lie to the right of *B* and possibly to the right of *A*. If, on the other hand, gasoline is an inferior good, George will consume less gasoline as his income rises from the compensated budget, implying a new optimal point to the left of point *B*. Since we are dealing with a model in which income is determined *endogenously*, we will call the change from *B* to the new optimal point a *wealth effect*. This is analogous to the *income effect* we identified in the previous section in a model with fixed exogenous income.

When the price of gasoline changed for me, we concluded in Chapter 7 that we can be certain that my consumption of gasoline would decline (from the original bundle *A* to the final bundle *C*) so long as gasoline was a normal good, but we could not be certain whether it would increase or decline if gasoline was an inferior good because of offsetting income and substitution effects. The opposite is true in George Exxon's case: We know his consumption of gasoline will definitely decline if gasoline is an inferior good for him, but we cannot be sure whether his gasoline consumption will increase or decrease if gasoline is a normal good. Why the difference between what we can predict for George here and what we could predict for me in Chapter 7?

Despite the fact that both George and I experienced the same increase in price, our situations are vastly different because his income is derived from gasoline and mine is not. In fact, if you knew nothing about the particulars of this example and you simply looked at a change in choice sets like the one graphed in Graph 8.1a, you would conclude that this individual had experienced a *decrease in the price of "other consumption"* (the good on the vertical axis), not an increase in the price of gasoline. That is in fact precisely how we could treat the price change George experienced, and George would feel exactly the same about such a price change (with his income being exogenous) as the one we have analyzed (with income endogenous) because it would alter his budget constraint in exactly the same way. This is also why we cannot identify in George's case any behavior that would lead us to conclude that gasoline is a Giffen good for him, because for him, it is effectively the price of "other consumption" that has changed. To identify gasoline as a Giffen good, we would have to observe an effective change in the price of gasoline, as we did for me in Chapter 7.

Since George's situation is equivalent to a decrease in the price of other goods (with exogenous income), illustrate where on his final budget George would consume if other goods are normal, regular inferior, and Giffen.

EXERCISE 8A.1

8A.2 A Change in Wages

Our analysis of wealth and substitution effects can now be extended from models of consumer choices in goods markets to models of worker choices in labor markets. Recall from Chapter 3 that choices by workers can be analyzed as choices between leisure and consumption. Leisure time is an endowment, much like gasoline was for George Exxon. Its value in the labor market

depends on the wage that a worker can earn, which in turn determines how easily a worker can turn leisure hours into goods consumption. As in Chapter 3, we will model these choices by putting hours of leisure on the horizontal axis and dollars of consumption on the vertical.

8A.2.1 Do Higher Wages Make Us Work More or Less? Suppose we return to an example from Chapter 3 where you were choosing how many hours you will work per week, and suppose again that you have a total of 60 leisure hours per week that you could devote to work. Suppose further that you have no other income, which implies that you will not be able to consume anything (other than leisure) if you do not work. This implies that your endowment point E in Graph 8.2a falls at 60 hours of leisure and no consumption. Furthermore, suppose again that you could earn a wage of \$20 per hour, and suppose that you have decided it is optimal for you to work for 40 hours per week under these circumstances. This choice is illustrated as bundle A in Graph 8.2a, a point characterized by 20 hours of leisure, which leaves 40 hours for work given that the total number of hours you can allocate between work and leisure is 60.

Now suppose you are offered a wage increase of \$5 per hour, which rotates your budget out through point E as shown in the Graph 8.2a. Will you work more or less as you face this new choice set? On the one hand, you might think that work is really paying off now and therefore you should work more. On the other hand, you are making more every hour you work, so why not work a little less and still end up with more consumption than before? It is not immediately clear which way you might decide to go. *This is because you are most likely facing competing wealth and substitution effects.*

The substitution effect suggests workers work more when wages increase.

To see this, we begin again by drawing your compensated budget, the budget that keeps your real income the same but has the final budget line's opportunity cost (or slope). This is graphed (in green) in Graph 8.2b and, as always, it indicates that you would consume more of the good that has become relatively cheaper (consumption) and less of the good that has become relatively more expensive (leisure) if all you faced was the new opportunity costs with no change in real income. This is the pure substitution effect, the effect that makes you think that "work is really paying off now and you should thus work more."

In Graph 8.2c, we then isolate the wealth effect, which is the impact of going from bundle B under the (green) compensated budget to the (magenta) final budget. The graph looks identical

GRAPH 8.2 Substitution and Wealth Effects in Leisure/Consumption Choices

Go to MindTap to interact with this graph.

to George Exxon's Graph 8.1c, and the conclusion is the same for you as a worker as it was for George as an owner of gasoline. If leisure is an inferior good, the wealth effect will reinforce the substitution effect as you consume less leisure when your real income goes up. You would then end at a point like *C* to the left of *B*. It seems, however, unlikely that leisure is really an inferior good; it is probably a normal good for most of us. This implies that you would consume more of it as your real income rises from the compensated budget to the final budget, formalizing our intuition that "you are making more every hour, so why not work a little less."

If leisure is a normal good, it is therefore not clear whether an increase in your wage will cause you to work more or less. The substitution and wealth effects point in opposite directions, leaving us guessing unless we know more about your tastes. Suppose, for instance, that the only way you can enjoy your leisure time is by paying to go parasailing. If your tastes are really that extreme, there is little substitutability in your tastes between leisure hours and consumption—you *must* consume (parasail) to enjoy leisure. Your indifference curves would then be those of perfect complements. By doing the following exercise, you can then see that this would eliminate the substitution effect and leave you only with the wealth effect, leading to an unambiguous conclusion that you will work less (consume more leisure) as your wage goes up.

Whether you work more or less as wage increases typically depends on the size of the wealth effect relative to the substitution effect.

Illustrate substitution and wealth effects; that is, the initial bundle, the bundle that incorporates a substitution effect from a wage increase, and the final bundle chosen under the wage increase, assuming that your tastes for consumption and leisure are properly modeled as perfect complements.

EXERCISE 8A.2

On the other hand, suppose that your tastes were properly modeled as quasilinear in leisure. In that case, the only effect of a wage change on your labor supply decision is the substitution effect (because quasilinear tastes do not have income or wealth effects). This would imply that an increase in your wage would cause you to unambiguously work more (consume less leisure).

Replicate the previous exercise under the assumption that your tastes are quasilinear in leisure.

EXERCISE 8A.3

As it turns out, labor economists who estimate the relationship between labor supply from a worker and that worker's wage have concluded that an average worker responds to wage increases by working more when his or her current wage is relatively low. As wages increase, however, the same average worker eventually will tend to work less as wages increase even further.

Illustrate a set of indifference curves that gives rise to the kind of response to wage changes as described.

EXERCISE 8A.4

8A.2.2 Taxes on Labor Income Politicians like to convince us that their policies help everyone and hurt no one. Those who propose to cut taxes on wages, for instance, often argue that such tax cuts will not only benefit workers but will also cause an *increase* in government revenue as workers work harder when they get to keep more of their money and thus will pay more in overall taxes even though the tax rates have come down.² Is this true?

²The argument made in favor of this position is actually a little more complicated. It generally assumes not only that workers will work more as their after-tax wage increases but also that this will have an effect on the macroeconomy that will cause the economy to grow faster. Since the second part of the argument falls in the area of macroeconomics, we will not treat it here explicitly.

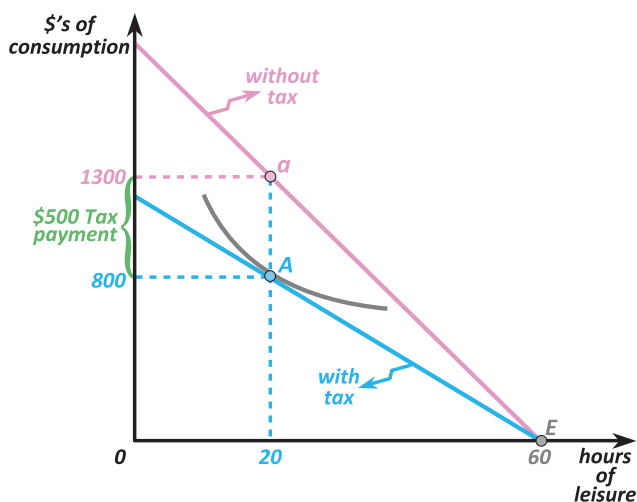

Our analysis of your labor/leisure choices suggests that it all depends on what we assume about wealth and substitution effects. For workers, a cut in wage taxes is equivalent to an increase in their take-home wages. Thus, our analysis of a wage increase in the previous section applies directly. We have concluded that substitution effects will cause workers to increase their hours when wages go up, while wealth effects are likely to cause workers to decrease their work hours as their wages rise (assuming that leisure is a normal good). Thus, the politician is more likely to be correct the larger the substitution effect and the smaller the wealth effect. Put differently, politicians who make this argument are either dishonest or they believe one (or both) of the following: (1) that our tastes allow for a great deal of substitutability between consumption and leisure, implying that our indifference curves are relatively flat making substitution effects large, and/or (2) that leisure is an inferior good, which causes wealth effects for wage changes to point in the same direction as the substitution effect. Were they to believe that leisure and consumption are very complementary and that leisure is a normal good, their prediction would almost certainly be false.

Even the combination of substitution and wealth effects leading workers to work more when their after-tax wage increases, however, is not sufficient for the government to increase tax revenue by cutting taxes. To see this, we first have to see how to illustrate tax revenues from a single worker in our leisure/consumption graphs. Consider Graph 8.3 that contains one budget line without taxes and another that shows an effective lower wage because of a wage tax. The worker's optimal choice under the tax is then determined on his after-tax (blue) budget constraint and is denoted by *A* in the graph. From point *A*, we can read off directly how much in "dollars of other goods" this worker is consuming after paying taxes: \$800. Since the only difference between the two budget lines in Graph 8.3 is the wage tax, we also know that this same worker could have consumed \$1,300 in other goods had he not had to pay any taxes and had he worked exactly the same number of hours (40) as he does at bundle *A*. Thus, the vertical difference between bundle *A* and bundle "*a*" is how much the government collected in tax revenue: \$500. Note that this does *not* mean that we are assuming this worker would have consumed bundle "*a*" in the absence of taxes. We are simply using bundle "*a*" to identify this worker's before-tax income when he is choosing bundle *A* on his after-tax budget line.

Now consider the case where the government can choose between two different wage taxes, say one of 20% and another of 40%. Suppose further that we are considering two different workers for whom wealth and substitution effects combine to increase the amount they work when

To find how much tax a worker pays, we have to know how much the worker works after the tax is imposed.

GRAPH 8.3 Finding a Wage Tax Payment when Observing After-Tax Behavior

GRAPH 8.4 Tax Revenue Can Rise (a) or Fall (b) with an Increase in Tax Rates

they face a higher after-tax wage. Graphs 8.4a and 8.4b then illustrate two different possibilities, with A representing the workers’ optimal bundles at a 20% wage tax and A' representing their optimal bundles at the 40% wage tax. In the first graph, a decrease in the wage tax from 40% to 20% results in a decrease in tax revenue from the worker (because the distance between A and a is smaller than the distance between A' and a'), while in the second graph it results in an increase in tax revenues (because the distance between A and a is larger than the distance between A' and a'). We will return to the question of when exactly we might expect the former scenario to hold and when we might expect the latter to hold in later chapters.

For now, it is worth noting one final lesson from understanding substitution and wealth effects in a labor market that is taxed. While it may not always be the case that tax revenues will rise as tax rates fall or vice versa, the presence of substitution effects in labor markets does suggest that we may overpredict how much tax revenues we are likely to get from a given tax increase. This is because substitution effects in the labor market suggest that workers will work less as wage taxes increase. Unless leisure is not only a normal good but also produces a wealth effect sufficiently large to outweigh the substitution effect, workers will work less as taxes increase, which means they will pay less in additional tax revenues than we would predict if we did not take this “substitution” change in behavior into account.

The greater the substitution effect, the more likely it is that a tax cut will increase tax revenue.

True or False: For decreases in wage taxes, substitution effects put positive pressure on tax revenues while wealth effects typically put negative pressure on revenues.

EXERCISE 8A.5

8A.3 A Change in (Real) Interest Rates

Just as our choices over consumption and leisure are impacted by the size of the wage we can earn, so our financial planning for the future is impacted by the size of the financial return we receive from saving or the financial cost we incur from borrowing—the real interest rate. We illustrated this in Chapter 3 in simple models in which we saw how our choice sets between

current and future consumption change as interest rates change. It is worth emphasizing that, as microeconomists, we always mean the *real* interest rate, or the interest rate adjusted for inflation. Much of the “CNBC-type” discussion of interest rates by talking heads on TV relates to *nominal* interest rates, which are real interest rates plus the expected rate of inflation. You have (or will) discuss the role of nominal interest rates in more detail in your macroeconomics courses, which emphasize the Federal Reserve’s ability to affect *nominal* interest rates through monetary policy. Most macroeconomists would agree that monetary policy, at least in the long run, cannot set *real* interest rates, which are determined through the forces of supply and demand in capital markets (as we will see in later chapters).

8A.3.1 Do Higher Interest Rates Make Us Save More? Wealth and substitution effects play important roles in the choices consumers make regarding their financial planning just as they do in their choices in labor and consumer goods markets. When we asked in the previous section whether an increase in wages will cause us to work more, we were unsure of the answer even before we discussed the relevant wealth and substitution effects. Similarly, it is not immediately clear whether higher interest rates lead to increased savings. On the one hand, you might think that saving now really pays off and thus you might be inclined to save more. On the other hand, you might decide that, since you are getting more in the future for every dollar you put in your savings account, you might as well consume a little more now knowing that the somewhat smaller savings account will grow faster. The first temptation is an informal statement of the substitution effect while the latter gives expression to the wealth effect.

Suppose, for instance, that we return to our example (from Chapter 3) of you choosing to use your \$10,000 income from this summer to plan for your consumption now and next summer. Your endowment point in this example is point *E* in Graph 8.5 because this is the bundle that is always available for you regardless of what the interest rate is. Suppose then that your initial planning is based on the fact that you know you can earn interest at an annual rate of 10%, and suppose that you have concluded that you will consume \$5,000 this summer and \$5,500 next summer as indicated by point *A* in Graph 8.5a. Then suppose that you just found a new investment opportunity that will get you a 20% annual return, yielding the larger (magenta) choice set with different opportunity costs depicted in the same graph.

GRAPH 8.5 The Impact of an Increase in Interest Rates on Savers

Graph 8.5b then begins by isolating the substitution effect with the hypothetical (green) compensated budget tangent to your original optimal indifference curve. As always, the movement from *A* to *B* results in less consumption of the good that has become relatively more expensive (consumption this summer) and more of the good that has become relatively cheaper (consumption next summer). This substitution effect suggests you will tend to save more because consuming now as opposed to later has just become more expensive.

Whether or how much your wealth effect will counteract this substitution effect then depends on whether consumption this summer and consumption next summer are normal or inferior goods. It seems reasonable to assume that consumption is in fact a normal good in both periods, and so we will restrict ourselves to this assumption in this example. Starting from the optimal point *B* on the compensated budget, we would then expect you to increase your consumption this and next summer as your income rises from the compensated (green) to the final (magenta) budget in Graph 8.5c.

Your new optimal bundle will therefore likely lie somewhere in the darkened segment of your final budget line. All bundles on this segment have higher consumption next summer than the \$5,500 you had originally planned, but this does not mean that the increase in the interest rate has led you to save more (in the sense of putting more money into your savings account now). Notice that the darkened segment of the final budget contains some bundles with more consumption *this* summer than at point *A* and some with less. Since your savings—the amount you put away in a savings account—is simply the amount you do not consume *this summer*, we cannot tell whether you will *save* more or less, only that you will consume more next summer. Your increased consumption next summer *may* happen despite lower saving this summer simply because each dollar in your savings account now earns more than before. This happens if your optimal bundle lies on the darkened segment to the right of point *A*. It may also be the case that higher consumption next summer happens in part because of additional savings this summer, if your optimal bundle ends up to the left of point *A*.

Without more information about your tastes, we cannot tell precisely which of these scenarios will come to be. All we know for now is that the more substitutable consumption is across time periods (i.e., the flatter are your indifference curves), the more likely it is that the substitution effect will outweigh the wealth effect and lead to an increase in savings. The opposite is true as consumption becomes more complementary across periods.

The substitution effect suggests savers save more when interest rates rise.

Whether you save more or less as interest rates rise typically depends on the size of the wealth effect relative to the substitution effect.

Illustrate that your savings will decline with an increase in the interest rate if consumption this summer and next summer are perfect complements.

EXERCISE 8A.6

8A.3.2 Will an Increase in the (Real) Interest Rate Make Us Borrow Less? The previous example assumed that your endowment point was consumption this summer because that was the point that you could consume regardless of what happened to interest rates. Suppose instead, however, that your endowment point is future consumption. This would occur if you chose not to work this summer but instead borrowed against income that the bank knows you will earn next summer. In Chapter 3, we used the example of your employer assuring the bank that you will earn \$11,000 next summer, which causes the bank to be willing to lend you as much as \$10,000 for current consumption when the interest rate is 10%. Thus, the beginning (blue) choice set in this example looks identical to the beginning choice set in the previous example (Graph 8.5a) except that the endowment point occurs on the vertical rather than the horizontal axis. Given that the choice sets are the same across the two examples, the optimal bundle *A* for you is the same.

Now suppose that the interest rate again rises to 20%. While your original (blue) budget is the same across the two examples, your final (magenta) budget after the interest rate change is quite

GRAPH 8.6 The Impact of an Increase in Interest Rates on Borrowers

different and is illustrated in Graph 8.6a. In both cases, the slope becomes steeper to reflect the new interest rate, but now it rotates through the new endowment point. Because the slope is the same across the two examples, however, the (green) compensated budget will also be the same since it simply assumes a constant real income under the new interest rate. The difference is that the compensated budget now requires *positive* compensation while previously it required *negative* compensation. This should make intuitive sense: If the interest rate rises and you are a saver, you are made better off and thus need less money to be just as well off as you were originally. If, on the other hand, you are a borrower, then an increase in the interest rate makes you worse off, requiring that I give you additional money to make you just as well off as you were originally.

Since your indifference curve that contains point A is the same across the two examples and since the original as well as the compensated budgets are the same, it follows that point B will be the same. Thus, you again experience a substitution effect that tells us you should consume less now and more later when the interest rate (and thus the cost of consuming now) goes up. The wealth effect, however, now points in the opposite direction from the previous example because, in going from the (green) compensated to the final (magenta) budget, you now lose rather than gain income. If consumption in both periods is a normal good (as we have assumed throughout), you will consume less than at point B during both summers as your income falls from the compensated to the final budget. In Graph 8.6c, you will therefore end up somewhere on the high-lighted portion of the final budget line.

Since both wealth and substitution effects suggest that you will consume less this summer, we can then unambiguously conclude that your consumption this summer will decline, and you will thus unambiguously borrow less. But on the vertical axis of Graph 8.6c, the substitution and wealth effects point in opposite directions, leaving us uncertain about whether consumption next summer will be higher or lower as the interest rate for borrowing increases. Whether you consume more or less next summer thus depends on the degree to which consumption this period and next period are substitutable, and thus whether or not the substitution effect outweighs the wealth effect.

Borrowing falls unambiguously when interest rates rise.

EXERCISE 8A.7 Illustrate how consumption next summer changes with an increase in the interest rate if consumption this summer and next summer are perfect complements (and all your income occurs next summer).

8A.3.3 “Neither a Borrower nor a Lender Be . . .” Shakespeare advises us in *Hamlet*: “Neither a borrower nor a lender be . . .” Suppose you had taken this advice to heart and had decided to arrange your work plans over the next two summers so that you can consume \$5,000 this summer and \$5,500 next summer without borrowing or saving (which is equivalent to lending to the bank). Let’s suppose that you accomplished this by finding an employer (as you did in Chapter 3) who is willing to employ you half-time this summer for \$5,000 and half-time again next summer for \$5,500. This implies that we have a new endowment bundle in our model, which is labeled E in Graph 8.7. This is your new endowment bundle because it is the bundle that you can consume regardless of what happens to the interest rate.

Suppose again that the interest rate was 10% when you made your work arrangements and then changed to 20% afterward. Your initial (blue) choice set then again looks precisely the way it did in the previous two examples, but your final budget constraint now rotates through your new endowment point. Can we tell whether this change in the interest rate will cause you to violate Shakespeare’s advice?

This is one case where it is in fact not necessary to decompose the behavioral change into substitution and wealth effects. We can simply observe in Graph 8.7a that all the bundles in the final choice set that lie above your original indifference curve (and are thus preferred) lie to the left of bundle E . Your new optimal choice therefore involves less consumption this period, and this implies you will start saving. The change in the interest rate thus causes you to violate Shakespeare’s advice as you open a savings account and become a “lender” of money to the bank. To see why this is the case, notice in Graph 8.7b that the (green) compensated budget is quite close to the final (magenta) budget, implying that almost the entire behavioral change is a substitution effect. The small wealth effect that remains is not sufficient to overcome the substitution effect *regardless* of how much substitutability is built into the indifference map. (In fact, the entire effect is a “Slutsky” substitution effect as discussed in Section 7A.2.4.)

Demonstrate that the only way you will not violate Shakespeare’s advice as the interest rate goes up is if consumption this summer and next are perfect complements. **EXERCISE 8A.8**

GRAPH 8.7 From No Saving to Positive Saving when Interest Rates Rise

EXERCISE
8A.9

Illustrate that (unless consumption this summer and consumption next summer are perfect complements) you will violate the first part of Shakespeare's advice—not to be a borrower—if the interest rate fell instead of rose.

8A.3.4 A Policy Example: IRAs, 401ks, and Retirement Policy For a number of years now, the federal government in the United States has attempted to increase personal savings by providing tax incentives for investing in retirement accounts known as IRAs and 401k plans.³ Essentially, these accounts work as follows: For each dollar that an individual puts into the account, the individual does not have to pay taxes until he or she takes it out of the account after retirement. This allows individuals to earn interest on money that they otherwise would have had to send to the government as tax payments. For instance, if I earn \$1,000 and I face a tax rate of 30%, I typically have to pay \$300 in federal income tax, which leaves me with \$700 that I can invest for the future. If, on the other hand, I invest the same earnings in an IRA or a 401k account, I can invest the whole \$1,000 and defer paying taxes until the future. Suppose the rate of return on my investments is 10% per year. Under the non-tax-deferred savings plan, I will have earned \$70 in interest on my \$700 investment after one year, which is income that I again have to pay 30% tax on. This leaves me \$749 in my investment account: My original \$700 plus the interest left over after I pay 30% tax on my \$70 interest income. Under the tax-deferred savings plan, on the other hand, I will have earned \$100 in interest on my \$1,000 investment, leaving me with \$1,100 that I have to pay taxes on only if I take it out of the account. If I do choose to take it out and consume it after one year, I have to pay my usual 30% tax on the whole amount (\$1,100), leaving me with \$770 rather than \$749. While this difference may seem small after one year, it accumulates quickly over a longer period. For instance, if I compared the same non-tax-deferred savings plan with the tax-deferred plan over a 30-year period, I would have \$12,215 available to me under the latter plan and only \$7,423 under the former—a difference of \$4,792! You can convince yourself of this by setting up a simple spreadsheet in which you keep track of interest and tax payments over the 30 years.

The basic effect that federal retirement policy has on individual choice sets, then, is to provide individuals with a higher rate of return through deferral of tax payments into the future. This is exactly equivalent to an increase in the interest rate we face, and we have already seen that it is not clear whether such a change in circumstances leads to an increase or a decrease in savings (when savings is defined as current income minus current consumption). To the extent that the aim of federal retirement policy is to increase the amount that we put away for savings today, the policy may therefore not be successful since we know that higher interest rates may lead to less savings. At the same time, to the extent to which federal retirement policy aims to increase our consumption possibilities when we retire, our model would predict that the policy will succeed. After all, we ended Section 8A.3.1 with the conclusion that, while we cannot tell whether savings today will increase when real interest rates rise, we *can* tell that consumption in the future will rise (whether because of higher returns on less savings or higher returns on more savings).

³IRAs, or Individual Retirement Accounts, are accounts that are set up by individuals. 401k plans, on the other hand, are set up by for-profit corporations who may invest on behalf of their employees and/or give employees opportunities to invest in the account themselves. Non-profit corporations and organizations may set up similar accounts for their employees; these are called 403b accounts rather than 401k accounts. If you have done end-of-chapter exercise 3.7, you will have already done a simpler version of what is done in this section.

8B

CONSTRAINED OPTIMIZATION WITH WEALTH EFFECTS

Fundamentally, the mathematics underlying models with endowments is not different from what we already introduced for models with exogenous fixed incomes. Again, we will treat consumers (or workers or investors) as maximizing utility subject to a budget constraint, but now the “income” term in the budget constraint will be replaced with a “wealth” term that depends on the prices in the economy. We illustrated in detail how such budgets can be written in Chapter 3, and we will now merge that treatment of budgets into our mathematical optimization framework.

8B.1 George Exxon and the Price of Gasoline

In Section 8A.1, we introduced my friend George Exxon, who owns large reserves of gasoline and derives all his income from selling gasoline. Letting the number of gallons of gasoline he gets out of the ground each week be denoted by e_1 , George’s weekly income then depends on the price p_1 he can get for his gasoline. Thus, his weekly income from gasoline extractions is p_1e_1 . How much gasoline he is able to extract per week, e_1 , is of course different from how much gasoline he *consumes* each week. Letting gallons of weekly gasoline consumption be denoted by x_1 and “Dollars of Other Weekly Consumption” be represented by x_2 , we can then write George’s weekly budget constraint as

$$p_1x_1 + x_2 = p_1e_1 \text{ or } x_2 = p_1(e_1 - x_1). \quad (8.1)$$

Notice that the second formulation in (8.1) simply has non-gasoline consumption on the left-hand side and income from the sale of gasoline that is not directly consumed by George on the right-hand side. This budget constraint is just the more general budget constraint we derived in Chapter 3 for someone with endowment income,

$$p_1x_1 + p_2x_2 = p_1e_1 + p_2e_2, \quad (8.2)$$

except that the price of “Dollars of Other Weekly Consumption” in our example is by definition equal to 1 (thus making $p_2 = 1$) and George has no endowment of “Dollars of Other Weekly Consumption” (thus making $e_2 = 0$).

Now suppose George’s tastes could be captured by the Cobb–Douglas utility function $u(x_1, x_2) = x_1^{0.1}x_2^{0.9}$. Then we can write his constrained optimization problem as

$$\max_{x_1, x_2} u(x_1, x_2) = x_1^{0.1}x_2^{0.9} \text{ subject to } x_2 = p_1(e_1 - x_1). \quad (8.3)$$

The Lagrange function used to calculate the optimal consumption bundle is then

$$\mathcal{L}(x_1, x_2, \lambda) = x_1^{0.1}x_2^{0.9} + \lambda(x_2 - p_1(e_1 - x_1)). \quad (8.4)$$

Solving this in the usual way, we get

$$x_1 = 0.1e_1 \text{ and } x_2 = 0.9(p_1e_1). \quad (8.5)$$

Suppose, for instance, that the price of gasoline p_1 is \$2 per gallon and that George’s weekly gallons of gasoline extraction e_1 is 1,000. Then expression (8.5) tells us that George’s optimal consumption bundle is $x_1 = 100$ and $x_2 = 1,800$; that is, 100 gallons of gasoline and \$1,800 in other consumption.

With the numbers in the previous paragraph, George’s income is \$2,000 per week. Verify that you would get the same optimal consumption bundle if you modeled this as a constrained optimization problem in which income was exogenously set at \$2,000 per week.

EXERCISE
8B.1

8B.1.1 Revisiting the Substitution Effect Now suppose an oil shortage caused the price of gasoline to rise to \$4 per gallon. We can immediately see from expression (8.5) what the impact on George's consumption will be: He will continue to consume 100 gallons of gasoline each week, but his other consumption will rise from \$1,800 to \$3,600. This is illustrated in Graph 8.8a, where bundle A represents George's initial optimal consumption under the \$2 gasoline price and bundle C represents his new optimal consumption under the \$4 price.

This change in behavior from A to C, however, bundles the substitution and wealth effects. To isolate the substitution effect from the wealth effect, we first need to calculate how George's consumption would have changed when the price of gasoline increases from \$2 to \$4 per gallon if we took enough money away from George to make him just as well off as he was originally; that is, if only his opportunity costs change without a change in real income as measured by his indifference curve.

To find this effect, we defined an expenditure minimization problem in Chapter 7, one that aims to find the lowest possible exogenous money income that George could have at the new \$4 price of gasoline and still reach the same indifference curve that contained his original optimal bundle (100, 1800). By plugging this optimal bundle into the utility function $u(x_1, x_2) = x_1^{0.1}x_2^{0.9}$, we find that this indifference curve was assigned a value of approximately 1,348 by George's utility function. We can therefore state the expenditure minimization problem used to identify the substitution effect as

$$\min_{x_1, x_2} E = 4x_1 + x_2 \text{ subject to } x_1^{0.1}x_2^{0.9} = 1,348. \quad (8.6)$$

Notice that this problem makes no reference to George's endowment because that endowment is irrelevant for finding the substitution effect. Put differently, once we know the indifference curve we would like George to reach, identifying the level of exogenous income that it would take to get there has nothing to do with how much stuff George actually owns.

We can solve for a substitution effect by setting up an expenditure minimization problem.

GRAPH 8.8 Wealth and Substitution Effects for George Exxon: From Math Back to Graphs

Setting up the Lagrange function and solving for x_1 and x_2 , you can verify for yourself that

$$x_1 = 53.59 \text{ and } x_2 = 1,929.19, \quad (8.7)$$

implying that George would consume 53.59 gallons of gasoline and \$1,929.19 of other consumption each week.

Verify that the solutions in the previous paragraph are correct.

EXERCISE 8B.2

Graph 8.8b illustrates what we have just done. Beginning with the optimal bundle A before the price change, we have identified the smallest possible new (green) budget (or what we have called the compensated budget in Chapter 7) that incorporates the new price of gasoline and will still permit George to reach the indifference curve that contains bundle A . The impact of the change in opportunity costs is thus isolated from the impact of the change in wealth that arises from the price change, giving rise to a pure substitution effect. As always, this substitution effect, the change in behavior that takes George from bundle A to bundle B , tells us that the change in opportunity costs causes our consumer to reduce his consumption of the good that has become relatively more expensive (gasoline) in favor of increased consumption of the good that has become relatively cheaper (other consumption).

How much (negative) compensation was required to get George to be equally well off when the price of gasoline increased?

EXERCISE 8B.3

8B.1.2 The Wealth Effect Given that we have already identified George's final consumption bundle at the \$4 gasoline price (and graphed it in Graph 8.8a), we could now combine Graphs 8.8a and 8.8b to illustrate the initial substitution effect (from A to B) and the remaining wealth effect (from B to C). The wealth effect is similar to the income effect in Chapter 7 in that it represents a change of behavior between two budget constraints that exhibit the same opportunity costs (i.e., the same slopes). But the direction of the wealth effect for this example is opposite to the direction of an income effect; as the price of gasoline increased, George's real income went *up* rather than down.

As a result, we computed that George will consume 100 gallons of gasoline at bundle C rather than 53.59 gallons at bundle B . As George's real income goes up (without a change in opportunity costs), George therefore consumes more gasoline. Thus gasoline is a normal good in this example. Similarly, George's consumption of other goods rises from \$1,929.19 to \$3,600 for the same increase in real income, implying "other goods" are normal goods as well. Of course, from the work we have done in our analysis of Cobb–Douglas utility functions, we already know that goods that are modeled using this function are normal goods.

8B.2 A Change in Wages

In Section 8A.2, we saw that the example of George Exxon is in no fundamental way different from the example of you facing an increase in your wage rate in the labor market while choosing how many hours to devote to leisure as opposed to labor. This analytic similarity holds because, in both examples, income is derived from the sale of a good that we value. In the case of George Exxon, he owns gasoline that he also consumes. Similarly, in the case of you choosing how much to work, you own leisure that you consume just as George consumes gasoline. When the price of gasoline is \$2 per gallon, the opportunity cost of consuming one more gallon of gasoline

is \$2 of other consumption. When your hourly wage rate is \$20, the opportunity cost of consuming one more hour of leisure is similarly \$20 of other consumption. The price of gasoline in the George Exxon example is thus exactly analogous to the wage rate in the example of you choosing how much to work.

8B.2.1 Will an Increase in Your Wage Make You Work More or Less? We have already demonstrated in Graphs 8.2a through 8.2c how substitution and wealth effects work intuitively in the labor market. Since these effects are exactly analogous to the effects already identified mathematically in the George Exxon example, we have in a sense already demonstrated how one would use our mathematical framework to solve for substitution and wealth effects when wages change in the labor market. We begin by setting up the constrained optimization problem. Suppose again that you have 60 hours per week you can devote to leisure or labor, that your wage rate is w , and that your tastes over consumption (c) and leisure (ℓ) can be represented by a utility function $u(c, \ell)$. The mathematical formulation of the problem is then

$$\max_{c, \ell} u(c, \ell) \text{ subject to } c = w(60 - \ell). \quad (8.8)$$

The budget constraint in expression (8.8) thus simply states that your total spending on consumption goods c is equal to the wage rate w times the hours you work; that is, the hours you do not take as leisure ($60 - \ell$).

Suppose that your tastes over consumption and leisure can be modeled using the quasilinear utility function

$$u(c, \ell) = c + 400 \ln \ell. \quad (8.9)$$

Using our usual Lagrange Method, we can compute that the optimal bundle of consumption and leisure is then

$$c = 60w - 400 \text{ and } \ell = \frac{400}{w}. \quad (8.10)$$

Thus, we know that the optimal bundle A in Graph 8.9a when the wage rate is \$20 per hour is \$800 of weekly consumption and 20 hours of leisure, or, equivalently, 40 hours of labor. If the

GRAPH 8.9 Wealth and Substitution Effects in Labor Choices: From Math Back to Graphs

wage rate rises to \$25 per hours, your optimal leisure consumption declines to 16 hours (implying 44 hours of work) while other good consumption increases to \$1,100 per week. For tastes that can be represented by the utility function (8.9), an increase in the wage thus causes you to work more.

To see why, we can again decompose the total move from A to C in Graph 8.9a into substitution and wealth effects. To find the substitution effect, we follow our previous method by specifying a minimization problem that seeks to find the minimum expenditure necessary to achieve the utility level originally attained at A when the wage rate is \$25 (rather than the initial \$20) per hour. Plugging the leisure and consumption values at bundle A into the utility function in (8.9), we get a utility level of approximately 1,998. The relevant minimization problem is then

$$\min_{c, \ell} E = c + 25\ell \quad \text{subject to} \quad c + 400 \ln \ell = 1,998. \quad (8.11)$$

Notice that we are treating the goods “consumption” and “leisure” as we have always treated goods in such minimization problems: We are simply asking how much we would have to spend on these two goods at the market prices to reach the indifference curve that contains bundle A . The market price of “consumption” is \$1 while the market price of leisure is the market wage (or \$25 in our example).

Solve the problem defined in equation (8.11).

EXERCISE 8B.4

The solution to this minimization problem is $c \approx 889$ and $\ell = 16$. Thus, at bundle B in Graph 8.9b, you would consume 16 hours of leisure per week, or, put differently, you would work for 44 hours. Just as our graphical approach suggested in Section 8A.2, the substitution effect from an increase in the wage leads to less consumption of leisure because consuming leisure has just become more expensive.

Putting panels (a) and (b) of Graph 8.9 together in panel (c), we can depict graphically what we have just calculated mathematically: In terms of its effect on leisure (and labor supply), an increase in your wage from \$20 per hour to \$25 per hour results in a 4-hour substitution effect away from leisure (and toward labor), and no wealth effect. This arises, of course, from the fact that the underlying utility function (8.9) is quasilinear in leisure, which eliminates income or wealth effects in the consumption of leisure and leaves us only with the substitution effect. For utility functions that model leisure as normal, the wealth effect will point in the opposite direction of the substitution effect (much as was the case in the example of the price of gasoline changing for George Exxon), making it ambiguous as to whether or not you will work more when your wage goes up.

Suppose your tastes were more accurately modeled by the Cobb–Douglas utility function $u(c, \ell) = c^{0.5}\ell^{0.5}$. Determine wealth and substitution effects and graph your answer.

EXERCISE 8B.5

8B.2.2 Tax Rates and Tax Revenues We raised in Section 8A.2.2 the issue of whether the labor supply response to a wage tax would ever be sufficiently strong to ensure that tax revenues would actually increase as taxes on wages declined. The intuition of the graphical approach (in Graph 8.4) clearly tells us that, in order for tax revenues to increase with a decrease in the tax rate, it must at a minimum be the case that either leisure is an inferior good or the substitution effect outweighs the wealth effect if leisure is a normal good. These are, however, only necessary conditions; that is, we showed in Graph 8.4 that it is logically possible for work effort to increase as labor taxes decrease but for tax revenue nevertheless to fall. Continuing with our example can shed some further clarity on this.

In particular, suppose that your tastes can be described as in equation (8.9), that you are earning a \$25 per hour pre-tax wage, and that you have up to 60 hours per week you can devote

to working. Now suppose that you find out that the government will reduce your take home pay by t percent through a wage tax. Then your effective wage becomes $\$25(1 - t)$ instead of $\$25$. Replacing w by $25(1 - t)$ in expression (8.10), we then get that your optimal leisure choice is

$$\ell = \frac{400}{25(1 - t)}, \quad (8.12)$$

with your optimal labor choice $(60 - \ell)$. Government tax revenue from this worker is simply the tax rate t times the worker's before tax income, $25(60 - \ell)$. Table 8.1 then calculates the number of hours you would work (column 2) under different tax rates (column 1), as well as the tax revenue the government receives (column 3). In addition, column 4 of the table indicates the tax revenue one would expect to receive if you were not going to adjust your labor supply to changing tax rates (and thus always worked 44 hours per week regardless of the tax rate), and column 5 indicates the difference in the predicted tax revenue from the economic analysis of column 3 as opposed to the more naive analysis of column 4.

By specifying your tastes as quasilinear in leisure, we have eliminated any wealth effect from the analysis and thus are left with a pure substitution effect. As a result, your work effort (represented by the number of hours you work) declines as your after-tax wage declines (see column 2). This results in tax revenues initially increasing with the tax rate because, although you work less as the tax increases, each dollar you earn is taxed more heavily. Eventually, however, your work hours decline sufficiently such that tax revenues decline when the tax rate increases further. This happens in the table when the tax rate increases from 50% to 60%, but if you were

TABLE 8.1 $u(c, \ell) = c + 400 \ln \ell$, $L = 60$, $w = 25$

Impact of Wage Tax on Labor Supply and Tax Revenue				
Tax Rate t	Labor Hours $(60 - \ell)$	Tax Revenue $t(25(60 - \ell))$	Tax Rev. w/o Subst. Effect	Difference
0.00	44.00	\$0.00	\$0.00	-\$0.00
0.05	43.16	\$53.95	\$55.00	-\$1.05
0.10	42.22	\$105.56	\$110.00	-\$4.44
0.15	41.18	\$154.41	\$165.00	-\$10.59
0.20	40.00	\$200.00	\$220.00	-\$20.00
0.25	38.67	\$241.67	\$275.00	-\$33.33
0.30	37.14	\$278.57	\$330.00	-\$51.43
0.35	35.38	\$309.62	\$385.00	-\$75.38
0.40	33.33	\$333.33	\$440.00	-\$106.67
0.45	30.91	\$347.73	\$495.00	-\$147.27
0.50	28.00	\$350.00	\$550.00	-\$200.00
0.55	24.44	\$336.11	\$605.00	-\$268.89
0.60	20.00	\$300.00	\$660.00	-\$360.00
0.65	14.29	\$232.14	\$715.00	-\$482.86
0.70	6.67	\$116.67	\$770.00	-\$653.33
0.75	0.00	\$0.00	\$825.00	-\$825.00

to fill in tax rates in between those in the table, the actual turning point occurs at a tax rate of 48.4%. Thus, if the government were to try to maximize tax revenue from you, it would levy a 48.4% tax rate. Notice, however, that well before this turning point, the tax revenue actually collected (column 3) diverges rather dramatically from the tax revenue predicted without taking the substitution effect into account.

One further thing to note is that were you to solve the maximization problem the usual way when the tax rate equals 75%, your solution would actually indicate that you will take 64 hours of leisure and $-\$25$ of consumption. Since such a bundle is not possible—you cannot, after all, take more than 60 hours of leisure or consume negative amounts of goods—you know immediately that the actual solution to the problem is a corner solution where you simply choose to consume nothing and only take leisure. This, in fact, happens for any tax rate higher than 73.34%.

The relationship between tax rates and tax revenue that emerges from this table is plotted in Graph 8.10a with the tax rate on the horizontal and tax revenue on the vertical. It is a common shape economists expect and is known as the *Laffer Curve*.⁴ Simply put, it illustrates that when tax rates become sufficiently high, eventually tax revenue will drop as individuals choose to avoid the tax by consuming less of the taxed good. Furthermore, as illustrated in Graph 8.10b, this Laffer Curve relationship suggests that the difference between actual tax revenues and those predicted without taking changes in economic behavior into account widens as the tax rate increases.

What is the equation for the Laffer Curve in Graph 8.10?

EXERCISE
8B.6*

Solve for the peak of the Laffer Curve (using the equation you derived in the previous exercise) and verify that it occurs at a tax rate of approximately 48.4%.

EXERCISE
8B.7**

GRAPH 8.10 The Laffer Curve: Substitution Effects when Tastes Are Quasilinear in Leisure

⁴This "curve" is named after Arthur Laffer (1940–), an economist who was influential in policy circles during the 1970s and 1980s. Laffer himself admits that the basic idea is not original to him. Jude Wanniski, a writer for the *Wall Street Journal*, appears to be the first to name the curve after Laffer following a 1974 meeting during which Laffer reportedly sketched the curve on a napkin with Wanniski and Dick Cheney, then a deputy assistant to the president.

8B.3 A Change in (Real) Interest Rates

In Section 8A.3, we turned next to the question of how changes in real interest rates affect your consumption, savings and borrowing decisions under different scenarios. We returned in this discussion to an example first raised in Chapter 3, an example in which you chose how to allocate income between consumption this summer and next summer. While the mathematics developed in Chapter 3 allows us to model more complicated savings and borrowing decisions, we will illustrate the basics of substitution and wealth effects in regard to savings and borrowing with just this two-period example. In such a setting, we had denoted the amount of income (or wealth) that you receive this summer as e_1 and the amount of income (or wealth) you receive next summer as e_2 . We then wrote your “intertemporal” (or across-time) budget constraint as

$$(1 + r)c_1 + c_2 = (1 + r)e_1 + e_2, \quad (8.13)$$

where c_1 stands for consumption this summer, c_2 for consumption next summer, and r for the real interest rate.

8B.3.1 Do Higher Interest Rates Make Us Save More? We begin again with the example of you earning \$10,000 this summer and choosing how much of it to allocate between consumption this summer and consumption next summer. In Graph 8.5, we illustrated that, without knowing more about tastes, it is unclear whether an increase in the real interest rate from 10% to 20% will cause you to save more or less this summer, although we concluded that you will unambiguously choose to consume more next summer.

In terms of equation (8.13), $e_1 = 10,000$ and $e_2 = 0$ in this example. Thus, equation (8.13) can be written as

$$(1 + r)c_1 + c_2 = 10,000(1 + r). \quad (8.14)$$

Now suppose that your tastes can be described by the Cobb–Douglas utility function $u(c_1, c_2) = c_1^{0.5}c_2^{0.5}$. Then your utility maximization problem is

$$\max_{c_1, c_2} c_1^{0.5}c_2^{0.5} \text{ subject to } (1 + r)c_1 + c_2 = 10,000(1 + r). \quad (8.15)$$

Solving this in the usual way, we get that your optimal consumption levels this summer and next summer are

$$c_1 = 5,000 \text{ and } c_2 = 5,000(1 + r). \quad (8.16)$$

EXERCISE 8B.8

Verify that this is indeed the solution to the problem defined in (8.15).

Thus, at the initial interest rate of 10% you will choose to consume \$5,000 this summer and \$5,500 next summer, and at the new interest rate of 20% you will continue to consume \$5,000 this summer but will raise your consumption next summer to \$6,000. This corresponds to our usual bundles *A* and *C*, and we can already tell that the substitution and wealth effects must have exactly offset one another since your savings—the amount you chose not to consume this summer—remained constant.

For many interesting policy questions, however, it will be important to know just how large the substitution effect was. We can calculate this effect using our expenditure minimization approach in which we simply ask how much we would have to give to you (instead of the \$10,000 you are making this summer) in order for you to remain just as happy under the new interest rate as you were under the old interest rate when you made \$10,000 this summer.

Plugging bundle A —\$5,000 this summer and \$5,500 next summer—into the utility function, we can calculate that you attained a utility level of 5,244 as measured by the Cobb–Douglas function used to represent your tastes. Thus, to calculate our usual bundle B , we need to solve

$$\min_{c_1, c_2} E = (1 + r)c_1 + c_2 \quad \text{subject to} \quad c_1^{0.5}c_2^{0.5} = 5,244, \quad (8.17)$$

with r set to the new interest rate 0.2. Solving this in the usual way, we get that

$$c_1 = 4,787.14 \quad \text{and} \quad c_2 = 5,744.56. \quad (8.18)$$

Verify that this is indeed the solution to the problem defined in (8.17).

EXERCISE
8B.9

Thus, the substitution effect in this example indicates that you would increase your savings this summer by \$212.86 if you only faced a change in opportunity costs without a change in real income (as indicated by your initial indifference curve), but this temptation to increase your savings is undone by the wealth effect, by the fact that you are richer as a result of the increase in the interest rate. As we will show in more detail in Chapter 9, this result (that substitution and wealth effects will exactly offset each other) is a special case for Cobb–Douglas tastes and is due to the built-in assumption of an elasticity of substitution equal to 1. In the more general class of constant elasticity of substitution (CES) utility functions (of which the Cobb–Douglas function is a special case), we will see that the substitution effect is outweighed by the wealth effect when the elasticity of substitution falls below 1, leading to a decline in savings with an increase in the real interest rate. Analogously, the wealth effect is outweighed by the substitution effect when the elasticity of substitution is greater than 1, leading to an increase in savings when the real interest rate increases.

Using a set of graphs similar to those depicted in Graph 8.5, label the bundles that we have just calculated.

EXERCISE
8B.10

8B.3.2 Will an Increase in the (Real) Interest Rate Make Us Borrow Less? We next considered in Section 8A.3.2 how the situation changes if, instead of having a \$10,000 income this summer and no income next summer, you had an \$11,000 income next summer and no income this summer. In this case, you would have to borrow against your future income to consume anything this summer, and the example is structured in such a way that your intertemporal budget across the two summers is the same as it was in our previous example when the interest rate is 10%. The intuition for how your choices are now affected as the interest rate rises to 20% was illustrated in Graph 8.6 where we showed that, while such an increase in the interest rate will certainly make you consume less (and thus borrow less) this summer because of the increased cost of borrowing, it is unclear without knowing more about your tastes whether you will consume more or less next summer.

Suppose, then, that your tastes can continue to be described by the Cobb–Douglas utility function $u(c_1, c_2) = c_1^{0.5}c_2^{0.5}$. The only change in the mathematical analysis from the previous section is then that your budget constraint differs. In terms of equation (8.13), we now have $e_1 = 0$ and $e_2 = 11,000$, giving us a new budget constraint of

$$(1 + r)c_1 + c_2 = 11,000. \quad (8.19)$$

You should now be able to verify, following exactly the same steps as in the previous section, that bundles A and B will be exactly the same as before (as already indicated by the intuition emerging from Graphs 8.5 and 8.6), but that the new bundle C will be

$$c_1 = 4,583.33 \text{ and } c_2 = 5,500. \quad (8.20)$$

Thus, for tastes described by the Cobb–Douglas function in this example, your consumption next summer will remain unchanged from your original consumption, indicating that substitution and wealth effects again exactly offset one another on that dimension. But since your consumption this summer declines from \$5,000 at bundle A to \$4,583.33 at bundle C , you have chosen to borrow \$416.67 less as a result of the increase in the interest rate (with \$212.86 of that accounted for by the substitution effect and the remainder by the wealth effect).

EXERCISE 8B.11

Illustrate what we have just calculated in a graph.

EXERCISE 8B.12

We calculated that consumption next summer is unchanged as the interest rate rises when tastes can be represented by the Cobb–Douglas utility function we used. This is because this function assumes an elasticity of substitution of 1. How would this result change if the elasticity of substitution is larger or smaller than 1?

8B.3.3 “Neither a Borrower nor a Lender Be ...” Finally, we considered in Section 8A.3.3 the case where you had put in place plans to earn \$5,000 this summer and \$5,500 next summer knowing that, at an interest rate of 10%, this implied that you would have to neither borrow nor lend to consume your optimal bundle: \$5,000 this summer and \$5,500 next summer. Continuing with the Cobb–Douglas tastes from the previous section, you can verify that this is indeed the optimal bundle given a summer income of \$5,000 this summer and \$5,500 next summer by simply recognizing that we are once again solving the exact same maximization problem, except that now $e_1 = 5,000$ and $e_2 = 5,500$. Thus, the budget constraint (8.13) simply becomes

$$(1 + r)c_1 + c_2 = 5,000(1 + r) + 5,500. \quad (8.21)$$

Going through the same steps as before, you will find that your new optimal bundle when the interest rate rises to 20% is

$$c_1 = 4,791.67 \text{ and } c_2 = 5,750, \quad (8.22)$$

with the substitution effect accounting for most of the change in behavior (as suggested by the intuition gained from Graphs 8.7a and 8.7b in Section 8A.3.3). Specifically, point B , the bundle representing just the substitution effect, is

$$c_1 = 4,787.14 \text{ and } c_2 = 5,744.56, \quad (8.23)$$

just a few dollars off the bundle C of expression (8.22).

EXERCISE 8B.13

Verify that (8.22) and (8.23) are correct.

CONCLUSION

In this chapter, we have extended our treatment of income and substitution effects for models in which incomes are exogenous to those where incomes arise endogenously. In the process, we have defined a new “wealth effect” that arises as prices of endowments change and thus alter a person’s wealth. This is particularly important as we discuss the application of our basic model to labor/leisure choices and financial planning choices.

We are now ready to proceed to an analysis of demand in consumer goods markets (and supply in labor and capital markets). While these concepts are often discussed early in an economics course, they actually derive directly from the optimizing behavior of consumers (and workers and financial planners). Understanding the engine of optimization that underlies demand and supply will become quite important as we apply some of the tools we have learned to real-world issues. Chapter 10 then follows with a discussion of consumer welfare and deadweight loss, and it is in this discussion that we will see further evidence of the importance of understanding the difference between substitution and income (or wealth) effects.

END-OF-CHAPTER EXERCISES

- 8.1†** As we have suggested in the chapter, it is often important to know whether workers will work more or less as their wage increases.
- A.** In each of the following cases, can you tell whether a worker will work more or less as his or her wage increases?
- The worker’s tastes over consumption and leisure are quasilinear in leisure.
 - The worker’s tastes over consumption and leisure are homothetic.
 - Leisure is a luxury good.
 - Leisure is a necessity.
 - The worker’s tastes over consumption and leisure are quasilinear in consumption.
- B.** Suppose that tastes take the form $u(c, \ell) = (0.5c^{-\rho} + 0.5\ell^{-\rho})^{-1/\rho}$.
- Set up the worker’s optimization problem assuming his or her leisure endowment is L and his or her wage is w .
 - Set up the Lagrange function corresponding to your maximization problem.
 - Solve for the optimal amount of leisure.
 - * Does leisure consumption increase or decrease as w increases? What does your answer depend on?
 - Relate this to what you know about substitution and wealth effects in this type of problem.
- 8.2** Suppose that an invention has just resulted in everyone being able to cut their sleep requirement by 10 hours per week, thus providing an increase in their weekly leisure endowment.
- A.** For each of the following cases, can you tell whether a worker will work more or less?
- The worker’s tastes over consumption and leisure are quasilinear in leisure.
 - The worker’s tastes over consumption and leisure are homothetic.
 - Leisure is a luxury good.
 - Leisure is a necessity.
 - The worker’s tastes over consumption and leisure are quasilinear in consumption.
 - Do any of your answers have anything to do with how substitutable consumption and leisure are? Why or why not?

*conceptually challenging

**computationally challenging

†solutions in Study Guide

- B.** Suppose that a worker's tastes for consumption c and leisure ℓ can be represented by the utility function $u(c, \ell) = c^\alpha \ell^{(1-\alpha)}$.
- Write down the worker's constrained optimization problem and the Lagrange function used to solve it, using w to denote the wage and L to denote the leisure endowment.
 - Solve the problem to determine leisure consumption as a function of w , α , and L . Will an increase in L result in more or less leisure consumption?
 - Can you determine whether an increase in leisure will cause the worker to work more?
 - Repeat parts (a) through (c) using the utility function $u(c, \ell) = c + \alpha \ln \ell$ instead.
 - ** Can you show that if tastes can be represented by the CES utility function $u(c, \ell) = (\alpha c^{-\rho} (1 - \alpha) \ell^{-\rho})^{-1/\rho}$, the worker will choose to consume more leisure as well as work more when there is an increase in the leisure endowment L ? (Warning: The algebra gets a little messy. You can occasionally check your answers by substituting $\rho = 0$ and checking that this matches what you know to be true for the Cobb–Douglas function $u(c, \ell) = c^{0.5} \ell^{0.5}$.)

8.3[†] In this chapter, we began by considering the impact of an increase in the price of gasoline on George Exxon, who owns a lot of gasoline. In this exercise, assume that George and I have exactly the same tastes and that gasoline and other goods are both normal goods for us.

- A.** Unlike George Exxon, however, I do not own gasoline but simply survive on an exogenous income provided to me by my generous wife.
- With “gallons of gasoline” on the horizontal and “dollars of other goods” on the vertical, graph the income and substitution effects from an increase in the price of gasoline.
 - Suppose George (who derives all his income from his gasoline endowment) had exactly the same budget before the price increase that I did. On the same graph, illustrate how his budget changes as a result of the price increase.
 - Given that we have the same tastes, can you say whether the substitution effect is larger or smaller for George than it is for me?
 - Why do we call the change in behavior that is not due to the substitution effect an *income effect* in my case but a *wealth effect* in George Exxon's case?
- B.** In Section 8B.1, we assumed the utility function $u(x_1, x_2) = x_1^{0.1} x_2^{0.9}$ for George Exxon as well as an endowment of gasoline of 1,000 gallons. We then calculated substitution and wealth effects when the price of gasoline goes up from \$2 to \$4 per gallon.
- Now consider me with my exogenous income $I = 2,000$ instead. Using the same utility function we used for George in the text, derive my optimal consumption of gasoline as a function of p_1 (the price of gasoline) and p_2 (the price of other goods).
 - Do I consume the same as George Exxon prior to the price increase? What about after the price increase?
 - Calculate the substitution effect from this price change and compare it with what we calculated in the text for George Exxon.
 - Suppose instead that the price of “other goods” fell from \$1 to \$0.50 while the price of gasoline stayed the same at \$2. What is the change in my consumption of gasoline due to the substitution effect? Compare this with the substitution effect you calculated for the gasoline price increase.
 - How much gasoline do I end up consuming? Why is this identical to the change in consumption we derived in the text for George when the price of gasoline increases? Explain intuitively using a graph.

8.4 Business Application: Merchandise Exchange Policies: Suppose you have \$200 in discretionary income that you would like to spend on ABBA CDs and Arnold Schwarzenegger DVDs.

- A.** On the way to work, you take your \$200 to Walmart and buy 10 CDs and 5 DVDs at CD prices of \$10 and DVD prices of \$20.
- On a graph with DVDs on the horizontal and CDs on the vertical, illustrate your budget constraint and your optimal bundle A .
 - On the way home, you drive by the same Walmart and see a big sign: “All DVDs half price—only \$10!” You also know that Walmart has a policy of either refunding returned items for the

price at which they were bought if you provide them with a Walmart receipt or, alternatively, giving store credit in the amount that those items are currently priced in the store if you have lost your receipt.⁵ What is the most in store credit that you could get?

- c. Given that you have no more cash and only a bag full of DVDs and CDs, will you go back into Walmart and shop?
 - d. On the way to work the next day, you again drive by Walmart and notice that the sale sign is gone. You assume that the price of DVDs is back to \$20 (with the price of CDs still unchanged), and you notice you forgot to take your bag of CDs and DVDs out of the car last night and have it sitting right there next to you. Will you go back into Walmart (assuming you still have an empty wallet)?
 - e. Finally, you pass Walmart again on the way home and this time see a sign: “Big Sale—All CDs only \$5, All DVDs only \$10!” With your bag of merchandise still sitting next to you and your wallet still empty, will you go back into Walmart?
 - f. If you are the manager of a Walmart with this “store credit” policy, would you tend to favor—all else being equal—across the board price changes or sales on selective items?
 - g. *True or False:* If it were not for substitution effects, stores would not have to worry about people gaming their “store credit” policies as you did in this example.
- B.** Suppose your tastes for DVDs (x_1) and CDs (x_2) can be characterized by the utility function $u(x_1, x_2) = x_1^{0.5}x_2^{0.5}$. Throughout, assume that it is possible to buy fractions of CDs and DVDs.
- a. Calculate the bundle you initially buy on your first trip to Walmart.
 - b. Calculate the bundle you buy on your way home from work on the first day (when p_1 falls to 10).
 - c. If you had to pay the store some fixed fee for letting you get store credit, what’s the most you would be willing to pay on that trip?
 - d. What bundle will you eventually end up with if you follow all the steps in part A?
 - e.** Suppose that your tastes were instead characterized by the function $u(x_1, x_2) = (0.5x_1^{-\rho} + 0.5x_2^{-\rho})^{-1/\rho}$. Can you show that your ability to game the store credit policy diminishes as the elasticity of substitution goes to zero (i.e., as ρ goes to ∞)?

8.5*+ Policy Application: Savings Behavior and Tax Policy: Suppose you consider the savings decisions of three households: households 1, 2, and 3. Each household plans for this year’s consumption and next year’s consumption, and each household anticipates earning \$100,000 this year and nothing next year. The real interest rate is 10%. Assume throughout that consumption is always a normal good.

- A.** Suppose the government does not impose any tax on interest income below \$5,000 but taxes any interest income above \$5,000 at 50%.
- a. On a graph with “Consumption this period” (c_1) on the horizontal axis and “Consumption next period” (c_2) on the vertical, illustrate the choice set each of the three households faces.
 - b. Suppose you observe that household 1 saves \$25,000, household 2 saves \$50,000, and household 3 saves \$75,000. Illustrate indifference curves for each household that would make these rational choices.
 - c. Now suppose the government changes the tax system by exempting the first \$7,500 rather than the first \$5,000 from taxation. Thus, under the new tax, the first \$7,500 in interest income is not taxed, but any interest income above \$7,500 is taxed at 50%. Given what you know about each household’s savings decisions before the tax change, can you tell whether each of these households will now save more? (*Note:* It is extremely difficult to draw the scenarios in this question to scale, and when not drawn to scale, the graphs can become confusing. It is easiest simply to worry about the general shapes of the budget constraints around the relevant decision points of the households that are described.)
 - d. Instead of the tax change in part (c), suppose the government had proposed to subsidize interest income at 100% for the first \$2,500 in interest income while raising the tax on any interest income above \$2,500 to 80%. (Thus, if someone earns \$2,500 in interest, he or she would

⁵“Store credit” means that you get a card to which you can charge the amount of credit for anything you buy in the store.

receive an additional \$2,500 in cash from the government. If someone earns \$3,500, on the other hand, he or she would receive the same \$2,500 cash subsidy but would also have to pay \$800 in a tax.) One of the households is overheard saying: “I actually don’t care whether the old policy (i.e., the policy described in part A) or this new policy goes into effect.” Which of the three households could have said this, and will that household save more or less (than under the old policy) if this new policy goes into effect?

- B.** Now suppose that our three households had tastes that can be represented by the utility function $u(c_1, c_2) = c_1^\alpha c_2^{(1-\alpha)}$, where c_1 is consumption now and c_2 is consumption a year from now.
- Suppose there were no tax on savings income. Write down the intertemporal budget constraint with the real interest rate denoted r and current income denoted I (and assume that consumer anticipate no income next period).
 - Write down the constrained optimization problem and the accompanying Lagrange function. Then solve for c_1 , current consumption, as a function of α , and solve for the implied level of savings as a function of α , I , and r . Does savings depend on the interest rate?
 - Determine the α value for consumer 1 as described in part A.
 - Now suppose the initial 50% tax described in part A is introduced. Write down the budget constraint (assuming current income I and before-tax interest rate r) that is now relevant for consumers who end up saving more than \$50,000. (*Note:* Don’t write down the equation for the kinked budget; write down the equation for the linear budget on which such a consumer would optimize.)
 - Use this budget constraint to write down the constrained optimization problem that can be solved for the optimal choice given that households save more than \$50,000. Solve for c_1 and for the implied level of savings as a function of α , I , and r .
 - What value must α take for household 3 as described in part A?
 - With the values of α that you have determined for households 1 and 3, determine the impact that the tax reform described in (c) of part A would have?
 - What range of values can α take for household 2 as described in part A?

8.6 Policy Application: The Negative Income Tax: Suppose the current tax system is such that the government takes some fixed percentage t of any labor income that you make.

- A.** Some in Congress have proposed the following alternative type of tax system known as the *negative income tax*: You get a certain guaranteed income x even if you do not work at all. Then, for any income you earn in the labor market, the government takes a certain percentage k in taxes. To finance the guaranteed income x , the tax rate on labor income in this alternative system has to be higher than the tax rate under the current system (i.e., $t < k$).⁶
- On a graph with leisure on the horizontal axis and consumption on the vertical, illustrate what your budget constraint under the current tax system looks like, and indicate what the intercepts and slopes are assuming a leisure endowment of E and before-tax wage w .
 - On a similar graph, illustrate what your budget constraint looks like under the alternative system.
 - You hear me say: “You know what? After looking at the details of the tax proposal, I can honestly say I don’t care whether we keep the current system or switch to the proposed one.” Without knowing what kind of goods leisure and consumption are for me, can you tell whether I would work more or less under the negative income tax? Explain.
 - What would your tastes have to look like in order for you to be equally happy under the two systems while also working exactly the same number of hours in each case?
 - True or False:* The less substitutable consumption and leisure are, the less policy makers have to worry about changes in people’s willingness to work as we switch from one system to the other.
- B.** Consider your weekly decision of how much to work, and suppose that you have 60 hours of available time to split between leisure and work. Suppose further that your tastes over consumption and leisure can be captured by the utility function $u(c, \ell) = c\ell$ and that your market wage is $w = 20$ per hour.

⁶In some proposals, the requirement that $t < k$ actually does not hold because proponents of the negative income tax envision replacing a number of social welfare programs with the guaranteed income x .

- Write down the budget constraint under the two different tax policies described; that is, write down the first budget constraint as a function of c , ℓ , and t and the second as a function of c , ℓ , k , and x .
- Derive the optimal choice under the current tax system (as a function of t). In the absence of anything else changing, do changes in wage taxes cause you to change how much you work? Can you relate your answer (intuitively) to wealth and substitution effects?
- Now derive your optimal leisure choice under a negative income tax (as a function of k and x). How is your work decision now affected by an increase in k or an increase in x ?
- Suppose that $t = 0.2$. Using your utility function to measure happiness, what utility level do you attain under the current tax system?
- Now the government wants to set $k = 0.3$. Suppose you are the pivotal voter; if you approve of the switch to the negative income tax, then it will pass. What is the minimum level of guaranteed income x that the negative income tax proposal would have to include to win your support?
- How much less will you work if this negative income tax is implemented (assuming x is the minimum necessary to get your support)?

8.7[†] Policy Application: The Earned Income Tax Credit: Since the early 1970s, the U.S. government has had a program called the Earned Income Tax Credit (previously mentioned in end-of-chapter exercises in Chapter 3). A simplified version of this program works as follows: The government subsidizes your wages by paying you 50% in addition to what your employer paid you, but the subsidy applies only to the first \$300 (per week) you receive from your employer. If you earn more than \$300 per week, the government gives you only the subsidy for the first \$300 you earned but nothing for anything additional you earn. For instance, if you earn \$500 per week, the government would give you 50% of the first \$300 you earned, or \$150.

- Suppose you consider workers 1 and 2. Both can work up to 60 hours per week at a wage of \$10 per hour, and after the policy is put in place you observe that worker 1 works 39 hours per week while worker 2 works 24 hours per week. Assume throughout that leisure is a normal good.
 - Illustrate these workers' budget constraints with and without the program.
 - Can you tell whether the program has increased the amount that worker 1 works? Explain.
 - Can you tell whether worker 2 works more or less after the program than before? Explain.
 - Now suppose the government expands the program by raising the cut off from \$300 to \$400. In other words, now the government applies the subsidy to earnings up to \$400 per week. Can you tell whether worker 1 will now work more or less? What about worker 2?
- Suppose that workers have tastes over consumption c and leisure ℓ that can be represented by the function $u(c, \ell) = c^\alpha \ell^{(1-\alpha)}$.
 - Given you know which portion of the budget constraint worker 2 ends up on, can you write down the optimization problem that solves for his optimal choice? Solve the problem and determine what value α must take for worker 2 in order for him to have chosen to work 24 hours under the EITC program.
 - Repeat the same for worker 1 but be sure you specify the budget constraint correctly given that you know the worker is on a different portion of the EITC budget. (*Hint:* If you extend the relevant portion of the budget constraint to the leisure axis, you should find that it intersects at 75 leisure hours.)
 - Having identified the relevant α parameters for workers 1 and 2, determine whether either of them works more or less than he or she would have in the absence of the program.
 - Determine how each worker would respond to an increase in the EITC cut off from \$300 to \$400.
 - For what ranges of α would a worker choose the kink-point in the original EITC budget you drew (i.e., the one with a \$300 cutoff)?

8.8 Policy Application: Advising Congress on Savings Subsidies and Substitution Effects: Suppose you are asked to model the savings decisions of a household that has an income of \$100,000 this year but expects to have no income a period into the future.

- A.** Suppose the interest rate is 10% over this period and we consider the trade-off between consuming now and consuming one period from now.
- On a graph with “Consumption Now” on the horizontal and “Future Consumption” on the vertical axis, illustrate how an increase in the interest rate to 20% over the relevant period would change the household’s choice set.
 - Suppose that you know that the household’s tastes can accurately be modeled as perfect complements over consumption now and consumption in the future period. Can you tell whether the household will save more or less as a result of the increase in the interest rate?
 - You are asked to advise Congress on a proposed policy of subsidizing savings to increase the amount of money people save. Specifically, Congress proposes to provide 5% in interest payments in addition to the interest households earn in the market. You are asked to evaluate the following statement: “Assuming that consumption is always a normal good, small substitution effects make it likely that savings will actually decline as a result of this policy, but large substitution effects make it likely that savings will increase.”
 - True or False:* If the purpose of the policy described in the previous part of the problem is to increase the amount of consumption households have in the future, then the policy will succeed so long as consumption is always a normal good.
- B.** Now suppose that tastes over consumption now, c_1 , and consumption in the future, c_2 , can be represented by the Constant Elasticity of Substitution utility function $u(c_1, c_2) = (c_1^{-\rho} + c_2^{-\rho})^{-1/\rho}$.
- Write down the constrained optimization problem assuming that the real interest rate is r and no government programs dealing with savings are in effect.
 - Solve for the optimal level of c_1 as a function of ρ and r . For what value of ρ is the household’s savings decision unaffected by the real interest rate?
 - Knowing the relationship between ρ and the elasticity of substitution, can you make the statement quoted in (c) of part A more precise?

8.9[†] Policy Application: *International Trade and Child Labor*: The economist Jagdish Bhagwati explained in one of his public lectures that international trade causes the wage for child labor to increase in developing countries. He then discussed informally that this might lead to more child labor if parents are “bad” and less child labor if parents are “good.”

- A.** Suppose that households in developing countries value two goods: “Leisure time for Children in the Household” and “Household Consumption.” Assume that the adults in a household are earning $\$y$ in weekly income regardless of how many hours their children work. Assume that child wages are w per hour and that the maximum leisure time for children in a household is E hours per week.
- On a graph with “weekly leisure time for children in the household” on the horizontal axis and “weekly household consumption” on the vertical, illustrate the budget constraint for a household and label the slopes and intercepts.
 - Now suppose that international trade expands and, as a result, child wages increase to w' . Illustrate how this will change the household budget.
 - Suppose that household tastes are homothetic and that households require their children to work during some but not all the time they have available. Can you tell whether children will be asked to work more or less as a result of the expansion of international trade?
 - In the context of the model with homothetic tastes, what distinguishes “good” parents from “bad” parents?
 - When international trade increases the wages of children, it is likely that it also increases the wages of other members of the household. Thus, in the context of our model, y —the amount brought to the household by others—would also be expected to go up. If this is so, will we observe more or less behavior that is consistent with what we have defined as “good” parent behavior?
 - In some developing countries with high child labor rates, governments have instituted the following policy: If the parents agree to send a child to school instead of work, the government pays the family an amount x . (Assume the government can verify that the child is in fact sent to school and does in fact not work, and assume that the household views time at school as leisure time for the child.) How does that alter the choice set for parents? Is the policy more or less likely to succeed the more substitutable the household tastes treat child “leisure” and household consumption?

- B.** Suppose parental tastes can be captured by the utility function $u(c, \ell) = c^{0.5}\ell^{0.5}$. For simplicity, suppose further that $y = 0$.
- Specify the parents' constrained optimization problem and set up the appropriate Lagrange function.
 - Solve the problem you have set up to determine the level of leisure the parents will choose for their children. Does w have any impact on this decision?
 - Explain intuitively what you have just found. Consider the CES utility function (that has the Cobb–Douglas function you just worked with as a special case). For what ranges of ρ would you expect us to be able to call parents “good” in the way that Bhagwati informally defined the term?
 - Can parents for whom household consumption is a quasilinear good ever be “good”?
 - Now suppose (with the original Cobb–Douglas tastes) that $y > 0$. If international trade pushes up the earnings of other household members thus raising y , what happens to child leisure?
 - Suppose again that $y = 0$ and the government introduces the policy described in part A(f). How large does x have to be to cause our household to send its child to school (assuming again that the household views the child's time at school as leisure time for the child)?
 - Using your answer to the previous part, put into words what fraction of the market value of the child's time the government has to provide in x in order for the family to choose schooling over work for its child?

8.10* Policy Application: Subsidizing Savings versus Taxing Borrowing: In end-of-chapter exercise 6.10, we analyzed cases where the interest rates for borrowing and saving are different. Part of the reason they might be different is because of government policy.

- A.** Suppose banks are currently willing to lend and borrow at the same interest rate. Consider an individual who has income e_1 now and e_2 in a future period, with the interest rate over that period equal to r . After considering the trade-offs, the individual chooses to borrow on his or her future income rather than save. Suppose in this exercise that the individual's tastes are homothetic.
- Illustrate the budget constraint for this individual, and indicate his or her optimal choice.
 - Now suppose the government would like to encourage this individual to save for the future. One proposal might be to subsidize savings (through something like a 401k plan); that is, a policy that increases the interest rate for saving without changing the interest rate for borrowing. Illustrate how this changes the budget constraint. Will this policy work to accomplish the government's goal?
 - Another alternative would be to penalize borrowing by taxing the interest the banks collect from loans, thus raising the effective interest rate for borrowing. Illustrate how this changes the budget. Will this policy cause the individual to borrow less? Can it cause him or her to start saving?
 - In reality, the government often does the opposite of these two policies: Savings (outside qualified retirement plans) are taxed while some forms of borrowing (in particular borrowing to buy a home) are subsidized. Suppose again that initially the interest rate for borrowing and saving is the same, and then suppose that the combination of taxes on savings (which lowers the effective interest rate on savings) and subsidies for borrowing (which lowers the effective interest rate for borrowing) reduce the interest rate to $r' < r$ equally for both saving and borrowing. How will this individual respond to this combination of policies?
 - Suppose that instead of taxing or subsidizing interest rates, the government simply “saves for” the individual by taking some of the individual's current income e_1 and putting it into the bank to collect interest for the future period. How will this change the individual's behavior?
 - Now suppose that instead of taking some of the person's current income and saving it for him or her, the government simply raises the Social Security benefits (in the future period) without taking anything away from the person now. What will the individual do?
- B.** Suppose your tastes can be captured by the utility function $u(c_1, c_2) = c_1^\alpha c_2^{(1-\alpha)}$.
- Assuming you face a constant interest rate r for borrowing and saving, how much will you consume now and in the future (as a function of e_1 , e_2 and r)?
 - For what values of α will you choose to borrow rather than save?
 - Suppose that $\alpha = 0.5$, $e_1 = 100,000$, $e_2 = 125,000$ and $r = 0.10$. How much do you save or borrow?

- d. If the government could come up with a “financial literacy” course that changes how you view the trade-off between now and the future by impacting α , how much would this program have to change your α to get you to stop borrowing?
- e. Suppose the “financial literacy” program had no impact on α . How much would the government have to raise the interest rate for saving (as described in A(b)) in order for you to become a saver? (*Hint:* You need to first determine c_1 and c_2 as a function of just r . You can then determine the utility you receive as a function of just r , and you will not switch to saving until r is sufficiently high to give you the same utility you get by borrowing.)
- f. Verify your conclusion about the impact of the policy proposal outlined in A(c).
- g. Verify your conclusion to A(d).
- h. Verify your conclusion to A(e); that is, suppose the government takes x of your current income e_1 and saves it, thus increasing e_2 by $x(1 + r)$.
- i. Finally, suppose the increase in Social Security benefits outlined in A(f) is implemented. How and by how much does your borrowing change?

8.11[†] Policy Application: *Tax Revenues and the Laffer Curve:* In this exercise, we will consider how the tax rate on wages relates to the amount of tax revenue collected.

- A. As introduced in Section B, the *Laffer Curve* depicts the relationship between the tax rate on the horizontal axis and tax revenues on the vertical. (See the footnote in Section 8B.2.2 for background on the origins of the name of this curve.) Because people’s decision on how much to work may be affected by the tax rate, deriving this relationship is not as straightforward as many think.
 - a. Consider first the extreme case in which leisure and consumption are perfect complements. On a graph with leisure hours on the horizontal and consumption dollars on the vertical, illustrate how increases in the tax on wages affect the consumer’s optimal choice of leisure (and thus labor).
 - b. Next, consider the less extreme case where a change in after-tax wages gives rise to substitution and wealth effects that exactly offset one another on the leisure axis. In which of these cases does tax revenue rise faster as the tax rate increases?
 - c. On a graph with the tax rate (ranging from 0 to 1) on the horizontal and tax revenues on the vertical, how does this relationship differ for tastes in (a) and (b)?
 - d. Now suppose that the substitution effect outweighs the wealth effect on the leisure axis as after-tax wages change. Illustrate this and determine how it changes the relationship between tax rates and tax revenue.
 - e. Laffer suggested (and most economists agree) that the curve relating tax revenue (on the vertical axis) to tax rates (on the horizontal) is initially upward sloping but eventually slopes down, reaching the horizontal axis by the time the tax rate goes to 1. Which of the preferences we described in this problem can give rise to this shape?
 - f. *True or False:* If leisure is a normal good, the Laffer Curve can have an inverted U-shape only if leisure and consumption are (at least at some point) sufficiently substitutable such that the substitution effect (on leisure) outweighs the wealth effect (on leisure).
- B.** In Section 8B.2.2, we derived a Laffer Curve for the case where tastes were quasilinear in leisure. Now consider the case where tastes are Cobb–Douglas, taking the form $u(c, \ell) = c^\alpha \ell^{(1-\alpha)}$. Assume that a worker has 60 hours of weekly leisure endowment that he or she can sell in the labor market for wage w .
 - a. Suppose the worker’s wages are taxed at a rate t . Derive the worker’s optimal leisure choice.
 - b. For someone with these tastes, does the Laffer Curve take the inverted U-shape described in Section 8B.2.2. Why or why not? Which of the cases described in A does this represent?
 - c. Now consider the more general CES function $(\alpha c^{-\rho} + (1 - \alpha)\ell^{-\rho})^{-1/\rho}$. Again, derive the optimal leisure consumption.
 - d. Does your answer simplify to what you would expect when $\rho = 0$?
 - e. Determine the range of values of ρ such that leisure consumption increases with t .
 - f. When ρ falls in the range you have just derived, what happens to leisure consumption as t approaches 1? What does this imply for the shape of the Laffer Curve?
 - g. Suppose $\alpha = 0.25$, $w = 20$, and $\rho = -0.5$. Calculate the amount of leisure a worker would choose as a function of t . Then derive an expression for this worker’s Laffer Curve and graph it.

Demand for Goods and Supply of Labor and Capital

CHAPTER

9

If you have ever taken an economics class before, you probably dived right into drawing demand and supply curves.¹ You may be puzzled by the lack of any attention we have given to these concepts thus far. The reason for this is not that demand and supply curves are unimportant. Rather, demand and supply arise from individual decision making, from economic actors choosing to do the best they can given their circumstances. It is difficult to fully appreciate the concepts of demand and supply—to know what they tell us and what they do not tell us—without first understanding how demand and supply arise from such individual optimizing behavior. Having taken a close look at how economists think about individuals doing the best they can given their circumstances, we are now ready to see how such individual decision making leads to some types of demand and supply curves.

In particular, we have analyzed how individuals make choices in three different roles within the economy: as consumers choosing between various goods, as workers choosing between consumption and leisure, and as savers/borrowers choosing how to plan for the future. In their role as consumers, individuals become *demanders of goods and services*, while in their role as workers they become *suppliers of labor*. Finally, as savers they become *suppliers of financial capital*, while as borrowers they become *demanders of financial capital*. We will therefore be able to derive from what we have modeled so far: demand curves for goods and supply curves for labor. Depending on whether an individual borrows or saves, we will also be able to derive demand and supply curves for financial capital. In later chapters, we will complete the picture of goods and services markets, labor markets, and capital markets by adding the role played by producers, who supply goods and demand labor and capital.

9A

DERIVING DEMAND AND SUPPLY CURVES

We begin, as always, with a nonmathematical treatment of demand and supply curves that arise from individual optimizing behavior. Here we will use the graphs we have developed thus far to illustrate how the demand and supply curves you have probably seen in other classes arise from such models. Section 9A.1 will begin with demand relationships for goods and services, while later sections extend the analysis to similar relationships in labor and capital markets.

¹Chapter 2 and Chapters 4 through 7 are required for this chapter. Chapters 3 and 8 are required for Sections 9A.2 and 9A.3 as well as 9B.2 and 9B.3. Those sections can be skipped by students who are not reading Chapters 3 and 8.

9A.1 Demand for Goods and Services

In the previous chapters, we have analyzed how the quantity of a good that is demanded may change with changes in underlying economic circumstances, whether these are changes in income, wealth, or prices. Our answer has always depended on the underlying tastes that gave rise to sometimes competing income (or wealth) and substitution effects. It became important to know whether, for the particular individual in question, a good was normal or inferior, regular inferior or Giffen. Such distinctions between different types of tastes then become similarly important for understanding demand relationships more generally.

We will distinguish among three different kinds of demand relationships (or “curves”): *income-demand curves*, *own-price demand curves*, and *cross-price demand curves*. By an “income-demand curve” we mean the relationship between (exogenously given) income and the quantity of a good that is demanded; by “own-price demand curve” we mean the relationship between the price of a good and the quantity demanded of *that same* good; and by a “cross-price demand curve” we mean the relationship between one good’s price and the quantity demanded of a *different* good. In each of these cases, we will plot demand curves relating the quantity of a good demanded on the horizontal axis and the variable of interest—to income, the good’s own price or some other good’s price—on the vertical.

Income-demand curves relate changes in exogenous income to changes in the quantity of a good demanded (holding all prices fixed).

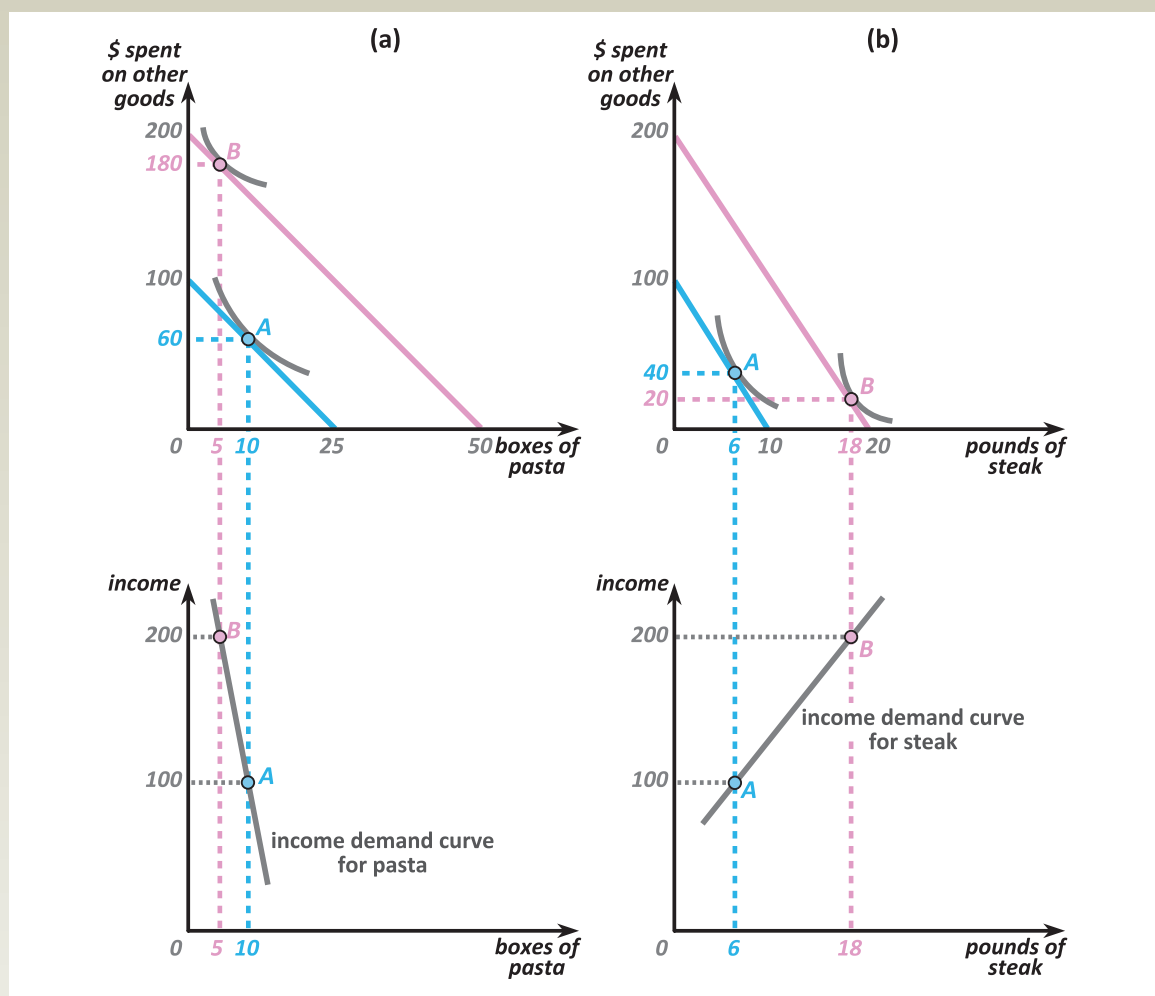

9A.1.1 Income-Demand Relationships Of the three types of demand relationships we are interested in, the relationship between income and the quantity of a good demanded is the most straightforward. These income-demand relationships are sometime referred to as Engel curves.²

Suppose, for instance, that we return to my example from Chapter 7 in which I revealed how, for my wife and me, pasta is an inferior good whereas steak is a normal good. In Graph 9.1, we then derive our income-demand curves for these two goods knowing what kinds of goods these are for my wife and me. Specifically, we begin in Graph 9.1a with an income of \$100 and a choice between boxes of pasta per week and “dollars of other consumption per week.” Since the good on the vertical axis is denominated in dollars, its price is simply 1 and the slope of the budget is minus the price of pasta. Suppose this price is \$4 and that our optimal bundle *A* contains 10 boxes of pasta per week. This then gives us one point on the income-demand graph directly below: at an income of \$100 (on the vertical axis), we consume 10 boxes of pasta.

Now suppose our income goes up to \$200 (without a change in the price of pasta). Since pasta is an inferior good for us, we know that our pasta consumption will now decline, perhaps to 5 boxes as indicated in the new optimal bundle *B*. This then gives us a second point on the income-demand graph: at an income of \$200, we consume 5 boxes of pasta. We can imagine going through these same steps again and again for different levels of income, each time finding the optimal point in the top graph and translating it to the lower graph. The curve connecting these points then forms the complete income-demand curve. For our particular example, the curve has a negative slope because we have assumed pasta is an inferior good, implying a negative relationship between income and consumption. Graph 9.1b then replicates the same analysis for steak when the price of steak is \$10 per pound. (In the example, we assume that my wife and I consume only steak and pasta.) As you would expect, this results in a positive income-demand relationship because steak is a normal good for us.

EXERCISE 9A.1 In an earlier chapter, we mentioned that it is not possible for a good to be inferior for all income levels. Can you see in the lower panel of Graph 9.1a why this is true?

²These are named after Ernst Engel (1821–1896), a German statistician and economist who studied how consumption behavior changes with income. He is particularly known for what has become known as “Engel’s Law,” which states that the proportion of income spent on food falls as income increases (i.e., food is a necessity as we have defined it) even though the overall expenditures on food increase (i.e., food is a normal good as we have defined it).

GRAPH 9.1 Income-Demand Curves when Pasta Is Inferior (a) and Steak Is Normal (b)

The graphical translation of optimizing choices in the top graphs to income-demand curves in the lower graphs is an intuitive way of accomplishing what can be accomplished straightforwardly with mathematical equations. Thus, in reality economists do not spend their time graphing points again and again as we would have to in order to get the lower relationship just right. Rather, we use the techniques developed in the B-portions of our chapters. Nevertheless, the graphical technique provides us with the intuition of what the mathematics accomplishes for us, and it is a technique we will use repeatedly here and throughout the rest of the book.

The income-demand curves derived in Graph 9.1 are valid for the prices used in the top portions of the graphs: \$4 for pasta and \$10 for steak. Now suppose that these prices changed. The resulting new optimal bundles in the top portion of the graphs will then translate to different points, and thus different income-demand curves, in the lower portion of the graphs. In particular, for normal and regular inferior goods, an increase in the price of a good will result in less consumption of that good for any given income level. This implies that *for normal or regular inferior goods, the income-demand curve will shift inward for an increase in the price of the good and outward for a decrease in price*. For Giffen goods, on the other hand, an increase in price results in increased consumption for any given income level, while a decrease in the price

A change in price causes a shift in the income-demand curve.

will result in decreased consumption. Thus, for *Giffen goods*, an increase in price results in an outward shift of the income-demand curve, while a decrease in price results in an inward shift.

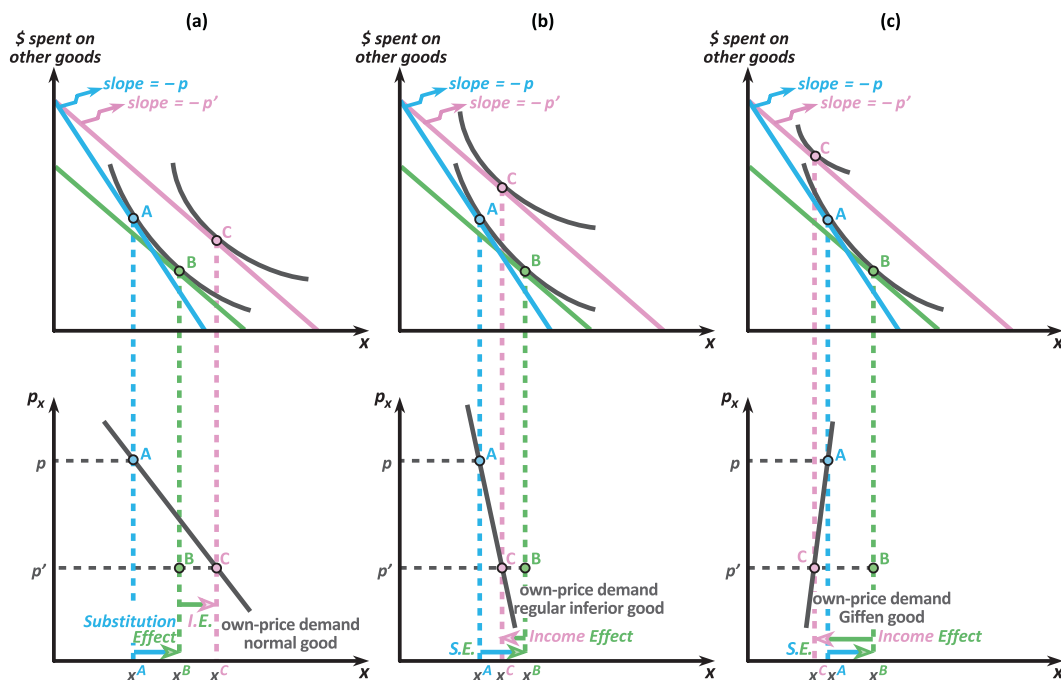

EXERCISE 9A.2

Suppose good x is an inferior good for an individual. Derive the income-demand curve as in Graph 9.1a. Then graph a decrease in the price for x for both income levels in the top panel and show how this affects the income-demand curve in the lower panel depending on whether x is Giffen or regular inferior.

9A.1.2 Own-Price Demand Relationships If you have ever heard of a demand curve before, chances are that you have also heard of an *own-price demand curve*. An *own-price demand curve for a good (or service)* illustrates the relationship between the price of the good (or service) and the quantity demanded by a consumer; holding all else fixed. We can derive such curves in much the same way that we derived the income-demand curves in Graph 9.1, except that we now have to change prices rather than incomes in the top portion of the graphs (and put prices rather than income on the vertical axis in the lower graph).

In Graph 9.2, we derive the own-price demand curves for a normal good, a regular inferior good, and a Giffen good. In each case, we model the good of interest on the horizontal axis and analyze the choices faced by a consumer between that good and a composite good denominated in dollars. We begin in the top panel of each graph with the same initial (blue) budget constraint

GRAPH 9.2 Three Types of Own-Price Demand Curves

Go to MindTap to interact with this graph.

and the same initial optimal point A , and in each case we analyze a decrease in the price of the good on the horizontal axis from p to p' . To make the illustration as clean as possible, we also assume in each case that the degree of substitutability built into the indifference curve at point A is the same across the three examples, which implies that the substitution effect that gives rise to point B on the compensated (green) budget is the same across the three examples. The only difference, then, lies in the size and direction of the income effect.

Consider first the derivation of the own-price demand curve for a normal good in panel (a) of Graph 9.2. At the initial price p , the consumer consumes x^A in the top graph, a quantity that is translated to the lower graph and placed at the vertical height p . Bundle B , the optimal choice under the compensated budget, is chosen at the lower price p' . Thus, we could translate the quantity x^B to the lower graph and place it at the vertical height p' . This is not, however, a point on the own-price demand curve since it is the hypothetical consumption level at the compensated budget. Still, this will turn out to be an important point in a different relationship we will introduce in Chapter 10.

For now, we want to focus on bundle C in the top graph, the bundle that is chosen on the actual final (magenta) budget. Because we are assuming in panel (a) of this graph that x is a normal good, C falls on the final budget to the right of B . As our income rises from the compensated to the final budget, we consume more of the normal good x . The quantity x^C that is chosen at the final price p' can then again be translated to the lower graph and placed at the height p' . As in the previous section, we can imagine going through this exercise many times to plot the optimal consumption of x at different prices and thus fully trace out the relationship between the price of good x and the quantity of x demanded. For our purposes, it is good enough simply to estimate the remaining points on the own-price demand curve by connecting points A and C on the lower graph.

Next we can see in panel (b) of Graph 9.2 how this analysis differs when x is a regular inferior rather than a normal good. Since bundles A and B are identical to those in panel (a) of the graph, these points translate to the lower graph in exactly the same way as they did for a normal good. (This simply reiterates what we have found all along, which is that substitution effects have nothing to do with whether a good is normal or inferior.) As our income rises from the compensated (green) to the final (magenta) budget in the top portion of the graph, however, we will now end up consuming less x rather than more because x is inferior. The quantity x^C therefore now falls to the left of x^B . Because we are assuming that the good is a regular inferior (rather than a Giffen) good, however, we know that the size of the income effect is smaller than the size of the substitution effect, thus causing C to fall in between A and B . When we connect A and C in the lower portion of the graph, we then get a demand curve that is steeper for the inferior good than it was for the normal good. The reason for this is, of course, that income and substitution effects now point in opposite directions.

As price changes, each optimal bundle in the consumer diagram corresponds to one point on the demand curve.

Repeat the derivation of own-price demand curves for the case of quasilinear tastes and explain in this context again how quasilinear tastes are borderline tastes between normal and inferior goods.

EXERCISE 9A.3

Finally, we can compare this to the own-price demand curve for a Giffen good in panel (c) of Graph 9.2. The difference now is that the income effect not only points in the opposite direction of the substitution effect but now it is also larger in size. As a result, point C in both the top and bottom portions of the graph falls not only to the left of B but also to the left of A . This leads to an own-price demand curve that is upward rather than downward sloping, giving expression to the definition of a Giffen good as a good whose consumption moves in the same direction as its own price.

EXERCISE 9A.4* How would the own-price demand curves in Graphs 9.2a through 9.2c change with a decrease in income? (*Hint:* Your answer for panel (a) should be different from your answers for panels (b) and (c).)

EXERCISE 9A.5 What kind of good would x have to be in order for the demand curve not to shift as income changes?

9A.1.3 Cross-Price Demand Relationships Suppose you are a producer of two goods that are used together: razors and razor blades, or printers and toner cartridges, for instance. As you think about how you should price the two different types of goods you produce, you may want to know not only how consumption of each good varies with its own price but also how consumption of one varies with the price of the other. Just as we could derive own-price demand curves in the previous section, we can then also derive cross-price demand curves under different scenarios. We will leave some of this for problems at the end of the chapter and offer only an illustration here.

Suppose, for instance, that you consume goods x_1 and x_2 , that your tastes are quasilinear in good x_1 , and that we are interested in the cross-price demand curve for good x_1 as the price of good x_2 varies. We would therefore begin in Graph 9.3 by modeling how your choices change as

GRAPH 9.3 Cross-Price Demand Curve when Tastes Are Quasilinear in x_1

the price of good x_2 decreases from p_2 to p'_2 . The optimal bundle A at the original price p_2 could then be translated to the lower portion of the graph, where we plot your optimal consumption x_1^A at the initial price p_2 . We can similarly translate bundle B but are ultimately interested in where bundle C will fall. Since we have assumed in this example that your tastes are quasilinear in good x_1 , we know that your consumption of good x_1 is unchanged as income changes and thus the same on the compensated and the final budget. Thus bundle C lies directly above bundle B in the top portion of the graph and exactly on top of the translated B point on the lower portion. The cross-price demand curve that connects A and C is therefore upward sloping. As the price of good x_2 increases, so does your consumption of good x_1 .

What kind of good would x_1 have to be in order for this cross-price demand curve to slope down?

EXERCISE 9A.6

9A.2 Labor Supply³

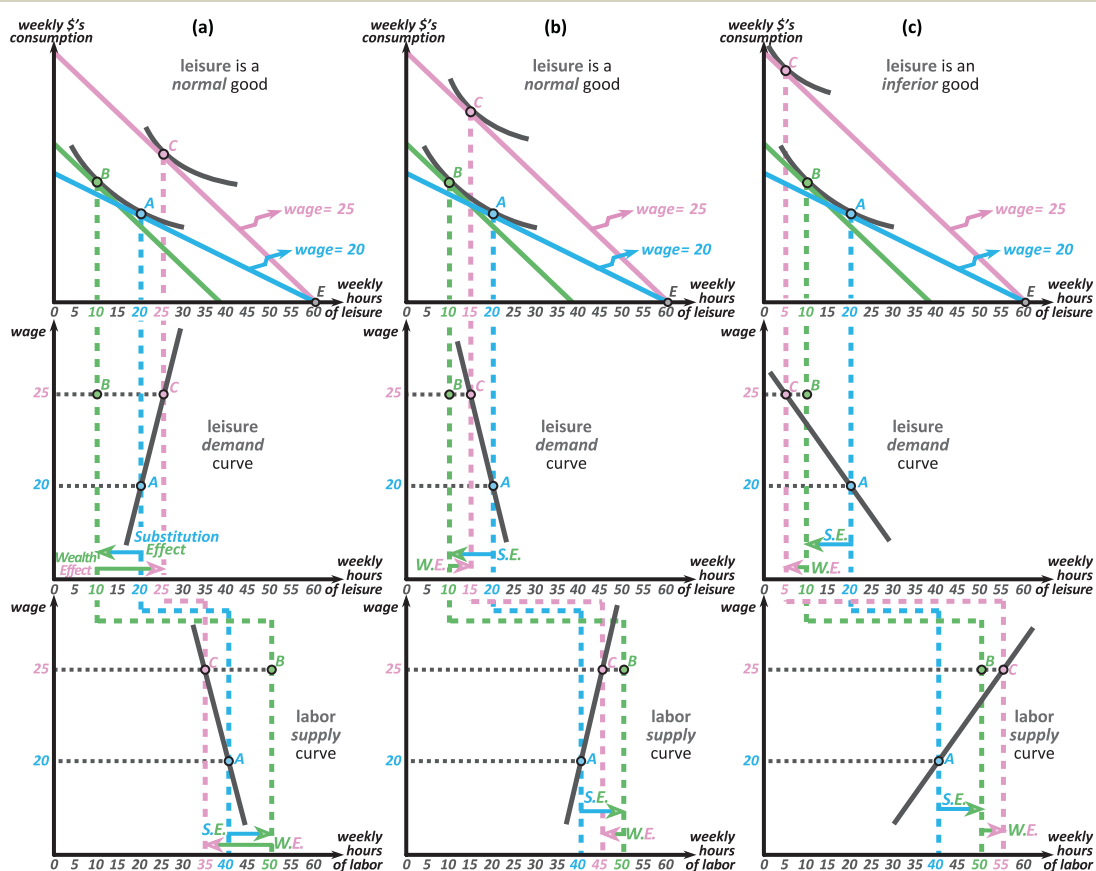

Economists and policy makers alike are often interested in how the supply of labor will respond to changes in the wages that workers can earn. Enormous effort has been devoted to determining how different types of workers respond differently to changes in wages, whether women respond differently than men, whether older workers respond differently than younger workers, high-wage workers differently than low-wage workers. How responsive workers are to changes in their take-home wage impacts the way we think about tax policy as well as labor issues like the minimum wage. At the root of these issues lies once again the question of the direction and relative size of income (or wealth) and substitution effects.

Labor supply curves simply plot the amount of labor an individual chooses to supply to the market at different wage rates. This choice emerges from an individual's choice of how to spend his or her leisure endowment; that is, how much of it to consume as leisure and how much of it to convert into consumption of other goods by selling leisure (i.e., by working). The wage itself is like any other price in the economy, and, while individuals can in the long run affect the wage they command in the market by gaining skills and earning higher levels of education, they typically must accept the wage offered by the market for a given set of skills and education.

Consider again your choice of how much labor to supply this summer given that you have 60 hours of leisure time per week. Suppose first that you can command a wage of \$20 per hour. We have previously modeled your choice graphically with weekly hours of leisure on the horizontal axis and dollars of weekly consumption on the vertical. This is done once again in each of the three cases in the top row of Graph 9.4, where in each case we assume that your tastes are such that your optimal level of leisure at the initial \$20 wage is equal to 20 hours per week, implying 40 hours of labor supplied. Thus, in each of the three bottom panels of Graph 9.4, point A indicates that you will supply 40 hours of work per week at an hourly wage of \$20 per hour. This is one point on the labor supply curve. Note, however, that unlike in the graphs of the previous section, we are not able simply to translate the horizontal axis of the top graph to the horizontal axis of the bottom graph because the bottom graph in each panel contains a different good (labor) on the horizontal axis than the top graph (leisure). Rather, we proceed in two steps: In the middle row of Graph 9.4, we derive the "leisure demand curve" in much the same way we derived demand curves in the previous section. Then we proceed to the lowest graph for each case to derive the corresponding *labor supply curve*, which follows straightforwardly from the leisure demand curve given that labor is equal to 60 minus leisure.

Labor supply curves emerge from consumption/leisure choices.

³Students who did not read Chapters 3 and 8 should skip this and the next section.

GRAPH 9.4 Leisure Demand (Middle Row) and Labor Supply (Bottom Row) Curves

Now suppose that you have gained some additional skills and your market wage increases to \$25 per hour. Several scenarios are now possible depending on which direction and what size the wealth effect assumes. In panel (a) of Graph 9.4, leisure is assumed to be normal, implying a wealth effect that points in the direction opposite to that of the substitution effect. In addition, this wealth effect is assumed in panel (a) of the graph to be larger in size than the substitution effect, thus causing an increase in the wage to result in an *increase* in leisure in the top and middle graph and thus a *decrease* in work hours on the bottom graph. As a result, the labor supply curve, estimated by simply connecting A and C in the bottom panel, is downward sloping.

EXERCISE 9A.7 In our analysis of consumer goods, we usually found that income and substitution effects point in the same direction when goods are normal. Why are wealth and substitution effects now pointing in opposite directions when leisure is a normal good?

As we hinted at in the previous chapter, leisure being a normal good is a *necessary* condition for the labor supply curve to slope down, but it is not sufficient. Panel (b) illustrates this by showing how we can assume that leisure is normal and get the opposite slope for the labor supply curve. The only change from the picture in panel (a) is that the wealth effect, while still pointing in the direction opposite to that of the substitution effect, now is smaller in size than the substitution effect. As a result, the worker takes less leisure at bundle *C* (when the wage is \$25) than he or she did at bundle *A* (when the wage was \$20 per hour), which results in more labor as the wage increases and thus an upward-sloping labor supply curve.

Finally, panel (c) of the graph illustrates what happens in the event that leisure is an inferior good. In this case, the substitution and wealth effects point in the same direction on the leisure axis, thus unambiguously indicating that leisure will decline as the wage increases and implying that work hours will increase with the wage.

When leisure is a normal good, labor supply curves can slope up or down depending on the size of the wealth effect relative to the substitution effect.

True or False: Leisure being an inferior good is sufficient but not necessary for labor supply to slope up.

EXERCISE 9A.8

As we have noted earlier, it is not possible to differentiate this case from the case where leisure is a Giffen rather than a regular inferior good. This is because in order to be able to make such a differentiation, we would have to observe the equivalent of a change in the price of leisure with income being exogenous rather than endogenous because a Giffen good is defined relative to price changes of *that* good when income is exogenous. A change in the wage, however, is graphically equivalent to a change in the price of consumption, with an *increase* in the wage being formally equivalent to a *decrease* in the price of consumption. When the wage increased from \$20 to \$25, for instance, you were unable to consume any more leisure on the horizontal axis but were able to consume more of other goods on the vertical. This is exactly what a decrease in the price of the good “consumption” would look like in a model with exogenous income in which leisure is treated like any other good.

Can you tell which way the labor supply curve will slope in the unlikely event that “other consumption” is a Giffen good?

EXERCISE 9A.9

9A.3 Demand and Supply Curves for Financial Capital

Finally, we have introduced in Chapter 3 a way of modeling the choices we face as we plan for the future by using graphs of budget constraints known as intertemporal budgets that illustrate the trade-offs between consuming now or at some point in the future. And we have demonstrated in Chapter 8 how we can combine such intertemporal choice sets with graphs of indifference curves to illustrate how income and substitution effects operate in our savings and borrowing decisions. We now proceed to show how this analysis can be extended to permit us to derive graphically supply and demand curves for financial capital, curves that illustrate how our behavior in financial markets changes as the real interest rate changes.

9A.3.1 Saving and the “Supply of Capital” Whenever we save money for the future, we are implicitly supplying financial capital to the market. Typically, we are doing this by putting our savings into a bank account or some other financial institution (like the stock market), which then either lends the bulk of this money to someone else or uses it directly to finance some operation. For instance, when I open a savings account in my local bank, you might come along the

Saving is equivalent to supplying financial capital to the market.

next day and ask the bank for a loan to buy a car. In this case, I have indirectly supplied financial capital that you demanded, all at some market interest rate. Or I might invest money by purchasing newly issued stocks or corporate bonds, in which case the firm that is issuing the stocks or bonds is demanding capital that I am supplying. Or I might purchase government treasury bonds, in which case I am lending money directly to the government. In each of these scenarios, “savings” is equivalent to “supplying capital” in the economy.

Consider the case we have raised before where you attempt to decide how much to save for next summer given that you earn \$10,000 this summer and expect to have no earnings next summer. As before, let us assume that consumption is always a normal good, whether it happens this summer or next summer, and let’s begin by assuming that the annual interest rate is 10% and that, at that interest rate, you find it optimal to save \$5,000 for next summer. This “optimum” is illustrated as point *A* in the top panels of Graphs 9.5a and 9.5b, and this bundle is translated to a lower graph in which we plot the interest rate against the amount of savings you will undertake under this interest rate. Thus, on the lower graphs, point *A* occurs at the vertical height of the interest rate 0.1 and indicates that you will save \$5,000 at that interest rate. Notice that in this case, the quantity on the horizontal axis of the top graph is the same as the quantity on the horizontal axis of the lower graph because you are consuming \$5,000 (the quantity on the top graph), which implies you are saving \$5,000 because you started out with a \$10,000 income. In general, however, the “good” on the horizontal axis in the lower panel is different from the “good” on the horizontal axis in the top panel, much as it was when we had leisure in the consumer diagram and then put labor on the horizontal axis when graphing the labor supply curve. Compared to what we did in Graph 9.4 of the previous section, we are in effect now skipping the intermediate step of illustrating the “consumption now” demand curve before illustrating the savings curve.

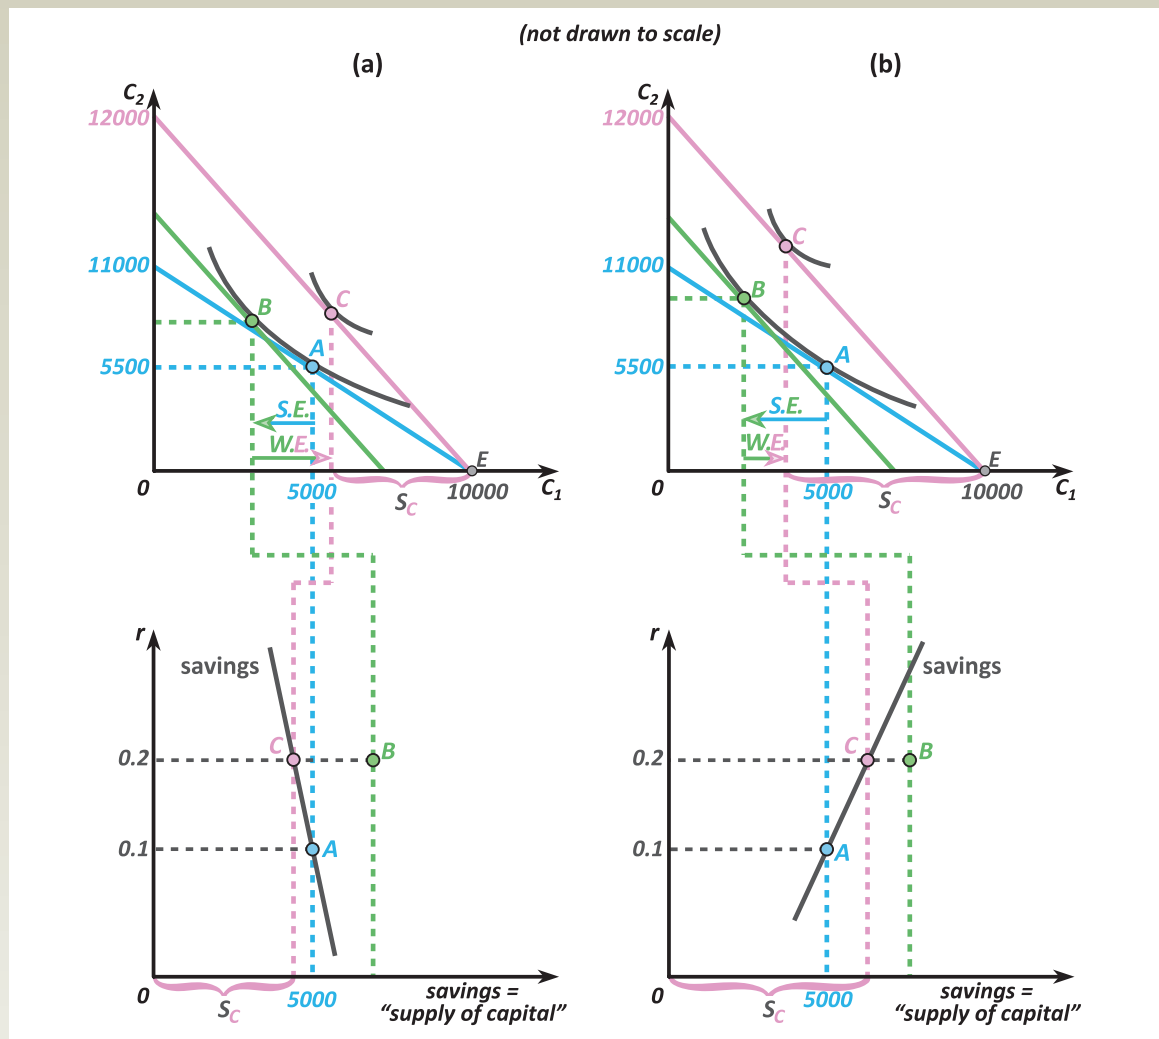

Next, suppose the interest rate rises to 20%. As in the previous chapter, the top graph in both panels of Graph 9.5 then illustrates the substitution effect to bundle *B*, an effect that causes you to consume less this summer (and thus to save more). When translated to the lower graphs, point *B* thus appears at the higher interest rate and to the right of point *A* where savings has increased. Notice that point *B* occurs at less than \$5,000 on the horizontal axis of the top graph because your consumption this summer has fallen, but it occurs at greater than \$5,000 in the lower graph because you are now saving more than \$5,000.

Finally, panels (a) and (b) of Graph 9.5 illustrate two differently sized wealth effects (while assuming that consumption in both summers is a normal good). In panel (a), the wealth effect on this summer’s consumption is larger than the substitution effect, thus causing bundle *C* to lie to the right of bundle *A* in the top graph, indicating that the increase in the interest rate causes you to consume more this summer. Since this implies less savings, point *C* on the lower panel of Graph 9.5a therefore falls to the left of point *A*, giving us a negative relationship between savings and the interest rate. Panel (b) of the graph, however, shows that a smaller wealth effect may lead to the opposite conclusion, with savings and the interest rate exhibiting a positive relationship. Once again, the underlying question is whether consumption this summer is relatively substitutable with consumption next summer, which would give rise to a large substitution effect and cause the positive interest rate/savings relationship in panel (b) of the graph. Alternatively, if consumption across the two time periods is relatively complementary, the substitution effect would be small, giving rise to the negative interest rate/savings relationship in panel (a) of Graph 9.5.

Saving supply curves can slope up or down depending on the size of the wealth effect relative to the substitution effect.

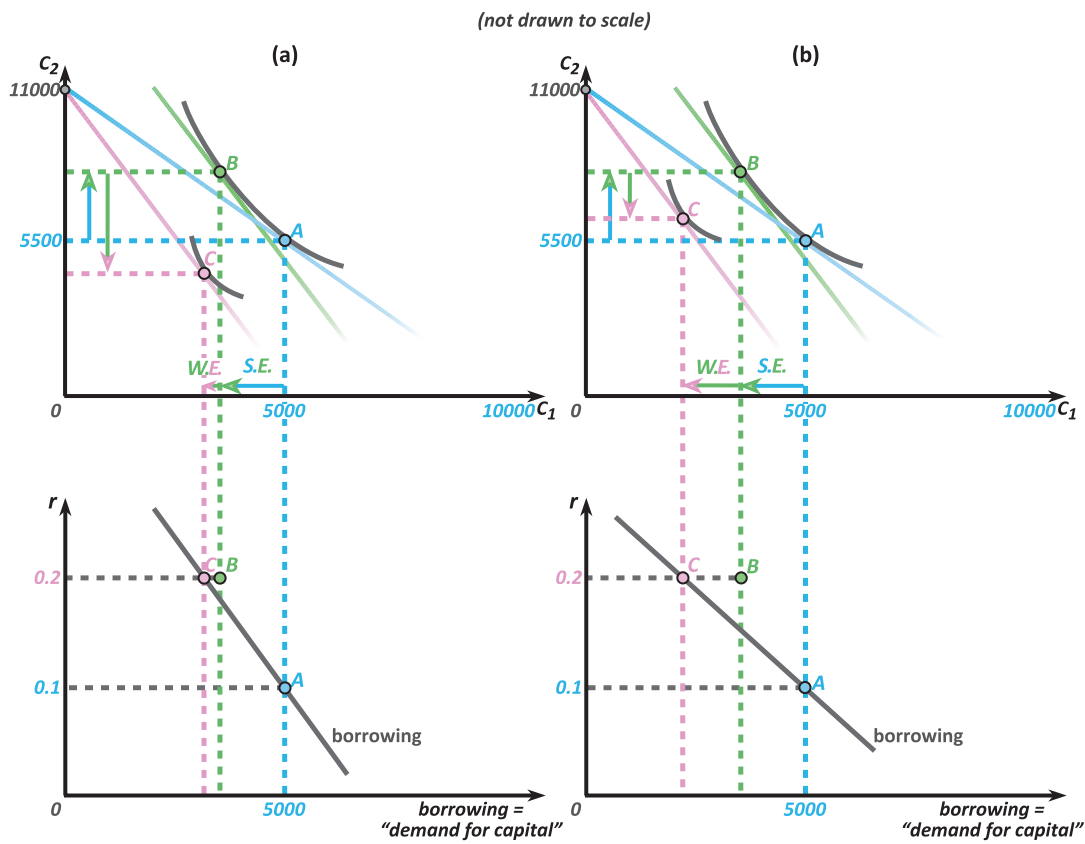

EXERCISE 9A.10 Would the interest rate/savings curve slope up or down if consumption during this period were an inferior good?

GRAPH 9.5 Supply Curves for Capital from Savers

9A.3.2 Borrowing and the “Demand for Capital” Just as “savings” is equivalent to “supplying capital” to the economy, “borrowing” is equivalent to “demanding capital.” When you borrow money to purchase a car or to finance your fancy trip to the Amazon, you are demanding capital that someone else is supplying. We can thus analyze how “borrowers” will respond to changes in the interest rate and thus how demand for capital changes with the interest rate.

Consider the case we have raised before where you expect to earn \$11,000 next summer and you need to decide how much of it to borrow against in order to finance your consumption this summer. Suppose again that you start out facing an annual interest rate of 10% and that, at that interest rate, you have decided it is optimal for you to borrow \$5,000 for consumption this summer. This is illustrated as bundle A in both panels of Graph 9.6, and this information is translated to a lower graph relating the interest rate to the amount of borrowing you undertake. Since in this case the amount that you borrow is equal to the amount that you consume this summer, we can simply translate horizontal quantities from the top graphs to horizontal quantities on the lower graphs.

GRAPH 9.6 Demand Curves for Capital from Borrowers

Demand for capital from borrowers is always downward sloping.

Next, suppose that the interest rate rises to 20%. As in the previous chapter, we can now draw two possible scenarios (under our maintained assumption that consumption is always a normal good regardless of when it occurs). Under the first scenario (in panel (a) of Graph 9.6), consumption next summer, on the vertical axis, declines because the wealth effect outweighs the substitution effect, while under the second scenario, consumption next summer rises because the substitution effect outweighs the wealth effect. In both cases, however, the wealth and substitution effects point in the same direction on the horizontal axis, thus indicating that you will unambiguously consume less this summer (and thus borrow less) as the interest rate rises. Therefore, the relationship between borrowing and the interest rate is negative regardless of which scenario you face; that is, regardless of how substitutable consumption is across the two time periods. The only impact of having greater substitutability built into the indifference curve that contains bundle A is that it will make the interest rate/borrowing curve in the lower panel shallower.

EXERCISE 9A.11 What kind of good would consumption this summer have to be in order for the interest rate/borrowing relationship to be positive in Graph 9.6?

9A.3.3 Switching between Borrowing and Saving In the previous two sections, we have considered the extreme cases when all your income falls either in this summer (Section 9A.3.1) or next summer (Section 9A.3.2). This has allowed us to definitively label you a “saver” or a “supplier of capital” in Section 9A.3.1 and a “borrower” or “demander of capital” in Section 9A.3.2. A more general case would be one in which you earn some income this summer and some next summer and you choose how much to save or borrow this summer knowing how much you will earn next summer.

Consider, for instance, the two budgets in Graph 9.7. The bundle E indicates the endowment bundle, with I_1 representing income this summer and I_2 representing income next summer. At the high interest rate, bundle S is optimal, indicating an optimal amount of saving of $(I_1 - c_1^S)$. At the low interest rate, on the other hand, bundle B is optimal, with an optimal amount of borrowing equal to $(c_1^B - I_1)$. In this case, then, the consumer will switch between borrowing and saving as the interest rate increases. This is indicated on the lower graph where the interest rate is plotted on the vertical axis, and the vertical axis is placed right underneath the endowment bundle E in the top graph. When the optimal bundle occurs to the right of bundle E in the top graph, the resulting borrowing is then plotted in the positive quadrant of the lower graph. When the optimal bundle occurs to the left of bundle E , on the other hand, the resulting savings (or negative borrowing) is plotted in the negative quadrant of the lower graph.

GRAPH 9.7 Switching from Borrowing to Saving as the Interest Rate Rises

EXERCISE 9A.12 Is it possible for someone to begin as a saver at low interest rates and switch to becoming a borrower as the interest rate rises?

EXERCISE 9A.13 The technique of placing the axis below the endowment point E developed in Graph 9.7 could also be applied to the previous two graphs, Graph 9.5 and Graph 9.6. How would those graphs change?

9B

DEMAND AND SUPPLY FUNCTIONS

In Section 9A, we have derived various demand and supply relationships graphically. We will now demonstrate that the “curves” we have graphed are in fact just special cases of more general demand and supply *functions*, cases where all but one of the variables of these functions are held fixed. In that sense, we can think of the curves we derived graphically as two-dimensional “slices” of multidimensional functions.

One peculiar feature of the way we have graphed demand and supply relationships should, however, be pointed out right up front and might already have occurred to you if you are mathematically inclined: Economists have gotten in the habit of graphing these relationships incorrectly, with the independent variable (like income or price) on the vertical axis (instead of the horizontal where it belongs) and the dependent variable (like the quantity demanded or supplied) on the horizontal (instead of the vertical where it belongs.) The number of Twinkies® I buy, for instance, may depend on my exogenous income, but my exogenous income is certainly *not* dependent on the number of Twinkies I buy. Or, in the case of own-price demand curves, the number of Twinkies I demand depends on the price of Twinkies, but the price of Twinkies in the grocery store does not depend on how many Twinkies I buy (given the grocery store barely knows of my individual existence). This would cause a mathematician to put income or price on the horizontal axis and the quantity demanded on the vertical axis, not the other way around as we have done in part A of the chapter. *When we are graphing demand curves with price on the vertical axis, we are therefore graphing the inverse of the demand functions we will be calculating mathematically.*

This tradition of graphing demand curves as *inverse* demand functions dates back to Alfred Marshall’s *Principles of Economics* published in 1890.⁴ It is only out of sheer habit that economists have never changed the way we graph these economic relationships as the discipline became more mathematical in the second half of the 20th century, and this will require us to be careful at certain stages when we map properties of demand functions into graphs from our intuitive treatment of the material. In particular, slopes that we calculate for demand *functions* will take on the inverse value in our graphs of demand *curves*, with a slope of $1/2$ becoming a slope of 2 , a slope of -3 becoming $-1/3$ and so forth. I had briefly contemplated writing this whole book with demand and supply curves graphed the way that mathematicians would, but, when I enthusiastically mentioned the idea to my wife (who has taken two economics classes in her whole life), she looked at me with genuine pity and told me to take a year’s sabbatical to recover my sanity. And, to be honest, I, too, am too brainwashed from years of graphing these curves as the profession has done. So I don’t think we’ll be able to single-handedly convince the discipline to change its habits, and we’ll therefore succumb to the weight of history and simply be careful as we translate math to graphs.

Demand curves are inverse slices of the more general demand function.

⁴In this regard, Marshall’s work stood in contrast to the influential work by Leon Walras (1834–1910), who graphed direct (as opposed to inverse) demand curves. Marshall’s treatment has, for better or worse, become the standard in economics.

Consider the function $f(x) = x/3$. Graph this as you usually would with x on the horizontal axis and $f(x)$ on the vertical. Then graph the inverse of the function, with $f(x)$ on the horizontal and x on the vertical.

**EXERCISE
9B.1**

Repeat the previous exercise for the function $f(x) = 10$.

**EXERCISE
9B.2**

9B.1 Demand for Goods and Services

In all the optimization problems that we have computed in the past few chapters, we always restricted ourselves to quite particular examples of tastes and economic circumstances in order to relate particular intuitive concepts to particular mathematical examples. In the process, however, we have set up a much more general approach that gives rise to all of the demand relationships we introduced in Section 9A, and we have already begun to use these in some of the end-of-chapter exercises in the previous chapters. We now move toward a more general specification of our optimization problem by letting the economic circumstances of the consumer be represented by simply I , p_1 , and p_2 —income, the price of good 1, and the price of good 2—without specifying exact values for these.

Suppose, for instance, that tastes can be represented by the Cobb–Douglas utility function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$. The consumer's utility maximization problem can then be written as

$$\max_{x_1, x_2} x_1^\alpha x_2^{(1-\alpha)} \quad \text{subject to } p_1 x_1 + p_2 x_2 = I, \quad (9.1)$$

with a corresponding Lagrange function

$$\mathcal{L}(x_1, x_2, \lambda) = x_1^\alpha x_2^{(1-\alpha)} + \lambda(I - p_1 x_1 - p_2 x_2). \quad (9.2)$$

The terms p_1 , p_2 , and I —the combination of variables that represents an individual's economic circumstances that he or she takes as given and has no control over—are then treated as simple parameters as we solve for the first order conditions, as is the term α which describes tastes that the person also cannot control. The first order conditions, or the first partial derivatives of \mathcal{L} with respect to x_1 , x_2 , and λ , can then be written as

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial x_1} &= \alpha x_1^{\alpha-1} x_2^{(1-\alpha)} - \lambda p_1 = 0, \\ \frac{\partial \mathcal{L}}{\partial x_2} &= (1 - \alpha) x_1^\alpha x_2^{-\alpha} - \lambda p_2 = 0, \\ \frac{\partial \mathcal{L}}{\partial \lambda} &= I - p_1 x_1 - p_2 x_2 = 0. \end{aligned} \quad (9.3)$$

Solving these in the usual way, we get that

$$x_1 = \frac{\alpha I}{p_1} \quad \text{and} \quad x_2 = \frac{(1 - \alpha) I}{p_2}. \quad (9.4)$$

These functions are called *demand functions* for tastes that can be represented by the Cobb–Douglas utility function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$. More generally, we can leave the functional form of the utility function unspecified, writing the optimization problem as

$$\max_{x_1, x_2} u(x_1, x_2) \quad \text{subject to } p_1 x_1 + p_2 x_2 = I. \quad (9.5)$$

Demand functions emerge from utility maximization.

Demand functions tell us how much a consumer will buy under all possible economic circumstances (p_1, p_2, I) .

Solving this, we would then get general expressions for the optimal values of x_1 and x_2 as simple functions of the consumer's economic circumstances; that is,

$$x_1 = x_1(p_1, p_2, I) \text{ and } x_2 = x_2(p_1, p_2, I). \quad (9.6)$$

9B.1.1 Income-Demand Relationships Income-demand curves such as those we derived graphically in Graph 9.1 are then simply (inverse) “slices” of the more general functions we derive mathematically. For instance, for the Cobb–Douglas utility function used to derive the demand functions in expression (9.4), we can now hold fixed the price terms and simply see how the function changes as income changes. Taking the first derivative of each of the two demand functions, we get

$$\frac{\partial x_1}{\partial I} = \frac{\alpha}{p_1} \text{ and } \frac{\partial x_2}{\partial I} = \frac{1 - \alpha}{p_2}, \quad (9.7)$$

and, since both $0 < \alpha < 1$ and the price terms are positive, we know immediately that, for the underlying Cobb–Douglas tastes, the income-demand relationship for each of the two goods is positive. Furthermore, holding prices fixed, this relationship is constant, implying income-demand curves that are straight lines with positive slope (and zero intercept). Put differently, the second partial derivative of each income-demand function with respect to income is zero, implying no change in the slope.

To map these into the income-demand *curves* from part A of the chapter, we begin by solving the demand functions in expression (9.4) for I to get

$$I_1 = \frac{p_1 x_1}{\alpha} \text{ and } I_2 = \frac{p_2 x_2}{(1 - \alpha)} \quad (9.8)$$

and note that the partial derivatives with respect to x_1 and x_2 are

$$\frac{\partial I_1}{\partial x_1} = \frac{p_1}{\alpha} \text{ and } \frac{\partial I_2}{\partial x_2} = \frac{p_2}{(1 - \alpha)}. \quad (9.9)$$

These slopes of our income-demand *curves* are then the inverse of the slopes of the demand functions in expression (9.7).

For instance, suppose that prices are equal to $p_1 = 1$ and $p_2 = 1$, and suppose that $\alpha = 0.75$. Then the slope of the income-demand curve for x_1 is $4/3$ while the slope of the income-demand curve for x_2 is 4. When $p_1 = 1/2$ and $p_2 = 1/2$, on the other hand, the slopes of the two income-demand curves are $2/3$ and 2, and when $p_1 = 1/4$ and $p_2 = 1/4$, the slopes become $1/3$ and 1. Thus, for each set of prices, we get a different “slice” of the inverse demand function that becomes an income-demand curve for that particular set of prices. Graphs 9.8a and 9.8b then graph these different income-demand curves for the two goods.

The fact that the income-demand curves for Cobb–Douglas tastes have positive slope should not be surprising. After all, we know from the previous chapters that such tastes represent tastes for normal goods, and normal goods are defined as goods that consumers consume more of as income rises. Beyond that, the fact that the income-demand curves in Graph 9.8 depend only on the price of one good is a special case that arises from the Cobb–Douglas specification of tastes. Other types of tastes will have the property (indicated in the functions in expression (9.6)) that demand for each good depends on the prices of both goods.

EXERCISE 9B.3*

Another special case of tastes that we have emphasized throughout is the case of quasilinear tastes. Consider, for instance, the utility function $u(x_1, x_2) = 100(\ln x_1) + x_2$. Calculate the demand function for x_1 and derive some sample income-demand curves for different prices.

GRAPH 9.8 Income-Demand Curves when $u(x_1, x_2) = x_1^{0.75}x_2^{0.25}$ 

9B.1.2 Own-Price Demand Relationships The own-price demand curves of the kind derived in Graph 9.2 are similarly just inverse slices of the more general demand functions in expression (9.6). This time, however, we are interested in the relationship between the quantity demanded and that good's price (rather than the quantity demanded and income). The slices of the inverse demand functions that we graph when we graph own-price demand curves then take the form

$$p_1 = p_1(x_1, p_2, I) \quad \text{and} \quad p_2 = p_2(x_2, p_1, I), \quad (9.10)$$

which simply involves solving the demand functions for prices. In the case of the Cobb–Douglas demand functions from expression (9.4), these are

$$p_1 = \frac{\alpha I}{x_1} \quad \text{and} \quad p_2 = \frac{(1 - \alpha) I}{x_2}. \quad (9.11)$$

The demand *curves* are then simply slices of these inverse demand functions that hold income and the price of the other good fixed. In the special case of Cobb–Douglas tastes, however, each good's demand is independent of the other good's price, so we only have to hold income fixed as we graph the demand curves. This is done in Graph 9.9a for x_1 and in Graph 9.9b for x_2 for three different income levels. Note that for relatively standard tastes such as those represented by Cobb–Douglas utility functions, these demand curves tend to have relatively nonlinear shapes. This gives us some sense of what is lost when we simply derive such demand curves graphically by estimating them from just two points (as we did in Graph 9.2). Note also that, in each of the panels of Graph 9.9, the demand curve shifts out as income increases. Put differently, holding p_1 fixed, the quantity demanded increases as income rises, implying once again that the tastes are such that each good is a normal good (as we know is the case for Cobb–Douglas tastes). Were one of the underlying goods an inferior good, the demand curve for that good would shift inward as income goes up. And, when tastes are quasilinear in one of the goods, then the demand curve for that good would be unchanged as income rises since such a good would be borderline normal/inferior.

GRAPH 9.9 Own-Price Demand Curves when $u(x_1, x_2) = x_1^{0.75}x_2^{0.25}$

The derivatives of the demand functions (from expression (9.4)) with respect to own prices are then

$$\frac{\partial x_1}{\partial p_1} = -\frac{\alpha I}{p_1^2} \quad \text{and} \quad \frac{\partial x_2}{\partial p_2} = -\frac{(1-\alpha)I}{p_2^2}, \quad (9.12)$$

and the derivatives of the *inverse* demand functions (in expression (9.11)) with respect to quantities are

$$\frac{\partial p_1}{\partial x_1} = -\frac{\alpha I}{x_1^2} \quad \text{and} \quad \frac{\partial p_2}{\partial x_2} = -\frac{(1-\alpha)I}{x_2^2}. \quad (9.13)$$

Suppose, for instance, that $\alpha = 0.75$ (as it is in the graphs), that $I = 100$, and that $p_1 = p_2 = 1$. The first equation in expression (9.12) then tells us that, when $p_1 = 1$, the slope of the demand function as p_1 changes is $-\alpha I/p_1^2 = -75$. The demand function $x_1 = \alpha I/p_1$ also tells us that $x_1 = 75$ when $p_1 = 1$. Plugging $x_1 = 75$ into the first equation in (9.13) then gives us the slope of the demand *curve* as $-\alpha I/x_1^2 = -1/75$, which is the inverse of what we got from taking the derivative of the demand *function*. More generally, the same steps allow us to write

$$\frac{\partial p_1}{\partial x_1} = -\frac{\alpha I}{x_1^2} = -\frac{\alpha I}{(\alpha I/p_1)^2} = -\frac{p_1^2}{\alpha I} = \left(\frac{\partial x_1}{\partial p_1}\right)^{-1}, \quad (9.14)$$

where we use the fact that $x_1 = \alpha I/p_1$ (from equation (9.4)) in the middle of the expression. Once again, our demand *curves* that treat quantities as if they were the independent variable have slopes at every point that are inverses of the slopes of the corresponding slices of the demand *functions* that treat price as the independent variable.

EXERCISE
9B.4

Can you derive the same result for x_2 ?

As in exercise 9B.3, consider again tastes that can be represented by the utility function $u(x_1, x_2) = 100(\ln x_1 + x_2)$. Using the demand function for x_1 that you derived in the previous exercise, plot the own-price demand curve when income is 100 and when $p_2 = 1$. Then plot the demand curve again when income rises to 200. Keep in mind that you are actually plotting inverse functions as you are doing this.

EXERCISE
9B.5

Knowing that own-price demand curves are inverse slices of own-price demand functions, how would the lower panels of Graph 9.2 look if you graphed slices of the actual functions (rather than the inverses); that is, when you put price on the horizontal and the quantities of goods on the vertical axis?

EXERCISE
9B.6

9B.1.3 Cross-Price Demand Relationships Finally, we noted in Section 9A.1.3 that the quantity demanded of one good often depends not only on that good's own price but also on the price(s) of other goods. For this reason, the general version of our demand functions in expression (9.6) includes both prices as arguments of the function, with $x_1 = x_1(p_1, p_2, I)$ and $x_2 = x_2(p_1, p_2, I)$. Yet another way of "slicing" inverses of these functions then results in what we called "cross-price demand curves" in Section 9A.1.3, curves that illustrate, for a given income and own price, how the quantity demanded varies with changes in the price of a different good.

Cobb–Douglas tastes represent once again a special case in which the demand functions are *not* functions of any prices other than the good's own price. In expression (9.4), we derived those functions as $x_1 = \alpha I/p_1$ and $x_2 = (1 - \alpha)I/p_2$. The partial derivatives of these functions with respect to the other price (i.e., $\partial x_1/\partial p_2$ and $\partial x_2/\partial p_1$) are zero, indicating a zero slope. A slope of zero then becomes a slope of ∞ when we reverse the axes to put price on the vertical axis; that is, we get cross-price demand curves that are perfectly vertical lines.

For a given taste parameter α and a given income I and own-price p_1 , the demand for good x_1 is therefore constant. Take, for example, the case when $\alpha = 0.75$, $I = 100$, and $p_1 = 1$. Plugging these values into the demand function for x_1 , we get that $x_1 = 75$. Similarly, if the price of good x_1 is 3, we get $x_1 = 25$, and if $p_1 = 5$, then $x_1 = 15$. The resulting cross-price demand curves are simply vertical lines at these respective quantities, as illustrated in Graph 9.10a. Similarly, you could derive vertical cross-price demand curves for different levels of income.

What would the slices of the demand function (rather than the inverse slices in Graph 9.10a) look like?

EXERCISE
9B.7

The reason for this shape of cross-price demand curves in the Cobb–Douglas case lies in the fact that income and substitution effects are exactly offsetting. In Graph 9.3 of Section 9A.1.3, we illustrated a cross-price demand curve for quasilinear tastes, tastes in which the income effect was zero and thus only the substitution effect operated. This substitution effect implied that, whenever p_2 decreases, a consumer would tend to consume more of x_2 and less of x_1 , which, in the absence of an income effect, gives rise to the positive slope of the cross-price demand curve. For Cobb–Douglas tastes, however, x_1 is a normal good, implying a positive income effect on x_1 consumption from a decrease in the price of x_2 . For a normal good, bundle C in Graph 9.3 would then lie to the right of bundle B (and possibly to the right of bundle A), and our analysis of Cobb–Douglas demand functions tells us that it would lie exactly above A when tastes can be represented by Cobb–Douglas utility functions.

Recall from our discussion of tastes in Chapter 5, however, that Cobb–Douglas tastes are a special case of a more general class of constant elasticity of substitution (CES) tastes, a case in which that elasticity of substitution is equal to 1. The elasticity of substitution determines the

GRAPH 9.10 Cross Price-Demand Curves for CES Utility with Different Elasticities of Substitution

size of the substitution effect, which implies that, as that elasticity decreases, the substitution effect will fall and will thus be more than offset by the income effect. Similarly, it should be the case that, when the elasticity of substitution is greater than 1, the size of the substitution effect increases and will thus no longer be offset by the income effect.

We can check this intuition by calculating the demand functions for the more general class of CES utility functions $u(x_1, x_2) = (\alpha x_1^{-\rho} + (1 - \alpha)x_2^{-\rho})^{-1/\rho}$, where (as noted in Chapter 5) the elasticity of substitution is equal to $1/(1 + \rho)$. Solving the maximization problem in expression (9.5) using this utility function (and slugging through some algebra), we get that

$$x_1 = \frac{\alpha^{1/(1+\rho)} I}{(\alpha^{1/(1+\rho)} p_1) + ((1 - \alpha) p_1 p_2^\rho)^{1/(1+\rho)}} \quad \text{and} \quad (9.15)$$

$$x_2 = \frac{(1 - \alpha)^{1/(1+\rho)} I}{((1 - \alpha)^{1/(1+\rho)} p_2) + (\alpha p_1^\rho p_2)^{1/(1+\rho)}}.$$

EXERCISE 9B.8** Verify that these are in fact the right demand functions for tastes represented by the CES utility function.

Notice that when $\rho = 0$, these functions collapse down to those in expression (9.4) because when $\rho = 0$, CES utility functions are Cobb–Douglas. We can then graph different (inverse) cross-price demand slices of this function by fixing all parameters and variables other than p_2 . Suppose, for instance, we set $\alpha = 0.75$, $p_1 = 3$, and $I = 100$. Graph 9.10b then graphs the resulting function for x_1 as it varies with p_2 for three different values of ρ (0.5, 0, and -0.5) corresponding to the elasticities of substitution of 0.67, 1, and 2. The middle (blue) curve represents the Cobb–Douglas tastes graphed in panel (a) of Graph 9.10. Notice that an elasticity of substitution below that of Cobb–Douglas tastes leads to a downward-sloping cross-price demand curve, while an elasticity greater than that of Cobb–Douglas tastes leads to an upward slope. You could

confirm this by showing that $\partial x_1/\partial p_2 < 0$ when $\rho > 0$ and $\partial x_1/\partial p_2 > 0$ when $\rho < 0$ (recalling again how this translates to inverse slopes). This confirms our intuition that the greater the elasticity of substitution, the larger will be the substitution effect that suggests a positive cross-price relationship. Cobb–Douglas tastes with an elasticity of substitution of 1 represent the boundary case where this substitution effect is just large enough to exactly offset the income effect.

In Graph 9.3, we intuitively concluded that cross-price demand curves slope up when tastes are quasi-linear. Verify this for tastes that can be represented by the utility function $u(x_1, x_2) = 100(\ln x_1) + x_2$ for which you derived the demand functions in exercise 9B.3. Draw the cross-price demand curve for x_1 when income is 2,000 and $p_1 = 5$.

EXERCISE
9B.9

Suppose that income was 500 instead of 2,000 in exercise 9B.9. Determine at what point the optimization problem results in a corner solution (by calculating the demand function for x_2 and seeing when it becomes negative). Illustrate how this would change the cross-price demand curve you drew in exercise 9B.9. (*Hint:* The change occurs in the cross-price demand curve at $p_2 = 5$.)

EXERCISE
9B.10

9B.2 Labor Supply⁵

As in the case of demand relationships in goods markets, we have already developed the basic technique of deriving labor supply curves of the kind drawn in Graph 9.4. The relevant budget constraint now arises from the fact that the amount spent on consumption c has to be equal to the value of the labor sold by the individual at the market wage w . Given that the individual starts with some particular leisure endowment L , the “hours spent working” is equivalent to “the hours *not* spent leisuring,” or $(L - \ell)$. Thus, along the budget constraint, $c = w(L - \ell)$, or written differently,

$$wL = c + w\ell. \quad (9.16)$$

When written in this form, the budget constraint most closely resembles the form we are used to seeing in the goods market, with wL being equal to the wealth endowment (rather than exogenous income), the price of the “ c ” good equal to 1, and the price (or opportunity cost) of leisure equal to w . The general form of the utility maximization problem that gives rise to labor supply can then be written as

$$\max_{c, \ell} u(c, \ell) \text{ subject to } wL = c + w\ell. \quad (9.17)$$

The solutions to this maximization problem are then of the form

$$\ell = \ell(w, L) \text{ and } c = c(w, L), \quad (9.18)$$

with both the optimal amount of leisure and the optimal amount of consumption a function of the wage rate and the leisure endowment.⁶

Once we have derived the function that tells us, for any wage w and leisure endowment L , the amount of leisure an individual will choose, we are one small step from having derived the labor supply functions. This is because the quantity of labor supplied is simply equal to the quantity of the leisure endowment that is not consumed as leisure, or $(L - \ell)$. Using the

Labor supply emerges from a utility maximization problem in which consumers choose consumption and leisure.

⁵Students who did not read Chapters 3 and 8 should skip this and the next section.

⁶Implicitly, of course, these functions are also a function of the price of consumption, but since that is simply equal to 1 given that we defined consumption as “a dollar’s worth of consumption,” it does not formally enter into the previous equations. Were one to use a price for consumption that can vary, then this price would become an argument in the functions in expression (9.18) and would appear in front of the c term in expression (9.17).

equation for optimal leisure consumption in expression (9.18), we can thus simply write the labor supply function as

$$l(w, L) = L - \ell(w, L). \quad (9.19)$$

Now, when we hold the leisure endowment fixed, this labor supply function becomes simply a “slice” of the more general function, a slice in which labor supply is a function of only the wage rate and can thus be represented in a two-dimensional graph as a labor supply curve (when we take its inverse). Notice how the mathematics behind this exactly mirrors the graphical derivation in Graph 9.4. First, holding L fixed at 60, we graphically maximized utility over the budget constraint between consumption and leisure. Then, in order to translate our findings into points on labor supply curves, we subtracted the optimal leisure level from the fixed leisure endowment to plot the labor supply on the lower graphs.

EXERCISE 9B.11 What function is graphed in the middle portion of each panel of Graph 9.4? What function is graphed in the bottom portion of each panel of Graph 9.4?

As in the section on consumer demand, we can again see how specific tastes now translate into labor supply functions. First, consider tastes that are quasilinear in leisure and can be represented by the utility function $u(c, \ell) = c + \alpha \ln \ell$. Solving the maximization problem defined in expression (9.17) for these tastes, we get

$$\ell = \frac{\alpha}{w} \text{ and } c = wL - \alpha, \quad (9.20)$$

with the resulting labor supply function equal to

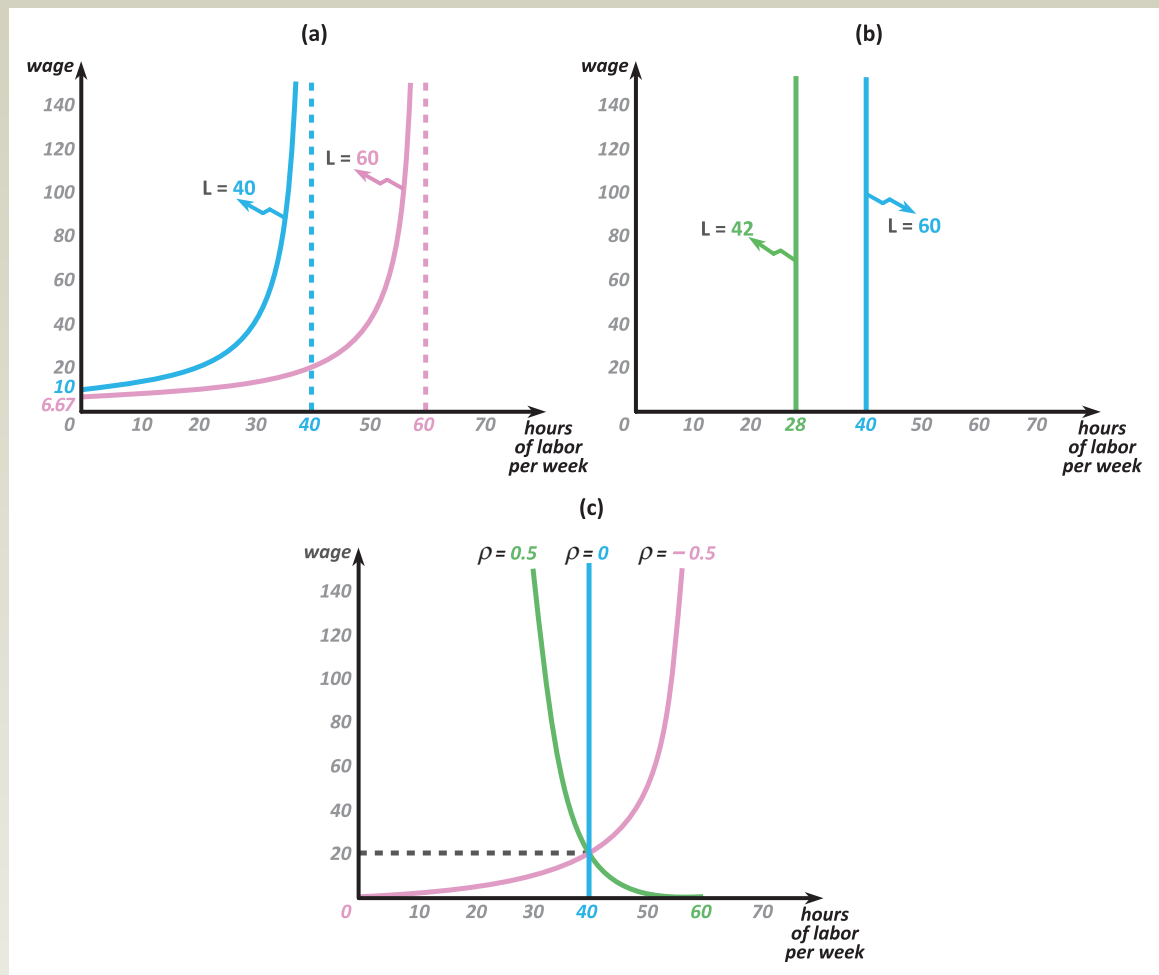

$$l(w, L) = L - \frac{\alpha}{w}. \quad (9.21)$$

EXERCISE 9B.12 Verify these results.

Suppose, for instance, that we hold L fixed at 60 hours per week, as we did in Section 9A.2, and suppose tastes are such that $\alpha = 400$. Then the labor supply function becomes $l(w) = 60 - (400/w)$, the inverse of which is graphed as a labor supply curve in Graph 9.11a (and is labeled “ $L = 60$ ” indicating we have assumed a leisure endowment of 60). Similarly, a second labor supply curve corresponding to a leisure endowment of 40 hours per week is graphed for comparison. (In each case, the labor supply curve asymptotically approaches the leisure endowment as the wage approaches infinity.)

The fact that labor supply is upward sloping for tastes that are quasilinear in leisure should not surprise us given the intuition regarding substitution and wealth effects we built in Section 9A.2. We know that the substitution effect will always suggest that an individual will work more as the wage rises because leisure has become relatively more expensive. When tastes are quasilinear in leisure, we also know that there is no counteracting wealth effect. Thus, the substitution effect is the only effect on the leisure axis, causing consumption of leisure to decline, and work hours to increase, as wage goes up.

GRAPH 9.11 Labor Supply with Tastes that Are (a) Quasilinear, (b) Cobb–Douglas, and (c) CES

Next, consider Cobb–Douglas tastes that can be represented by the utility function $u(c, \ell) = c^\alpha \ell^{(1-\alpha)}$. Solving the maximization problem in expression (9.17) for this utility function, we get that

$$\ell = (1 - \alpha)L \text{ and } c = \alpha wL, \tag{9.22}$$

with the resulting labor supply function equal to

$$l(w, L) = L - (1 - \alpha)L = \alpha L. \tag{9.23}$$

Thus, in this special Cobb–Douglas case, the labor supply function in fact does *not* depend on the wage, which implies that the labor supply curves are vertical lines (because $\partial l / \partial w = 0$) with substitution and wealth effects exactly offsetting one another. For instance, suppose that

$\alpha = 2/3$ and the leisure endowment L is equal to 60 hours per week. Then weekly labor supply is 40 hours regardless of the wage rate. Similarly, if the leisure endowment were 42 hours instead of 60, the number of hours of labor supplied per week would be 28 regardless of the wage. These different labor supply curves are depicted in Graph 9.11b.

Finally, consider the more general constant elasticity of substitution (CES) utility specification $u(c, \ell) = (\alpha c^{-\rho} + (1 - \alpha)\ell^{-\rho})^{-1/\rho}$. Solving the maximization problem in expression (9.17) with this utility function, and doing some tedious algebra, we get

$$\ell = \frac{L(1 - \alpha)^{1/(\rho+1)}}{(\alpha w^{-\rho})^{1/(\rho+1)} + (1 - \alpha)^{1/(\rho+1)}} \quad (9.24)$$

with corresponding labor supply function

$$l(w, L) = L - \frac{L(1 - \alpha)^{1/(\rho+1)}}{(\alpha w^{-\rho})^{1/(\rho+1)} + (1 - \alpha)^{1/(\rho+1)}}. \quad (9.25)$$

EXERCISE 9B.13**

Verify this leisure demand and labor supply function for the CES function that is given.

From our work in Chapter 5, we know that the elasticity of substitution, and thus the size of the substitution effect, is decreasing in the parameter ρ . More specifically, as ρ approaches -1 , indifference curves approach those of perfect substitutes; when $\rho = 0$, the tastes are Cobb–Douglas; and as ρ approaches positive infinity, indifference curves approach those of perfect complements. From equation (9.23), we also know that substitution and wealth effects are exactly offsetting on the leisure dimension when tastes are Cobb–Douglas, that is, when $\rho = 0$. This suggests that when $\rho > 0$, the wealth effect will outweigh the substitution effect and will thus result in a negatively sloped labor supply curve, while the opposite holds when $\rho < 0$.

Suppose, for instance, that the weekly leisure endowment L is again set to 60. Graph 9.11c then plots the labor supply curves for different levels of ρ , in each case setting α equal to the level required in order to make the optimal labor supply at a wage of 20 equal to 40 hours per week. (This is done so that the resulting labor supply curves have a common labor supply at $w = 20$.)⁷ Our intuition regarding the relative sizes of substitution and wealth effects is then confirmed, with tastes that exhibit a high level of substitutability between leisure and consumption ($\rho < 0$) generating substitution effects that outweigh wealth effects, and tastes that exhibit low substitutability between leisure and consumption generating substitution effects that are outweighed by wealth effects. You can formally check that this holds by taking the partial derivative of expression (9.25) and showing that $\partial l / \partial w < 0$ when $\rho > 0$ and that $\partial l / \partial w > 0$ when $\rho < 0$.

9B.3 Demand for and Supply of Financial Capital

Finally, we can show again that the supply and demand curves for financial capital, or the demand curves for savings and borrowing, we derived in Section 9A.3 are simply (inverse) slices of more general functions that arise from general intertemporal optimization problems. In Chapters 3 and 8, we already demonstrated that two-period versions of intertemporal budget constraints can be written as

$$(1 + r)c_1 + c_2 = (1 + r)e_1 + e_2, \quad (9.26)$$

⁷The resulting values of α are 0.24025 when $\rho = -0.5$, $2/3$ when $\rho = 0$, and 0.9267 when $\rho = 0.5$.

where e_1 and e_2 represent period 1 and 2 endowments (or income), r represents the relevant interest rate over the intervening period, and c_1 and c_2 represent consumption in the two periods. A consumer thus faces the optimization problem

$$\max_{c_1, c_2} u(c_1, c_2) \quad \text{subject to} \quad (1+r)c_1 + c_2 = (1+r)e_1 + e_2. \quad (9.27)$$

Solving this, we get general demand functions for c_1 and c_2 of the form

$$c_1 = c_1(r, e_1, e_2) \quad \text{and} \quad c_2 = c_2(r, e_1, e_2). \quad (9.28)$$

These functions tell us, for any set of economic circumstances faced by the consumer, how much he or she will consume this period and next period. Subtracting $c_1(r, e_1, e_2)$ from e_1 furthermore gives us the difference in period 1 consumption and period 1 income, or the amount of savings the consumer will choose to undertake under different economic circumstances. Thus, we can calculate the savings supply function

$$s(r, e_1, e_2) = e_1 - c_1(r, e_1, e_2). \quad (9.29)$$

When $s(r, e_1, e_2) > 0$, the consumer chooses to save this period (or supply financial capital), whereas when $s(r, e_1, e_2) < 0$, he or she chooses to borrow (or demand financial capital). A consumer will, of course, switch between saving and borrowing depending on the economic circumstances he or she faces. As we already showed intuitively in Section 9A.3, the consumer will save if $e_1 > 0$ and $e_2 = 0$ (Section 9A.3.1); he or she will borrow if $e_1 = 0$ and $e_2 > 0$ (Section 9A.3.2); and he or she may switch between borrowing and saving as the interest rate changes when $e_1 > 0$ and $e_2 > 0$ (Section 9A.3.3).

Solving the optimization problem in expression (9.27) for Cobb–Douglas tastes represented by the utility function $u(c_1, c_2) = c_1^\alpha c_2^{(1-\alpha)}$, for instance, we get

$$\begin{aligned} c_1(r, e_1, e_2) &= \alpha \left(\frac{(1+r)e_1 + e_2}{(1+r)} \right) \quad \text{and} \\ c_2(r, e_1, e_2) &= (1-\alpha)((1+r)e_1 + e_2), \end{aligned} \quad (9.30)$$

with a resulting savings function of

$$s(r, e_1, e_2) = e_1 - \alpha \left(\frac{(1+r)e_1 + e_2}{(1+r)} \right). \quad (9.31)$$

Verify that these three equations are correct.

EXERCISE 9B.14

9B.3.1 Saving and the “Supply of Capital” Suppose, then, that we return to the example of you earning \$10,000 this summer and expecting to earn nothing next summer as you cruise through the Amazon. Suppose further that you place equal value on consumption in both summers, with $\alpha = 0.5$. Then our savings function (9.31) simply becomes

$$s(r) = 5,000. \quad (9.32)$$

Put differently, your savings are independent of the interest rate in the Cobb–Douglas case, leading to a vertical relationship between savings and the interest rate (when the interest rate appears on the vertical axis and savings appears on the horizontal). We know from our intuitive analysis in Section 9A.3.1 that the substitution effect suggests that savings will increase with the interest rate, and that the wealth effect suggests the opposite (when consumption in period 1 is a normal good as it is under Cobb–Douglas tastes). Thus, the substitution and wealth effects are exactly offsetting for these tastes.

Capital demand (from borrowers) and supply (from savers) emerge from the intertemporal utility maximization problem.

Once again, then, the key to whether the relationship between savings and the interest rate is positive or negative lies in the relative weights of substitution and wealth effects. Thus, as consumption in periods 1 and 2 becomes more substitutable, leading to a greater substitution effect, the relationship becomes positive, whereas when consumption across the periods becomes more complementary, leading to a smaller substitution effect, the relationship becomes negative.

EXERCISE 9B.15** Consider the more general CES utility function $u(c_1, c_2) = (0.5c_1^{-\rho} + 0.5c_2^{-\rho})^{-1/\rho}$ and solve for the savings supply function when you earn \$10,000 this period and nothing in the future. Then verify that you obtain the vertical relationship between savings and the interest rate when $\rho = 0$ and determine how this slope changes when $\rho > 0$ (implying relatively low elasticity of substitution) and when $\rho < 0$ (implying relatively high elasticity of substitution).

9B.3.2 Borrowing and the “Demand for Capital” Similarly, we can consider the case in which all your income is earned next summer, with any consumption this summer financed through borrowing against next summer’s earnings. Again, suppose that your tastes are Cobb–Douglas with $\alpha = 0.5$, and suppose further that your earnings next summer will be \$11,000. We can then again use expression (9.31) to determine your savings this summer by simply plugging in $e_1 = 0$ and $e_2 = 11,000$ to get

$$s(r) = -\frac{5,500}{(1+r)}. \quad (9.33)$$

Since your income this summer is zero, you will (as we already concluded in Section 9A.3.2) naturally have to borrow in order to consume this summer, and the amount that you will borrow (unlike the amount that you saved in the previous example) will depend on the interest rate. In particular, note that $\partial s/\partial r > 0$, which means that your negative savings become smaller as the interest rate rises. Alternatively, we could phrase your behavior in terms of borrowing (instead of negative saving), in which case we would consider the negative of the savings function in expression (9.33). The partial derivative of that (negative savings) function with respect to the interest rate would be negative, implying that borrowing declines as the interest rate rises. These conclusions are once again consistent with our intuition from Section 9A.3.2 in which we demonstrated that the impact of both the substitution and the wealth effect causes the borrower to lower his or her borrowing as the interest rate rises.

EXERCISE 9B.16** Using the CES utility function from exercise 9B.15, verify that the negative relationship between borrowing and the interest rate arises regardless of the value that ρ takes (whenever $e_1 = 0$ and $e_2 > 0$).

9B.3.3 Switching between Borrowing and Saving We concluded Section 9A.3 with an example in which a consumer earns income in both periods and chooses to borrow or save depending on the interest rate. This type of savings function is also implicitly possible in our mathematical setup whenever e_1 and e_2 are both positive. In the Cobb–Douglas case, for instance, suppose that $e_1 = 4,600$ and $e_2 = 5,400$, and suppose again that $\alpha = 0.5$. Plugging these values into the savings function (9.31), we get

$$s(r) = 2,300 - \frac{2,700}{(1+r)}, \quad (9.34)$$

which is -400 at an interest rate of 0% but has positive slope ($\partial s/\partial r = 2700/(1+r)^2$) and becomes positive at an interest rate of 17.39%.

Graph this function in a graph similar to Graph 9.7 (which is the graph of an inverse borrowing (rather than saving) function).

EXERCISE
9B.17

CONCLUSION

Having investigated in detail what it means for individuals to “do the best they can given their circumstances,” or to “optimize subject to constraints,” this chapter took the next step of summarizing the results of such optimizing behavior in various demand relationships. This has allowed us to derive mathematically such concepts as consumer demand functions and labor supply functions, and it has enabled us to derive intuitively the graphical relationships known as demand and supply curves. These curves hold fixed all aspects of a consumer’s economic circumstances except one and then plot the relationship between the remaining variable and the quantity of a good demanded (or the quantity of labor supplied). In that sense, demand (and supply) curves are really just (inverse) “slices” (that hold a number of variables fixed) of multidimensional demand (and supply) functions (that allow all aspects of economic circumstances to vary).

In most undergraduate textbooks, demand curves are then treated as if they tell us something beyond what we have discussed thus far. In particular, it is often claimed that demand curves tell us not only how the quantity demanded of a particular good changes as some economic variable (like price) changes but also that these can be used to measure consumer welfare through notions such as consumer surplus. In the next chapter, we will see to what extent this claim is true and in the process will derive a more general way of thinking about consumer welfare. As it turns out, the claim is true only for one special case of tastes and not for the more general class of tastes that we have treated throughout. This will become important as we think more about policies in upcoming chapters.

END-OF-CHAPTER EXERCISES

9.1[†] The following are intended to explore what kinds of income-demand relationships are logically possible.

- A.** For each of the following, indicate whether the relationship is possible or not and explain:
- A good is a necessity and has a positive income-demand relationship.
 - A good is a necessity and has a negative income-demand relationship.
 - A good is a luxury and has a negative income-demand relationship.
 - A good is quasilinear and has a negative income-demand relationship.
 - Tastes are homothetic and one of the goods has a negative income-demand relationship.
- B.** Derive the income-demand relationships for each good for the following tastes:
- $u(x_1, x_2, x_3) = x_1^\alpha x_2^\beta x_3^{(1-\alpha-\beta)}$ where α and β lie between zero and 1 and sum to less than 1.
 - $u(x_1, x_2) = \alpha \ln x_1 + x_2$. (*Note:* To specify fully the income-demand relationship in this case, you need to watch out for corner solutions.) Graph the income-demand curves for x_1 and x_2 , carefully labeling slopes and intercepts.

9.2 The following are intended to explore what kinds of own-price demand relationships are logically possible in a two-good model with exogenous income (unless otherwise specified).

- A.** For each of the following, indicate whether the relationship is possible or not and explain:
- Tastes are homothetic and the own-price demand relationship is positive.
 - A good is inferior and its own-price relationship is negative.

*conceptually challenging

**computationally challenging

[†]Solutions in Study Guide

- c. In a model with endogenous income, a good is normal and its own-price demand relationship is negative.
- d. In a model with endogenous income, a good is normal and its own-price demand relationship is positive.
- B.** Suppose that tastes can be represented by the Cobb–Douglas utility function $u(x_1, x_2) = x_1^\alpha x_2^{1-\alpha}$.
- Derive the demand functions when income is exogenous and illustrate that own-price demand curves slope down.
 - Now suppose that all income is derived from an endowment (e_1, e_2) . If $e_2 = 0$, what is the shape of the own-price demand curve for x_1 ?
 - Continuing with part (b), what is the shape of the own-price demand curve for x_1 when $e_2 > 0$?
 - Suppose tastes were instead represented by the more general CES utility function. Without doing any additional math, can you guess what would have to be true about ρ in order for the own-price demand for x_1 to slope up when $e_1 > 0$ and $e_2 = 0$?
- 9.3[†]** The following are intended to explore what kinds of cross-price demand relationships are logically possible in a two-good model with exogenous income.
- A.** For each of the following, indicate whether the relationship is possible or not and explain:
- A good is normal and its cross-price demand relationship is positive.
 - A good is normal and its cross-price relationship is negative.
 - A good is inferior and its cross-price relationship is negative.
 - Tastes are homothetic and one of the good's cross-price relationship is negative.
 - Tastes are homothetic and one of the good's cross-price relationship is positive.
- B.** Now consider specific tastes represented by particular utility functions.
- Suppose tastes are represented by the function $u(x_1, x_2) = \alpha \ln x_1 + x_2$. What is the shape of the cross-price demand curves for x_1 and x_2 ?
 - Suppose instead tastes are Cobb–Douglas. What do cross-price demand curves look like?
 - Now suppose tastes can be represented by a CES utility function. Without doing any math, can you determine for what values of ρ the cross-price demand relationship is upward sloping?
 - ** Suppose tastes can be represented by the CES function $u(x_1, x_2) = (0.5x_1^{-\rho} + 0.5x_2^{-\rho})^{-1/\rho}$. Verify your intuitive answer from part (c).
- 9.4** In Graph 9.4, we illustrated how you can derive the labor supply curve from a consumer model in which workers choose between leisure and consumption.
- A.** In end-of-chapter exercise 3.1 you were asked to illustrate a budget constraint with labor rather than leisure on the horizontal axis. Do so again, assuming that the most you can work per week is 60 hours.
- Now add to this graph an indifference curve that would make working 40 hours per week optimal.
 - Beginning with the graph you have just drawn, illustrate the same wealth and substitution effects as drawn in the top panel of Graph 9.4a for an increase in the wage.
 - Then, on a second graph right below it, put weekly labor hours on the horizontal axis and wage on the vertical, and derive the labor supply curve directly from your work in the previous graph. Compare the resulting graph with the lowest panel in Graph 9.4a.
 - Repeat this for the case where wealth and substitution effects look as they do in Graph 9.4b.
 - Repeat this again for the case in Graph 9.4c.
 - True or False:* We can model the choices of workers either using our five standard assumptions about tastes defined over leisure and consumption, or we can model these choices using tastes defined over labor and consumption. Either way, we get the same answers so long as we let go of the monotonicity assumption in the latter type of model.
- B.** Now suppose that a worker's tastes over consumption and leisure can be defined by the utility function $u(c, \ell) = c^\alpha \ell^{1-\alpha}$ (and again assume that the worker has a leisure endowment of 60 hours per week).

- Derive the labor supply function by first deriving the leisure demand function.
- How would you define a utility function over consumption and *labor* (rather than consumption and *leisure*) such that the underlying tastes would be the same?
- Which of our usual assumptions about tastes do not hold for tastes represented by the utility function you have just derived?
- Using the utility function you have just given, illustrate that you can derive the same labor supply curve as before by making labor (rather than leisure) a choice variable in the optimization problem.

9.5[†] Everyday Application: Backward-Bending Labor Supply Curve: We have suggested in this chapter that labor economists believe that labor supply curves typically slope up when wages are low and down when wages are high. This is sometimes referred to as a *backward-bending labor supply curve*.

- Which of the following statements is inconsistent with the empirical finding of a backward-bending labor supply curve?
 - For the typical worker, leisure is an inferior good when wages are low and a normal good when wages are high.
 - For the typical worker, leisure is a normal good when wages are low and an inferior good when wages are high.
 - For the typical worker, leisure is always a normal good.
 - For the typical worker, leisure is always an inferior good.
- Suppose that tastes over consumption and leisure are described by a constant elasticity of substitution utility function $u(c, \ell) = (0.5c^{-\rho} + 0.5\ell^{-\rho})^{-1/\rho}$.
 - Derive the labor supply curve assuming a leisure endowment L .
 - ** Illustrate for which values of ρ this curve is upward sloping and for which it is downward sloping.
 - Is it possible for the backward-bending labor supply curve to emerge from tastes captured by a CES utility function?
 - For practical purposes, we typically only have to worry about modeling tastes accurately at the margin; that is, around the current bundles that consumers/workers are consuming. This is because low-wage workers, for instance, may experience some increases in wages but not so much that they are suddenly high-wage workers, and vice versa. If you were modeling worker behavior for a group of workers and you modeled each worker's tastes as CES over leisure and consumption, how would you assume ρ differs for low-wage and high-wage workers (assuming you are persuaded of the empirical validity of the backward-bending labor supply curve)?

9.6 Business Application: Price Discounts, Substitutes, and Complements: A business might worry that pricing of one product might impact demand for another product that is also sold by the same business. Here, we'll explore conditions under which such worries are more or less important before turning to some specific examples.

- Suppose first that we label the two goods that a firm sells as simply x_1 and x_2 . The firm considers putting a discount of δ on the price of x_1 , a discount that would lower the price from p_1 to $(1 - \delta)p_1$.
 - For a consumer who budgets I for consumption of x_1 and x_2 , illustrate the budget before and after the discount is put in place.
 - Assuming that tastes are homothetic, derive the relationship between δ on the vertical axis and x_1 on the horizontal axis.
 - Now derive the relationship between δ and x_2 ; can you tell if it slopes up or down? What does your answer depend on?
 - Suppose that x_1 is printers and x_2 is printer cartridges produced by the same company. Compare this to the case where x_1 is Diet Coke and x_2 is Zero Coke. In which case is there a more compelling case for discounts on x_1 ?

EVERYDAY
APPLICATION

BUSINESS
APPLICATION

- B. Suppose that tastes are defined by $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$.
- Derive the demand functions for x_1 and x_2 as a function of prices, I and δ .
 - Are these upward or downward sloping in δ ?
 - Under the more general specification of tastes as CES, that is, $u(x_1, x_2) = (\alpha x_1^{-\rho} + (1 - \alpha)x_2^{-\rho})^{-1/\rho}$, how would your answer change as ρ changes?

9.7[†] Business Application: Good Apples versus Bad Apples: People are often amazed at the quality of produce that is available in markets far away from where that produce is grown and that it is often the case that the average quality of produce is *higher* the farther the place is from where the produce originates. Here we will try to explain this as the result of producers' awareness of relative demand differences resulting from substitution effects.

- A. Suppose you own an apple orchard that produces two types of apples: high-quality apples x_1 and low-quality apples x_2 . The market price for a pound of high-quality apples is higher than that for a pound of low-quality apples, that is, $p_1 > p_2$. You sell some of your apples locally and you ship the rest to be sold in a different market. It costs you an amount c per pound of apples to get apples to that market.
- Begin with a graph of a consumer who chooses between high- and low-quality apples in the local store in your town. Illustrate the consumer's budget and optimal choice.
 - The only way you are willing to ship apples to a far-away market is if you can get as much for those apples as you can get in your town, which means you will add the per-pound transportation cost c to the price you charge for your apples. How will the slope of the budget constraint for the far-away consumer differ from that for your local consumer, and what does that imply for the opportunity cost of good apples in terms of bad apples?
 - Apples represent a relatively small expenditure category for most consumers, which means that income effects are probably very small. In light of that, you may assume that the amount of income devoted to apple consumption is always an amount that gets the consumer to the same indifference curve in the "slice" of tastes that holds all goods other than x_1 and x_2 fixed. Can you determine where consumer demand for high-quality apples is likely to be larger: in the home market or in the far-away market?
 - Explain how, in the presence of transportation costs, one would generally expect the phenomenon of finding a larger share of high-quality products in markets that are far from the production source than in markets that are close.
- B. Suppose that we model our consumers' tastes as $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$.
- What has to be true about α in order for x_1 to be the good apples?
 - Letting consumer income devoted to apple consumption be given by I , derive the consumer's demand for good and bad apples as a function of p_1 , p_2 , I , and c . (Recall that c is the per-pound transportation cost that is added to the price of apples.)
 - What is the ratio of demand for x_1 over x_2 ?
 - Can you tell from this in which market there will be greater relative demand for good versus bad apples: the local market or the far-away market?
 - In part A, we held the consumer's indifference curve in the graph fixed and argued that it is reasonable to approximate the consumer's behavior this way given that apple expenditures are typically a small fraction of a consumer's budget. Can you explain how what you just did in part B is different? Is it necessarily the case that consumers in far-away places will consume more high-quality apples than consumers (with the same tastes) in local markets? Can we still conclude that far-away markets will have a higher *fraction* of high-quality apples?

9.8* Policy Application: Tax and Retirement Policy: In Chapter 3, we illustrated budgets in which a consumer faced trade-offs between working and leisuring now as well as between consuming now and consuming in the future. We can use a model of this kind to think about tax and retirement policy.

- A. Suppose period 1 represents the period over which a worker is productive in the labor force and period 2 represents the period during which the worker expects to be retired. The worker earns a wage w and has L hours of leisure time that could be devoted to work l or leisure consumption ℓ . Earnings this period can be consumed as current consumption c_1 or saved for retirement consumption c_2 at an interest rate r . Suppose throughout that consumption in both periods is a normal good, as is leisure this period.

- a. Illustrate this worker's budget constraint in a three-dimensional graph with c_1 , c_2 , and ℓ on the axes.
 - b. For certain types of tastes (as for those used in part B of this question), the optimal labor decision does not vary with the wage or the interest rate in this problem. Suppose this implies that taking ℓ^* in leisure is always optimal for this worker. Illustrate how this puts the worker's decision on a slice of the three-dimensional budget you graphed in part (a).
 - c. Assume that optimal choices always occur on the two-dimensional slice you have identified. Illustrate how you could derive a demand curve for c_1 , that is, a curve that shows the relationship between c_1 on the horizontal axis and the interest rate r on the vertical. Does this curve slope up or down? What does your answer depend on?
 - d. Can you derive a similar economic relationship except this time with w rather than r on the vertical axis? Can you be certain about whether this relationship is upward sloping (given that consumption in both periods is a normal good)?
 - e. Suppose that the government introduces a program that raises taxes on wages and uses the revenues to subsidize savings. Indicate first how each part of this policy—the tax on wages and the subsidy for savings (which raises the effective interest rate)—impacts current and retirement consumption.
 - f. Suppose the tax revenue is exactly enough to pay for the subsidy. Without drawing any further graphs, what do you think will happen to current and retirement consumption?
 - g. There are two ways that programs such as this can be structured: Method 1 puts the tax revenues collected from the individual into a personal savings account that is used to finance the savings subsidy when the worker retires; Method 2 uses current tax revenues to support current retirees and then uses tax revenues from future workers to subsidize current workers when they retire. (The latter is often referred to as pay-as-you-go financing.) By simply knowing what happens to current and retirement consumption of workers under such programs, can you speculate what will happen to overall savings under Method 1 and Method 2 (given that tax revenues become savings under Method 1 but not under Method 2)?
- B.** Suppose the worker's tastes can be summarized by the utility function $u(c_1, c_2, \ell) = (c_1^\alpha \ell^{1-\alpha})^\beta c_2^{1-\beta}$.
- a. Set up the budget equation that takes into account the trade-offs this worker faces between consuming and leisuring now as well as between consuming now and consuming in the future.
 - b. Set up this worker's optimization problem and solve for the optimal consumption levels in each period as well as the optimal leisure consumption this period. (Using the natural log transformation of the utility function will make this algebraically easier to solve.)
 - c. In part A, we assumed that the worker would choose the same amount of work effort regardless of the wage and interest rate. Is this true for the tastes used in this part of the exercise?
 - d. How does consumption before retirement change with w and r ? Can you make sense of this in light of your graphical answers in part A?
 - e. In A(e), we described a policy that imposes a tax t on wages and a subsidy s on savings. Suppose that the tax lowers the wage retained by the worker to $(1 - t)w$ and the subsidy raises the effective interest rate for the worker to $(r + s)$. Without necessarily redoing the optimization problem, how will the equations for the optimal levels of c_1 , c_2 , and ℓ change under such a policy?
 - f. Are the effects of t and s individually as you concluded in A(e)?
 - g. For a given t , how much tax revenue does the government raise? For a given s , how much of a cost does the government incur? What do your answers imply about the relationship between s and t if the revenues raised now are exactly offset by the expenditures incurred next period (taking into account that the revenues can earn interest until they need to be spent)?
 - h. Can you now verify your conclusion from A(f)?
 - i. What happens to the size of personal savings that the individual worker puts away under this policy? If we consider the tax revenue the government collects on behalf of the worker (which will be returned in the form of the savings subsidy when the worker retires), what happens to the worker's overall savings—his or her personal savings plus the forced savings from the tax?
 - j. How would your answer about the increase in actual overall savings change if the government, instead of actually saving the tax revenue on behalf of the worker, were simply to spend current tax revenues on current retirees? (This, as mentioned in part A, is sometimes referred to as a pay-as-you-go policy.)

9.9*[†] Policy Application: *Demand for Charities and Tax Deductibility:* One of the ways in which government policy supports a variety of activities in the economy is to make contributions to those activities tax deductible. For instance, suppose you pay a marginal income tax rate t and that a fraction δ of your contributions to charity are tax deductible. Then if you give \$1 to a charity, you do not have to pay income tax on δ and thus you end up paying δt less in taxes. Giving \$1 to charity therefore does not cost you \$1, it only costs you $\$(1 - \delta t)$.

- A.** In the remainder of the problem, we will refer to $\delta = 0$ as “no deductibility” and $\delta = 1$ as “full deductibility.” Assume throughout that giving to charity is a normal good.
- How much does it cost you to give \$1 to charity under no deductibility? How much does it cost under full deductibility?
 - On a graph with “dollars given to charity” on the horizontal and “dollars spent on other consumption” on the vertical, illustrate a taxpayer’s budget constraint (assuming the taxpayer pays a tax rate t on all income) under no deductibility and under full deductibility.
 - On a separate graph, derive the relationship between δ (ranging from zero to 1 on the vertical) and charitable giving (on the horizontal).
 - Next, suppose that charitable giving is fully deductible and illustrate how the consumer’s budget changes as t increases. Can you tell whether charitable giving increases or decreases as the tax rate rises?
 - Suppose that an empirical economist reports the following finding: “Increasing tax deductibility raises charitable giving, and charitable giving under full deductibility remains unchanged as the tax rate changes.” Can such behavior emerge from a rationally optimizing individual?
 - Shortly after assuming office, President Barack Obama proposed repealing the 2001 tax cuts implemented by President George W. Bush, thus raising the top income tax rate to 39.6%, back to the level it was under President Bill Clinton in the 1990s. At the same time, Obama made the controversial proposal only to allow deductions for charitable giving as if the marginal tax rate were 28%. For someone who pays the top marginal income tax under the Obama proposal, what does the proposal imply for δ ? What about for someone paying a marginal tax rate of 33% or someone paying a marginal tax rate of 28%?
 - Would you predict that the Obama proposal would reduce charitable giving?
 - Defenders of the Obama proposal point out the following: After President Ronald Reagan’s 1986 Tax Reform, the top marginal income tax rate was 28%, implying that it would cost high earners 72 cents for every dollar they contribute to charity, just as it would under the Obama proposal. If that was good enough under Reagan, it should be good enough now. In what sense is the comparison right, and in what sense is it misleading?
- B.** Now suppose that a taxpayer has Cobb–Douglas tastes over charitable giving (x_1) and other consumption (x_2).
- Derive the taxpayer’s demand for charitable giving as a function of income I , the degree of tax deductibility δ , and the tax rate t .
 - Is this taxpayer’s behavior consistent with the empirical finding by the economist in part A(e) of the question?

CHAPTER
10

Consumer Surplus and Deadweight Loss

Economists and policy makers may want to know whether particular policies make people better off or worse off, but sometimes they also need to quantify *how much* better off or worse off different consumers are.¹ At first glance, this may seem an impossible task given what we have said in Chapter 4 about the inherent impossibility of measuring happiness or satisfaction in an objective way. It turns out, however, that the tools we have developed will allow us to measure consumer welfare in objective terms without us having to measure happiness directly. Rather, we will find ways of quantifying how much better off or worse off consumers are in different economic circumstances by asking how much they are willing to pay to avoid particular circumstances or how much compensation would be required to make it up to them when circumstances change.

This way of thinking about welfare effects from institutional or policy changes allows us then to address the following question: Is it at least in principle possible to compensate those who lose from the policy with part of the gains accruing to those who gain from the policy? If the answer is yes, then, at least in principle, there is a way to make some people better off without making anyone worse off, which we will say enhances *efficiency*. If the answer is no, on the other hand, then we know that the new situation will be less *efficient*. Put differently, if the winners from a policy gain more than the losers lose, the policy could *in principle* be accompanied by a compensation scheme that would result in unanimous approval of the policy!

Of course, just because it is *in principle* possible to come up with such a compensation scheme does not mean it is possible *in practice*. Real-world policies come, at best, with imperfect compensation schemes, and thus, they rarely enjoy unanimous approval. As a result, it is not immediately obvious that we should in fact favor all policies that create more benefits than costs because in some instances we may in fact place more weight on the decline in welfare of those who lose than on the gains in welfare of those who win. For instance, suppose a group of wealthy citizens would be willing to pay \$100 million to have a certain policy implemented, and a group of poor citizens would lose \$1 million as a result. If we can't figure out a way to accompany this policy with compensation to those who would otherwise lose, we might decide that the policy is not worth it, that we in essence place more weight on the \$1 million loss than on the \$100 million gain because the loss would be borne by the most vulnerable among us.

Before we can even begin to think about such trade-offs, however, we need to be able to quantify gains and losses, which is what we will do for the rest of this chapter. The issue of whether it is

If the winners from a policy gain enough to compensate the losers, such a policy is efficiency enhancing.

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

¹Chapters 2, 4 through 7, and the first sections (Sections 9A.1 and 9B.1) in 9 are required reading for this chapter. Chapters 3 and 8 as well as the remainder of Chapter 9 (i.e., Sections 9A.2, 9A.3, 9B.2, and 9B.3) are not necessary for this chapter.

enough for us to know that overall gains outweigh losses, or whether the distribution of gains and losses should matter, is one that arises in various parts of the book and is dealt with most explicitly in Chapter 29.

10A

MEASURING CONSUMER WELFARE IN DOLLARS

We will begin our analysis of this measurement of consumer welfare by quantifying how much better off or worse off consumers are for being able to purchase goods voluntarily at given market prices. Put differently, we will ask how much better off a consumer is for being able to participate in a market rather than be excluded from it. This will lead us to define terms like *marginal* and *total willingness to pay* as well as *consumer surplus*. We will then proceed to demonstrate how policy makers might analyze the impact of particular proposals on consumers when those proposals change the relative prices in an economy. In the process, we will see once again the importance of recognizing the difference between income and substitution effects and how the substitution effect contributes to *deadweight losses* for society while the income effect does not.

10A.1 Consumer Surplus

Let us return to our example of my choices over gasoline and a composite good denominated in dollars. In Graph 10.1, we begin with a particular set of economic circumstances: my choice set determined by the price of gasoline and my current (exogenous) income. My optimal choice *A* then falls on the indifference curve that is tangent to my choice set (assuming I am not at a corner solution).

EXERCISE
10A.1

As a way to review material from previous chapters, can you identify assumptions on tastes that are sufficient for me to know for sure that my indifference curve will be tangent to the budget line at the optimum?

Now let's ask the following question: How much better off am I for being able to purchase gasoline at its current price rather than being excluded from the market for gasoline? Or, to be more precise, how much would I be willing to pay for the opportunity to participate in the current market for gasoline?

10A.1.1 Marginal Willingness to Pay To formulate an answer to this question, we could simply look at each gallon of gasoline that I consume and ask how much I would have been willing to pay for that gallon given that I ended up at my optimal bundle *A*. For the first gallon, I can measure this willingness to pay by finding the slope of my indifference curve—the marginal rate of substitution—at 1 gallon. Suppose that this slope is -20 . This tells me that I was willing to trade \$20 worth of other consumption for the first gallon of gasoline. We can then proceed to the second gallon and find the marginal rate of substitution at 2 gallons. Suppose that it is -19 . This tells me that I would have been willing to give up \$19 of other consumption to get the *second* gallon of gasoline. We could keep doing this for each gallon of gasoline, with the marginal rate of substitution at bundle *A* being equal to the price of gasoline. At the end of this exercise, we will have identified my *marginal willingness to pay (MWTP)* for each of the gallons of gasoline I consumed and all the additional gallons that I chose not to consume. In the lower panel of Graph 10.1, we simply plot gallons of gasoline on the horizontal axis and dollars on the vertical. The *marginal willingness to pay curve* for a consumer who ends up on the indifference curve containing bundle *A* is then simply plotted by plotting the dollar values of the *MRS* at each gallon of gasoline.

A MWTP curve is derived from the marginal rates of substitution of the indifference curve on which an actual choice is made.

10A.1.2 Marginal Willingness to Pay Curves and Substitution Effects There is, however, a slightly different way of deriving marginal willingness to pay curves that builds more directly on material we have covered in the previous chapters and is similar to the way we derived

GRAPH 10.1 Deriving $MWTP$ from MRS of Indifference Curve Containing Bundle A 

Go to MindTap to interact with this graph.

own-price demand curves in Chapter 9. The top panel of Graph 10.2 begins with the same initial budget and optimal bundle A as we started with in Graph 10.1. Instead of directly identifying the marginal rates of substitution on the indifference curve that contains bundle A , however, we now imagine a price increase from p to p' and then illustrate the compensated budget as we have done in previous chapters to get bundle B and the substitution effect. In Chapter 9, we then illustrated the final bundle C either to the right or left of B depending on whether the good on the horizontal axis is normal or inferior. Here, we are assuming that gasoline is a normal good and thus place bundle C to the left of B . In Chapter 9, we then plotted the own-price demand curve on a lower panel by bringing points A and C down to a graph with price (denominated in dollars) on the vertical and gasoline on the horizontal axis. We simply ignored a similarly derived point B in the lower graph as unimportant for purposes of drawing own-price demand curves.

Now, however, we will focus on bundles A and B rather than bundles A and C . Specifically, in the lower panel of Graph 10.2, we illustrate the quantity consumed at bundle A at the original price p and the quantity consumed at bundle B at the new price p' (when I receive compensation

GRAPH 10.2 Deriving MWTP from Compensated Budgets

Go to MindTap to interact with this graph.

Every MWTP curve is equivalent to a compensated demand curve.

to make me as well off as I was originally). But notice that all we are doing is plotting the slope of the indifference curve that contains bundle A at two different quantities, just as we did in Graph 10.1. We could imagine doing this for many different price changes, each time finding the corresponding compensated budget and the new optimal bundle on that compensated budget. In doing so, we would end up plotting the marginal rates of substitution at the different quantities, leaving us with the same marginal willingness to pay curve as in the lower panel of Graph 10.1. For this reason, the marginal willingness to pay curve is often referred to as the *compensated demand curve* whereas the regular demand curve is sometimes referred to as the *uncompensated demand curve*.²

In Chapter 9, we translated bundle B to the lower graphs but said little more about it. At the time we were concerned with plotting own-price demand curves that connect points A and C,

²The uncompensated demand curve is also known as the *Marshallian demand* after Alfred Marshall, and the compensated demand curve is also known as the *Hicksian demand* after John Hicks.

and we merely indicated that point B would come in useful later on. Now it has just become useful—it has given us a way to graph the marginal willingness to pay curve and a way to compare it to the own-price demand curve. It is also now clear that the two curves are generally not the same because point C is usually different from point B since it (unlike point B) incorporates both the income and the substitution effect. The only time when the own-price demand curve and the marginal willingness to pay curve are the same is when there are no income effects with respect to the good whose demand curve we are drawing, and that is true only for tastes that are quasilinear in that good.

Own-price demand curves and $MWTP$ curves overlap for quasilinear goods.

Demonstrate that own-price demand curves are the same as marginal willingness to pay curves for goods that can be represented by quasilinear tastes.

EXERCISE
10A.2

Using the graphs in Graph 9.2 of the previous chapter, determine under what condition own-price demand curves are steeper and under what conditions they are shallower than marginal willingness to pay curves.

EXERCISE
10A.3

What does the $MWTP$ or compensated demand curve look like if the two goods are perfect complements?

EXERCISE
10A.4

Finally, you should note that, since compensated demand curves only include substitution (and not income) effects, and since the direction of the substitution effect is always unambiguously away from the good that has become more expensive, *compensated demand (or $MWTP$) curves must be downward sloping*. This is at least in principle not true for own-price demand curves that might slope upward when income effects are sufficiently large and in the opposite direction of substitution effects for Giffen goods. (However, as we acknowledged when we introduced Giffen goods in Chapter 7, such circumstances are rare and therefore own-price demand curves rarely actually slope up.)

$MWTP$ curves slope down because they only incorporate substitution effects.

10A.1.3 Total Willingness to Pay and Consumer Surplus We began Section 10A.1 by asking how much I might be willing to pay for the opportunity to be able to purchase gasoline at the market price rather than not being able to get access to the gasoline market. The answer can now be read off the marginal willingness to pay curve we have just derived once we have identified two further concepts in the marginal willingness to pay graph. First, we need to identify my *total willingness to pay* for *all* of the gasoline I am purchasing in the market, and second we need to subtract from this the amount that I actually *had to* pay in the market. The difference between these two amounts is how much better off I am for being able to participate in this market—how much more I would have been willing to pay than I actually had to pay.

Graph 10.3 replicates the marginal willingness to pay curve we just derived, illustrating my marginal willingness to pay for each of the gallons of gasoline that I am consuming (and for each of the gallons that I am not consuming), given that I end up consuming at bundle A when I face the market price p . My total willingness to pay is equal to my marginal willingness to pay for the first gallon plus my marginal willingness to pay for the second gallon, and so on, which is roughly equal to the area below the marginal willingness to pay curve (i.e., the green and blue areas together). My total willingness to pay is therefore the area under the marginal willingness to pay curve up to the quantity that I consume.

Total willingness to pay is an area under the $MWTP$ curve.

The amount I *actually* had to pay is simply equal to the price per gallon of gasoline times the number of gallons I chose to consume, which is equal to the shaded (green) rectangle (in Graph 10.3) formed by the vertical distance equal to price and the horizontal distance equal to the number of gallons of gasoline consumed.

Finally, *consumer surplus*, the difference between what I was willing to pay for my gasoline consumption and what I actually paid, is the difference between the two areas we have identified

GRAPH 10.3 MWTP, TWTP, and Consumer Surplus

(or the shaded blue area). This is how much better off I am for being able to participate in the gasoline market and therefore the most I would be willing to pay to get access to a market where gasoline sells at p per gallon.

10A.2 MWTP and Own-Price Demand Curves

Consumer surplus is properly measured along own-price demand curves only when tastes over the good are quasilinear.

If you have taken an economics course in the past, chances are that you encountered a graph similar to Graph 10.3. However, you probably graphed consumer surplus along own-price (uncompensated) demand curves, not along the marginal willingness to pay (or compensated demand) curves we just learned to derive.³ As it turns out, it is correct to use the own-price demand curve to find consumer surplus only in one specific case: when tastes are quasilinear. In all other cases, consumer surplus as we have defined it cannot be identified on own-price demand curves, and policy analysis that uses such curves to identify changes in consumer surplus can give very misleading and incorrect answers. In this section, we will explore in more detail the relationship between demand curves and marginal willingness to pay curves.

10A.2.1 Many MWTP and Demand Curves for Any Individual In Section 10A.1, we showed how we can derive a marginal willingness to pay curve assuming that the consumer currently consumes a particular bundle associated with a particular indifference curve. The curves that we derived in Graphs 10.1 and 10.2 are then labeled $MWTP^A$, with the superscript A indicating that the curve was derived from the indifference curve that contains bundle A . We had picked this as the indifference curve that was relevant for the exercise of deriving $MWTP$ in our

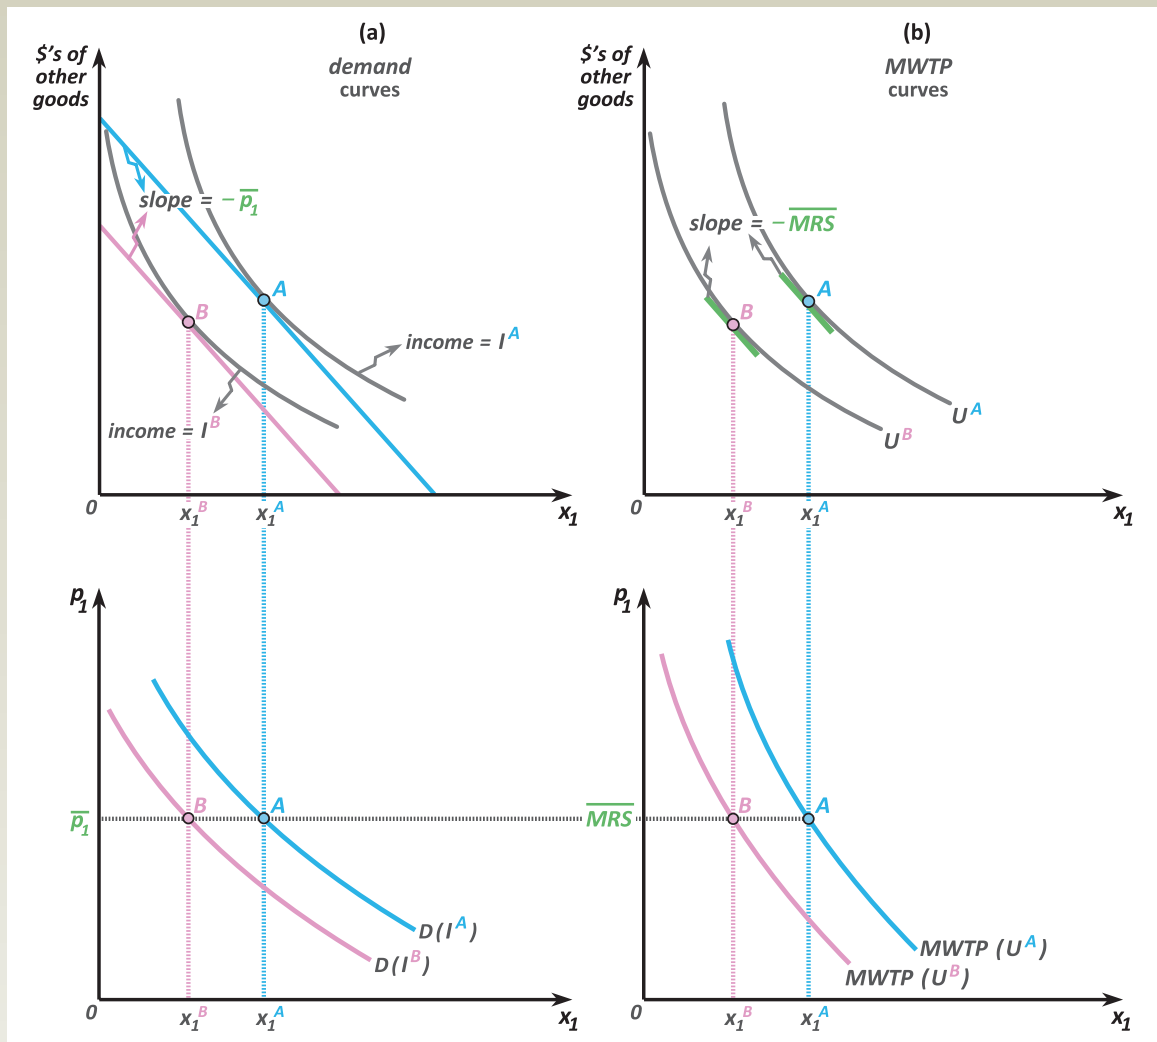

³When measured along the (uncompensated) own-price demand curve, this area is sometimes called *Marshallian Consumer Surplus*. Many texts in fact still define consumer surplus in this way and then separately develop measures of welfare changes along uncompensated (or Hicksian) demand curves. We are attempting to be more consistent here by always measuring welfare along compensated curves and behavior along uncompensated curves.

example because the consumer was assumed to be consuming at A . Of course, had the consumer been consuming at some other bundle, we would have used a different indifference curve to derive $MWTP$ and thus would have derived a curve different from $MWTP^A$.

In fact, there generally exists a different $MWTP$ curve for each indifference curve. This is quite analogous to the case of own-price demand curves. When we derive an own-price demand curve, we hold income fixed, just as when we derive $MWTP$ curves we hold the indifference curve (or “utility”) fixed. If income changes, own-price demand curves shift, just as $MWTP$ curves shift if utility changes.

Consider, for instance, Graph 10.4. In the top panels of parts (a) and (b), we illustrate the same bundles A and B with the same indifference curves. On the left, we indicate two income levels at which A and B are optimal bundles, and on the lower panel of Graph 10.4a we illustrate how these two bundles translate to two points on different (uncompensated) demand curves, one for the higher level of income and one for the lower level. Notice that we are implicitly assuming that x_1 is a normal good, with consumption falling when income falls. Of course we are simply

GRAPH 10.4 Multiple Demand Curves (for Different Incomes) and Multiple $MWTP$ Curves (for Different Utility Levels)

guessing what the rest of the demand curves look like and would have to change the price of x_1 in the top graph to derive the rest of the demand curves formally.

EXERCISE 10A.5

How would Graph 10.4a change if x_1 were an inferior rather than a normal good?

MWTP curves shift as utility changes just as demand curves shift when income changes.

On part (b) of Graph 10.4, we use points *A* and *B* in the top graph to plot the *MWTP*, or the negative *MRS*, at two different consumption levels. Since the *MRS* is the same at bundle *A* and *B* in the top graph, the derived points on the lower graph happen at the same height. As in the case of the (uncompensated) demand curves in Graph 10.4a, we then simply guess the shape of the rest of the *MWTP* curves but could formally derive these using either of the methods developed (in Graphs 10.1 and 10.2) in the previous section. The lower part of panel (b) therefore demonstrates shifts in the *MWTP* curve as utility changes, just as the lower portion of panel (a) demonstrates shifts in the own-price demand curve as income changes.

EXERCISE 10A.6

How would Graph 10.4b change if x_1 were an inferior rather than a normal good?

10A.2.2 Relating Demand Curves to *MWTP* Curves To understand how the own-price demand curves we derived in Chapter 9 relate to *MWTP* curves introduced in this chapter, it is useful to relate them to one another on the same graph. Consider, for instance, our example of my consumption of gasoline. In Graph 10.2, we assumed that I currently consumed bundle *A* when the price of gasoline is p (and when the price of “\$’s of other goods” is simply 1). We then derived the *MWTP* curve by simply illustrating how my consumption behavior would change when the price of gasoline rises to p' and when I am compensated enough to remain just as happy as I was originally.

Graph 10.2 is then replicated in the top panel of Graph 10.5a. In addition, bundle *C*, the bundle I actually consume when facing a price increase to p' in the absence of any compensation, is plotted and translated to the lower graph exactly as we would do when deriving my own-price demand curve. This then allows us to plot the demand curve and the *MWTP* curve on the same graph. The demand curve is the one that is relevant for my *income* level at bundle *A*, and the *MWTP* curve is relevant for the *utility* level I attain at bundle *A*. The *MWTP* curve, however, only incorporates the substitution effect, while the demand curve incorporates both income and substitution effects. Because we are assuming that gasoline is a normal good, the demand curve ends up shallower than the *MWTP* curve (i.e., *C* lies to the left of *B*).

Panel (b) of Graph 10.5 then repeats the exercise for a good x_1 that is assumed to be quasilinear, a good that is borderline between normal and inferior and one where my consumption behavior (with respect to x_1) therefore does not exhibit an income effect. Since the only difference between own-price demand and *MWTP* curves arises from income effects, the disappearance of the income effect then causes the two curves to be identical. *MWTP and (uncompensated) demand curves are thus the same if and only if the tastes for the good we are modeling are quasilinear.* Consequently, the only time the demand curve measures consumer surplus correctly arises when tastes are quasilinear.

Demand curves are shallower than *MWTP* curves when goods are normal and steeper when goods are inferior.

EXERCISE 10A.7

On the lower panel of Graph 10.5b, where does the *MWTP* curve corresponding to the indifference curve that contains bundle *C* lie?

EXERCISE 10A.8

How do the upper and lower panels of Graph 10.5a change when gasoline is an inferior good?

GRAPH 10.5 Relationship of Demand and MWTP Curves

10A.3 What's So Bad about Taxes? Or, Why Is the Bucket Leaking?

Governments use taxes to raise revenues that in turn fund expenditures on a variety of government programs. These programs may have enormous benefits, but, to the extent that they are funded through taxes, they come at an economic cost that economists refer to as the *deadweight loss from taxation*. Often, students think that pointing this out makes all economists raving anarchists, that being an economist means being against all taxes and all government expenditures that are funded through taxes. But recognizing an economic cost of taxation does not mean that one has to oppose all taxes any more than recognizing a cost to going to the movies implies that one is against going to the movies. After all, the benefits from certain government programs may well outweigh these costs just as the enjoyment of the movie might outweigh the cost of watching it. It does, however, lead us to think more carefully about the relative cost of different kinds of taxes, and we can now use the tools we have developed to illustrate how such costs can be measured.

Deadweight loss from a tax is the difference between what is paid under the tax and how much could have been raised (without distorting prices) while leaving the consumer equally well off.

To see what makes a particular tax costly and to see how we can measure this cost objectively, we will try to answer the following question: How much would a taxed individual be willing to bribe the government to get the tax rescinded? We will then compare this amount with the amount that the individual is actually paying in tax. If the maximum size of the bribe the individual is willing to pay is larger than the individual's actual tax payment, then we know that there exists, at least in principle, a way to raise more revenue from the individual without making him or her worse off. The difference between the hypothetical bribe and the actual tax payment is a measure of how much more the government could have raised without making anyone worse off, and it is our measure of deadweight loss.

One way to think of deadweight loss from taxation is to imagine the government collecting taxes in a bucket that has a hole in it; as the government passes the bucket, the bucket leaks. What remains in the bucket is what the government gets to use to provide public programs and services; what leaks from the bucket is the deadweight loss that no one gets but that we could get to if we just found a better bucket. The challenge is to find a bucket—a tax—that has a small hole so that the leakage is minimized. But why is there a hole in the first place?

10A.3.1 Some Intuition on the Deadweight Loss and Inefficiency of Taxation The question is not rhetorical, and the answer is not immediately obvious. In fact, often students are puzzled at this point. Why would anyone ever be willing to pay more in a bribe to get rid of a tax than he or she is paying in taxes when the tax is in place? Why do we think that we can find another tax that will raise more revenue while not making people worse off?

Consider the following extreme example. I like to drink beer, and I especially like to drink the imported beer Amstel Light. Suppose the domestic beer brewer Miller convinces the government to impose a large tax on imported beers, and suppose that this leads to a sufficient increase in the domestic price of Amstel Light to cause me to switch to Miller Lite (which I like somewhat less because I can't make up my mind about whether it tastes great or is less filling).⁴ Notice that because I have substituted away from (the taxed) Amstel Light and toward (the untaxed) Miller Lite, I end up paying no tax at all. At the same time, I have clearly been made worse off by the imposition of a tax on imported beers and would therefore be willing to pay *something* to get the government to abolish this tax, despite the fact that I do not pay *any* of the tax when it is imposed. With the government not raising any revenue and me being made worse off, we have identified a “bucket” that has no bottom; no tax revenue from me is actually reaching the government even though the imposition of the tax is making me worse off. Stated more loftily, society has been made worse off without anyone getting a benefit, and that is called *deadweight loss*. It is also what makes taxes *inefficient*.

Recall that in Chapter 6, we defined a situation to be inefficient if there is a way to change the situation and thus make someone better off without making anyone worse off. The tax on imported beer is *inefficient* because the government could have raised more money from me without making me any worse off (than I am when I drink Miller Lite) by thinking of a different way of raising money—finding a different “bucket” that doesn't leak so much. For instance, they could have just come by my house and taken some money, leaving the price of Amstel Light unchanged and thus not giving me an incentive to switch to Miller Lite just to avoid a tax. The example, though extreme, gives us an initial insight into what it is about taxes that makes taxes costly. *By altering the relative prices in an economy, taxes cause consumers, workers, and savers to substitute away from taxed goods and services and toward untaxed goods and services.* To the extent that this substitution activity happens solely because of a change in opportunity costs, to the extent to which taxes give rise to substitution effects, taxes are distortionary and inefficient ways of raising revenues.

Many real-world examples may be less extreme—they may lead us to consume less of the taxed good and more of other goods without causing us to eliminate our consumption of

⁴That's a reference to one of the most successful advertising campaigns of the 20th century that featured ads in which various people get into big fights over what's great about Miller Lite: that it tastes great or is less filling.

particular taxed goods (like Amstel Light) entirely. But the basic intuition remains: To the extent to which taxes change opportunity costs and thus cause us to alter our consumption plans solely because of those changed opportunity costs, we are worse off without contributing to the government's effort to raise revenues, and society has incurred a deadweight loss. We can now use the tools we have developed to show more formally that this entire deadweight loss happens because of substitution effects, which are therefore the underlying cause of the leak in the "bucket."

10A.3.2 Identifying Deadweight Losses in a Consumer Diagram Suppose that instead of a tax on Amstel Light we considered a tax on housing. We can model such a tax in our usual two-good framework as resulting in an increase in the price of each square foot of housing we consume. Alternatively, we can model removal of such a tax as a decrease in the price of housing. Graph 10.6a illustrates the change in the choice set resulting from such a tax, with bundle A representing a consumer's optimal after-tax choice.

In Chapter 8 (Graph 8.3), we illustrated how one can identify the total tax paid by a consumer in a situation where the good modeled on the horizontal axis is taxed. In particular, we can first identify c^A as the dollars of "other goods consumption" the consumer is able to afford *after the tax* given that she is consuming h^A . Second, we can identify c^α as the dollars of "other goods consumption" had she consumed the same amount of housing in the absence of the tax. The difference between these amounts, labeled T in Graph 10.6a, is the total tax payment the consumer makes under the tax. As explained in Chapter 8, this does not presume that the consumer's optimal consumption bundle without the tax is α . Rather, the bundle α simply helps us identify the magnitude of T .

Graph 10.6b then replicates panel (a) but gives the answer to our second question: How much of this consumer's income could we have taken *without changing opportunity costs* to make the consumer just as well off as she is under the tax on housing? Put differently, how much can we shift the (blue) before-tax budget constraint without changing its slope and still end up on the indifference curve labeled u^A ? The answer is that we could shift this budget inward until we get to the (green) budget line that is tangent to u^A at B . The dollar value of this parallel shift can then be measured on the vertical axis (which is denominated in dollar units), and since the two budget lines are parallel, this distance can equivalently be measured as a vertical distance between the two lines anywhere. In particular, we can measure it as a distance below the bundle α , a distance labeled L in Graph 10.6b.

GRAPH 10.6 Distortionary Tax on Housing

Go to MindTap to interact with this graph.

The distance L is how much we could have taxed this consumer using what is called a *lump sum tax*. A *lump sum tax* is a tax that does not change opportunity costs (i.e., slopes of budget constraints). Graph 10.6b then clearly indicates that this consumer would have been willing to pay a larger amount L in a lump sum tax than the amount T she is paying under the tax on housing, with each tax leaving the consumer exactly on the same indifference curve and thus equally happy. The difference between T and L is the deadweight loss from the tax on housing. Since, beginning with a housing tax, the lump sum tax represents a way to make someone better off (government revenue is higher) without making anyone worse off (our consumer has the same utility in either case), we can equivalently say that the housing tax is *inefficient*.

Deadweight losses from taxes arise because of substitution effects.

10A.3.3 Deadweight Losses and Substitution Effects We can now investigate the reason why most taxes are inefficient and result in deadweight losses. First, consider the same tax on housing we modeled in Graph 10.6, but now assume that the consumer views housing and “other goods” as perfect complements. Graph 10.7a illustrates such tastes, with A representing the consumer’s optimal bundle after the tax is imposed and with u^A representing the consumer’s indifference curve at A . We can then identify the amount of tax she pays under the housing tax as T just as we did in Graph 10.6a. But when we now ask how much we could have taken from the consumer in a lump sum tax and still ensured that the consumer reaches the indifference curve u^A , we find that the consumer would end up at exactly the same consumption bundle (i.e. $B = A$). Thus, the amount we could have extracted from the consumer in a lump sum tax is exactly equal to the amount we received from the consumer under the tax on housing (i.e., $L = T$). We have therefore identified a case where a tax on housing does *not* produce a deadweight loss and is therefore efficient.

The reason why $B = A$ in Graph 10.7a is that we have given the consumer tastes that eliminate substitution effects. As the substitution effect disappears, so does the deadweight loss from a tax that changes the opportunity cost of housing. Graph 10.7b, on the other hand, assumes tastes that incorporate a great deal of substitutability, with bundles A and B far from each other. As a result, L is significantly larger than T , implying a large deadweight loss. As the degree of substitutability between housing and other goods consumption increases from zero in Graph 10.7a to some substitutability in Graph 10.6b to a large amount of substitutability in Graph 10.7b, the deadweight loss increases as well. And as the degree of substitutability shrinks, the leak in our tax “bucket” disappears.

GRAPH 10.7 Distortionary Taxes and Substitution Effects

Note one other important fact that emerges from this analysis: What makes taxes inefficient is not that consumers respond by consuming less of the taxed good. (After all, the consumer responds to the tax in Graph 10.7a by consuming less than she would at the blue budget, but there is no inefficiency.) Rather, the inefficiency emerges to the extent to which a substitution effect lies behind the change in behavior. As demonstrated in some of the end-of-chapter exercises, this is particularly important in labor markets where income and substitution effects tend to point in opposite direction with respect to the good leisure.

Can you think of a scenario under which a consumer does not change his or her consumption of a good when it is taxed but there still exists an inefficiency from taxation?

EXERCISE 10A.9

Some years ago, I asked students on a final exam to comment on the following statement: “People hate taxes because of income effects; economists hate taxes because of substitution effects.” One student commented that the statement is true because it implies that economists are not people. Be that as it may, the statement is true in another sense: Few taxpayers think about income and substitution effects when they write their check to the tax authorities—they don’t like writing these checks because they’d rather have the money for themselves. Economists who care about efficiency, on the other hand, may have no problem with checks going from some people to other people through the government *as long as wealth does not get lost in the process*, or as long as some do not get hurt without someone else at least benefiting. But that is precisely what happens when taxes result in changes of opportunity costs that then result in substitution effects. It is what is causing the “bucket” to leak. Thus, while individual taxpayers may not easily identify a tax that results in Graph 10.7a as better than a tax that results in Graph 10.7b, economists would (all else being equal) tend to have a clear preference for the tax that results in no substitution effects and thus no deadweight losses to society. We may disagree on how big the bucket should be, but we generally agree that it should not have big leaks if we can help it.

10A.3.4 Almost All Real-World Taxes Are Inefficient From our discussion thus far, we can then identify two scenarios under which a tax may be efficient: (1) if the tax does not change opportunity costs and is thus a lump sum tax; or (2) if the tax does not give rise to substitution effects even though it causes changes in opportunity costs. (In Chapter 21, we will add a third scenario that emerges in the presence of externalities.) Scenario (2) is difficult to count on since we have little control over what kinds of tastes consumers have, although it is possible to identify certain combinations of goods that are less substitutable than others (as we discussed in Chapter 5). And the first scenario (lump sum taxes) rarely represents real-world policy options. As a result, almost all real-world taxes give rise to deadweight losses and are thus inefficient, at least until we get to the topic of externalities in Chapter 21.

Why are lump sum taxes so hard to come by? In order for a tax to truly represent a lump sum tax, it must be such that the consumer cannot engage in any substituting behavior that allows him or her to avoid at least part of the tax. As soon as taxes are imposed differentially on different goods, the possibility of such substituting behavior arises as opportunity costs of different goods are altered. If you think carefully about the implications of this, you will quickly realize how difficult it is in practice to come up with a true lump sum tax. In our example of the tax on housing, for instance, you might think that we can eliminate the “distortionary” (or “deadweight loss-inducing”) aspects of the tax by simply taxing “all other consumption” by the same amount, thus keeping the slope of the budget constraint from changing and not causing changes in the opportunity cost of anything. But “all other goods” includes, for instance, “savings.” Well, you

As long as there is some change in behavior that can reduce a person’s tax burden, the tax will create at least some *DWL* (if there are substitution effects).

might say, let's tax savings at the same rate, thus again keeping opportunity costs unchanged. But yet another "other good" that we have not modeled in our two-good diagram is leisure. Can we think of easy ways to tax leisure at the same rate? If not, the "bucket" has sprung a leak.

EXERCISE 10A.10 On a graph with consumption on the vertical axis and leisure on the horizontal, illustrate the deadweight loss of a tax on all consumption (other than the consumption of leisure).

The most common taxes are taxes on different forms of consumption (sales taxes, value added taxes) or taxes on different forms of income (payroll taxes, wage taxes, income taxes, capital gains taxes). Each of these can be avoided in part through a change in behavior. To truly be a lump sum tax, a tax must be such that consumers can do *nothing* to avoid the tax. In the early 1990s, for instance, Prime Minister Margaret Thatcher attempted to introduce such a tax in Great Britain by imposing what is known as a "head tax." A head tax is a fixed tax payment (say, \$2,000 per year) that consumers have to pay as long as they have a head. It is not easy for someone to change the fact that he or she has a head, and so the tax cannot be avoided by changes in behavior and thus is truly a lump sum tax without substitution effects. Yet, despite the efficiency argument in favor of such a tax, few people in Great Britain liked the concept. Margaret Thatcher was out of office within a few weeks, and her successor immediately repealed the head tax.

The British head tax example illustrates why lump sum taxes are rarely considered in the real-world and why, as a result, almost all real-world taxes are inefficient to some degree: Because they must be based on something other than changeable behavior, lump sum taxes usually offend our sense of fairness. It does not seem fair to send everyone the same tax bill, nor does it seem right to base people's tax payments on other unchangeable characteristics such as age, race, sex, or other genetic traits. But something like that is usually necessary in order for a tax not to give rise to substitution effects and the resulting inefficiencies. Sometimes the "bucket" does not leak, but we don't like it for other reasons. (One possible exception to this is a tax on land value, which is explored in Chapter 19.)

While our analysis thus suggests that virtually any tax we might advocate is inefficient and produces deadweight loss, it also suggests that different types of taxes will have different magnitudes of deadweight losses depending on just how big the substitution effects—the leaks in the "bucket"—are that these taxes produce. We will say more about how this might impact tax policy at the end of the next section and again in later chapters.

10A.4 Deadweight Loss Measured on MWTP Curves

In Section 10A.2, we have already shown how the concept of consumer surplus can be measured as an area to the left of marginal willingness to pay curves and, under the special case of quasilinear tastes, as the same area to the left of own-price demand curves. We can now show that deadweight loss can be similarly measured along marginal willingness to pay (and, when tastes are quasilinear, own-price demand) curves. We will do this within the context of the example of a housing tax discussed in the previous section.

10A.4.1 T , L , and DWL on MWTP Curves The top panel in Graph 10.8a is identical to Graph 10.6b and derives, within the consumer diagram, the tax payment T made by a consumer with indifference curve u^A , the largest possible lump sum tax payment L the consumer would have been willing to make to not incur the tax on housing, and the deadweight loss $DWL = (L - T)$ from the tax on housing. The lower panel of Graph 10.8a then derives the marginal willingness

GRAPH 10.8 Translating DWL to MWTP Curves

to pay curve that corresponds to the indifference curve that includes bundle A. This is done by the same process as the derivation of marginal willingness to pay in Graph 10.2, except that we are now deriving the *MWTP* curve corresponding to the optimal indifference curve at the higher (tax-inclusive) price.

We can now identify the distances T , L , and $(L - T)$ from the top graph as areas on the lower graph by carefully thinking about what A and B represent on the lower graph. Point A represents the actual housing consumption this consumer undertakes after a housing tax has been implemented. The difference between the price level $(p + t)$ and the price level p on the vertical axis is just t , or the per square foot tax rate on housing paid by the consumer. Thus, if we multiply the tax paid per square foot of housing t by the square feet of housing (h^A) consumed under the tax, we get the total tax payment this consumer makes under the housing tax. Area (b) in the lower panel of Graph 10.8a is exactly that, which implies that area (b) is equal to distance T in the top graph.

Next, from the work we did in Section 10A.2, we know that area (a) is equal to the consumer surplus this consumer received in the housing market after she paid the tax-inclusive price $(p + t)$ for housing and chose to consume h^A square feet of housing. Similarly, the area $(a + b + c)$ is the consumer surplus our consumer would attain in the housing market if she faced the budget constraint that makes bundle B optimal in the top part of the graph. Put differently, $(a + b + c)$ is the consumer surplus in the housing market when the consumer pays the before-tax price (p) for housing but also pays the lump sum tax L that produces the relevant budget constraint in the top graph.

Consumer surplus is thus greater at point B than it is at point A . But we also know that our consumer is equally happy at A and B ; after all, both these points correspond to bundles on the same indifference curve u^A . How can it be that the consumer gets more consumer surplus at point B than at A but is equally happy? The answer is that the consumer had to pay a lump sum tax at point B but not at point A . Put differently, the consumer surplus at point A already takes into account the fact that our consumer is paying a tax on housing that raised the price of housing to $(p + t)$, while the consumer surplus at point B does not reflect any tax payments. Since our consumer is equally happy at the two points but gets a higher consumer surplus at point B than at point A , it must therefore logically be true that the lump sum tax she is implicitly paying to get to point B is the difference between the two consumer surpluses, that is, $(b + c)$. Thus, the distance L in the top panel of the graph is equal to the area $(b + c)$ in the lower panel. Since T is equal to area (b) , and since the deadweight loss is the difference between L and T , the area (c) is then the deadweight loss from the tax.

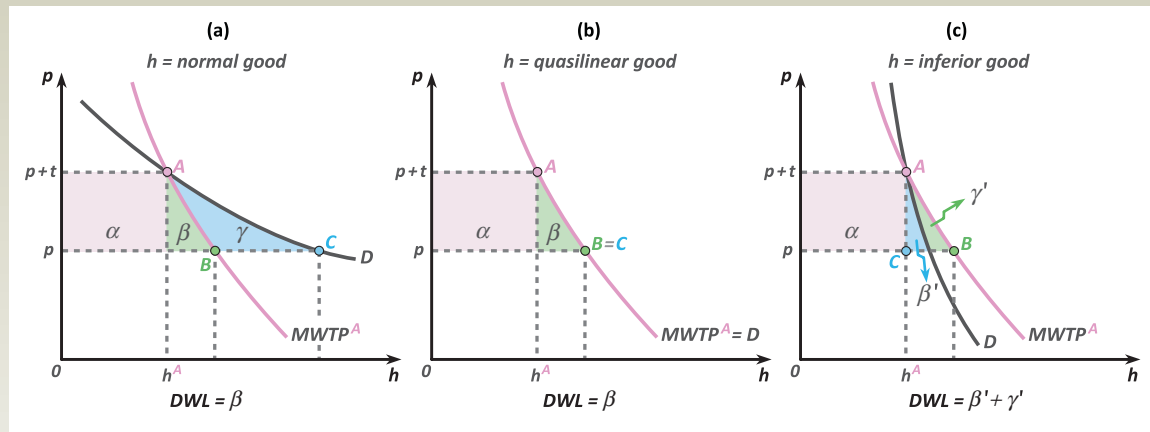

10A.4.2 Substitution Effects Once Again We have already shown in Section 10A.3.3 that the size of the deadweight loss is closely related to the size of the substitution effects that are produced by the imposition of a tax. We can see the same to be true once again when we measure deadweight loss on marginal willingness to pay curves.

Graph 10.8b repeats the analysis in Graph 10.8a with the exception that we now assume our consumer's tastes do not give rise to substitution effects; that is, they can be represented by indifference curves that treat housing and other goods as perfect complements. It begins with a top panel identical to what we already derived in Graph 10.7a, illustrating that $T = L$ and thus there is no deadweight loss from a tax on housing. The lower panel of Graph 10.8b then illustrates how the $MWTP$ curve corresponding to the indifference curve u^A in the top panel is a vertical line: A and B happen at different prices but at the same quantities because of the absence of substitution effects that moved B to the right of A in Graph 10.8a. As a result, area (c) in Graph 10.8a disappears and with it the deadweight loss. By comparing the lower panels in Graph 10.8, we can again see how deadweight losses get larger the farther B lies to the right of A on the $MWTP$ curve. And the only force that moves B away from A is the substitution effect in the top panel of the graphs.

10A.4.3 Measuring the DWL on Demand Curves Most of you have probably seen deadweight loss from taxation in a previous economics course, and chances are you did not bother with marginal willingness to pay curves but simply used areas on own-price demand curves to measure deadweight loss. Whoever was teaching you this implicitly assumed that underlying tastes are quasilinear, which represents the only case under which it is truly legitimate to use own-price demand curves to measure consumer welfare and deadweight loss. Of course, we can approximate the deadweight loss on own-price demand curves as long as we think income effects are small, which is the same as saying that tastes are close to quasilinear. But in cases where income effects are likely to be large, it will be misleading to use the own-price demand curve to approximate consumer surplus and deadweight loss.⁵

In Graph 10.9, we extend the lower panel of Graph 10.8a slightly by adding a point C that represents the level of housing consumption if the consumer faced neither a housing tax nor a lump sum tax. Panel (a) does this for the case where housing is a normal good, panel (b) does it for the case where housing is a quasilinear good, and panel (c) does it for the (unlikely) case where housing is an inferior good.

⁵Historically, the idea of measuring deadweight loss on own-price demand curves dates back to Alfred Marshall's 1895 *Principles of Economics* text. The modern treatment of consumer welfare and deadweight loss, on the other hand, is due to Sir John Hicks, whom we first credited with the related idea of decomposing price changes into income and substitution effects in Chapter 7.

GRAPH 10.9 *DWL from Taxation for Different Types of Goods*

Using Graph 10.8a, verify that the relationship between own-price demand and marginal willingness to pay is as depicted in panels (a) through (c) of Graph 10.9.

EXERCISE 10A.11

It is now easy to read on these graphs whether a measurement of *DWL* approximated on own-price demand curves would over- or understate the true *DWL* from the tax on housing. Clearly, there is no difference between using the *MWTP* and using the demand curve to measure deadweight loss when housing is a quasilinear good (panel (b) of Graph 10.9). In this case, the demand curve is exactly equal to the *MWTP* curve, and either can be used for consumer welfare analysis. When housing is a normal good, however, a *DWL* measurement on the demand curve will *overstate* the true *DWL* (by γ in Graph 10.9a), and when housing is an inferior good, it will *understate* it (by γ' in Graph 10.9c). We will see in Chapter 19 that the problem of using uncompensated curves to approximate *DWL* will become much more severe when we discuss taxes on labor or capital, where wealth effects usually mask the very substitution effects that lie at the heart of tax inefficiency.

10A.4.4 Geometric Increases in *DWL* and the Case for Broad Tax Bases One lesson for tax policy that has emerged from our analysis of taxes and deadweight loss is that taxes give rise to greater deadweight losses the more they give rise to substitution effects. Now that we know how to measure *DWL* along marginal willingness to pay curves, we are ready to derive a second lesson: As tax rates on any given good increase, *DWL* from the tax increases substantially faster; that is, as tax rates increase, the leak in our “bucket” grows at an increasing rate.

You can see the intuition behind this result in our housing tax example in which we assume that tastes for housing are quasilinear, and the *MWTP* curve is therefore equal to the own-price demand curve. Graph 10.10 depicts a special case of this where the demand (and *MWTP*) curve is linear. Tax-inclusive housing prices for five different levels of housing taxes are indicated on the vertical axis, from no tax (p) going through tax increases starting with t , then $2t$, then $3t$, and finally $4t$. For each level of the housing tax, we can identify the corresponding *DWL*. For instance, when the tax rate is t , the *DWL* is simply a . When it is $2t$, the *DWL* becomes $(a + b + c + d)$. Since each letter

GRAPH 10.10 Geometrically Increasing DWL When Tastes Are Quasilinear and Demand Is Linear

As tax rates go up linearly, DWL tends to increase geometrically.

corresponds to a triangle with the same area, we can conclude that *doubling the tax led to a quadrupling of the DWL*. When the tax is raised to $3t$, the deadweight loss becomes $(a + b + c + d + e + f + g + h + i)$. Thus, *multiplying the tax rate by 3 leads to a DWL 9 times as large*. And you can verify for yourself that multiplying the tax rate by 4 leads to a DWL 16 times as great. While this is a special case since we assumed quasilinear tastes and linear demand curves, the example has led tax economists to use the rule of thumb that *multiplying tax rates by a factor of x leads to an increase of DWL by a factor of approximately x^2* ! Put differently, as tax rates go up linearly, DWL increases geometrically.

This has furthermore led to the commonly given advice to policy makers that *it is better from an efficiency perspective to have low tax rates on large tax bases rather than high tax rates on small tax bases*. The *tax base* is the set of goods that are taxed, whereas the tax rate is the rate at which goods are taxed. Suppose, for instance, that there are two markets, single-family housing and condominium housing, and suppose that consumer tastes in both markets lead to exactly the same demand and MWTP curves and that these are furthermore as depicted in Graph 10.10. Now suppose that you are a policy maker who has to choose between two tax proposals: One imposes a tax of $2t$ on the single-family housing market and no tax on the condominium housing market; the other imposes a tax of t on both markets. The first proposal imposes a high tax rate ($2t$) on a small base (single-family housing), and the second proposal imposes a low tax rate (t) on a large tax base (single-family and condominium housing). The DWL of the first proposal is $(a + b + c + d)$ while the DWL from the second proposal is $(a + a)$, which is half the DWL of the first proposal. Thus, *because DWL goes up geometrically as tax rates rise, imposing low tax rates on broader bases typically results in less DWL*. If topics like this are of interest, you should consider taking a course in public finance.

The two proposals also result in different levels of tax revenue. Which proposal actually results in higher revenue for the government? Does this strengthen or weaken the policy proposal “to broaden the base and lower the rates”?

EXERCISE
10A.12

10B

THE MATHEMATICS OF CONSUMER WELFARE AND “DUALITY”

The mathematical generalization of consumer welfare, as introduced intuitively in part A of this chapter, serves two purposes. First, it allows us, as in concepts introduced in previous chapters, to see how the mathematics of the consumer model can help us generalize the graphical analysis and the intuitions that emerge from it. Second, it provides us a forum in which to bring together all the mathematical techniques introduced so far to paint a full picture of consumer theory, a picture that is commonly referred to as the “duality” of utility maximization and expenditure minimization approaches we have used in the past few chapters.

We will depart in this section from our previous practice of following the same order for our mathematical development in part B of chapters as for the graphical development in part A. Rather, we will begin by demonstrating how the intuitive concepts developed in part A help us generate a full picture of how all the intuitive and mathematical aspects of the consumer model fit together. We do this in Section 10B.1 and then proceed to an application of duality to the topic of consumer welfare, taxation, and deadweight loss.

10B.1 Duality of Utility Maximization and Expenditure Minimization

In previous chapters, we have essentially formulated two different ways of solving optimization problems that (typically) lead to a solution that can be graphed as a tangency between an indifference curve and a budget line. Which of these optimization problems we solved at a particular time depended on what we were trying to answer. Whenever we tried to calculate how much a consumer will actually consume as his or her economic conditions (i.e., the consumer’s income and the prices in the market) change, we solved the utility maximization problem

$$\max_{x_1, x_2} u(x_1, x_2) \text{ subject to } p_1x_1 + p_2x_2 = I. \quad (10.1)$$

On the other hand, when we attempted to see how much a consumer will change his or her consumption as prices change while being compensated to keep his or her utility from changing, we solved the expenditure minimization problem

$$\min_{x_1, x_2} E = p_1x_1 + p_2x_2 \text{ subject to } u(x_1, x_2) = u \quad (10.2)$$

that gave us the least expenditure necessary for the consumer to reach the same indifference curve u as prices change.

We already showed in Chapter 9 how the solution to problem (10.1) can be written as the (uncompensated) *demand functions*

$$x_1 = x_1(p_1, p_2, I) \text{ and } x_2 = x_2(p_1, p_2, I) \quad (10.3)$$

and how (inverse) slices of these demand functions are related to the various demand curves we have derived graphically. Now consider the solution to problem (10.2), which can be written as

$$x_1 = h_1(p_1, p_2, u) \text{ and } x_2 = h_2(p_1, p_2, u). \quad (10.4)$$

Uncompensated demand functions are derived from utility maximization problems.

Compensated demand functions are derived from expenditure minimization problems.

These functions tell us, for any set of prices, how much a consumer will consume of each good *assuming that the consumer is given just enough money to be able to reach utility level u* . For this reason, the functions given in expression (10.4) are often referred to as *compensated demand functions*. They are also known as *Hicksian demand functions* after the economist John Hicks whose work originally identified them, and it is in his honor that we denote the functions in expression (10.4) with “ h ” to distinguish them from the (uncompensated) demand functions in expression (10.3).

10B.1.1 Compensated (or Hicksian) Demand and MWTP In Graph 10.2, we demonstrated how we can derive *MWTP* curves by tracing out the quantity of a good that a consumer would consume at different prices *assuming the consumer gets sufficient compensation to always reach the same indifference curve*. This is exactly what problem (10.2) formalizes mathematically, and the compensated demand functions in expression (10.4) are therefore a simple generalization of the *MWTP* curve derived in Graph 10.2. In fact, when we discussed this derivation in Section 10A.1.2, we mentioned that *MWTP* curves are sometimes referred to as compensated demand curves.

More precisely, note that compensated demand functions are functions of prices and utility. Consider the function $h_1(p_1, p_2', u^A)$ with p_2' set to 1 (as we would do if good x_2 represents “other consumption” denominated in dollars) and utility fixed at the quantity associated with indifference curve u^A . With the other arguments of the function held fixed, this leaves a function of only p_1 , a function that tells us how the consumer will change his or her consumption of x_1 as p_1 changes assuming the consumer is compensated sufficiently to permit him or her to reach indifference curve u^A . The inverse of this function is what is derived graphically in the lower panel of Graph 10.2, the marginal willingness to pay curve associated with the indifference curve u^A . The fact that there exist many *MWTP* curves as demonstrated in Graph 10.4b, one corresponding to each indifference curve, then falls straight out of the underlying mathematics: As different utility levels are plugged into the compensated demand function (instead of u^A), different *MWTP* (or compensated demand) curves emerge.

MWTP curves are inverse slices of compensated demand functions.

EXERCISE 10B.1 In Graph 10.5b, we illustrated that *MWTP* curves and own-price demand curves are the same when tastes are quasilinear. Suppose tastes can be modeled with the quasilinear utility function $u(x_1, x_2) = \alpha \ln x_1 + x_2$. Verify a generalization of the intuition from Graph 10.5b that demand functions and compensated demand functions are identical for x_1 in this case.

10B.1.2 Linking Indirect Utility and Expenditure Functions in the Duality Picture

Once we have solved for demand functions (using utility maximization) and compensated demand functions (using expenditure minimization), we can formally define two further functions that we have already used in previous chapters without naming them: the *indirect utility function*, which tells us for any set of economic circumstances (i.e., prices and income) how much utility the consumer will achieve if she does the best she can; and the *expenditure function*, which tells us for any price and utility level how big a money budget is required for the consumer to reach that utility level.

To find the utility level a consumer can attain under different economic circumstances, all we have to do is plug the demand functions (which tell us how much the consumer will consume of each of the goods under different circumstances) into the utility function. The indirect utility function $V(p_1, p_2, I)$ can then simply be written as

$$V(p_1, p_2, I) = u(x_1(p_1, p_2, I), x_2(p_1, p_2, I)). \quad (10.5)$$

Similarly, the money required to reach a particular utility level u under different prices is found simply by multiplying the compensated demands for the goods (which tell us how much

of each good a person will consume if the person always gets just enough money to reach the utility level u by the prices and adding them up; that is, the expenditure function $E(p_1, p_2, u)$ can be written as

$$E(p_1, p_2, u) = p_1 h_1(p_1, p_2, u) + p_2 h_2(p_1, p_2, u). \quad (10.6)$$

Consider, for example, the case of a Cobb–Douglas utility function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$. The utility maximization and expenditure minimization problems yield demand functions

$$x_1(p_1, p_2, I) = \frac{\alpha I}{p_1} \text{ and } x_2(p_1, p_2, I) = \frac{(1-\alpha)I}{p_2} \quad (10.7)$$

and compensated demand functions

$$h_1(p_1, p_2, u) = \left(\frac{\alpha p_2}{(1-\alpha)p_1} \right)^{(1-\alpha)} u \quad (10.8)$$

$$h_2(p_1, p_2, u) = \left(\frac{(1-\alpha)p_1}{\alpha p_2} \right)^\alpha u.$$

Verify the solutions given in equations (10.8).

EXERCISE
10B.2

Plugging (10.7) into the Cobb–Douglas utility function, we get the indirect utility function

$$V(p_1, p_2, I) = \frac{I \alpha^\alpha (1-\alpha)^{(1-\alpha)}}{p_1^\alpha p_2^{(1-\alpha)}}. \quad (10.9)$$

and multiplying the equations in (10.8) by the relevant prices and adding, we get the expenditure function

$$E(p_1, p_2, u) = \frac{u p_1^\alpha p_2^{(1-\alpha)}}{\alpha^\alpha (1-\alpha)^{(1-\alpha)}}. \quad (10.10)$$

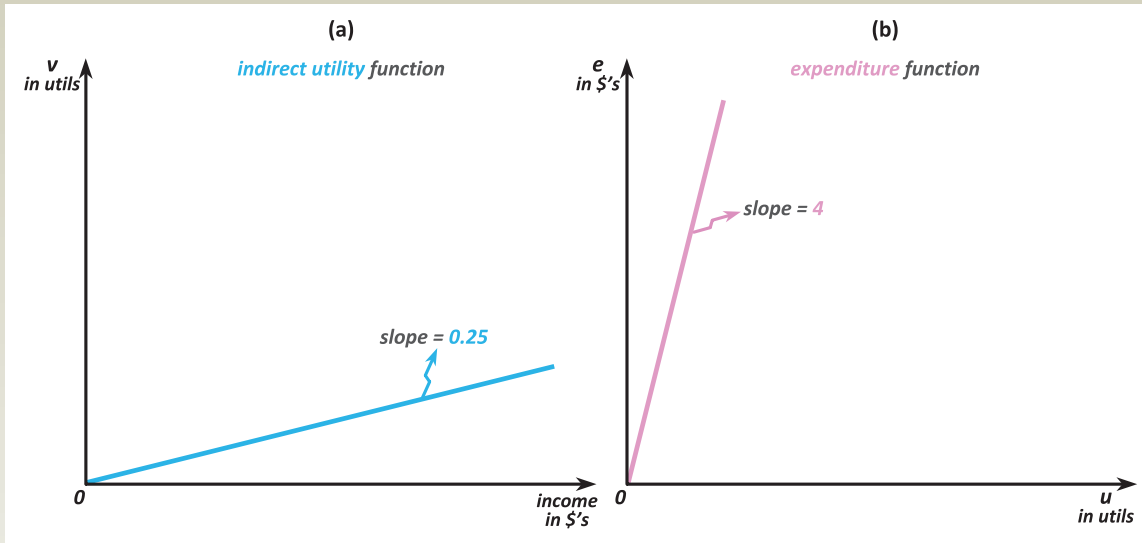

Verify the solutions given in equations (10.9) and (10.10).

EXERCISE
10B.3

Now notice the following: If you set the left-hand side of (10.9) equal to u and solve for I , you get the right-hand side of (10.10). Similarly, if you set the left-hand side of (10.10) equal to I and solve for u , you get the right-hand side of (10.9). That is because *the indirect utility function is the inverse of the expenditure function and vice versa*. Graph 10.11 shows the intuition behind this by graphing first the indirect utility as a function of income when $p_1 = 4$, $p_2 = 1$, and $\alpha = 0.5$, and then graphing the expenditure function (evaluated at the same prices and the same α) as a function of utility. The only difference between the two graphs is that we have inverted the first graph to get the second, switching the utility and dollar axes in the process!

Other linkages between the utility maximization and the expenditure minimization results can also be identified and should make intuitive sense once you have fully internalized what these functions represent. For instance, suppose we plug the expenditure function in for the

The indirect utility function and the expenditure function are inverses of each other.

GRAPH 10.11 Indirect Utility and Expenditure Function

income variable I in demand functions. Then, rather than letting income be fixed, we have constructed a new demand function that always provides the consumer sufficient income to reach utility level u . But that is precisely the definition of a compensated demand function. As a result, we can establish the following logical relationship:

$$x_i(p_1, p_2, E(p_1, p_2, u)) = h_i(p_1, p_2, u). \quad (10.11)$$

Similarly, suppose we plug the indirect utility function in for the utility term u in compensated demands. Then rather than letting utility be fixed, the compensated demand function would give us the optimal consumption level assuming you have enough income to reach the level of utility you would reach with just income I . In other words, the compensated demand function would then tell you the optimal bundle assuming your income (rather than utility) is fixed, which is just the definition of a regular (or uncompensated) demand function:

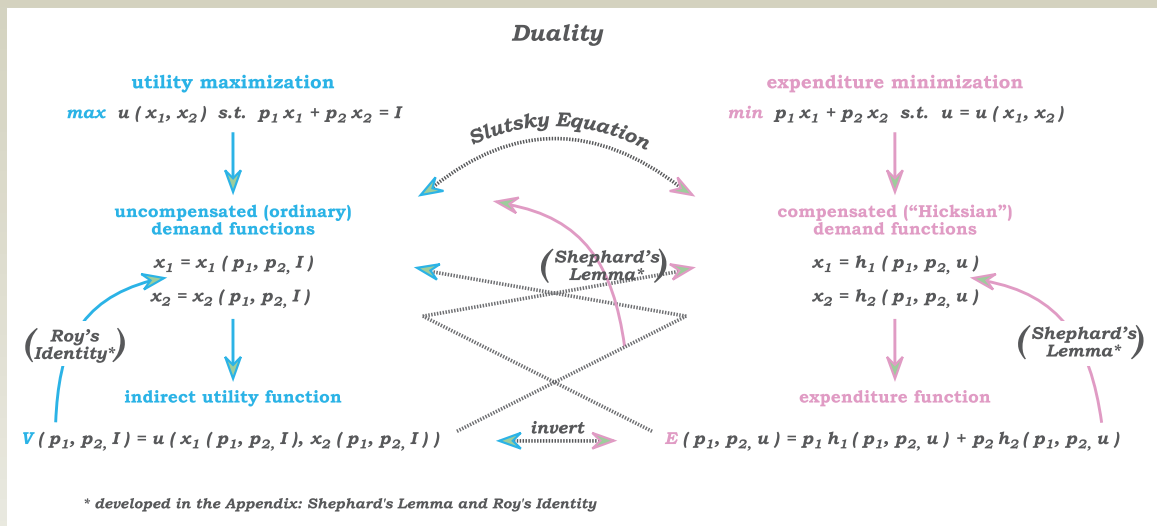

$$h_i(p_1, p_2, V(p_1, p_2, I)) = x_i(p_1, p_2, I). \quad (10.12)$$

EXERCISE 10B.4 Verify that (10.11) and (10.12) are true for the functions that emerge from utility maximization and expenditure minimization when tastes can be modeled by the Cobb–Douglas function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$.

Graph 10.12 summarizes the “duality” picture as we have developed it in this section, and indicates through arrows the linkages between the utility maximization and expenditure minimization problems that we have developed thus far. The arrows labeled “Roy’s Identity” and “Shephard’s Lemma” are developed in the appendix, and the dotted line labeled “Slutsky Equation” is developed next.

10B.1.3 The Slutsky Equation There is one final link between the two sides of our duality picture. It is known as the Slutsky Equation, and it relates the slopes (with respect to prices) of

GRAPH 10.12 “Duality” of Utility Maximization and Expenditure Minimization

uncompensated demand curves to the slopes of compensated demand curves.⁶ To be more precise, we would like to begin with a point that lies on both the demand and the compensated demand functions and then derive the relationship between the slopes of the two functions at that point. We have already done this intuitively in Graphs 10.5 and 10.9. In those graphs, this common point is point A, and it is at that point that we could say which of the two curves is steeper depending on whether the good is normal or inferior. It is easiest for us to begin our mathematical derivation of the Slutsky Equation with expression (10.11), which already relates demand functions to compensated demand functions (but does not relate their slopes to one another). To identify the relationship of the slopes, we simply take the partial derivative (with respect to one of the prices) of each side of equation (10.11). This requires us to invoke the chain rule from calculus since the function on the left-hand side contains the expenditure function E that itself is a function of prices:

The Slutsky Equation relates the slopes of uncompensated demands to the slopes of compensated demands.

$$\frac{\partial x_i}{\partial p_j} + \left(\frac{\partial x_i}{\partial E}\right)\left(\frac{\partial E}{\partial p_j}\right) = \frac{\partial h_i}{\partial p_j} \tag{10.13}$$

Rearranging terms and replacing the E term in $(\partial x_i/\partial E)$ with I (since expenditure is the same as income in the consumer model), we can write this equation as

$$\frac{\partial x_i}{\partial p_j} = \frac{\partial h_i}{\partial p_j} - \left(\frac{\partial x_i}{\partial I}\right)\left(\frac{\partial E}{\partial p_j}\right) \tag{10.14}$$

Equation (10.14) is written in terms of good x_i and price p_j . To help us investigate precisely how this equation relates to the intuitions we have developed so far, suppose that we focus on good x_1 and a change in p_1 . Equation (10.14) can then be written as

$$\frac{\partial x_1}{\partial p_1} = \frac{\partial h_1}{\partial p_1} - \left(\frac{\partial x_1}{\partial I}\right)\left(\frac{\partial E}{\partial p_1}\right) \tag{10.15}$$

⁶The Slutsky Equation is named after the Russian economist and statistician Eugene Slutsky (1880–1948). The equation was so named by John Hicks who also called it the “Fundamental Equation of Value Theory.”

The left-hand side of equation (10.15) is the change in the actual quantity demanded of good x_1 when p_1 changes marginally. This is analogous to the move from A to C in Graphs 10.5 and 10.8, although the calculus here corresponds to marginal (or very small) changes. The first term on the right-hand side of equation (10.15) is the change in the quantity of x_1 demanded assuming the consumer has been compensated to keep his or her utility constant. It is analogous to the move from A to B in Graphs 10.5 and 10.9, or the substitution effect. This must mean that the final term in equation (10.15) is analogous to the move from B to C in Graphs 10.5 and 10.9, or the income effect. Indeed, that is precisely what the final term suggests: $(\partial x_1/\partial I)$ is the change in the quantity of x_1 demanded when income changes, and $(\partial E/\partial p_1)$ is the size of the required compensation given that p_1 changes.

First, note that $\partial h_1/\partial p_1 < 0$; when price increases, the substitution effect always suggests we will purchase less of that good when we are compensated. Now suppose that we know that a consumer's tastes are quasilinear in x_1 ; that is, x_1 is borderline between a normal and an inferior good. This implies that consumption of x_1 does not change as income changes, or $\partial x_1/\partial I = 0$, reducing equation (10.15) to

$$\frac{\partial x_1}{\partial p_1} = \frac{\partial h_1}{\partial p_1}. \quad (10.16)$$

This is precisely what is illustrated intuitively in Graph 10.5b, where we demonstrated that demand curves and $MWTP$ (or compensated demand) curves are the same for quasilinear goods. The reason for this is that the income effect disappears in this special case, leaving us with only the substitution effect.

Now suppose we knew instead that x_1 was a normal good. In that case, $\partial x_1/\partial I > 0$. Whenever the price of a good we are consuming goes up, it must furthermore be true that the expenditure required to reach the same utility level increases, thus $\partial E/\partial p_1 > 0$. Together, these two statements imply that the second term in equation (10.15) is negative (two positive terms multiplied by each other and preceded by a negative sign). Thus, when x_1 is a normal good, the quantity demanded falls first because of the substitution effect ($\partial h_1/\partial p_1 < 0$) and then again because of the income effect ($-(\partial x_1/\partial I)(\partial E/\partial p_1) < 0$). When x_1 is an inferior good, on the other hand, $\partial x_1/\partial I < 0$, which implies that the second term on the right-hand side of equation (10.15) is positive. Thus, income and substitution effects point in opposite directions. All this is precisely as we have concluded in our graphs of consumer choices.

10B.1.4 Graphs and Inverse Graphs Sometimes students get confused when looking at a graph like the lower panel of Graph 10.5 and attempting to relate the slopes of the demand and $MWTP$ curves in the graph to the slopes represented by partial derivatives in equation (10.15). For instance, suppose again that x_1 is a normal good. Then it appears that the slope of the demand curve ($\partial x_1/\partial p_1$) is negative because of the negative slope of the $MWTP$ curve ($\partial h_1/\partial p_1$) and because of an additional negative component implicit in the second term of equation (10.15), the income effect. This would mean that the slope of the demand curve at any point is a negative number that is larger in absolute value than the slope of the $MWTP$ curve at that same point. Put differently, it means that the demand curve is downward sloping and steeper than the $MWTP$ curve (which is also downward sloping). But Graph 10.5a suggests the opposite, that the demand curve is downward sloping and *shallower* than the $MWTP$ curve for a normal good.

The reason for the appearance of a discrepancy between the intuition developed in Graph 10.5a and the math implicit in equation (10.15) can once again be found in the unfortunate fact that economists graph demand curves as slices of *inverse* demand functions. Thus, the slopes derived from the mathematics represent the inverse of the slopes derived in our graphs. Taking an inverse of a slope does not change the sign of that slope (i.e., downward-sloping curves remain

The Slutsky Equation captures income and substitution effects mathematically.

downward sloping), but it does change whether one curve is relatively steeper than the other (i.e., steep slopes become shallow slopes and vice versa). Graph 10.13 illustrates this relationship by plotting demand curves as inverse slices of demand functions in panel (a) (which illustrate demand and *MWTP* curves as depicted in Graph 10.9) and as simple slices of the same demand functions (with the axes reversed) in panel (b). The arrows in each graph begin with the demand curve representing a normal good and end with the demand curve representing a Giffen good. The slopes in the Slutsky Equation correspond to the slopes in the second graph.

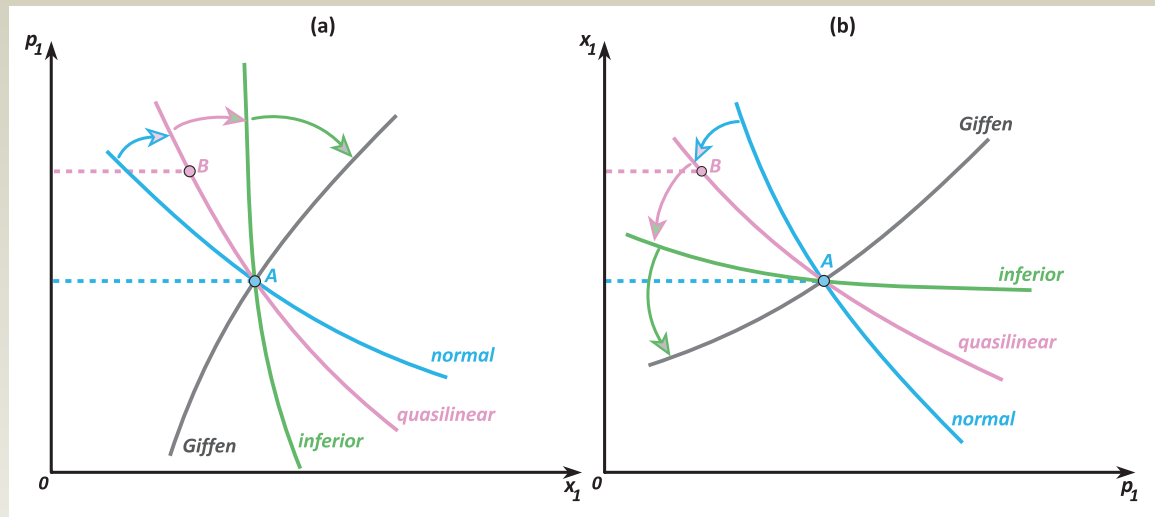

10B.2 Taxes, Deadweight Losses, and Consumer Welfare

As suggested in Section 10A, concepts like consumer surplus and deadweight loss can be read off as distances in the consumer diagram or as areas below *MWTP* curves. Areas under curves can be calculated mathematically as integrals, but we do not have to resort to integral calculus to be able to calculate changes in consumer surplus or deadweight loss mathematically. This section thus uses the same example of a housing tax discussed throughout Section A to demonstrate how the relevant concepts can be calculated without any additional calculus and simply using the various parts of our duality picture. (The more mathematically inclined students can turn to the end of the appendix to see an explanation of how areas along compensated demand curves correspond to distances in the consumer diagram.)

10B.2.1 Using Duality Concepts to Calculate Deadweight Loss We concluded in Section 10A.3 that taxes are inefficient because of substitution effects. We furthermore defined the size of the inefficiency through a measure of deadweight loss (*DWL*)—the difference between actual tax revenue *T* and the tax revenue *L* that could have been raised (without making the consumer worse off) had a lump sum tax been imposed instead.

Suppose, then, that x_1 represents square feet of housing, and t is the tax rate paid by consumers of housing. The tax revenue *T* raised from a consumer is then just equal to the tax rate t times

GRAPH 10.13 Inverse Demand and Demand for Different Types of Goods

the square footage $x_1(p_1 + t, p_2, I)$ of housing she consumes when the tax is in place, where x_1 is the demand function for housing and $(p_1 + t)$ is the price of housing faced by consumers under the housing tax. Put in terms of the mathematical functions in our duality picture,

$$T = tx_1(p_1 + t, p_2, I). \quad (10.17)$$

The lump sum tax we could have imposed instead without making the consumer worse off is slightly more challenging to calculate and easiest derived using our graphical intuition from Graph 10.6b. First, we have to determine the value (u^A in Graph 10.6b) associated with the indifference curve the consumer ends up on under the housing tax. This is the utility the consumer receives when she has income I and faces the tax inclusive price $(p_1 + t)$ for housing. The indirect utility function evaluated at the relevant prices and income gives us precisely that utility level. Put differently, u^A in Graph 10.6b is equivalent to $V(p_1 + t, p_2, I)$.

Next, we have to determine the minimum expenditure (or income) necessary for the consumer to reach his or her after-tax utility level $V(p_1 + t, p_2, I)$ if the price of housing is p_1 instead of $(p_1 + t)$. This is given by the expenditure function evaluated at the relevant prices and utility level; that is, $E(p_1, p_2, u^A)$ or $E(p_1, p_2, V(p_1 + t, p_2, I))$. The lump sum tax we could have taken from the consumer is then simply the difference between the income she starts out with and this expenditure level; that is,

$$L = I - E(p_1, p_2, V(p_1 + t, p_2, I)). \quad (10.18)$$

If the underlying utility function is $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$, for instance, we calculated demand, compensated demand, indirect utility, and expenditure functions in Section 10B.1.2 in equations (10.7) through (10.10). Using these and gathering terms, we can get the following expressions for T and L :

$$\begin{aligned} T &= \frac{t\alpha I}{p_1 + t} \\ L &= I - I \left(\frac{p_1}{p_1 + t} \right)^\alpha = I \left[1 - \left(\frac{p_1}{p_1 + t} \right)^\alpha \right]. \end{aligned} \quad (10.19)$$

EXERCISE 10B.5 Verify that the equations in (10.19) are correct for the Cobb–Douglas utility function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$.

Using these equations and knowing that $DWL = L - T$, we could calculate the deadweight losses under a variety of taste parameters (α), prices, and incomes, and for a variety of possible tax rates. For instance, suppose the rental price of a square foot of housing is \$10, the price of “other goods” is (by definition) \$1, the taste parameter α is 0.25, and the housing tax raises the price of housing by \$2.50. Then a consumer whose income is \$100,000 will reduce her consumption of housing from 2,500 square feet to 2,000 square feet, and, while the consumer pays a total housing tax of \$5,000, she would have been willing to pay \$5425.84 in a lump sum tax to avoid the housing tax. Thus, the tax gives rise to a deadweight loss of roughly \$426, or roughly 8.5% of total tax revenue from the housing tax. Put differently, \$426 of wealth is lost in society because of the substitution effect of the housing tax for this one consumer.

Verify that the numbers calculated in the previous paragraph are correct.

EXERCISE
10B.6

10B.2.2 Deadweight Loss and Substitution Effects All our work in Section 10A suggested that deadweight losses from taxation arise from substitution effects, and when tastes are such that substitution effects do not arise (as in Graph 10.8b), there is no deadweight loss from taxation. With the underlying mathematics developed, we can now see how this intuition plays out as elasticities of substitution (and thus substitution effects) get larger.

Suppose, for instance, that tastes can be summarized by the CES utility function

$$u(x_1, x_2) = (\alpha x_1^{-\rho} + (1 - \alpha)x_2^{-\rho})^{1/\rho}, \quad (10.20)$$

where the elasticity of substitution σ , as introduced in Chapter 5, is given by $1/(1 + \rho)$. Suppose further that, as in our example, the rental price of a square foot of housing is \$10, the price of “other goods” is (by definition) \$1, and income is \$100,000. Now we can consider the impact of a tax that raises the price of housing from \$10 to \$12.50 under different assumptions about the underlying elasticity of substitution σ .

Table 10.1 does precisely that, with the column labeled σ varying the elasticity of substitution and with α (in the right-most column) set to ensure that in each case the consumer rents 2,500 square feet of housing in the absence of a tax. The third column in the table then indicates the square footage consumed after the imposition of the tax, and the remaining columns give the

resulting values for tax revenue (T), a utility-equivalent lump sum tax (L), the resulting deadweight loss (DWL), and the deadweight loss as a fraction of tax revenue (DWL/T).

The figures in the table provide potential magnitudes for the distortionary effects of a relatively modest tax on housing. When the elasticity of substitution is low, so is the deadweight loss, but the deadweight loss can rise dramatically as the elasticity of substitution (and thus the substitution effect) increases. For the case of housing, empirical estimates of likely elasticities of substitution lie around 1, suggesting that our Cobb–Douglas example in the previous section (which is equivalent to the CES utility example with $\sigma = 1$) may be most relevant. Other goods that we commonly tax, however, may have significantly higher or lower elasticities of substitution.

10B.2.3 DWL Rising Faster than Tax Rates A second lesson from our work in Section 10A relates to the change in DWL as tax rates increase. We can now use our Cobb–Douglas example (where $\sigma = 1$) to calculate the changing impact of our housing tax as the tax increases. Table 10.2 does just that—it presents the impact of a tax that raises the price of housing from 10 to $(10 + t)$ as t increases. Notice that the DWL of the tax increases much faster than the tax itself, almost quadrupling, for instance, when the tax is doubled from 0.5 to 1.0 and almost increasing nine-fold when the tax is tripled from 0.5 to 1.5. This is in line with the rule of thumb we developed when we used a linear demand curve in Graph 10.10 to conclude that, as the level of a tax is increased by a factor of x , the DWL from the tax increases by a factor of x^2 . (The increase in DWL in Table 10.2 is slightly below what this rule of thumb predicts because compensated demand curves derived from Cobb–Douglas tastes contain some curvature that is not accounted for in Graph 10.10.)

In the last column of Table 10.2, the geometric growth in DWL results in a steady increase of DWL as a fraction of tax revenue. This is a common measure of just how inefficient a particular tax is, because it tells us how much of the revenue that is raised society has lost in wealth along the way.

TABLE 10.2 Housing Tax Increases under Cobb-Douglas Tastes (with $\alpha = 0.25$)

CONCLUSION

This chapter has introduced a method by which to measure changes in consumer welfare as the economic environment (i.e., prices faced by consumers) changes. More precisely, we have defined marginal willingness to pay (or compensated demand) curves along which such welfare changes can be measured. In the process, we have identified conditions under which such curves are similar to regular demand curves, and conditions (i.e., in the presence of income effects) when they are different. And this analysis is further extended in the B-portion of the chapter to show a whole series of similarities in the optimization approaches that lead to uncompensated demand and compensated demand curves, similarities that together have painted a “duality” picture that summarizes all the various techniques developed so far as well as their logical connections.

Given the new tool of marginal willingness to pay curves, we can then ask how much is gained by the “winners” and how much is lost by the “losers” of any policy that distorts prices from what they would be in the absence of the policy, and whether it is in principle possible to compensate the losers from the gains experienced by the winners. If the answer to the latter question is yes, then we know we have identified a policy that is efficiency enhancing. On the other hand, when we identify a policy as producing more economic losses than economic gains, we know we have a policy that is not efficient.

As emphasized at the outset of the chapter, we need to be cautious not to read too much into this, however. In Chapter 1, we discussed the difference between normative and positive economics, and we noted that there will be times when the line between the two types of analyses becomes blurred. If we conclude from the type of welfare analysis we have introduced in this chapter that a policy produces more economic gains for the “winners” than economic losses for the “losers,” that is still a *positive* statement because it is simply a statement of fact (assuming the analysis was done correctly) with no particular value judgments attached to it. However, if we interpret the statement as an endorsement of the policy, we have slipped into *normative* economics and have made some explicit value judgments regarding the desirability of benefiting the winners at the expense of the losers.

Consider, for instance, the chapter’s analysis of price-distorting (i.e., non-lump sum) taxes. We concluded that, with a few exceptions, all such taxes are *inefficient* because price-distorting taxes give rise to substitution effects. We also concluded the inefficiency (or deadweight loss) from such taxes increases geometrically as tax rates increase linearly, implying that lower tax rates on larger tax bases are generally more efficient than higher tax rates on smaller tax bases. These are *positive* statements so long as they are not interpreted as endorsements of particular policies. All the *positive* economist does is provide the policy maker with estimates of the economic costs of various policy alternatives; it is then up to the policy maker to determine, in light of the relevant costs, what is the best policy option. A policy maker might, for instance, choose a less efficient tax that produces greater deadweight losses because he or she thinks that the burdens of such a tax are more *fairly distributed* than in the case of a more efficient alternative.

This concludes our development of consumer theory for now. We began by modeling economic circumstances and tastes, then put them together in our optimization model, and finally developed the concepts of demand and compensated demand (or *MWTP*) curves. When we return to these in later chapters (after developing basic producer theory in the next section of the book), keep in mind what these two types of demands are used for: demand curves (or, analogously, labor supply curves) describe *how behavior actually changes with economic circumstances*; and compensated demand (or *MWTP*) curves (or compensated labor supply curves, which we will define in Chapter 19), on the other hand, allow us to measure welfare changes for consumers (and workers). They do not describe actual behavior and thus are useful only when we want to ask what the welfare impact of changing economic circumstances might be.

APPENDIX: SHEPHARD’S LEMMA AND ROY’S IDENTITY

Two further relationships indicated in parentheses in the duality picture of Graph 10.12 are frequently highlighted in more advanced treatments of duality and deserve some supplemental treatment here for those students interested in going a little deeper. The first and more important of these is known as *Shephard’s Lemma* and it simply states that

$$\frac{\partial E(p_1, p_2, u)}{\partial p_i} = h_i(p_1, p_2, u).^7 \quad (10.21)$$

⁷This relationship, while expressed for the two-good case here, holds more generally for the *n*-good case as well. The same is true for Roy’s Identity, which follows.

The second relationship is known as *Roy's Identity* and states that

$$-\frac{\partial V(p_1, p_2, I)/\partial p_i}{\partial V(p_1, p_2, I)/\partial I} = x_i(p_1, p_2, I). \quad (10.22)$$

Both of these results are a direct application of the *Envelope Theorem* from mathematics. We will briefly state this theorem and then apply it to derive Shephard's Lemma and Roy's Identity.⁸ Finally, we can show at the end of the appendix that these insights let us demonstrate quickly how consumer welfare translates into areas on marginal willingness to pay curves.

The Envelope Theorem

Suppose you face a maximization or minimization problem that can be written as one of the following:

$$\begin{aligned} \max_{x_1, x_2, \dots, x_n} f(x_1, x_2, \dots, x_n; \alpha_1, \alpha_2, \dots, \alpha_m) \quad \text{subject to } g(x_1, x_2, \dots, x_n; \alpha_1, \alpha_2, \dots, \alpha_m) &= 0 \\ \min_{x_1, x_2, \dots, x_n} f(x_1, x_2, \dots, x_n; \alpha_1, \alpha_2, \dots, \alpha_m) \quad \text{subject to } g(x_1, x_2, \dots, x_n; \alpha_1, \alpha_2, \dots, \alpha_m) &= 0 \end{aligned} \quad (10.23)$$

where (x_1, x_2, \dots, x_n) are the choice variables (analogous to the consumption bundle in our utility maximization and expenditure minimization problems) and $(\alpha_1, \alpha_2, \dots, \alpha_m)$ are parameters (such as utility function parameters or prices and income). The Lagrange function for this problem is

$$\mathcal{L}(x_1, x_2, \dots, x_n, \lambda) = f(x_1, x_2, \dots, x_n; \alpha_1, \alpha_2, \dots, \alpha_m) + \lambda g(x_1, x_2, \dots, x_n; \alpha_1, \alpha_2, \dots, \alpha_m) \quad (10.24)$$

and the solution to the first order conditions takes the form

$$x_i^* = x_i(\alpha_1, \alpha_2, \dots, \alpha_m) \quad \text{for all } i = 1, 2, \dots, n, \quad (10.25)$$

which is analogous to our uncompensated or compensated demand functions. Finally, suppose we call the function that arises when we plug these solutions into the objective function in (10.23) to get

$$F(\alpha_1, \alpha_2, \dots, \alpha_m) = f(x_1^*, x_2^*, \dots, x_n^*). \quad (10.26)$$

Then the Envelope Theorem states that, for all $j = 1, 2, \dots, m$,

$$\frac{\partial F}{\partial \alpha_j} = \frac{\partial \mathcal{L}}{\partial \alpha_j} \Big|_{(x_1^*, x_2^*, \dots, x_n^*)} = \left(\frac{\partial f}{\partial \alpha_j} + \lambda \frac{\partial g}{\partial \alpha_j} \right) \Big|_{(x_1^*, x_2^*, \dots, x_n^*)} \quad (10.27)$$

where the “ $(x_1^*, x_2^*, \dots, x_n^*)$ ” following the vertical lines is read as “evaluated at $(x_1^*, x_2^*, \dots, x_n^*)$ ” or “with the derivatives evaluated at the optimum of the choice variables.”

The Envelope Theorem Applied to Expenditure Minimization and Utility Maximization

Consider, then, the expenditure minimization problem on the right side of the duality Graph 10.12. In terms of the notation of our definition of the Envelope Theorem, the problem is written with

$$\begin{aligned} (x_1, x_2, \dots, x_n) &\text{ represented by the goods } (x_1, x_2) \\ (\alpha_1, \alpha_2, \dots, \alpha_m) &\text{ represented by the parameters } (p_1, p_2, u) \\ f(x_1, x_2, \dots, x_n; \alpha_1, \alpha_2, \dots, \alpha_m) &\text{ represented by } E = p_1 x_1 + p_2 x_2 \end{aligned} \quad (10.28)$$

⁸Shephard's Lemma is named after Ronald Shephard who formally proved the result in 1953 after it had already been used in work by others over the previous two decades. Rene Roy, a French economist, is credited with the proof for Roy's Identity in a paper in 1947.

$g(x_1, x_2, \dots, x_n; \alpha_1, \alpha_2, \dots, \alpha_m) = 0$ represented by $u - u(x_1, x_2) = 0$
 $x_i^* = x_i(\alpha_1, \alpha_2, \dots, \alpha_m)$ represented by $x_i^* = h_i(p_1, p_2, u)$ and
 $F(\alpha_1, \alpha_2, \dots, \alpha_m)$ represented by $E(p_1, p_2, u)$.

We can then apply the Envelope Theorem in equation (10.27) directly to get

$$\frac{\partial E(p_1, p_2, u)}{\partial p_i} = \left(\frac{\partial(p_1x_1 + p_2x_2)}{\partial p_i} \right) \Big|_{(x_1^*, x_2^*)} + \lambda \left(\frac{\partial(u - u(x_1, x_2))}{\partial p_i} \right) \Big|_{(x_1^*, x_2^*)}. \quad (10.29)$$

Since p_i does not appear in the equation $u - u(x_1, x_2)$, the term following λ is zero. This simplifies the expression in (10.29) to

$$\frac{\partial E(p_1, p_2, u)}{\partial p_i} = x_i \Big|_{(x_1^*, x_2^*)} = h_i(p_1, p_2, u), \quad (10.30)$$

which is Shephard's Lemma (and can be straightforwardly extended to an expenditure minimization problem with more than two goods). In the utility maximization problem on the left side of the duality Graph 10.12, on the other hand, we have

(x_1, x_2, \dots, x_n) represented by the goods (x_1, x_2)
 $(\alpha_1, \alpha_2, \dots, \alpha_m)$ represented by the parameters (p_1, p_2, I)
 $f(x_1, x_2, \dots, x_n; \alpha_1, \alpha_2, \dots, \alpha_m)$ represented by $u(x_1, x_2)$ (10.31)
 $g(x_1, x_2, \dots, x_n; \alpha_1, \alpha_2, \dots, \alpha_m) = 0$ represented by $I - p_1x_1 - p_2x_2 = 0$
 $x_i^* = x_i(\alpha_1, \alpha_2, \dots, \alpha_m)$ represented by $x_i^* = x_i(p_1, p_2, I)$ and
 $F(\alpha_1, \alpha_2, \dots, \alpha_m)$ represented by $V(p_1, p_2, I)$.

The Envelope Theorem then implies

$$\frac{\partial V(p_1, p_2, I)}{\partial p_i} = \left(\frac{\partial u(x_1, x_2)}{\partial p_i} \right) \Big|_{(x_1^*, x_2^*)} + \lambda \left(\frac{\partial(I - p_1x_1 - p_2x_2)}{\partial p_i} \right) \Big|_{(x_1^*, x_2^*)}. \quad (10.32)$$

Since $(\partial u(x_1, x_2)/\partial p_i) = 0$, equation (10.32) reduces to

$$\frac{\partial V(p_1, p_2, I)}{\partial p_i} = -\lambda x_i \Big|_{(x_1^*, x_2^*)} = -\lambda x_i(p_1, p_2, I). \quad (10.33)$$

The Envelope Theorem also implies

$$\frac{\partial V(p_1, p_2, I)}{\partial I} = \left(\frac{\partial u(x_1, x_2)}{\partial I} \right) \Big|_{(x_1^*, x_2^*)} + \lambda \left(\frac{\partial(I - p_1x_1 - p_2x_2)}{\partial I} \right) \Big|_{(x_1^*, x_2^*)} = \lambda. \quad (10.34)$$

Dividing equations (10.33) by (10.34) and multiplying both sides by -1 , we then get Roy's Identity:

$$-\frac{\partial V(p_1, p_2, I)/\partial p_i}{\partial V(p_1, p_2, I)/\partial I} = x_i(p_1, p_2, I). \quad (10.35)$$

Intuition Behind Shephard's Lemma and the Concavity of the Expenditure Function

Suppose that a consumer initially consumes bundle A when prices of x_1 and x_2 are p_1^A and p_2^A , and suppose that the consumer attains utility level u^A as a result. This is illustrated in panel (a) of Graph 10.14 with the tangency between the indifference curve and the blue budget line, which involves an overall expenditure level of $E^A = p_1^A x_1^A + p_2^A x_2^A$. This is then one point on the expenditure function $E(p_1, p_2, u)$, in particular the point $E(p_1^A, p_2^A, u^A)$.

GRAPH 10.14 Substitution Effects, Shephard's Lemma, and the Concavity of $E(p_1, p_2, u)$ in Prices

Now suppose we wanted to graph the “slice” of the expenditure function that holds the price of x_2 fixed at p_2^A and utility fixed at u^A ; that is, the slice $E(p_1, p_2^A, u^A)$ that illustrates how expenditure varies with changes in p_1 . The point A' in panel (b) of Graph 10.14 is then one point on this slice of the expenditure function, the point $E(p_1^A, p_2^A, u^A)$.

Without knowing about substitution effects, we could then naively assume that a consumer would always have to consume bundle A in order to remain equally happy as p_1 changes. If this were the case, then the slice of the expenditure function would simply be $E = p_1 x_1^A + p_2^A x_2^A$, an equation of a line with intercept $p_2^A x_2^A$ and slope x_1^A when expenditure is graphed on the vertical axis and p_1 on the horizontal. This is illustrated as the blue line in panel (b) of Graph 10.14.

The real expenditure function, however, takes account of the fact that individuals substitute away from goods that become more expensive and toward goods that become cheaper. For instance, suppose the price of x_1 rises from the initial p_1^A to p_1^B , represented in panel (a) of Graph 10.14 in the slope of the magenta budget line tangent to the indifference curve u^A at bundle B . The actual expenditure required to have this individual reach utility level u^A under the prices (p_1^B, p_2^A) is then $p_1^B x_1^B + p_2^A x_2^B$, not $p_1^B x_1^A + p_2^A x_2^A$ as suggested by the blue line in panel (b), and the former amount is smaller than the latter (which you can see in the fact that when the budget line has the steeper (magenta) slope, bundle A lies outside the budget set that contains bundle B). The actual point $E(p_1^B, p_2^A, u^A)$ in panel (b) of the graph therefore lies somewhere below the blue line and is graphed as point B' . The same is true for a decrease in p_1 to p_1^C , which is represented in the slope of the green budget line tangent to the indifference curve u^A at bundle C ; the actual expenditure $E(p_1^C, p_2^A, u^A)$ at bundle C is below the expenditure $p_1^C x_1^A + p_2^A x_2^A$ graphed on the blue line in panel (b).

The presence of substitution effects therefore implies that the “slices” of the expenditure function with a price change on the horizontal axis are *concave* with

$$\frac{\partial E(p_1, p_2, u)}{\partial p_i} > 0 \text{ and } \frac{\partial^2 E(p_1, p_2, u)}{\partial p_i^2} \leq 0. \quad (10.36)$$

EXERCISE 10B.7

What shape must the indifference curves have in order for the second derivative of the expenditure function with respect to price to be equal to zero (and for the “slice” of the expenditure function in panel (b) of Graph 10.14 to be equal to the blue line)?

Panel (b) of Graph 10.14 furthermore is a graphical depiction of Shephard's Lemma (and of the intuition behind the Envelope Theorem): The slope of the actual (magenta) expenditure function at p_1^A is x_1^A , and x_1^A is the expenditure minimizing level of consumption of good 1 to reach the indifference curve u^A when prices are (p_1^A, p_2^A) ; that is,

$$x_1^A = h_1(p_1^A, p_2^A, u^A). \quad (10.37)$$

The fact that the slope of the (magenta) slice of the actual expenditure function at A' is equal to x_1^A can therefore be expressed as

$$\frac{\partial E(p_1^A, p_2^A, u^A)}{\partial p_1} = h_1(p_1^A, p_2^A, u^A), \quad (10.38)$$

which is precisely what Shephard's Lemma tells us. Since we derived this intuition for an arbitrary initial set of prices and utility level, the same intuition applies for any combination of prices and utility levels.

Concavity of the Expenditure Function and the Slope of Compensated Demand Curves

The combination of Shephard's Lemma and the concavity of expenditure functions (that implies the conditions in equation (10.36)) then allows us to conclude

$$\frac{\partial h_i(p_1, p_2, u)}{\partial p_i} = \frac{\partial^2 E(p_1, p_2, u)}{\partial p_i^2} \leq 0, \quad (10.39)$$

which states that the slope of compensated demand curves is always negative; that is, compensated demand curves that isolate only substitution effects must be downward sloping. This is something we have concluded to be true intuitively already, and it has become mathematically easy to demonstrate given the additional material developed in this appendix.

In a two-panel graph with the top panel containing an indifference curve and the lower panel containing a compensated demand curve for x_1 derived from that indifference curve, illustrate the case when the inequality in equation (10.39) becomes an equality. (*Hint:* Remember that our graphs of compensated demand curves are graphs of the inverse of a slice of the compensated demand functions, with a slope of 0 turning into a slope of infinity.)

EXERCISE 10B.8

Using Shephard's Lemma to Illustrate Consumer Welfare Changes as Areas on Compensated Demand Curves

At the beginning of Section 10B.2, and in Section 10A.4 before that, we indicated that one can use integral calculus to calculate deadweight loss. Now that we have derived Shephard's Lemma, it is relatively straightforward to demonstrate this mathematically in the context of our example of a tax on housing. In particular, consider the measurement of the lump sum tax L that is equivalent (in terms of utility for the consumer) to a housing tax that raises the price of housing by t . The amount L is the difference between the consumer's actual income and the hypothetical income required to get the consumer to his or her after-tax utility level without changing any of the prices. One way to express a consumer's income is to note that it is equivalent to the consumer's expenditures after the housing tax is put in place; that is, $I = E(p_1 + t, p_2, u^A)$, where u^A represents the after-tax utility level. The compensated budget that gets the consumer to the same utility level at the pre-tax prices, on the other hand, is $E(p_1, p_2, u^A)$. Thus,

$$L = E(p_1 + t, p_2, u^A) - E(p_1, p_2, u^A). \quad (10.40)$$

Now note that Shephard's Lemma implies

$$\frac{\partial E(p_1, p_2, u)}{\partial p_1} = h_1(p_1, p_2, u). \quad (10.41)$$

We can then use this directly to expand equation (10.40)

$$L = E(p_1 + t, p_2, u^A) - E(p_1, p_2, u^A) = \int_{p_1}^{p_1+t} h_1(p_1, p_2, u^A) dp. \quad (10.42)$$

In other words, the amount L needed to calculate the DWL from a tax can be measured as an integral on the compensated demand function that corresponds to the after-tax utility level u^A , exactly as indicated in Graph 10.8a.

END-OF-CHAPTER EXERCISES

- 10.1†** Consider a good x_1 in a model where a consumer chooses between x_1 and a composite good x_2 .
- A.** Explain why the following either cannot happen or, if you think it can happen, how:
- Own-price demand for a good is perfectly vertical but taxing the good produces a deadweight loss.
 - Own-price demand is downward sloping (not vertical) and there is no deadweight loss from taxing the good.
- B.** Now suppose that the consumer's tastes can be summarized by the CES utility function $u(x_1, x_2) = (0.5x_1^{-\rho} + 0.5x_2^{-\rho})^{-1/\rho}$.
- Are there values for ρ that would result in the scenario described in A(a)?
 - Are there values for ρ that would result in the scenario described in A(b)?
 - Would either of these scenarios work with tastes that are quasilinear in x_1 ?
- 10.2** Suppose that both consumption and leisure are always normal goods. Keep in mind the underlying cause for deadweight losses from wage-distorting taxation as you answer the following questions.
- A.** Explain why the following either cannot happen or, if you think it can happen, how:
- Labor supply is perfectly vertical, but there is a significant deadweight loss from taxing wages.
 - Labor supply is perfectly vertical, and there is no deadweight loss from taxing wages.
 - Labor supply is downward sloping, and there is a deadweight loss from taxation of wages.
 - Labor supply is upward sloping, and there is a deadweight loss from taxing wages.
 - Labor supply is downward sloping, and there is no deadweight loss from taxing wages.
 - Labor supply is upward sloping, and there is no deadweight loss from taxing wages.
- B.*** Now suppose that tastes can be summarized by the CES utility function $u(c, \ell) = (0.5c^{-\rho} + 0.5\ell^{-\rho})^{-1/\rho}$, where c is consumption and ℓ is leisure.
- Are there values for ρ that would result in the scenario in A(a)?
 - Are there values for ρ that would result in the scenario in A(b)?
 - Are there values for ρ that would result in the scenario in A(c)?
 - Are there values for ρ that would result in the scenario in A(d)?
 - Are there values for ρ that would result in the scenarios in A(e) and A(f)?

*conceptually challenging

**computationally challenging

†solutions in Study Guide

- 10.3[†]** Suppose that consumption takes place this period and next period, and consumption is always a normal good. Suppose further that income now is positive and income next period is zero.
- A.** Explain why the following either cannot happen or, if you think it can happen, how:
- Savings behavior is immune to changes in the interest rate, but taxing interest income causes a deadweight loss.
 - Savings behavior is immune to changes in the interest rate, and taxing interest income causes no deadweight loss.
 - Savings decreases with increases in the interest rate, and there is a deadweight loss from taxation of interest.
 - Savings increases with increases in the interest rate, and there is a deadweight loss from taxation of interest.
 - Savings decreases with an increase in the interest rate, and there is no deadweight loss.
 - Savings increases with an increase in the interest rate, and there is no deadweight loss.
- B.*** Now suppose that tastes can be summarized by the CES utility function $u(c_1, c_2) = (0.5c_1^{-\rho} + 0.5c_2^{-\rho})^{-1/\rho}$, where c_1 is consumption in the first period and c_2 is consumption in the second period.
- Are there values for ρ that would result in the scenarios in A(a) and A(b)?
 - Are there values for ρ that would result in the scenarios in A(c)?
 - Are there values for ρ that would result in the scenario in A(d)?
 - Are there values for ρ that would result in the scenarios in A(e) or A(f)?
- 10.4*** Suppose that your tastes do not satisfy the convexity assumption. In particular, suppose the indifference curve corresponding to utility level u^A has a shape like the indifference curves depicted in Graph 6.8, with good x_1 on the horizontal axis and “other consumption” on the vertical. Illustrate what the *MWTP* (or compensated demand) curve corresponding to utility level u^A would look like. How would your answer change if the indifference curve instead satisfied convexity but contained a “flat” portion along which the *MRS* is constant (but not zero or infinite)?
- 10.5[†] Everyday Application: Teacher Pay and Professional Basketball Salaries: Do we have our priorities in order?** We trust our school-aged children to be taught by dedicated teachers in our schools, but we pay those teachers only about \$50,000 per year. At the same time, we watch professional-basketball games as entertainment, and we pay some of the players 400 times as much!
- A.** When confronted with these facts, many people throw their hands up in the air and conclude we are just hopelessly messed up as a society, that we place more value on our entertainment than on the future of our children.
- Suppose we treat our society as a single individual. What is our marginal willingness to pay for a teacher? What is our marginal willingness to pay for a star basketball player?
 - There are about 4 million teachers that work in primary and secondary schools in the United States. What is the smallest dollar figure that could represent our total willingness to pay for teachers?
 - Do you think our *actual* total willingness to pay for teachers is likely to be much greater than that minimum figure? Why or why not?
 - For purposes of this problem, assume there are 10 star basketball players at any given time. What is the least our total willingness to pay for star basketball players could be?
 - Is our actual total willingness to pay for basketball players likely to be much higher than this minimum?
 - Do the facts cited at the beginning of this question really warrant the conclusion that we place more value on our entertainment than on the future of our children?
 - Adam Smith puzzled over an analogous dilemma: He observed that people were willing to pay exorbitant amounts for diamonds but virtually nothing for water. With water essential for sustaining life and diamonds just items that appeal to our vanity, how could we value diamonds so much more than water? This became known as the *diamond-water paradox*. Can you explain the paradox to Smith?
- B.** Suppose our marginal willingness to pay for teachers (x_1) is given by $MWTP = A - \alpha x_1$ and our marginal willingness to pay for star basketball players (x_2) is given by $MWTP = B - \beta x_2$.
- Given the previously cited facts, what is the lowest that A and B could be?
 - If A and B were as you just concluded, what would α and β be?

- c. What would be our marginal and total willingness to pay for teachers and star basketball players?
- d. Suppose $A = B = \$100$ million. Can you tell what α and β must be?
- e. Using the parameter values you just derived (with $A = B = \$100$ million), what is our total willingness to pay for teachers and star basketball players?

10.6 Everyday Application: Ordering Appetizers: I recently went out to dinner with my brother and my family. We decided we wanted chicken wings for an appetizer and had a choice of getting 10 wings for \$4.95 or 20 wings for \$7.95. I thought we should get 10; my brother thought we should get 20 and prevailed.

- A. At the end of the meal, we noticed that there were 4 wings left. My brother then commented: “I guess I am vindicated. It really was the right decision to order 20 rather than 10 wings.”
 - a. Is this a correct assessment; that is, the evidence of 4 wings at the end of the meal sufficient to conclude that my brother was right?
 - b. What if no wings were left at the end of the meal?
 - c. What if 10 wings were left?
 - d. In order for us to leave wings on the table, which of our usual assumptions about tastes must be violated?
- B. Suppose that our *MWTP* for wings (x) can be approximated by the function $MWTP = A - \alpha x$.
 - a. Given that 4 wings were left at the end of the meal, what must be the relationship between α and A ?
 - b. Suppose $A = 8/3$. Was my brother right to want to order 20 instead of 10 wings?
 - c. Suppose instead that $A = 2$. Does your answer change? What if $A = 4$?
 - d. If our tastes were Cobb–Douglas, could it ever be the case that we leave wings on the table?

10.7*+ Everyday Application: To Trade or Not to Trade Pizza Coupons: Exploring the Difference between Willingness to Pay and Willingness to Accept: Suppose you and I are identical in every way, same exogenous income, same tastes over pizza and “other goods.” The only difference between us is that I have a coupon that allows the owner of the coupon to buy as much pizza as he or she wants at 50% off.

- A. Now suppose you approach me to see if there was any way we could make a deal under which I would sell you my coupon. In the following, you will explore under what conditions such a deal is possible.
 - a. On a graph with pizza on the horizontal axis and “other goods” on the vertical, illustrate (as a vertical distance) the most you are willing to pay me for my coupon. Call this amount P .
 - b. On a separate but similar graph, illustrate (as a vertical distance) the least I would be willing to accept in cash to give up my coupon. Call this amount R .
 - c. Below each of the graphs you have drawn in (a) and (b), illustrate the same amounts P and R (as areas) along the appropriate marginal willingness to pay curves.
 - d. Is P larger or smaller than R ? What does your answer depend on? (*Hint:* By overlaying your lower graphs that illustrate P and R as areas along marginal willingness to pay curves, you should be able to tell whether one is bigger than the other or whether they are the same size depending on what kind of good pizza is.)
 - e. *True or False:* You and I will be able to make a deal so long as pizza is not a normal good. Explain your answer intuitively.
- B. Suppose your and my tastes can be represented by the Cobb–Douglas utility function $u(x_1, x_2) = x_1^{0.5} x_2^{0.5}$, and suppose we both have income $I = 100$. Let pizza be denoted by x_1 and “other goods” by x_2 , and let the price of pizza be denoted by p . (Since “other goods” are denominated in dollars, the price of x_2 is implicitly set to 1.)
 - a. Calculate our demand functions for pizza and other goods as a function of p .
 - b. Calculate our compensated demand for pizza (x_1) and other goods (x_2) as a function of p (ignoring for now the existence of the coupon).
 - c. Suppose $p = 10$ and the coupon reduces this price by half (to 5). Assume again that I have the coupon but you do not. How much utility do you and I get when we make optimal decisions?

- d. How much pizza will you consume if you pay me the most you are willing to pay for the coupon? How much will I consume if you pay me the least I am willing to accept?
- e. Calculate the expenditure function for you and me.
- f. Using your answers so far, determine R —the least I am willing to accept to give up my coupon. Then determine P —the most you are willing to pay to get a coupon. (*Hint*: Use your graphs from A(a) to determine the appropriate values to plug into the expenditure function to determine how much income I would have to have to give up my coupon. Once you have done this, you can subtract my actual income $I = 100$ to determine how much you have to give me to be willing to let go of the coupon. Then do the analogous to determine how much you'd be willing to pay, this time using your graph from A(b).)
- g. Are we able to make a deal under which I sell you my coupon? Make sense of this given what you found intuitively in part A and given what you know about Cobb–Douglas tastes.
- h. Now suppose our tastes could instead be represented by the utility function $u(x_1, x_2) = 50 \ln x_1 + x_2$. Using steps similar to what you have just done, calculate again the least I am willing to accept and the most you are willing to pay for the coupon. Explain the intuition behind your answer given what you know about quasilinear tastes.
- i.** Can you demonstrate, using the compensated demand functions you calculated for the two types of tastes, that the values for P and R are in fact areas under these functions (as you described in your answer to A(c)?) (*Note*: This part requires you to use integral calculus.)

10.8 Everyday Application: To Join or Not to Join the Local Pool: Where I live, most people do not have swimming pools despite the fact that it gets very hot in the summers. Thus, families, especially those with children, try to find swimming pools in the area. Our local swimming pool offers two ways in which we can get by the entrance guard: We can either purchase a “family pass” for the whole season, or we can pay an entrance fee for the family every time we want to go swimming.

- A. Suppose we have \$1,000 to spend on activities to amuse ourselves during the summer, and suppose that there are exactly 100 days during the summer when the swimming pool is open and usable. The family pass costs \$750, while the daily passes cost \$10 each (for the whole family).
 - a. With “days swimming” on the horizontal axis and “dollars spent on other amusements” on the vertical, illustrate our budget constraint if we choose not to buy the season pass.
 - b. On the same graph, illustrate the budget constraint we face if we choose to purchase the season pass.
 - c. After careful consideration, we decided that we really did not prefer one option over the other, so we flipped a coin with “heads” leading to the season pass and “tails” to no season pass. The coin came up “tails,” so we did not buy the season pass. Would we have gone swimming more or less had the coin come up “heads” instead? Illustrate your answer on your graph.
 - d. My brother bought the season pass. After the summer passed by, my mother said: “I just can’t understand how two kids can turn out so differently. One of them spends all his time during the summer at the swimming pool, while the other barely went at all.” One possible explanation for my mother’s observation is certainly that I am very different from my brother. The other is that we simply faced different circumstances but are actually quite alike. Could the latter be true without large substitution effects?
 - e. On a separate graph, illustrate the compensated (Hicksian) demand curve that corresponds to the utility level u^* that my family reached during the summer. Given that we paid \$10 per day at the pool, illustrate the consumer surplus we came away with from the summer experience at the pool.
 - f.* Since we would have had to pay no entrance fee had we bought the season pass, can you identify the consumer surplus we would have gotten? (*Hint*: Keep in mind that, once you have the season pass, the price for going to the pool on any day is zero. The cost of the season pass is therefore not relevant for your answer to this part.)
 - g.* Can you identify an area in the graph that represents how much the season pass was?
- B. Suppose that my tastes can be represented by the utility function $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$ with x_1 denoting days of swimming and x_2 denoting dollars spent on other amusements.
 - a. In the absence of the possibility of a season pass, what would be the optimal number of days for my family to go swimming in the summer? (Your answer should be in terms of α .)
 - b. Derive my indirect utility as a function of α .

- c. Suppose $\alpha = 0.5$. How much utility do I get out of my \$1,000 of amusement funds? How often do I go to the swimming pool?
- d. Now suppose I had bought the season pass instead (for \$750). How much utility would I have received from my \$1,000 amusement funds?
- e. What is my marginal willingness to pay for days at the pool if I am going 100 times?
- f. On a graph with the compensated demand curve corresponding to my utility this summer, label the horizontal and vertical components of the points that correspond to me taking the season pass and the ones corresponding to me paying a per-use fee.
- g. Derive the expenditure function for this problem in terms of p_1 , p_2 , and u (with $\alpha = 0.5$).
- h.* In (g) of part A, you identified the area in the *MWTP* graph that represents the cost of the season pass. Can you now verify mathematically that this area is indeed equal to \$750? (*Hint*: If you have drawn and labeled your graph correctly, the season pass fee is equal to an area composed of two parts: a rectangle equal to 2.5 times 100 and an area to the left of the compensated demand curve between 2.5 and 10 on the vertical axis. The latter is equal to the difference between the expenditure function $E(p_1, p_2, u)$ evaluated at $p_1 = 2.5$ and $p_1 = 10$ (with $p_2 = 1$ and u equal to the correct utility value associated with the indifference curve in your earlier graph).)

10.9† Everyday Application: To Take, or not to Take, the Bus: After you graduate, you get a job in a small city where you have taken your sister's offer of living in her apartment. Your job pays you \$20 per hour and you have up to 60 hours per week available. The problem is you also have to get to work.

- A. Your sister's place is actually pretty close to work, so you could lease a car and pay a total (including insurance and gas) of \$100 per week to get to work, spending essentially no time commuting. Alternatively, you could use the city's sparse bus system, but unfortunately there is no direct bus line to your place of work and you would have to change buses a few times to get there. This would take approximately 5 hours per week.
 - a. Now suppose that you do not consider time spent commuting as "leisure," and you don't consider money spent on transportation as "consumption." On a graph with "leisure net of commuting time" on the horizontal axis and "consumption dollars net of commuting costs" on the vertical, illustrate your budget constraint if you choose the bus and a separate budget constraint if you choose to lease the car.
 - b. Do you prefer the bus to the car?
 - c. Suppose that before you get to town you find out that a typo had been made in your offer letter and your actual wage is \$10 per hour instead of \$20 per hour. How does your answer change?
 - d. After a few weeks, your employer discovers just how good you are and gives you a raise to \$25 per hour. What mode of transportation do you take now?
 - e. Illustrate in a graph (not directly derived from what you have done so far) the relationship between wage on the horizontal axis and the most you'd be willing to pay for the leased car.
 - f. If the government taxes gasoline and thus increases the cost of driving a leased car (while keeping buses running for free), predict what will happen to the demand for bus service and indicate what types of workers will be the source of the change in demand.
 - g. What happens if the government improves bus service by reducing the time one needs to spend to get from one place to the other?
- B. Now suppose your tastes were given by $u(c, \ell) = c^\alpha \ell^{1-\alpha}$, where c is consumption dollars net of commuting expenses and ℓ is leisure consumption net of time spent commuting. Suppose your leisure endowment is L and your wage is w .
 - a. Derive consumption and leisure demand assuming you lease a car that costs you \$ Y per week, which therefore implies no commuting time.
 - b. Next, derive your demand for consumption and leisure assuming you take the bus instead, with the bus costing no money but taking T hours per week from your leisure.
 - c. Express the indirect utility of leasing the car as a function of Y .
 - d. Express your indirect utility of taking the bus as a function of T .

- e. Using the indirect utility functions, determine the relationship between Y and T that would keep you indifferent between taking the bus and leasing the car. Is your answer consistent with the relationship you illustrated in A(e) and your conclusions in A(f) and A(g)?
- f. Could you have skipped all these steps and derived this relationship directly from the budget constraints? Why or why not?

10.10 Business Application: Pricing at Disneyland: In the 1970s, Disneyland charged an entrance fee to get into the park and then required customers to buy tickets separately for each ride once they were in the park. In the 1980s, Disneyland switched to a different pricing system that continues to this day. Now, customers simply pay an entrance fee and then all rides in the park are free.

- A. Suppose you own an amusement park with many rides (and assume, for the sake of simplicity, that all rides cost the same to operate). Suppose further that the maximum number of rides a customer can take on any given day (given how long rides take and how long the average wait times are) is 25. Your typical vacationing customer has some exogenous daily vacation budget I to allocate between rides at your park and other forms of entertainment (that are, for purposes of this problem) bought from vendors other than you. Finally, suppose tastes are quasilinear in amusement park rides.
 - a. Draw a demand curve for rides in your park. Suppose you charge no entrance fee and only charge your customers per ride. Indicate the maximum price per ride you could charge while ensuring that your consumer will in fact spend all her day riding rides (i.e., ride 25 times).
 - b. On your graph, indicate the total amount that the consumer will spend.
 - c. Now suppose that you decide you want to keep the price per ride you have been using but you'd also like to charge a separate entrance fee to the park. What is the most you can charge your customer?
 - d. Suppose you decide that it is just too much trouble to collect fees for each ride, so you eliminate the price per ride and switch to a system where you only charge an entrance fee to the park. How high an entrance fee can you charge?
 - e. How would your analysis change if x_1 , amusement park rides, is a normal good rather than being quasilinear?
- B. Consider a consumer on vacation who visits your amusement park for the day. Suppose the consumer's tastes can be summarized by the utility function $u(x_1, x_2) = 10x_1^{0.5} + x_2$ where x_1 represents daily rides in the amusement park and x_2 represents dollars of other entertainment spending. Suppose further that the consumer's exogenous daily budget for entertainment is \$100.
 - a. Derive the uncompensated and compensated demand functions for x_1 and x_2 .
 - b. Suppose again there is only enough time for a customer to ride 25 rides a day in your amusement park. Suppose further that you'd like your customer to ride as much as possible so he can spread the word on how great your rides are. What price will you set per ride?
 - c. How much utility will your consumer attain under your pricing?
 - d.** Suppose you can charge an entrance fee to your park in addition to charging the price per ride you calculated. How high an entrance fee would you charge? (*Hint:* You should be evaluating an integral, which draws on some of the material from the appendix.)
 - e.** Now suppose you decide to make all rides free (knowing that the most rides the consumer can squeeze into a day is 25) and you simply charge an entrance fee to your park. How high an entrance fee will you now charge to your park? (*Note:* This part is not computationally difficult. It is designated with ** only because you have to use information from the previous part.)
 - f.** How does your analysis change if the consumer's tastes instead were given by $u(x_1, x_2) = (3^{-0.5})x_1^{0.5} + x_2^{0.5}$?

10.11* Business Application: Negotiating an Endorsement Deal and a Bribe: Suppose you are an amateur athlete and your uncle owns the cereal company "Wheaties." Your uncle offers you a job working for his company at a wage of w per hour. After looking around for other jobs, you find that the most you could make elsewhere is w' , where $w' < w$. You have a weekly leisure endowment of L and can allocate any amount of that to work. Given the higher wage at Wheaties, you accept your uncle's job offer.

- A. Then you win a gold medal in the Olympics. "Greetings," the makers of grits, ask you for an endorsement. As part of the deal, they will pay you some fixed weekly amount to appear on their boxes of

grits. Unfortunately, your uncle (who hates his competitor “Greetings” with the white hot intensity of a thousand suns) will fire you if you accept the deal offered by “Greetings.” Therefore, if you accept the deal, your wage falls to w' .

- a. On a graph with consumption on the vertical and leisure on the horizontal axis, graph your budget constraint before the “Greetings” offer.
 - b. On the same graph, illustrate your budget if you worked for someone other than your uncle prior to your success in the Olympics.
 - c. Illustrate the minimum amount that “Greetings” would have to pay you (weekly) for your endorsement in order for you to accept the deal. Call this amount E .
 - d. How does this amount E compare to the amount necessary to get you to be able to consume bundle A under a Greeties endorsement deal?
 - e. Now suppose that you accepted the endorsement deal from “Greetings” but, unfortunately, the check for the endorsement bounces because “Greetings” goes bankrupt. Therefore the deal is off, but your angry uncle has already fired you. Deep down inside, your uncle still cares about you and will give you back your old job if you come back and ask him for it. The problem is that you have to get past his greedy secretary who has full control over who gets to see your uncle. When you get to the “Wheaties” office, she informs you that you have to commit to pay her a weekly bribe if you want access to your uncle. On a new graph, illustrate the largest possible (weekly) payment you would be willing to make. Call this F .
 - f. If your uncle’s secretary just asks you for a weekly bribe that gets you to the bundle C that you would consume in the absence of returning to Wheaties, would you pay her such a bribe?
 - g. Suppose your tastes are such that the wealth effect from a wage change is exactly offset by the substitution effect; that is, no matter what the wage, you will always work the same amount (in the absence of receiving endorsement checks or paying bribes). In this case, can you tell whether the amount E (i.e., the minimum endorsement check) is greater than or equal to the amount F (i.e., the maximum bribe)?
- B.** Suppose that your tastes over weekly consumption c and weekly leisure ℓ can be represented by the utility function $u(c, \ell) = c^{0.5}\ell^{0.5}$ and your weekly leisure endowment is $L = 60$.
- a. If you accept the initial job with Wheaties, how much will you work?
 - b. Suppose you accept a deal from Greeties that pays you a weekly amount \bar{E} . How much will you work then? Can you tell whether this is more or less than you would work at Wheaties?
 - c. Suppose that the wage w at Wheaties is \$50 per hour and the wage w' at Greeties (or any other potential employer other than Wheaties) is \$25 per hour. What is the lowest possible value for E —the weekly endorsement money from Greeties—that might get you to accept the endorsement deal?
 - d. How much will you work if you accept this endorsement deal E ?
 - e. Suppose you have accepted this deal but Greeties now goes out of business. What is the highest possible weekly bribe F you’d be willing to pay your uncle’s secretary in order to get your job at Wheaties back?
 - f. How much would you work assuming that the secretary has successfully extracted the maximum amount you are willing to pay to get your Wheaties job back?
 - g. Redraw your graphs from part A but now label all the points and intercepts in accordance with your calculations. Does your prediction from A(g) about the size of the maximum bribe relative to the size of the minimum endorsement hold true?

POLICY APPLICATION

10.12 Policy Application: Distortionary Taxes: Suppose that you have tastes for grits and “other goods” (where the price of “other goods” is normalized to 1). Assume throughout (unless otherwise stated) that your tastes are quasilinear in grits.

- A.** The government decides to place a tax on grits, thus raising the price of grits from p to $(p + t)$.
- a. On a graph with grits on the horizontal axis and “other goods” on the vertical, illustrate the before- and after-tax budget.
 - b. Illustrate your optimal consumption bundle after the tax is imposed; then indicate how much tax revenue T the government collects from you.
 - c. Illustrate the most L you would be willing to pay to not have the tax.

- d. Does your answer depend on the fact that you know your tastes are quasilinear in grits?
 - e. On a graph below the one you have drawn, derive the regular demand curve as well as the *MWTP* curve.
 - f. Illustrate T and L on your lower graph and indicate where in the graph you can locate the deadweight loss from the tax.
 - g. Suppose you only observed the demand curve in the lower graph, and you knew nothing else about tastes. If grits were actually a normal good (rather than a quasilinear good), would you under- or overestimate that deadweight loss by assuming grits are quasilinear?
- B.** Suppose that your tastes could be represented by the utility function $u(x_1, x_2) = 10x_1^{0.5} + x_2$, with x_1 representing weekly servings of grits and x_2 representing dollars of other breakfast food consumption. Suppose your weekly (exogenous) budget for breakfast food is \$50.
- a. Derive your uncompensated and compensated demand for grits.
 - b. Suppose the tax on grits raises its price from \$1.00 to \$1.25 per serving. How does your consumption of grits change?
 - c. How much tax revenue T does the government collect from you per week?
 - d. Use the expenditure function for this problem to determine how much L you would have been willing to pay (per week) to avoid this tax?
 - e.** Verify your answer about L by checking that it is equal to the appropriate area on the *MWTP* curve. (For this, you need to take an integral, using material from the appendix.)
 - f. How large is the weekly deadweight loss?
 - g. Now suppose that my tastes were represented by $u(x_1, x_2) = x_1^{0.5} + x_2^{0.5}$. How would your answers change?
 - h.** Under these new tastes, suppose you only observed the regular demand curve and then used it to calculate deadweight loss while incorrectly assuming it was the same as the *MWTP* curve. By what percentage would you be overestimating the deadweight loss? (*Hint*: You again need to evaluate an integral. Note that the integral of $1/(p(1+p))$ with respect to p is $\ln p - \ln(1+p)$.)

10.13[†] Policy Application: Price Subsidies: Suppose the government decides to subsidize (rather than tax) consumption of grits.

- A.** Consider a consumer who consumes boxes of grits and “other goods.”
- a. Begin by drawing a budget constraint (assuming some exogenous income) with grits on the horizontal axis and “other consumption” on the vertical. Then illustrate a new budget constraint with the subsidy, reflecting that each box of grits now costs the consumer less than it did before.
 - b. Illustrate the optimal consumption of grits with an indifference curve tangent to the after-subsidy budget. Then illustrate in your graph the amount that the government spends on the subsidy for you. Call this amount S .
 - c. Next, illustrate how much the government could have given you in a lump sum cash payment instead and made you just as happy as you are under the subsidy policy. Call this amount L .
 - d. Which is bigger, S or L ?
 - e. On a graph below the one you have drawn, illustrate the relevant *MWTP* curve and show where S and L can be found on that graph.
 - f. What would your tastes have to be like in order for S to be equal to L .
 - g. *True or False:* For almost all tastes, price subsidies are inefficient.
- B.** Suppose the consumer’s tastes are Cobb–Douglas and take the form $u(x_1, x_2) = x_1^\alpha x_2^{(1-\alpha)}$ where x_1 is boxes of grits and x_2 is a composite good with price normalized to 1. The consumer’s exogenous income is I .
- a. Suppose the government price subsidy lowers the price of grits from p to $(p - s)$. How much S will the government have to pay to fund this price subsidy for this consumer?
 - b. How much utility does the consumer attain under this price subsidy?

- c. How much L would the government have had to pay this consumer in cash to make the consumer equally happy as she is under the price subsidy?
- d. What is the deadweight loss from the price subsidy?
- e. Suppose $I = 1,000$, $p = 2$, $s = 1$, and $\alpha = 0.5$. How much grits does the consumer buy before any subsidy, under the price subsidy, and under the utility-equivalent cash subsidy? What is the deadweight loss from the price subsidy?
- f.** Continue with the values from the previous part. Can you calculate the compensated demand curve you illustrated in A(e) and verify that the area you identified as the deadweight loss is equal to what you have calculated? (*Hint*: You need to take an integral and use some of the material from the appendix to answer this.)

10.14 Policy Application: Taxing Interest on Savings: Suppose I care only about consumption this year and consumption next year, and suppose I earn an income this year but do not expect to earn an income next year.

- A. The government announces an increase in the tax on interest income. Illustrate my before- and after-tax intertemporal budget constraint.
 - a. Suppose I save 50% of my income after the new tax is imposed. Illustrate the amount of the tax the government will collect from me next year. Call this T .
 - b. Illustrate the most I would be willing to pay next year to keep the government from imposing this tax on interest income. Call this amount L .
 - c. Is L larger or smaller than T ? What does your answer depend on?
 - d. If consumption is always a normal good, will I consume more or less next year if the tax on interest income is removed?
 - e. If consumption is always a normal good, will I consume more or less *this* year if the tax on interest income is eliminated?
 - f. Can you redraw your graph but this time indicate how much T' you are paying in taxes in terms of *this* year's consumption, and how much L' you would be willing to pay to avoid the tax in terms of *this* year's consumption?
- B. Now suppose that my tastes over consumption now, c_1 , and consumption next period, c_2 , can be captured by the utility function $u(c_1, c_2) = c_1^\alpha c_2^{(1-\alpha)}$.
 - a. Suppose the interest rate is r . What does α have to be in order for me to optimally save 50% of my income this year?
 - b. Assume from now on that α is as you calculated and suppose that my current income is \$200,000. Suppose the interest rate before the tax increase was 10% and the after-tax interest rate after the tax increase is 5%. How much tax revenue T does the government collect from me? What is the present value of that this period?
 - c. What is the most (L) I would be willing to pay to avoid this tax increase (in either today's dollars or in next period's dollars)?
 - d. Does the amount that I save today change as a result of the tax increase?
 - e. Is the tax efficient? If not, how big is the deadweight loss?

10.15+ Policy Application: International Trade and Child Labor: Consider again the end-of-chapter problem 8.9 about the impact of international trade on child labor in the developing world.

- A. Suppose again that households have non-child income Y , that children have a certain weekly time endowment L , and that child wages are w in the absence of trade and $w' > w$ with trade.
 - a. On a graph with child leisure hours on the horizontal axis and household consumption on the vertical, illustrate the before and after trade household budget constraints.
 - b. Suppose that tastes over consumption and child leisure were those of perfect complements. Illustrate in your graph how much a household would be willing to pay to permit trade; that is, how much would a household be willing to pay to increase the child wage from w to w' ?

- c. If the household paid the maximum it was willing to pay to cause the child wage to increase, will the child work more or less than before the wage increase?
- d. Redraw your graph, assume that the same bundle (as at the beginning of part (b)) is optimal, but now assume that consumption and leisure are quite (though not perfectly) substitutable. Illustrate again how much the household would be willing to pay to cause the wage to increase.
- e. If the household actually had to pay this amount to get the wage to increase, will the child end up working more or less than before trade?
- f. Does your prediction of whether the child will work more or less if the household pays the maximum bribe to get the higher wage depend on how substitutable consumption and child leisure are?
- g. Can you make a prediction about the relative size of the payment the household is willing to make to get the higher child wage as it relates to the degree of substitutability of consumption and child leisure? Are “good” parents willing to pay more or less?

B.** Suppose that the household’s tastes over consumption and leisure can be represented by the CES utility function $u(c, \ell) = (\alpha c^{-\rho} + (1 - \alpha)\ell^{-\rho})^{-1/\rho}$.

- a. Derive the optimal household consumption and child leisure levels assuming the household has non-child weekly income Y , the child has a weekly time endowment of L , and the child wage is w .
- b. Verify your conclusion from end-of-chapter problem 8.9 that parents are neither “good” nor “bad” when $Y = 0$ and $\rho = 0$; that is, parents will neither increase nor decrease child labor when w increases.
- c. If international trade raises household income Y , what will happen to child labor in the absence of any change in child wages? Does your answer depend on how substitutable c and w are?
- d. When $\alpha = 0.5$ and $w = 1$, does your answer depend on the household elasticity of substitution between consumption and child leisure?
- e. How much utility will the household get when $\alpha = 0.5$ and $w = 1$?
- f. Derive the expenditure function for this household as a function of w and u . What does this reduce to when $\alpha = 0.5$? (*Hint*: You can assume $\$Y = 0\$$ for this part.)
- g. Suppose non-child income $Y = 0$, child time is $L = 100$, $\alpha = 0.5$, $\rho = 1$, and w is initially 1. Then international trade raises w to 2. How does the household respond in its allocation of child leisure?
- h. Using your expenditure function, can you determine how much the household would be willing to pay to cause child wages to increase from 1 to 2? If it did in fact pay this amount, how would it change the amount of child labor?
- i. Repeat the two previous steps for the case when $\rho = -0.5$ instead of 1.
- j. Are your calculations consistent with your predictions in (f) and (g) of part A of the question?

10.16 Policy Application: Efficient Land Taxes: We have argued in this chapter that it is difficult to find taxes that are efficient; that is, taxes that do not give rise to a deadweight loss. Economists have long pointed to one exception to this proposition: taxation of land.

- A.** Suppose a particular plot of commercial land generates approximately \$10,000 in income for its owner each year into the foreseeable future.
 - a. Assuming an annual interest rate of 10%, what is the most that you would be willing to pay for this land? (*Hint*: Recall from our Chapter 3 exercises that the present discounted value of an annual stream of income of y is y/r where r is the annual interest rate.)
 - b. Now suppose the government announces that, from now on, it will impose a 50% tax on all income derived from land. How does your answer regarding how much you would be willing to pay for this plot of land change?

- c. If you currently own this land, how are you affected by this tax? Is there any way you can change your behavior and avoid some portion of the tax; that is, are there any substitution effects that might arise to create a deadweight loss?
 - d. If you currently don't own this land but are about to buy it, how are you affected by the imposition of this land tax?
 - e. *True or False:* Regardless of whether the current owner of the land keeps it or sells it to me (after the announcement of the tax), the current owner effectively pays all future taxes associated with income from this land.
 - f. In light of your previous answers, how is this an example of an efficient lump sum tax?
- B.** Consider the more general case where a particular plot of land yields \$ y in annual income.
- a. What is the value of this land assuming an interest rate of r ?
 - b. Now suppose the government announces a tax rate t (with $0 < t \leq 1$) that will be levied on income obtained purely from land. What happens to the value of the plot of land?
 - c. Who is affected by this, current land owners or future land owners?
 - d. Suppose the government decides to set $t = 1$; that is, it announces that it will from now on tax income from land at 100%. What happens to the price of land?
 - e. Defend the following statement: A 100% tax on income from land is equivalent to the government confiscating land and asking for annual rental payments, with the present value of all future rental payments equal to the previous price of the land.

Profit-Maximizing Choice: Producers (or “Firms”)

Chapter 11 One Input and One Output:
A Short-Run Producer Model

Chapter 12 Production with Multiple Inputs

Chapter 13 Production Decisions in the Short
and Long Run

In Part 1, we modeled individual choice when the chooser’s objective is to maximize “happiness.” This model applied to consumers and resulted in the demand curve for goods, but it also applied to workers and savers to give us labor and capital supply curves. We now turn to the case where the chooser’s objective is instead to maximize something more specific: profit. We will refer to the individuals in an economy whose goal is to maximize profit as *producers* or *firms*, and their decisions will lead to supply curves for goods as well as demand curves for labor and capital. Once we have completed this part, we will then be ready to think about the interaction of supply and demand in goods, labor, and capital markets.

We will see that the basic logic of choice that underlies our model of Part 1 applies also for producers. Just like consumers, they try to maximize something given the constraints that they face, except that what they choose when they maximize and what they face as constraints is now a bit different. Consumers choose goods and services to maximize happiness given their incomes and the prices they face. Firms, on the other hand, choose *inputs like labor and capital*; they maximize *profit—the difference between revenue and cost*; and they face *technological constraints* that limit how easy it is to convert inputs into outputs and *economic constraints* that emerge from the prices of inputs and outputs. Thus, in place of goods and services, we now choose combinations of inputs; instead of somewhat ambiguous “tastes,” we now have the more concrete objective of profit; and we add the constraints imposed by technology to the economic constraints of prices.

We begin in Chapter 11 with the simplest possible model of producers: a model where a single output is produced from a *single input* given a particular technology available to the producer. We then see how the technology that tells us how easy it is to convert the input into the output serves as the constraint for the firm. The firm may want to produce something from nothing, but that is no more an option in our world of scarcity than it is for consumers to consume beyond their means. We can also see easily in this model that the “tastes” for profit are shaped by the prices of the output and input, with more profit possible when output price is high and input price is low. Combining these, we can show how the firm chooses its optimal (or profit-maximizing) level of output using the lowest possible input level under which it is technologically feasible to produce the desired output. From this choice process, we can then illustrate *output supply* and *input demand* relationships, or how output and input decisions are affected by changes in prices in the economy.

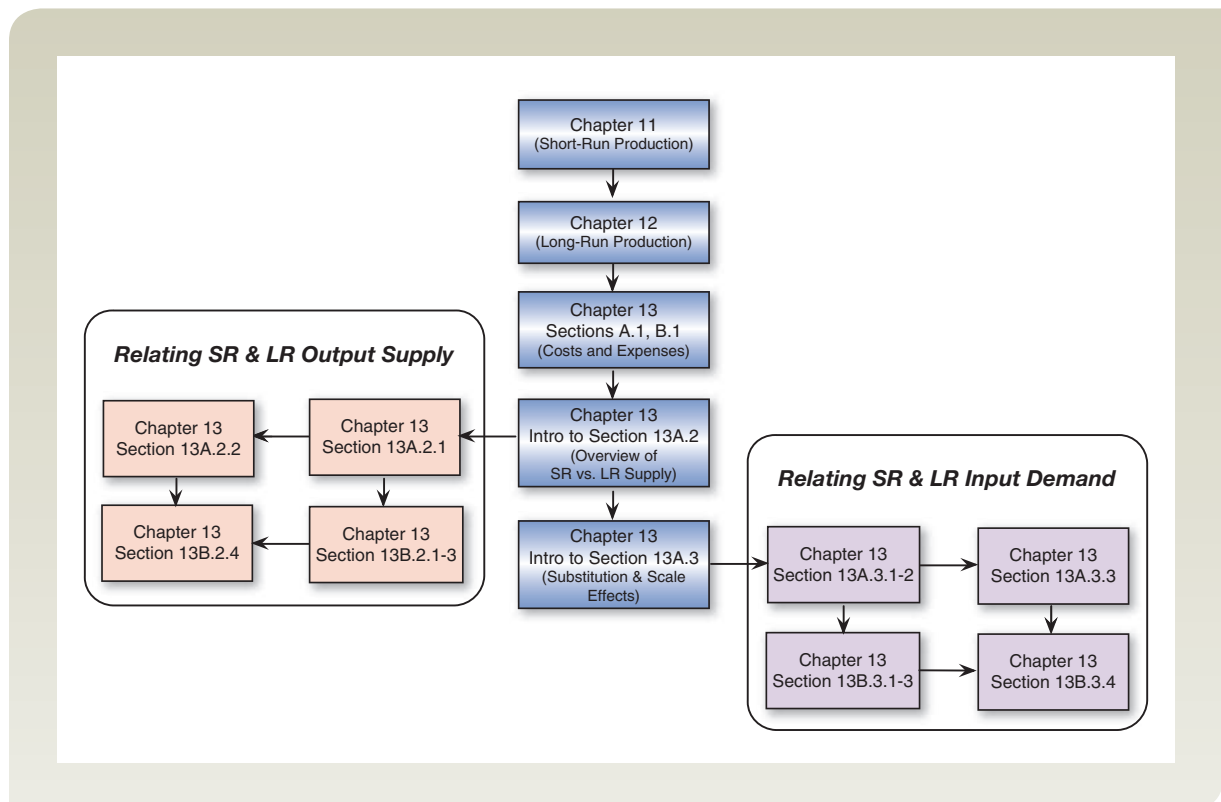

The unrealistic simplification in Chapter 11 involves the assumption that only a single input is needed for production. In reality, goods can typically be produced in multiple different ways by combining a little labor with lots of capital or lots of labor with a little capital, and this implies that profit-maximizing producers will typically have to choose the optimal bundle of inputs with which to produce. Put differently, producers have to decide not only *how much* to produce but also *how* to produce the goods, that is how much to rely on labor versus capital (or some other input). Chapter 12 therefore expands the model of Chapter 11 to include multiple inputs and thus multiple ways of producing any level of output. This allows us to distinguish between *technologically efficient* production that simply involves not wasting any inputs and *economically efficient* production that involves producing output at the least cost possible (given the input prices in the marketplace).

In this expanded model with multiple inputs, we will see that it is often useful to separate the producer’s problem into two separate stages: First, we can think of producers as looking only at their technology and the prices of inputs, and using this information to determine the least costly way of producing different levels of output. We will refer to this part of the problem as the firm’s *cost minimization* problem. After solving this problem, firms will know how much it costs to produce any level of output, but they will not yet know what level of output is profit maximizing. Thus, they are not done until they compare the cost of producing different levels of output (from their cost minimization problem) to the revenue they can get from different levels of output. Finding the level of output where the gap between revenue and cost is the largest is then equivalent to finding the profit-maximizing level of output (and the accompanying profit-maximizing levels of inputs).

Finally, we introduce in Chapter 13 a distinction between *short-run* and *long-run* decisions by producers. This distinction arises because firms often face short-run constraints that are more binding than long-run constraints. In the short run, for instance, a firm might already have committed to a certain factory space (and thus a certain level of the input “capital”). While this factory space might have been optimal given the circumstances that the producer faced when committing to the space, it may no longer be optimal when prices change. In the short run, the producer is then locked into the space and is able to decide only how intensively to use the space. In the two-input model, this implies that one input might be fixed in the short run but the other can be changed, so that effectively the short run is characterized by a single-input production process like the one we began with in Chapter 11. When it becomes possible to change the factory space, however, the firm will typically reevaluate its short-run response to changing circumstances and respond some more.

Throughout this part of the text, we will continue to assume that economic actors, consumers and producers alike, are “small” relative to the economic environment; that is, we will assume that everyone is a “price taker” who cannot influence the output and input prices in the market. In Part 5 of the text, we will relax this assumption and allow producers to be sufficiently “large” such that they can influence the prices in the economy through their decisions. This will involve a role for strategic thinking that is absent for now as we continue to focus on competitive environments. We will see later, however, that the “cost-minimizing” part of the producer problem that we develop here can be used even in cases where firms become large. We are therefore already also building a foundation for thinking about other economic contexts even as we wait to investigate these contexts until later on in the text.

Chapters 11 and 12 are core chapters that are best read as preparation for future chapters. Chapter 13, on the other hand, has some material that we will rely on in later chapters and other material that simply goes into greater depth but isn’t strictly necessary to move along in the text. The flow chart provides a map through this, with the material in gray boxes more central and the material in white boxes more optional.

CHAPTER

11

One Input and One Output: A Short-Run Producer Model

In our exposition of the consumer choice model, we have developed a particular lens through which we can view the choices of economic actors: individuals, whether as consumers, workers, or financial planners, attempt to do *the best they can given their economic circumstances*.¹ Put into the more mathematical language of the B parts of our chapters, we can equivalently say that individuals *optimize subject to constraints*. We will now turn this same lens away from the consumer choice model and toward producers or firms. These are the economic actors who combine “inputs” like labor, raw materials and land to produce “outputs,” which are the goods and services that we consume in the marketplace.

As in our development of the consumer model, we will for now maintain the assumption that every economic actor including a producer, is “small” relative to the market and thus lacks the power to influence prices in the economy. In the language we developed in Chapter 1, we will therefore begin our exploration of producers as economic actors in a “nonstrategic” environment, an environment where their actions have no impact on the larger economy and where they, just as consumers, are “price takers.” Only after we have fully explored the implications of optimizing behavior in such a nonstrategic environment will we turn in later chapters to considerations that enter our models when firms are sufficiently powerful to have an impact on prices in an economy through their actions.

In some ways, the models of competitive producers and consumers are not all that different: Both producers and consumers make choices that are under their control in an attempt to do the best they can given their economic circumstances (that they cannot control). Producers will in fact be a bit more transparent than consumers, because while consumers might have all sorts of tastes that we can’t really observe easily, producers, at least as we model them, are pretty shallow: they simply care about profit. But in other ways, we will find that the producer model is more complicated. For this reason, we will start in this chapter with a simple case of a producer who uses a single input to produce a single output. This will permit us to illustrate the idea of profit maximization in two different ways: First, we will show directly how producers maximize profits by choosing the production plan that puts them on their highest “indifference curve,” and second, we will show that we can split the profit maximization problem into two steps (that

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

¹No material from prior chapters is directly used in this chapter. However, the chapter contains frequent analogies to the consumer model and thus to material covered in Chapter 2 and Chapters 4 through 6. It is therefore highly recommended that material in those chapters be covered prior to Chapter 11.

will then form the basis for our analysis of more complex producers in Chapter 12). This latter approach is actually pretty intuitive: We will suppose that producers first analyze their costs, and once they have gotten a good picture of the costs of different production plans, they look at how much revenue can be generated to see which plan results in the most profit. In the end, the two approaches to profit maximization result in exactly the same “solution” for the producer, but sometimes it will be more convenient to use one and sometimes the other.

11A A SHORT-RUN ONE-INPUT/ONE-OUTPUT MODEL

The simplest possible producer to consider is one that converts a single input into a single output. To be honest, it is not easy to think of many real-world production processes that are that simple; in almost every production process that I know, the producer uses both labor and some other input to produce the output she sells. But it is possible to think of realistic production processes in which some of the inputs simply cannot be varied *in the short run*. Perhaps a certain factory space has been leased for a one-year period, and the lease has to be paid regardless of how much or how little is produced. In that case, a producer might be “locked into” a particular level of the input “factory space” over the next year even though the producer can choose a smaller or larger space after the current lease runs out. However, while it might not be possible for the producer to vary the factory space in the short run, he or she might well be able to vary the intensity with which the space is utilized; that is, the number of work hours that go into actually using the space for production. In such a scenario, we would say that this producer’s input of factory space is *fixed in the short run* while his or her labor input is *variable in the short run*.

Single-input production can be interpreted as short-run production when all but one input is fixed in the short run.

Some time ago, for instance, I had a bright idea: I had noticed that children love baseball cards but was disturbed that baseball players had become the object of such intense admiration by the children that will one day have to pay for my Social Security benefits. Would this really make them into productive citizens capable of producing at the level required in order to keep my Social Security checks coming? Why not give them a better mix of heroes to look up to and aspire to be like? So I thought it would be great to replicate the baseball card concept for famous economists—put the picture of the economist in an impressive lecturing pose on the front of the card, and some career statistics like “number of academic publications” and “number of citations by other economists” on the back. Unfortunately, my wife refused to fund my little idea, but that won’t keep me from pretending that I went ahead with it anyhow and telling you all about it in this chapter.²

So as my children would say, “Let’s pretend.” Suppose I wanted to put my brilliant idea into practice, and suppose that one of my former students (who naturally remains an ardent fan of mine) has arranged for me to have free factory space in one of the old tobacco-processing plants in Durham (where I live). Suppose further that it turns out that the same equipment previously used to make packets of cigarettes is appropriate for making economist cards and that the same paper used to wrap cigarettes can be used as well. So my former student is providing the factory space, the machines, and the raw material for my innovation for free, and all I have to do is decide how many workers to hire to start producing.

11A.1 Technological Constraints Faced by Producers

In my role as a producer, I would love to produce an endless supply of economist cards and sell them to every child in need of a hero, just as I would like to be able to consume without end in

²Some time after I requested spousal funding for this, I actually discovered that I was too late: The University of Michigan undergraduate economics club is already producing such cards, and one of the economics textbook publishers is also making them as a marketing gimmick, mixing cards with their textbook authors with very famous economists to make their authors seem more distinguished. I missed my chance to get myself on one of those cards when I went with a different publisher for this book.

my role as a consumer and buy my own Air Force One to avoid commercial air traffic. I can't consume without end because *my finite resources limit my consumer choice set*, and in an exactly analogous way, I cannot produce without end because *the technology available to me as a producer constrains my producer choice set*.

11A.1.1 Production Plans, Producer Choice Sets, and Production Frontiers Let's begin by defining a *production plan* as a *proposed bundle of inputs and outputs*. This is analogous to the concept of a consumption bundle in consumer theory. In a model in which consumers have only two goods to choose from, we located the set of all possible consumption bundles as points in a two-dimensional space with the good x_1 on the horizontal axis and the good x_2 on the vertical. We can do exactly the same for production plans in models where there is a single input and a single output. For instance, in a model illustrating all possible production plans for economist cards, I can put “hours of labor per day” on the horizontal axis and “packets of economist cards per day” on the vertical, and each point in the resulting two-dimensional space is a production plan that proposes to use a certain number of labor hours to produce a certain number of economist cards per day. Not all of these production plans are, however, technologically feasible given the technology I have available to me, just as not all consumption bundles are feasible choices for consumers on fixed incomes facing a fixed set of prices.

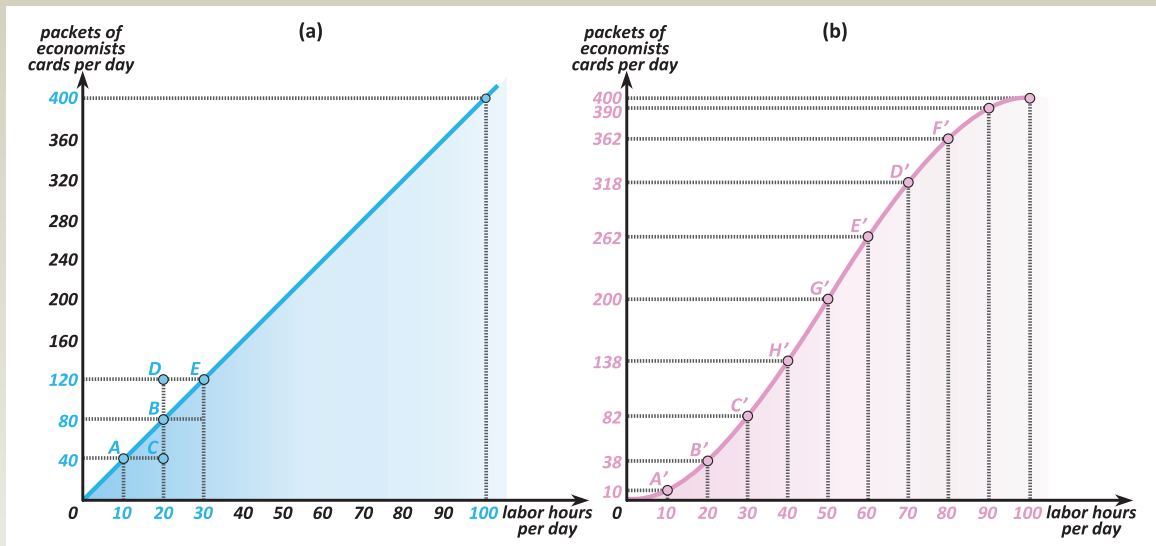

In the consumer model, we then illustrated the set of consumption bundles that are feasible for a particular consumer as the consumer's choice set. In the same way, we can now represent the set of production plans that are technologically feasible as the producer's choice set. The *producer choice set* is then simply defined as the set of all production plans that are feasible given the technology available to the producer.

Graph 11.1a illustrates one such possible producer choice set for economist cards as the shaded area under the blue line. It assumes a very particular underlying technology under which every labor hour can always be turned into *at most* four packets of economist cards. For instance, production plan A calls for 10 labor hours to be transformed into 40 packets of economist cards,

A production plan is a bundle of inputs and outputs.

The set of technologically achievable production plans constitutes the producer choice set.

GRAPH 11.1 Two Types of Producer Choice Sets and Associated Production Frontiers

and plan B calls for 20 labor hours to be transformed into 80 packets. Of course, this logically implies that plan C is feasible as well. At C , I would be producing 40 packets with 20 labor hours. Since I know I can produce that many packets with 10 labor hours (under production plan A), it should not be hard to hire 10 additional labor hours and still produce 40 packets. Thus the production plan C lies *inside* the producer choice set, indicating that we could in fact produce more with the labor input called for in production plan C . The production plan D , on the other hand, is not feasible under this technology; I need at least 30 worker hours to produce 120 packets of cards (under plan E), and it is not possible given the available technology to produce that many cards with only 20 worker hours. Thus, plan D lies *outside* the producer choice set.

Notice once again the analogy to consumer choice sets. Consumption bundles that lie within the consumer choice set are bundles that leave some of a consumer's budget unspent, implying that the consumer can do better (assuming "more is better"). Similarly, production plans that lie *inside* the producer choice set are plans under which some of our input stands idle, implying I can produce more with the same level of input. We then defined the boundary of the consumption set as the budget constraint, and we now *define the boundary of the producer choice set as the production frontier*. Only plans along this production frontier represent plans that do not waste inputs. As a result, just as consumers doing the best they can pick consumption bundles on the budget constraint, producers doing the best they can will pick production plans along the production frontier.

Production plans that waste no inputs lie on the production frontier.

Can you model a worker as a "producer of consumption" and interpret his or her choice set within the context of the single-input, single-output producer model?

EXERCISE 11A.1

The technology graphed in panel (a) of Graph 11.1 does not, however, seem very realistic. It can't possibly be true that I can keep producing at the same rate in my current factory space regardless of how much I am producing. When I first hire workers for my factory, they would not be able to specialize and probably could not produce as much per worker as when I have more workers. So it would seem more realistic to assume a production frontier along which workers initially become more and more productive as they specialize. At the same time, I have only so much factory floor space and machinery to work with, and adding workers endlessly would seem to eventually lead to lower and lower increases in output as the workers begin to run into each other on the factory floor.

Panel (b) therefore illustrates a more realistic technology for this example: It begins with initial workers not producing nearly as much as initial workers did in the technology represented in panel (a), but as more worker hours are added, each worker hour initially becomes more productive than the last (as workers can begin to specialize in particular tasks). The first 10 worker hours, for instance, result in an output of 10 cards per day (A'), while 20 worker hours can produce as many as 38 cards per day (B'). The second 10 worker hours therefore add as much as 28 cards per day, 18 more than the first 10 workers. Similarly, the next 10 worker hours add up to 44 more cards to my daily production, allowing me to produce at the production plan C' . Eventually, however, this increasing productivity per additional worker hour declines (as my factory workers begin to run into each other on my factory floor). For instance, 70 worker hours can produce as many as 318 cards per day (D'), 56 more than I am able to produce at E' with just 60 worker hours. But the next 10 worker hours can produce only 44 more cards (to get me to production plan F').

Which of the producer choice sets in Graph 11.1 is non-convex? What makes it non-convex?

EXERCISE 11A.2

EXERCISE 11A.3 Suppose my technology was such that each additional worker hour, beginning with the second one, is less productive than the previous. Would my producer choice set be convex? What if my technology was such that each additional worker hour, beginning with the second one, is more productive than the previous?

11A.1.2 Slopes of Production Frontiers: The Marginal Product of Labor In our development of consumer choice sets, we were then able to give a specific economic interpretation to the slope of the budget constraint (as the opportunity cost of one additional unit of the good on the horizontal axis in terms of the good on the vertical axis). Put differently, we could say that the slope of a consumer’s budget constraint represents the *marginal cost* of an additional unit of the good on the horizontal axis in terms of the good on the vertical axis. Slopes of production frontiers turn out to have an analogous economic interpretation.

Consider first the production frontier in Graph 11.1a. The slope of this frontier is 4, indicating that every additional hour of labor results in 4 additional packets of economist cards. In other words, the slope of the production frontier in Graph 11.1a is the *marginal benefit of one more worker hour in terms of increased production*. Turning to panel (b) of Graph 11.1, we can now see how this same interpretation of the slope of the production frontier continues to hold, except that now the marginal benefit of hiring additional workers initially increases but eventually decreases. The slope between production plans A' and B' , for instance, is approximately 2.8, indicating that the marginal benefit of 1 additional worker hour is approximately 2.8 packets of economist cards when we have between 10 and 20 labor hours employed already. The approximate slope between G' and E' , on the other hand, is 6.2, indicating a marginal benefit of approximately 6.2 additional packets of economist cards for every additional labor hour when I already have 50 to 60 labor hours employed.

EXERCISE 11A.4 Under the production technology in Graph 11.1b, what is the approximate marginal benefit of hiring an additional labor hour when I already have 95 labor hours employed?

The slope of the production frontier, or the marginal benefit of hiring additional inputs in terms of increased production, is of such economic interest to producers that we frequently graph it separately from the production frontier and call it the *marginal product curve*. The *marginal product of an hour of labor, denoted MP_ℓ* , is thus *the increase in total production that results from hiring one additional labor hour when all other inputs remain fixed*, and it is simply the slope of the single-input production frontier (of the type graphed in Graph 11.1) when all other possible inputs (such as factory space) are fixed. Graph 11.2(a) and (b) then plot the marginal product of labor curves for the production frontiers in Graph 11.1(a) and (b). While the marginal product curve in panel (a) is correct, in panel (b) we have plotted the “approximate” marginal product curve by plotting the slope between each of the production plans on the frontier of Graph 11.1b for the input level that occurs halfway in between the input levels of the two relevant production plans. For instance, given that production increases by 28 when labor input rises from 10 to 20, we have plotted a marginal product of 2.8 for the 15th labor hour.

The additional output produced by hiring one more input unit is the marginal product of that input.

EXERCISE 11A.5 Relate your answer from exercise 11A.4 to a point on the MP_ℓ curve plotted in Graph 11.2b.

EXERCISE 11A.6 What would the MP_ℓ curves look like for the technologies described in within-chapter exercise 11A.3?

GRAPH 11.2 The MP_ℓ Associated with the Production Frontiers in Graph 11.1

11A.1.3 The Law of Diminishing Marginal Product Now notice that the marginal product curve derived from the more realistic production frontier in Graph 11.1b is eventually downward sloping. This downward slope is the direct result of the fact that we assumed a production frontier on which each additional labor hour will *eventually* add less to our total output than the previous labor hour. It turns out, however, that this is more than a mere assumption; it is an economic reality that arises directly from the fact that we live in a world governed by scarcity, and it is known as the *Law of Diminishing Marginal Product*.

The easiest way to see this is to consider a case where the marginal product of an input never declines. First, recall the definition of marginal product: It is the *additional* output produced from adding one more unit of the input *assuming all other inputs are held fixed*. Suppose the marginal product of labor in my production process for economist cards never declines in the fixed factory space that my student has provided for me. This would mean that I can keep squeezing more and more workers into my factory and have them use the same amount of paper and ink, and each additional worker I hire will increase my output by at least as much as the previous worker did. Suppose my factory space is 1,000 square feet. How many human beings can I really squeeze into 1,000 square feet and still get them to produce? If the marginal product of labor never declines, I would be able to squeeze the population of the entire world into my 1,000 square feet space, and the last person I squeezed in would have added at least as much to my output of economist cards as any person I hired previously. And not only would I be able to squeeze all these people into my 1,000 square feet but they would also be able to squeeze more and more economist cards out of the same quantity of paper and ink. Perhaps technologies that give rise to such production processes exist in a world beyond ours, but such a world would not be characterized by the scarcity that governs the world we live in, nor would it be a world in which an economist who studies scarcity could find employment. Thus, at least in the world we currently occupy, it *must* be the case that the marginal product of an input like labor at some point declines.

The marginal product of any input must eventually diminish as more of that input is hired (with all other inputs held fixed).

EXERCISE 11A.7 *True or False:* The Law of Diminishing Marginal Product implies that producer choice sets in single-input models must be convex beginning at some input level.

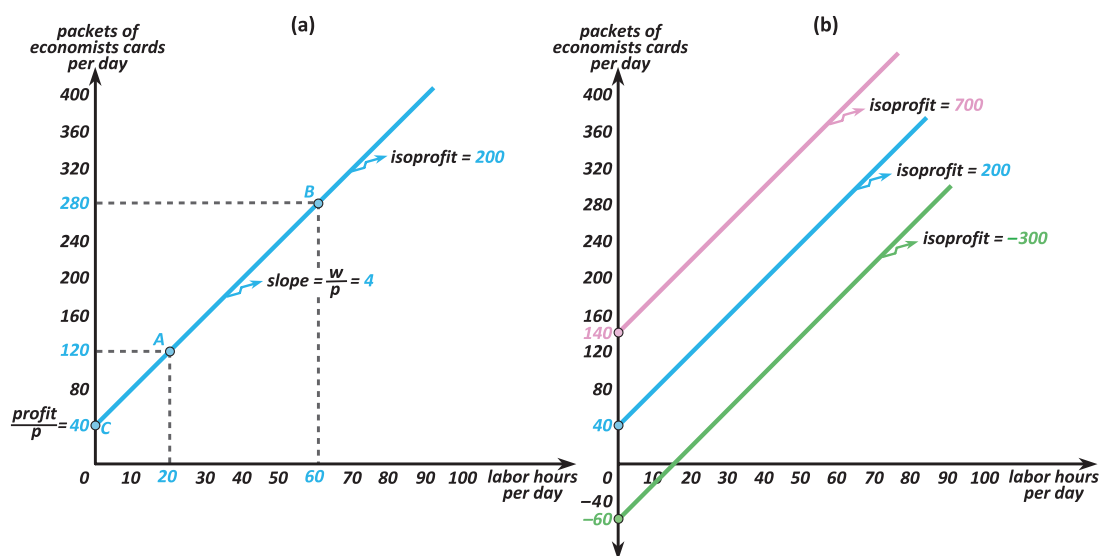

EXERCISE 11A.8 *True or False:* If the Law of Diminishing Marginal Product did not hold in the dairy industry, I could feed the entire world milk from a single cow. (*Hint:* Think of the cow as a fixed input and feed for the cow as the variable input for which you consider the marginal product in terms of milk produced per day.)

11A.2 “Tastes” for Profits

In the case of the consumer model, we began by acknowledging that different consumers have very different tastes. For producers, however, we will assume that tastes are defined in a relatively straightforward way: Producers—in their role as producers—prefer production plans that generate greater profit over those that generate less, and they are indifferent between production plans that generate the same profit. *Profit* is defined simply as *all economic revenue (generated from the sale of outputs) minus all economic cost (incurred from the purchase of inputs)*.

11A.2.1 Isoprofit Curves: The Producer’s “Indifference Curves” In our single-input/single-output model of economist card production, we can then illustrate “producer indifference curves” as sets of production plans that all yield the same amount of profit, with production plans that yield greater profit valued more than production plans that yield less profit. Consider, for instance, the production plans *A* and *B* in Graph 11.3a. Plan *A* calls for 20 daily hours of labor to be converted into 120 daily packets of economist cards, while plan *B* calls for 60 daily hours of labor to be converted into 280 daily packets of economist cards. Now suppose that the

GRAPH 11.3 Producer Indifference—or Isoprofit—Curves

market wage for the type of labor I need to hire is \$20 per hour, and suppose the per packet price of cards such as the ones I am producing is \$5. Revenues will then be \$600 under plan *A* and \$1,400 under plan *B*, while costs will be \$400 under plan *A* and \$1,200 under plan *B*. Subtracting costs from revenues, both plans result in a daily profit of exactly \$200. For producers who care only about profits, *A* and *B* are then equally desirable production plans whenever a packet of cards sells for \$5 and an hour of labor costs \$20.

But these are not the only production plans that would yield a profit of \$200 per day under the assumed price and wage. For instance, the production plan *C* suggests producing 40 economist cards without using *any* inputs, a feat that might violate the laws of physics but, if one could pull it off, would again result in exactly \$200 in profit per day. In fact, since inputs cost four times as much as outputs, we can start at the production plan *C* and find a production plan for any level of input that will yield \$200 per day in profit so long as we include four times as much additional output in the production plan. The plan *A*, for instance, has 20 more labor hours than the plan *C* and 80 more output units, thus keeping profit constant at \$200 per day. When we then plot the level of output required for each level of input to keep profit at \$200, we get the blue line in Graph 11.3a. Notice that the line has a vertical intercept of 40 (because it takes 40 economist cards to make a \$200 profit if there are no costs) and has a slope equal to 4, the wage rate w over price of the output p . If I really care only about profits, then I must be indifferent between all of the production plans on this blue line. An indifference curve such as this for a price-taking producer is called an *isoprofit curve* or, more specifically, the blue indifference curve is the *isoprofit curve corresponding to \$200 in daily profit when the wage rate is \$20 per hour and the output price is \$5*.

A producer's indifference (or "isoprofit") curve contains all production plans that result in a given profit.

As with consumer indifference curves, the full "tastes" of producers are of course not characterized by a single indifference or isoprofit curve. Each profit level carries with it a different isoprofit curve, with the magenta and green isoprofit curves in Graph 11.3b representing production plans that result in \$700 and $-\$300$ profit respectively. Notice that, since the slope of isoprofit curves is w/p , all isoprofit lines have the same slope when wages and prices are fixed from the perspective of the producer. The vertical intercept, on the other hand, is simply the profit associated with the particular isoprofit curve divided by the price of the output.

Without knowing what prices and wages are in the economy, can you tell by looking at a single isoprofit curve whether profits for production plans along this curve are positive or negative? What has to be true about an isoprofit curve in order for profit to be zero?

EXERCISE
11A.9

What would have to be true in order for an isoprofit curve to have a negative slope?

EXERCISE
11A.10

11A.2.2 The Role of Prices in Consumer and Producer Models Throughout our development of producer choice sets and tastes (as represented by isoprofit curves), we have thus far emphasized similarities between the consumer and the producer model. For instance, only some consumption bundles are available to consumers because of the budget constraint they face, just as only some production plans are technologically feasible because of production frontiers. Both consumers and producers have tastes that can be represented by points over which they are indifferent: consumption bundles that lie on the same indifference curve in the consumer model, and production plans that lie on the same isoprofit curve in the producer model. And, as we will see in the next section, both consumers and producers generally find their "best" point on the boundary of their choice set.

While these similarities are conceptually important, it is equally worthwhile to point out some of the significant conceptual differences between consumer and producer models. Most

important, the prices in the economy affect indifference curves and choice sets differently in the two models. In our consumer model, prices (including wages and interest rates) affected the size and shape of the consumer choice set, but prices have *nothing* whatsoever to do with consumer tastes and the indifference curves that represent them. Whether I like peanut butter, how much I like to work rather than leisure, and whether I can tell the difference between Coke and Pepsi: These are internal features that define who I am, features that have arisen in some process that can perhaps be explained by psychologists and biologists but remain outside the area of expertise of most economists.³ Economists usually just take tastes as given and recognize that, while optimal consumer choices have a lot to do with prices, how a consumer *feels* about the trade-off between different types of goods is a matter of taste, not prices.

In the producer model, on the other hand, things are exactly reversed. Prices have no impact on the producer choice set but have everything to do with what the indifference curves—or isoprofit curves—look like. The producer choice set is the set of production plans that are *technologically* feasible, which implies that the size and shape of the producer choice set is driven by technology. Put differently, whether I am *physically able* to produce 200 economist cards with 10 hours of labor has nothing to do with prices and wages; it is a matter for engineers and factory managers to figure out. The producer’s indifference curves, on the other hand, are determined entirely by the prices in the economy, with the intercept a function of prices and the slope a function of both wages and prices. We can see this distinction most clearly by asking the question: What will change in our graphs of producer choice sets and isoprofit curves if prices and wages in the economy change? Since neither prices nor wages entered our development of producer choice sets in Graph 11.1, nothing would change in those graphs (or in the accompanying graphs of marginal product curves). Our graph of isoprofits (in Graph 11.3), on the other hand will change.

Consider for instance a change in the hourly wage rate from \$20 to \$10. Since the vertical intercept of each isoprofit curve is profit divided by the output price p , a change in the wage w does not change the intercept. Intuitively, the production plans on the intercept give the output level required to attain a particular profit level *assuming the production plan does not envision hiring any labor*. Since labor is not part of the production plan at the vertical intercept of an isoprofit curve, profits for such production plans are therefore unaffected by the wage rate in the economy. The wage rate does become relevant, however, at any other production plan on an isoprofit curve since all production plans other than those located on the vertical axis contain some positive labor input. For a decline in wages from \$20 to \$10, our slope w/p therefore falls from 4 to 2 (assuming a fixed output price of $p = 5$), leading to a shallower slope for each isoprofit curve. Such an impact of a change in wages is then illustrated graphically in Graph 11.4a.

In Graph 11.4b, on the other hand, the impact of a change in the output price p is illustrated. Suppose, for instance, that p rises from \$5 per packet of economist cards to \$10 per packet (with the wage rate holding constant at \$20). Since the intercept of an isoprofit curve is profit divided by p , the intercept must now fall. Furthermore, given that the slope of each isoprofit curve is w/p an increase in p will result in a decline in the slope from 4 when $p = 5$ to 2 when $p = 10$. For a particular profit level (such as \$200), the isoprofit curve therefore falls at the intercept and becomes shallower as the output price increases. This, too, should make intuitive sense: If I can sell my cards for more, I should be able to make the same profit as before using production plans that contain less output for each level of input. In both panels of the graph, we of course illustrated only what happens to one of the infinite number of isoprofit curves that compose the isoprofit map, with similar changes happening for each of the other isoprofits.

Prices affect producer indifference curves (or “isoprofit”) curves but do not impact production frontiers.

EXERCISE 11A.11 How would the blue isoprofit curve in Graph 11.3a change if the wage rises to \$30? What if instead the output price falls to \$2?

³ My wife believes my tastes may more appropriately be explained by Chaos Theory.

GRAPH 11.4 Isoprofit Curve for \$200 Profit as Wages and Prices Change

11A.3 Choosing the Production Plan that Maximizes Profit

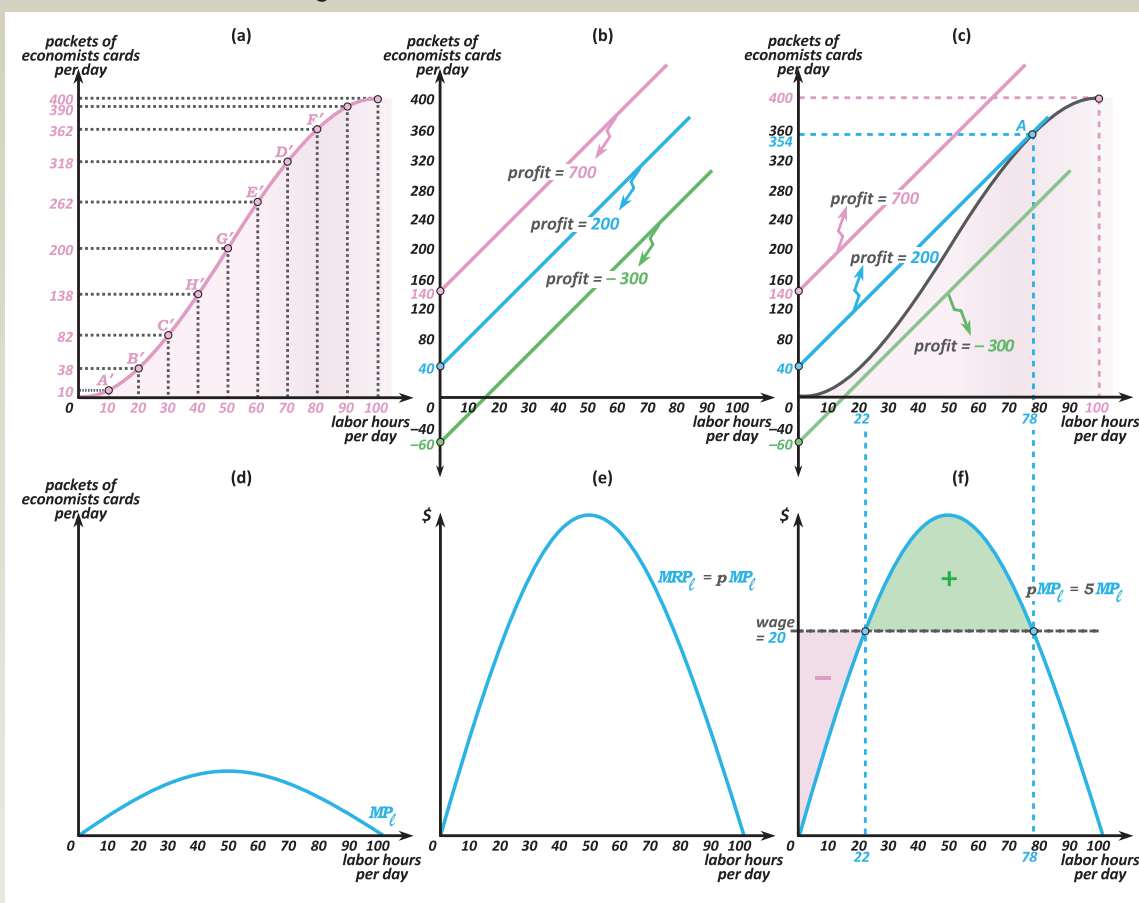

As soon as we had fully explored consumer choice sets and tastes (in Chapters 2 through 5) *independently*, we proceeded (in Chapter 6) to investigate how choice sets and indifference maps *jointly* allow us to identify the best bundle available to a consumer given her circumstances. We can now follow the same path for single-input/single-output producers like me. More precisely, in the last two sections we have already explored both my producer choice set and tastes *independently*, and we can therefore proceed directly to analyzing how choice sets and producer tastes *jointly* result in profit-maximizing producer behavior.

11A.3.1 Combining Production Frontiers with Isoprofit Curves Graph 11.5a begins by replicating my “realistic” producer choice set from Graph 11.1b, while Graph 11.5b replicates the three isoprofit curves developed in Graph 11.3b under the assumption that I have to purchase labor in the labor market at \$20 per hour and can sell my economist cards in the “hero card market” at \$5 per packet. Panel (c) of Graph 11.5 then combines the previous two panels into a single graph.

Beginning on the lowest (green) isoprofit curve, we can notice that many production plans that result in profit of $-\$300$ are technically feasible given that they lie within the shaded choice set. However, as a producer I become better off as I move to isoprofit curves that lie to the northwest. Since there are production plans that lie both within my choice set and above (i.e., to the northwest of) the green isoprofit curve, I know I can do better than a daily profit of $-\$300$. I also know from looking at Graph 11.5c that certain levels of profit are not feasible within the current economic and technological environment. For instance, the (magenta) isoprofit curve of production plans that yield \$700 in daily profit lies fully outside my choice set, indicating that no production plan that could yield \$700 in daily profits is technologically feasible.

My goal as a profit-maximizing producer of economist cards is then to find the highest isoprofit curve that contains at least one technologically feasible production plan, just as my goal as

GRAPH 11.5 Maximizing Profit

Go to MindTap to interact with this graph.

a utility maximizing-consumer is to find the highest indifference curve that contains at least one consumption bundle that is feasible given my budget constraint. Beginning on the green isoprofit curve in Graph 11.5c and moving northwest in the direction of the magenta isoprofit curve, we reach this highest possible profit at the production plan A where the (blue) isoprofit curve corresponding to a profit of \$200 is tangent to the frontier of my producer choice set. Thus, production plan A is the profit-maximizing plan in this case.

At the profit-maximizing production plan,
 $MP_L = w/p$.

11A.3.2 Marginal Product = w/p (or Marginal Revenue Product = w) From Graph 11.5c, you can see immediately that, at the profit-maximizing production plan A, the slope of the isoprofit curve (w/p) is equal to the slope of the production frontier (which is just the marginal product of labor MP_L). To see how this makes intuitive sense, it is useful for us to see the same profit-maximizing behavior play out in a variant of the marginal product of labor graph that we derived from the production frontier in Graph 11.2b.

Graph 11.5d therefore begins by replicating the MP_L curve from Graph 11.2b with the vertical axis rescaled for graphing convenience (which makes it appear that the curve creates a hill

that is “less steep” than before). Recall that this is simply a graph of the slope of the production frontier in panel (a). Panel (e) of the graph then plots a slight variant of the marginal product curve known as the *marginal revenue product* curve. While the marginal product of labor (MP_ℓ) tells us the increase in *output* resulting from one more hour of labor being hired, the marginal revenue product of labor (MRP_ℓ) tells us the increase in *revenue* resulting from one more hour of labor. Since revenue is just output times the price of the output p , $MRP_\ell = pMP_\ell$. Put differently, the MRP_ℓ curve is identical to the MP_ℓ curve when the output price is \$1 but is five times the MP_ℓ curve when the price of the output is \$5 (as in the case of my economist cards). Furthermore, while MP_ℓ is measured in “output” units on the vertical axis in panel (d), MRP_ℓ is measured in dollar units in panel (e).

The final panel (f) in Graph 11.5 then shows how profit maximization first illustrated along the production frontier in panel (c) relates to profit maximization illustrated along the MRP_ℓ curve. Along the production frontier, we noticed that $w/p = MP_\ell$ at the profit maximizing plan A, which we could write differently (by multiplying both sides of the equation by p) as $w = pMP_\ell$ or just $w = MRP_\ell$. In other words, at the optimum, the wage I pay for the last labor hour that I hire is just equal to the marginal dollar benefit I get from that labor hour. Because marginal product declines, the MRP_ℓ before the last one I hire is larger than the wage I have to pay. More precisely, Graph 11.5f shows that I actually make a loss on the first 22 labor hours that I hire, in each case paying a wage that is higher than the marginal dollar benefit I get from each labor hour. However, starting with the 23rd labor hour, the marginal dollar benefit of each hour I hire is higher than the wage I have to pay, until I stop hiring when this marginal dollar benefit (the MRP_ℓ) is again equal to the wage rate. I would not want to hire any additional labor hours since, from 78 hours on, the marginal dollar benefit of an additional labor hour is less than the wage I have to pay for that hour. My total profit of \$200 (read off the isoprofit curve that contains production plan A in panel (c) of the graph) is then the shaded green area minus the shaded magenta area in panel (f).

The marginal revenue product of an input is the output price times the marginal product of that input.

It appears from panel (f) of Graph 11.5 that profits are smallest (i.e., most negative) when I stop hiring at 22 labor hours per day. What can you conclude about the slope of the production frontier in panel (c) of the graph at 22 daily labor hours? Explain.

EXERCISE 11A.12

11A.3.3 What’s so Special about a \$200 Profit? Economic Costs and Revenues

You might pause at this point and question the conclusion that my best possible course of action is to implement the production plan A in Graph 11.5c. After all, if I am only going to make \$200 in profit per day, perhaps that’s not worth me staying in business. Perhaps there are better opportunities outside the economist card business. It turns out, however, that this is not the case *assuming we have defined all the variables correctly*.

Let’s be more precise. When we first defined the term *profit*, we casually mentioned that this is simply equal to all economic revenues (from sales of the output) minus all economic costs (from hiring inputs). The key words that casually slipped twice into this definition of profit are “all” and “economic.” Revenue is considered *economic revenue from production* if and only if it is generated from ongoing production and would not exist were the producer to stop production. Similarly, a cost is considered an economic cost incurred in production if and only if it is directly linked to ongoing production and would not arise if the producer chose to discontinue production. These statements may seem trivial at first, but two examples will illustrate how we might understand costs and revenues differently if we talked to boring accountants instead of exciting economists.

First, suppose my business has been running for a while and has paid city taxes in the past. This year, the city has a budget surplus and decides to return the surplus in the form of tax rebate

checks to businesses, with the amount of the check each business receives proportional to the tax revenue it paid last year. Is the check I receive in the mail “revenue” for my business? In an accounting sense, it clearly is; after all, I get to deposit money in my business’s checking account. The U.S. federal government would also treat this as revenue because, under U.S. tax laws, federal taxes must be paid on any state or local tax rebates. And I am clearly happy to receive the check! But is the check an *economic* revenue from producing economist cards? Put differently, is it revenue that is associated with my ongoing production of economist cards, revenue that would not materialize if I ceased production? When put this way, you can see that the answer is no; the check from the city is based on production decisions I made in the past (which led to my tax payments to the city last year), and the amount of the check will be no different whether I produce 10, 100, 1,000, or no economist cards per day this year. Since this “revenue” has nothing to do with my current economic decisions in my factory, it is not a relevant or “economic” revenue for those decisions.

Next, suppose my little factory had a faulty exhaust valve last year, which caused illegal pollution to escape into the environment. Suppose further that I became aware of the problem at the beginning of the year and quietly fixed it, breathing a sigh of relief that I had not been caught. But then I get a letter from the city telling me that satellite images taken last year reveal excessive pollution emanating from my factory. As a result, I am charged a fine of \$10,000 and ordered to fix the problem. Since I have already fixed the problem, I just have to pay the fine, which my tax accountant tells me is considered a current cost for my business. But is it an economic cost of producing? Put differently, does the size of the fine I owe the city depend on my current production decisions? The answer is again no; regardless of whether or how much I produce right now and in the future, the fine is based on something that happened in the past. It is no more an economic cost of producing economist cards than an increase in my children’s school tuition because, while neither is good news for my pocketbook, neither has anything to do with the economic choices I currently face in my business. From the perspective of my business, both are what we will call later *sunk costs*, not economic costs.

EXERCISE 11A.13

Suppose I have already signed a contract with my former student who is providing me with the factory space, machinery, and raw materials for my business, and suppose that I agreed in that contract to pay my former student \$100 per month for the coming year. Is this an economic cost with respect to my decision of whether and how much to produce this year?

When calculating economic profit, all opportunity costs—including the cost of the firm owner’s time—must be included.

So what does all this have to do with your concern that it might just not be worth it for me to stay in business for a measly \$200 a day, that perhaps it would be optimal for me to put my energies into something else that will make more profit for me? If I were to restate your concern, it would be that you are worried that I have not taken the opportunity cost of my time into consideration, and that my next best alternative to opening my economist cards business, perhaps writing another textbook, for instance, might be more lucrative. But notice that my opportunity cost of time, unlike the city fine for last year’s pollution, *is* an economic cost of producing economist cards. Put differently, to the extent that this business takes time away from me, that is an economic cost that must be included in any calculation of economic profit. By not explicitly including it in the model so far, I have merely assumed either (1) that my opportunity cost of time is the market wage of \$20 per hour (and my worker hours are thus part of what is hired to produce the cards) or (2) that this business actually takes no time for me at all and will run itself. In the first case, if I spend 8 hours a day at the factory, I am therefore already including in my profit calculations that I am paying myself a wage of \$20 per hour, for a total of \$160 per day. If that is in fact the opportunity cost of my time, that is the best I could do working anywhere else. But in my little business, I will end up bringing home \$360 per day—my \$160 paycheck *plus* my \$200 profit—and I am therefore doing \$200 better in my business than I could doing anything else.

In the second case, the business takes no time away from me, which implies that there is no time cost on my part, and the \$200 is just free gravy that I would otherwise not have.

The bottom line is that whenever you conclude that someone is making economic profits above zero, you have (assuming you have included everything that should be included in the calculation) by definition concluded that the individual does better in this economic activity than he or she could in any known alternative. No matter what story underlies the statement “I am making \$200 in economic profits,” it always means that “I am doing \$200 better in this economic activity than in the next best alternative.”

11A.4 Changing the Economic Environment

Now that we concluded I should produce 354 cards using 78 labor hours per day when the hourly wage is \$20 and the output price is \$5, we can ask how my profit-maximizing choice will change as either output prices or wages change in the economy. My response to such changes could be (1) to produce more, (2) to produce the same, (3) to produce less, or (4) to shut down and stop producing economist cards.

11A.4.1 A Change in the Market Wage Suppose first that hourly wages fall from \$20 to \$10. We have already seen in Graph 11.4a how such a change in wages alters each isoprofit curve: it changes the slopes (w/p) from 4 to 2 without altering the intercepts (Profit/p). This implies that the new optimal production plan *B* must lie to the right of the original optimal plan *A* because a shallower isoprofit line must now be tangent to the production frontier, *which becomes shallower to the right of A*. In the top panel of Graph 11.6a, the new optimal production plan then calls for 90 daily labor hours to produce 390 rather than the original 354 packets of economist cards. The intercept of the new optimal isoprofit curve is 209, which implies a profit at production plan *B* of \$1,045.⁴

There are also production plans to the left of *A* where the slope of the production frontier is shallower. Why are we not considering these?

**EXERCISE
11A.14**

The lower panel of Graph 11.6a then illustrates the same profit-maximization exercise in the marginal revenue product graph that is derived from the production frontier in the top panel.

Which areas in the lower panel of Graph 11.6a add up to the \$200 profit I made before wages fell? Which areas add up to the \$1,045 profit I make after wages fall?

**EXERCISE
11A.15**

Next, suppose the hourly wage rate in the labor market rises to \$30. This increases the slope of isoprofit curves (w/p) to 6, implying that the new tangency with the production frontier will lie to the left of *A*. This is illustrated in the top panel of Graph 11.6b where that tangency occurs at the production plan *C*, which employs 59 daily labor hours to produce 254 daily packets of economist cards. But notice how this looks on the lower panel of Graph 11.6b along the marginal revenue product curve: Were I to produce according to the production plan *C*, I would incur losses on each worker I hire up to the 42nd worker hour and only begin to generate marginal

⁴At first, it may appear that because there is a new intercept on the optimal isoprofit curve, the graph is contradicting what we said at the beginning of the paragraph, that a change in wages changes the slopes but not the intercepts of isoprofit curves. The statement that intercepts do not change when wages change, however, applies to *any particular isoprofit curve corresponding to a particular amount of profit*. In panel (a) of the graph, for instance, the original isoprofit curve will indeed change slope without changing the intercept. However, at the new wage, this isoprofit curve is *no longer the optimal isoprofit curve*, and so the producer moves to a higher isoprofit (that is tangent at *B*).

GRAPH 11.6 The Impact of Changing Wages on Profit-Maximizing Choices

benefits above the wage when hiring workers from the 43rd through the 59th worker hour. Thus, if I hire 59 hours of labor (as called for in the production plan C), my profit is the tiny shaded green area (in the lower right panel of the graph) minus the large shaded magenta area, which appears to sum to a negative number. Going back to the top panel, we can see that this is indeed the case because the intercept of the isoprofit curve tangent at production plan C is -100 .

Given an intercept of -100 of this isoprofit curve, what is the value of profit indicated by the shaded green minus the shaded magenta area in the lower panel of Graph 11.6b?

EXERCISE
11A.16

Thus, for an increase in the wage to \$30 per hour, my best course of action is actually not to implement production plan *C* but rather to implement production plan *D*, which calls for no hiring of labor and no production of output and thus zero profit along the dashed green isoprofit curve in Graph 11.6b. Put differently, I should go ahead and engage in the next best alternative economic activity and let the economist card business take a rest. This is an example of a *corner solution* in the producer model.

Producers shut down if profit from producing is negative.

Had the increase in the market wage been less dramatic, would my best course of action still necessarily have been to shut down production?

EXERCISE
11A.17

What would have to be true of the production frontier in order for the original optimal production plan *A* to remain optimal as wages either rise somewhat or fall somewhat? (*Hint*: Consider what role kinks in the producer choice set might play.)

EXERCISE
11A.18*

11A.4.2 The Labor Demand Curve In Graph 11.6, we have shown how a decrease in the wage I have to pay my employees will cause me to slide down on the MRP_ℓ curve to the new wage rate and thus to hire more workers (or at least more worker hours). Similarly, an increase in the wage I have to pay will cause me to slide up the MRP_ℓ curve and hire fewer labor hours so long as I can still make a profit, but once the wage goes so high that the best I could do was to make a negative profit, I would simply shut down and hire no labor (as shown in part (b) of Graph 11.6). A portion of the curve thus becomes the *demand curve for labor*; that is, the curve that shows how many labor hours I will hire at different wage rates.

Graph 11.7 illustrates this more exactly by first determining the wage rate at which the highest profit I could make is zero. More precisely, it plots a MRP_ℓ for a given output price p and then finds the wage rate w^* at which the negative profit I make on the initial workers I hire (the shaded magenta area) is just equal to the positive profit I make on the final workers I hire (the shaded green area). For any $w < w^*$, the magenta area shrinks and the green area gets larger, thus implying a positive overall profit. For any $w > w^*$, on the other hand, the magenta area gets larger while the green area shrinks, which implies a negative overall profit. Thus, I will hire labor along the declining portion of the MRP_ℓ so long as the wage I have to pay is less than (or equal to) w^* , and I will hire no workers for any wage rate above w^* . The darkened two line segments then represent my *labor demand curve*, which, due to the Law of Diminishing Marginal Product, *must slope down*.

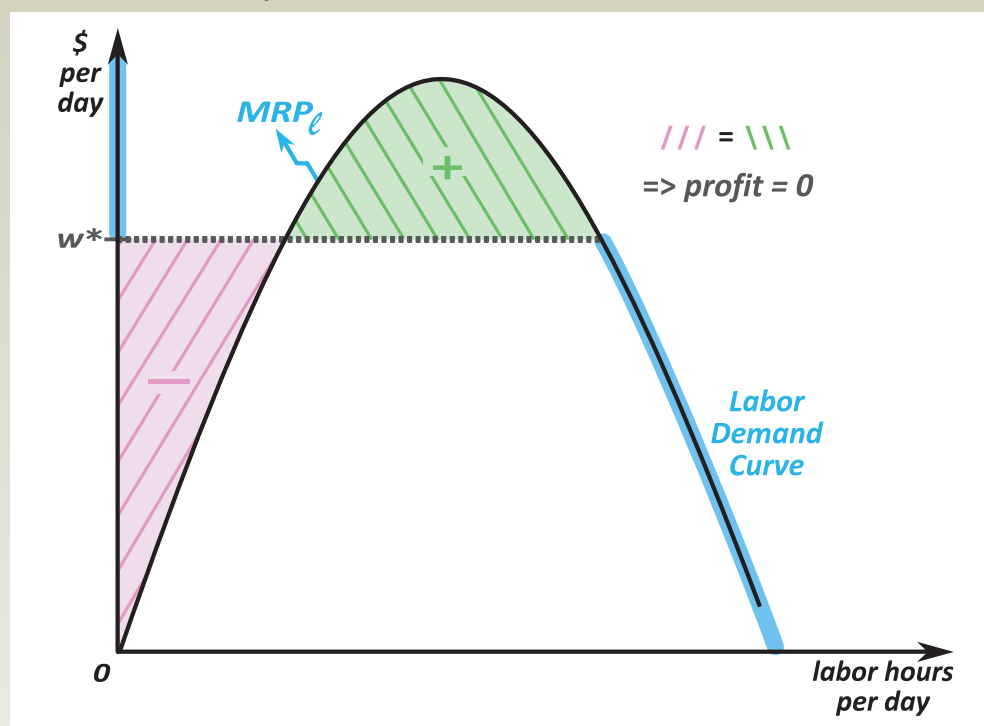

The short-run labor demand curve is a portion of the marginal revenue product of labor curve.

Why would it be economically rational for me to still stay open for business when $w = w^*$ where my profit is zero?

EXERCISE
11A.19

If I had signed a contract and agreed to make monthly payments for the next year to my former student who provided me with my factory space, would w^* —the highest wage at which I will still produce—be any different?

EXERCISE
11A.20

GRAPH 11.7 MRP_ℓ and Labor Demand

Go to MindTap to interact with this graph.

11A.4.3 A Change in the Output Price Now suppose that the wage was unchanged at \$20 per hour but the market price of “hero cards” (including my economist cards) increases to \$10 per packet. Again, we already saw in Graph 11.4b how such an increase in price alters the shape of isoprofit curves. In particular, note that the slope of isoprofit curves is now 2 (instead of 4), just as it was when wages fell to \$10 in Graph 11.6a. But if the isoprofits now again have a slope of 2, the tangency of the highest isoprofit curve must again fall exactly at the same production plan *B* as when wages fell to \$10! For this reason, the top panel of Graph 11.8 illustrating the change in profit maximization along the production frontier when price increases to \$10 *looks exactly the same as the top panel of Graph 11.6a*. Once again, it is optimal to produce 390 packets of economist cards per day using 90 labor hours.

Despite the fact that the profit maximization along the production frontier *looks* exactly identical for an increase in the price from \$5 to \$10 as it does for a decrease in the hourly wage from \$20 to \$10, there are underlying differences that emerge in the lower panels of the graphs. First, note that the marginal revenue product curve did not change when the wage changed because MRP_ℓ is just pMP_ℓ . Since p is by definition a part of MRP_ℓ , however, the marginal revenue product curve *does* move when price changes. In particular, since each packet of economist cards now sells for twice what it did before, each worker hour has just become twice as productive in dollar terms (even though it remains unchanged in output terms). Thus, each point on the new (magenta) marginal revenue product curve is twice as high as the corresponding point on the original (blue) marginal revenue product curve. While the optimal production plan is therefore the same when the price of my economist card packets increases to \$10 as it is when the wage rate falls to \$10, my profit is clearly higher under the former scenario than under the latter.

GRAPH 11.8 The Impact of Changing Prices on Profit-Maximizing Choices

EXERCISE 11A.21 What areas in the lower panel of Graph 11.8 add up to my new profit? What is the dollar value of this new profit (which you can calculate from the intercept of the isoprofit curve in the top panel of the graph)?

EXERCISE 11A.22 Can you tell from Graph 11.8 how the labor demand curve will change when p changes?

EXERCISE 11A.23 What value would p have to take in order for isoprofits to have the same slope as when wages increased to \$30 per hour (as in Graph 11.6b)? What would be my optimal course of action in that case?

11A.4.4 The Output Supply Curve From Graph 11.8, we can already see that an increase in the price of the output (without a change in price of the input) will unambiguously lead me to produce more output as a flatter isoprofit curve is fitted to the production frontier that becomes flatter as production increases. Panel (a) of Graph 11.9 then begins with a slight variant of the top panel of Graph 11.8 by plotting two isoprofit curves tangent to the production frontier. The blue isoprofit curve has a slope (w/p^*) where p^* is set so as to ensure that the intercept of the tangent isoprofit is exactly zero. This implies that profit for all production plans located along the blue isoprofit in Graph 11.9a is zero, and the optimal production plan when price is p^* is the plan A, which uses ℓ^* in labor hours to produce x^* in output.

For any price higher than p^* , the isoprofit curves then become shallower, implying optimal production plans that lie to the right of A. For price p' , for instance, the plan B, which uses ℓ' hours of labor input to produce x' in output, is optimal. For any price lower than p^* , on the other hand, isoprofits become steeper, and the tangency of such isoprofit curves would result in a production plan that lies to the left of A with negative intercept. Profit at such tangencies is then negative, and I could do better by just shutting down, producing nothing, and spending all of my

GRAPH 11.9 The Output Supply Curve

time in the company of my lovely wife who will employ me instead. Therefore, if the price of economist cards falls below p^* , my little factory will stand idle.

Panel (b) of Graph 11.9 then translates the output levels at production plans A and B onto the vertical axis and plots the output prices (p^* and p') at which these production plans are optimal on the horizontal axis. By connecting A' and B' in this new graph, we are approximating how my output of economist cards on the vertical axis responds to changes in prices above p^* on the horizontal axis. In addition, the line connecting A' and B' is supplemented by the blue line on the horizontal axis below p^* , which indicates that my optimal output at such prices is simply zero. Panel (c) of the graph then just inverts panel (b) by flipping the axes, putting output on the horizontal and price on the vertical (as we have come to get used to when graphing demand curves). The resulting two line segments in panel (c) then represent the *supply curve* for my factory, which is the curve illustrating the relationship between the price I can charge for my output and the amount of output I produce. Just as the labor demand curve unambiguously slopes down, the output supply curve unambiguously slopes up.

Output supply slopes up while labor demand slopes down.

In Graph 11.9, we implicitly held wage fixed. What happens to the supply curve when wage decreases?

EXERCISE 11A.24

11A.5 Two-Step Profit Maximization

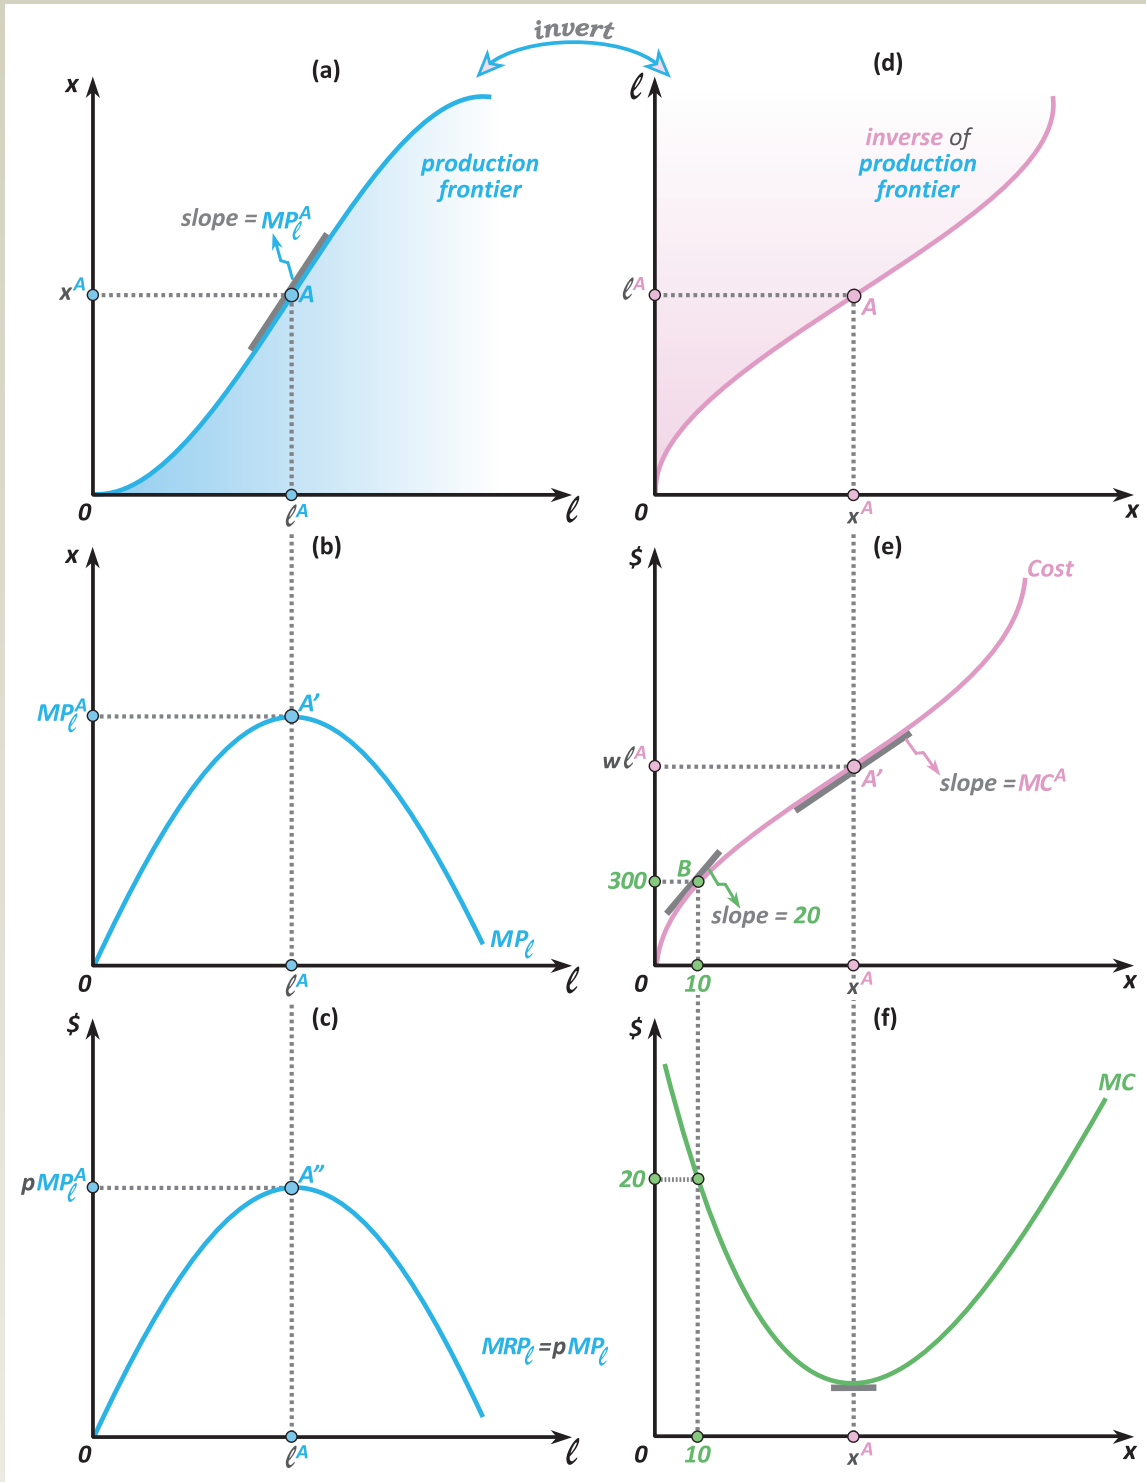

So far, we have explored the direct implications of a firm choosing a profit-maximizing production plan in one step. While this is straightforward to graph in the context of the one-input/one-output model, we will see in the next chapter that this one-step approach becomes considerably more difficult when we have two inputs (i.e., labor and capital) rather than one (i.e., just labor). Fortunately, there is a second way to conceptualize the firm's profit-maximization decision. It proceeds in two steps but gives exactly the same answer, and it generalizes more easily to a graphical treatment when the number of inputs goes to two. We will therefore illustrate this alternative conceptual approach here for the one-input model so that we can begin to get used to some of the underlying ideas as we prepare to expand our discussion to models with multiple inputs.

The approach will begin with the observation that *any profit maximizing-producer will choose to produce whatever quantity she produces at minimum cost*. The statement sounds almost trivial. Of course you will produce whatever quantity you do produce at the least cost possible. It is not profit-maximizing to waste inputs. But the insight allows us to split the profit-maximization problem into two parts: First, we will simply ask how much in terms of costs the firm will incur for all possible quantities of output it might choose to produce. This will permit us to derive *cost curves* that depend on *input prices* but not on the price of the output. We can then proceed to the second step and ask: How much should I produce in order to maximize the difference between my costs (derived in step 1) and my revenues (from selling the output on the market)?

Any profit-maximizing firm produces its output at the lowest possible cost—and is thus a cost minimizer.

11A.5.1 Step 1: Total Cost and Marginal Cost Curves Graph 11.10 derives a series of graphs from the same production frontier we have employed before. The graphs on the left (panels (a) through (c)) are already familiar to us from when we derived the shapes of marginal product of labor (MP_L) and marginal revenue product of labor (MRP_L) curves. In particular, we noted that the initially increasing slope of the production frontier implies that initially each additional labor hour I hire is more productive than the previous labor hour but eventually, after production plan A in Graph 11.10a, the diminishing slope of the frontier implies that each additional hour of labor is becoming less productive than the previous hour. Put differently, *until I reach the production level x^A , production becomes easier and easier as labor becomes more and more productive, but once I have reached production level x^A , each additional unit of output becomes harder to produce than the previous unit.*

GRAPH 11.10 Deriving Total and Marginal Cost from Production Frontiers

A logical implication of the last statement is that *each additional unit initially (up to x^A) is cheaper to produce than the last unit, but eventually (i.e., for production above x^A) each additional unit is more expensive to produce than the one before it*. This is illustrated in the panels on the right side of Graph 11.10. First, panel (d) simply inverts panel (a), flipping the ℓ axis from the horizontal to the vertical and the x axis from the vertical to the horizontal. As a result, the inverse production frontier graphed in panel (d) has the inverse shape of the production frontier in panel (a), with steep slopes becoming shallow and vice versa. For any quantity of output x , this inverse frontier tells us the minimum number of labor hours required to produce this output level. For the first unit of output, a lot of labor is necessary, but the additional labor necessary for each additional unit of output gets less and less until we reach output level x^A , when the additional labor required for each additional output starts to rise. This is again a reflection of the fact that the production technology is such that production initially gets easier and easier but eventually gets harder and harder.

Panel (e) then simply multiplies the inverse production frontier in panel (d) by the wage rate, converting the units on the vertical axis from labor hours to dollars. While panel (d) gives the total cost of production *in terms of labor hours*, panel (e) thus turns this into the *(total) cost curve*, which tells us how costly any given level of output is assuming I always hire the minimum number of employees necessary to get the job done. As in panel (d), this cost curve tells us that each additional unit initially adds less and less to our total cost up to output level x^A but after that adds more and more to our total cost as we produce more. Notice therefore that both the production frontier and the cost curve contain the same information: They each indicate that it initially becomes easier and easier to produce additional output but eventually it becomes harder and harder. While the production frontier in panel (a) conveys this by showing that labor initially becomes increasingly productive but eventually becomes less and less productive, the cost curve in panel (e) conveys the same information by showing that it initially becomes increasingly cheap to produce additional output but eventually it becomes increasingly expensive to add to production. Since production plan *A* in panel (a) is the turning point where the slope begins to become shallower (and thus labor begins to become increasingly less productive), the turning point for the cost curve in panel (e) also happens at output level x^A .

Finally, panel (f) plots the slope of the cost curve from panel (e) just as panel (b) plots the slope of the production frontier in panel (a). Earlier in this chapter we argued that the slope of the production frontier is a close approximation for the marginal product of labor because it tells us approximately how much total production increased when I hired the last labor hour. In exactly the same way, the slope of the total cost curve in panel (e) tells us approximately how much my total costs increased from the last output unit I produced or how much it is going to increase for the next output if I produce more. For instance, consider the production plan *B* in panel (e). The slope of the production frontier at *B* suggests that my total costs went up by approximately \$20 when I produced 10 rather than 9 units of output and will go up approximately \$20 more when I produce 11 rather than 10 units. This then represents one point on the curve plotted in panel (f) that is called the *marginal cost curve*. *The marginal cost of a particular unit of output is defined as the increase in (total) cost due to the last unit produced or, alternatively, the increase in total cost from producing one more unit.*

The cost curve illustrates the lowest cost a firm can incur when producing different levels of output.

The marginal cost curve derives from the slope of the (total) cost curve.

If the wage rate used to construct the panels on the right of Graph 11.10 is \$20, can you conclude what the slope of the production frontier in panel (a) at 10 units of output is? Can you conclude what labor input is required to produce 10 units of output, and then what the vertical values of the curves in panels (b) and (c) are for that level of labor input?

EXERCISE
11A.25

What would be the shape of the MRP_ℓ and MC curves if the entire producer choice set was strictly convex? What would the shape be for the production frontier graphed in Graph 11.1(a)?

EXERCISE
11A.26

To maximize profit, firms have to think about cost (curves) and revenue.

11A.5.2 Step 2: Profit Maximizing with Cost Curves Suppose then that, given my production technology as described by the production frontier and given a wage level w , I have derived the MC curve for my firm as we have just done. We have completed the first step of our new way of profit maximizing; that is, we have determined how much it will cost us to produce different amounts of output if we do so without wasting inputs. None of this had anything to do with the *output* price; what I can sell my output for has, after all, nothing to do with what it costs me to produce the output. To complete profit maximization in our new two-step approach, we now need to ask how much we should produce *given* we know what it costs us and given that the market has set an output price at which I can sell my goods. Put differently, we need to think about revenue, not just cost.

Panel (a) of Graph 11.11 begins by replicating the MC curve from panel (f) of Graph 11.10. Now suppose I face the output price p^* at which I can sell each unit of my output. Since p^* lies below the beginning of my MC curve, I will incur a cost for the first unit of output that exceeds the revenue I am able to make from selling that first unit, known as the *marginal revenue* of the first unit. The same is true for the second unit, with the MC for that unit indicating the increase in total costs when I produce 2 (rather than 1) units. Similarly, I will incur additional losses equal to the vertical distance between the dotted line at p^* and the MC curve for each additional unit I produce until I reach the output level x^C where $MC = p^*$. If I stopped producing at x^C , I would have incurred losses equal to the magenta area in Graph 11.11a. However, if I continue to produce, I will now be able to sell each additional unit that I produce at a price p^* that is higher than the additional cost I incur from producing that unit, until I reach output level x^D . Thus, if I produce x^D units of output, I will have incurred losses summing to the magenta area and gains summing to the green area in Graph 11.11a. Producing any more than that would not make any sense since my MC again rises above the price I am able to charge.

EXERCISE 11A.27 True or False: On a graph with output on the horizontal and dollars on the vertical, the marginal revenue curve must always be a flat line so long as the producer is a price taker.

For the price p^* depicted in the graph, the magenta area is just equal to the green area, indicating that my overall profit from producing x^D units of output is equal to zero. If the price of the output falls below p^* , the magenta area increases and the green area decreases, implying that

GRAPH 11.11 Deriving the Output Supply Curve from MC

Go to MindTap to interact with this graph.

I would incur overall negative profits by producing and thus would choose to shut down production (thereby making zero profit) instead. This is indicated by the blue line segment on the vertical axis below p^* . If, on the other hand, the output price rises above p^* , the magenta area shrinks and the green area increases, implying that my overall profit from producing wherever the price intersects MC is positive. The blue portion of the MC curve that lies above the “break-even” price p^* therefore indicates how much output I will choose to supply to the market when price rises above p^* . The combination of the two blue line segments then represents my output supply curve, which has *exactly the same shape as the output supply curve we derived in Graph 11.9c when we derived the curve directly using isoprofit curves and the production frontier*. That’s because it is exactly the same curve. All we have done here is split the profit maximization problem into two parts: First, we asked how much it *costs* to produce all possible output levels, and then we asked which of these output levels creates the largest difference between total revenues (from selling the output) and total production costs (which we identified in step 1).

11A.5.3 Using Average Cost Curves to Locate p^* Finally, it turns out that there is an easier way than adding magenta and green areas along the MC curve to find the point on the MC curve at which the profit-maximizing producer will choose to shut down. For this, we need to introduce yet another cost curve known as the *average cost curve*.

Average Cost is defined simply as (Total) Cost divided by output. At the production plan B in Graph 11.10e, for instance, the total cost curve indicates that I can produce 10 units of the output at a total cost of \$300. This implies that the average cost of producing 1 unit of output when I am producing an overall quantity of 10 units is \$30. Notice that this is different from the marginal cost, which is the cost of producing the last unit (or the cost of producing 1 additional unit). The *average cost curve (AC)* then plots the average cost for each quantity of production by simply dividing the total cost by that quantity. This curve has a U-shape for the same reason as the marginal cost curve: because we have assumed a production technology under which it initially becomes easier and easier to produce additional output (thus causing the average cost to fall) while eventually it becomes harder and harder (causing average cost at some point to rise again). In addition, however, the AC curve has a more precise logical relationship to the MC curve in the following two ways: First, *the average cost curve begins at essentially the same vertical intercept as the marginal cost curve and second, it attains its lowest point where the marginal cost curve crosses it*. This is depicted in panel (b) of Graph 11.11.

Marginal cost (MC) curves cross average cost (AC) curves at the lowest point of AC .

You can most easily develop the intuition for this relationship between average and marginal cost curves by thinking about average and marginal grades in one of your courses. Suppose you make a 95% on your first assignment in one of your courses. At this point, your marginal grade, the grade on your last assignment, is 95%. Furthermore, since you have had no other assignments, your average grade at this point is also 95%. Thus, when you have had only 1 assignment in the course, your average and marginal grades are the same just as when I have produced only 1 output my marginal and average costs are the same. Now suppose that you are not very ambitious and don’t want to get your parents used to such excellent grades. Thus, you want to make sure that your next assignment brings your grade *down*. Your (marginal) grade on the second assignment must then be lower than your average grade going into this assignment, in this case lower than 95%. Suppose you are successful and your second grade is 85%. After 2 assignments, you now have an average grade of 90% because your marginal second grade has brought down your average. Now suppose you want to aim for an even lower course average. You will again have to receive a marginal grade below the average in order to bring the average down further. Going into the final assignment of the course, you have finally reduced your average to 70%, but suppose now that you would like to land with a final grade average above this. In order to accomplish that, you must now get a final marginal grade above your average. Thus *averages are brought down if marginal quantities lie below the average and are brought up if marginal quantities lie above the average*. The same is true for average and marginal costs.

In panel (b) of Graph 11.11, I have therefore plotted the AC curve in such a way that it begins at the same intercept as the MC curve, declines as long as the MC lies below the AC , and increases once the MC lies above the AC . This implies that the MC curve must cross the AC at its lowest point, because as soon as the MC lies above AC , it brings up the average cost (just as when your marginal grade lies above your course average, it will raise your average grade for the course).

EXERCISE 11A.28* Can MC fall while AC rises? (*Hint:* The answer is yes.) Can you give an analogous example of marginal test grades falling while the average grade rises at the same time?

The AC curve reaches its lowest point at the break-even price.

In addition, I have plotted the lowest point of the AC curve at point D , which lies at the “break-even” price p^* . This was not an arbitrary choice on my part; *it is logically necessary that this is precisely where the AC reaches its lowest point because overall profits are zero when the output price is exactly equal to the lowest point of the average cost curve.*

This is by no means immediately obvious, but we can reason our way to this conclusion fairly easily. Suppose the price I face is not p^* but rather p' in Graph 11.11b. I would then choose to produce the quantity x' on my output supply curve, which implies that the average cost per unit of output I incur is AC' . If the average cost is AC' and I produce a total output of x' , then my *total cost* is AC' times x' , or the dark blue shaded area. (You can also see this from the definition of AC as $AC = TC/x$, which directly implies that $TC = x(AC)$.) My *total revenue*, on the other hand, is equal to the quantity I produce (x') times the price I charge for each unit of output (p'), which is equal to the dark blue area plus the light blue area in Graph 11.11b. This implies that my profit is the difference between these two areas, or just the light blue area.

The output supply curve contains the portion of the MC curve that lies above AC .

Now we can do the same calculation when the price of the output is p^* in panel (c) of Graph 11.11. In this case, I produce the quantity x^D at average cost AC^D . This implies that my total cost is the blue area. Since the output price is p^* , I can sell each of the x^D goods I produce at p^* , which implies that my total revenue is also equal to the blue area in panel (c). Because $p^* = AC^D$, my total revenue and total cost are therefore exactly equal and my overall profit is zero just as we concluded was true in panel (a) of the graph. The “break-even price” must therefore lie exactly at the lowest point of the AC curve where MC crosses AC . As a result, *if we have a graph with both the average and the marginal cost curves, we can immediately locate the output supply curve as the portion of the MC curve that lies above AC , with zero supply at prices below.*

EXERCISE 11A.29 How do the marginal and average cost curves look if the producer choice set is convex?

11B

THE MATHEMATICS OF THE SHORT-RUN MODEL

The single-input/single-output model developed graphically in Section A is easily translated into a mathematical framework, and we will see in upcoming chapters that this mathematical framework can then easily be extended into more complex and more realistic production settings. For now, we will stick with the example (introduced in Section A) of me attempting to produce “packets of economist cards” denoted x by using the input “labor hours” denoted by ℓ . (I realize we previously used the notation ℓ for “leisure hours” in Chapters 3 and 8, but I don’t think it will cause too much confusion to use it to indicate “labor hours” now. After all, I don’t know of any firm that would consider leisure hours by their workers as a productive input, although I have questioned myself on occasion as I watched the number of breaks taken by the construction crew that recently built an addition to my house.)

11B.1 Technological Constraints Faced by Producers

When we introduced consumer choice sets in Chapter 2, we did so by defining mathematical notation used to describe sets of points, with the first portion of the definition of a set indicating what geometric space the points occupy (i.e., are they an element of \mathbb{R}_+^2 , \mathbb{R}_+^3 , etc.), and the latter part of the definition indicating conditions that such points must satisfy in the form of an equation (i.e., the budget equation). Put differently, the first portion of the definition gave the *necessary conditions* that points must satisfy while the second portion gave the *sufficient conditions* for those points to lie in the set we were describing. We will follow the same practice here when we define producer choice sets and will then work directly with the equations that define producer choice sets to illustrate their mathematical properties.

11B.1.1 Production Plans, Producer Choice Sets, and Production Frontiers Production plans for single-input/single-output production processes are, as demonstrated already in Section A, simply points in a two-dimensional space just as consumption bundles in a two-good world. More precisely, the producer choice set is given by all production plans that lie below the production frontier that is defined by a *production function*. Defined formally, the producer choice set C defined by the production function $f: \mathbb{R}_+^1 \rightarrow \mathbb{R}_+^1$, can be written as

$$C(f: \mathbb{R}_+^1 \rightarrow \mathbb{R}_+^1) = \{(x, \ell) \in \mathbb{R}^2 \mid x \leq f(\ell)\}. \quad (11.1)$$

In principle, this producer choice set could take on all sorts of shapes, but in part A of the chapter we emphasized a particular kind of “sigmoid” shape. There are a number of ways we can derive such a shape of a production function that initially has increasing but eventually decreasing marginal product of labor. (Three such ways are explored in end-of-chapter exercise 11.6.) For instance, consider the function

$$f(\ell) = \begin{cases} \alpha(1 - \cos(\beta\ell)) & \text{for } 0 \leq \ell \leq \frac{\pi}{\beta} \approx \frac{3.1416}{\beta} \\ 2\alpha & \text{for } \ell > \frac{\pi}{\beta} \approx \frac{3.1416}{\beta}. \end{cases} \quad (11.2)$$

Since $\cos(0) = 1$, this function begins with zero output for zero labor input (i.e., $f(0) = 0$); and, since $\cos(\pi) = -1$, output reaches 2α when $\ell = \pi/\beta$. In between $\ell = 0$ and $\ell = \pi/\beta$, the function is upward sloping, with initially increasing slope (and thus increasing marginal product of labor) but eventually decreasing slope (and thus decreasing marginal product of labor).⁵

A production function is the mathematical representation of the production frontier.

How would this production function look differently if we did not specify that output levels off at 2α ?

EXERCISE 11B.1

The production function graphed in Graph 11.1b (and implicitly used throughout Section A) was derived from this general form, with $\alpha = 200$ and $\beta = 0.031416$ (or $\pi/100$); that is, we used the production function

$$f(\ell) = \begin{cases} 200 \left(1 - \cos\left(\frac{3.1416\ell}{100}\right) \right) & \text{for } 0 \leq \ell \leq 100 \text{ and} \\ 400 & \text{for } \ell > 100. \end{cases} \quad (11.3)$$

⁵Note that we are using π to denote the mathematical value of pi (used to calculate the circumference and area of a circle). Elsewhere we use the same Greek letter to denote profit.

EXERCISE 11B.2 Define the production function generating the production frontier in Graph 11.1a and define the corresponding producer choice set formally.

Marginal product of labor is the derivative (with respect to labor) of the production function.

11B.1.2 Slopes of Production Functions: The Marginal Product of Labor Now consider the definition of the marginal product of labor (MP_ℓ) as the increase in total output from hiring one more unit of the input. Once we have defined a production function f , we can restate this definition simply as the derivative of the production function with respect to the input; that is,

$$MP_\ell = \frac{df}{d\ell}. \quad (11.4)$$

Recalling that the derivative of $(\cos x)$ is $(-\sin x)$, the marginal product of labor for the production function defined in (11.3) is then

$$MP_\ell = 200 \left(\frac{3.1416}{100} \right) \sin \left(\frac{3.1416\ell}{100} \right) = 6.2832 \sin \left(\frac{3.1416\ell}{100} \right), \quad (11.5)$$

which is exactly what is graphed in Graph 11.2b.

EXERCISE 11B.3 Given that f is really defined as in equation (11.3), how should equation (11.5) be modified to reflect accurately the marginal product of labor for labor hours above 100?

EXERCISE 11B.4 Derive the marginal product of labor from the production function you derived in exercise 11B.2. Compare this to the graphical derivation in Graph 11.2a.

11B.1.3 Diminishing Marginal Product of Labor In Section 11A.1.3, we argued that, in a world of scarcity, the marginal product of any input must eventually decline. Knowing that the marginal product is just the derivative of the production function, we can now see how this Law of Diminishing Marginal Product relates directly to the mathematical properties of the production function f . In particular, we can translate the Law of Diminishing Marginal Product into the mathematical statement that “the slope, or the derivative, of MP_ℓ is negative (for sufficiently high levels of labor).” But since the MP_ℓ is the derivative of f , the Law of Diminishing Marginal Product can furthermore be stated as “the second derivative of the production function must be negative (for sufficiently high levels of labor),” or

$$\text{There exists } \ell^* < \infty \text{ such that } \frac{dMP_\ell}{d\ell} = \frac{d^2f}{d\ell^2} < 0 \text{ for all } \ell > \ell^*. \quad (11.6)$$

Of course, this simply means that the production function must at some point begin to get shallower and shallower.

EXERCISE 11B.5 Check to see that the Law of Diminishing Marginal Product (of labor) is satisfied for the production function in equation (11.3).

11B.2 “Tastes” for Profits

Having defined the technology constraint through producer choice sets, Section 11A.2 proceeded to argue that indifference curves for profit-maximizing (and price-taking) producers must be straight lines of production plans with each yielding the same amount of profit. The

intercept of such an indifference curve, or isoprofit, corresponding to the profit level π was then derived as (π/p) and the slope as w/p .

More formally, an isoprofit curve P containing all production plans that result in a particular profit level π when the output price is p and the wage rate is w can be defined as a set

$$P(\pi, w, p) = \{(x, \ell) \in \mathbb{R}^2 \mid \pi = px - w\ell\}, \quad (11.7)$$

where the equation contained in the definition of this set is precisely what we derived intuitively in Section 11A.2. More precisely, the equation $\pi = px - w\ell$ can be rewritten (by adding $w\ell$ to both sides and dividing by p) as

$$x = \left(\frac{\pi}{p}\right) + \left(\frac{w}{p}\right)\ell, \quad (11.8)$$

an equation with intercept (π/p) and slope (w/p) . The isoprofit curves in Graphs 11.3 and 11.4 are then depictions of equation (11.8) with different values plugged in for π , w , and p .

11B.3 Choosing the Production Plan that Maximizes Profits

In our development of the consumer model, we ultimately set up what we called a constrained optimization problem, which is a problem in which we defined the utility function as the “objective function” to be maximized and the budget line as the “constraint” over which the maximization would happen. In the producer model, on the other hand, we have defined profit π as the objective to be maximized over the technological constraint imposed by a production function that limits the set of production plans that are feasible.

Firms maximize profit subject to the technological constraint represented by the production function.

11B.3.1 Setting up the Producer’s Optimization Problem The producer then chooses the production plan (x, ℓ) that will maximize his or her profit $\pi = px - w\ell$ subject to the constraint that (x, ℓ) is technologically feasible. Stated more formally, the producer solves the problem

$$\max_{x, \ell} \pi = px - w\ell \quad \text{subject to } x = f(\ell). \quad (11.9)$$

In Chapter 6, we described several ways of solving such constrained optimization problems, with Method 1 simply plugging the constraint into the objective function and Method 2 setting up a Lagrange function to differentiate. In the case of the single-input/single-output model, Method 1 is often the simplest method, allowing us to convert the constrained optimization problem described in equation (11.9) into an unconstrained optimization problem

$$\max_{\ell} \pi = pf(\ell) - w\ell. \quad (11.10)$$

11B.3.2 Marginal Product = w/p (or Marginal Revenue Product = w) Solving the unconstrained optimization problem (11.10) is then a simple matter of taking the first derivative of the function π and setting it to zero; that is, the first order condition for the profit maximization problem (11.10) is

$$\frac{d\pi}{d\ell} = p\left(\frac{df(\ell)}{d\ell}\right) - w = 0, \quad (11.11)$$

or, with terms rearranged and substituting MP_{ℓ} for $df(\ell)/d\ell$,

$$MP_{\ell} = \frac{w}{p} \quad \text{or equivalently } pMP_{\ell} = MRP_{\ell} = w. \quad (11.12)$$

Thus, for our example of a production process defined by equation (11.3), this implies that the optimal production plan has to satisfy the condition that

$$MP_{\ell} = 6.2832 \sin\left(\frac{3.1416\ell}{100}\right) = \frac{w}{p}. \quad (11.13)$$

What we concluded from Graphs 11.5c and (f) then falls immediately out of the mathematics behind the graphs: At the optimum, the marginal product of labor is equal to w/p and the marginal revenue product of labor is equal to w . Put in terms of the language used in part A, this simply means that, as a producer, I will hire labor along the declining marginal revenue product curve so long as the marginal benefit of an additional labor hour in terms of revenue is greater than its marginal cost (in terms of the wage). When $w = 20$ and $p = 5$ (as in Graph 11.5), for instance, equation (11.13) simplifies to $\sin(0.031416\ell) = 0.6366$, which is satisfied for $\ell = 22$ and $\ell = 78$. The first of these solutions represents the first point at which wage crosses the marginal revenue product curve in panel (f) of Graph 11.5 and therefore represents a profit “minimum” rather than a maximum. The second solution, $\ell = 78$, then represents the true solution on the downward-sloping part of the marginal revenue product curve.

11B.4 Labor Demand, Output Supply, and “Real Optima”

The optimal solutions in Graphs 11.6 and 11.8 all depict profit-maximizing optima as either w or p changes. Each of these was calculated using the production function (11.3) as the optimization problem (11.10) was solved for these different economic conditions. In fact, the solution to the optimization problem (11.10) implicitly defines a *labor demand function* that gives the quantity of labor ℓ demanded for any wage rate w and price p ; that is,

$$\ell = \ell(p, w). \quad (11.14)$$

The initial *labor demand curve* derived in Graph 11.7 is then a simple “slice” of the *labor demand function*, with p held fixed at \$5 (i.e., $\ell(5, w)$). To be more precise, just as in the case of consumer demand curves, economists have gotten into the habit of graphing slices of *inverse* functions, and the labor demand *curve* in Graph 11.7 is actually the inverse of $\ell(5, w)$. We then noticed in Graph 11.8b that, as p changes, the MRP_{ℓ} curve shifts up for an increase in p (and down for a decrease in p). Since the labor demand curve is a part of the MRP_{ℓ} curve, an outward shift with an increase in p from \$5 to \$10 thus results in a shift in the labor demand curve, going from the slice $\ell(5, w)$ to $\ell(10, w)$. The labor demand function $\ell(p, w)$ can of course be similarly sliced holding w fixed and allowing p to vary, thus providing a curve relating output price to labor demand.

The labor demand curve is an inverse slice (that holds output price fixed) of the labor demand function.

EXERCISE 11B.6 Without doing the math, can you tell if the curve $\ell(p, 20)$ slopes up or down? How does it relate to $\ell(p, 10)$?

Once we have a function $\ell(p, w)$ that tells us for each output price and wage rate how many labor hours I will hire in my factory, I can also immediately derive the *output supply function* because the production function f tells me the output produced for any level of labor input. The supply of x from my factory is then a function of p and w given by

$$x(p, w) = f(\ell(p, w)). \quad (11.15)$$

In Graph 11.6, for instance, we can derive the output quantity $x = 354$ by simply plugging the optimal labor demand (of approximately 78) into the production function.

Thus, the graph of the supply curve that relates the output price to the quantity produced is again a simple (inverse) slice of the supply function in equation (11.15) with wage held fixed. In particular, Graph 11.9b depicts the function $x(p, 20)$ where wage is fixed at \$20 per hour, and the graph in Graph 11.9c depicts its inverse called the “supply curve.”

Finally, with expressions for output supply and labor demand we can derive a function that tells us, for any price and wage rate, the amount of profit I will earn in my business. This function is known as the *profit function* π and is simply written as:

$$\pi = \pi(p, w) = px(w, p) - w\ell(p, w). \tag{11.16}$$

The output supply curve is an inverse slice (that holds wage fixed) of the output supply function.

11B.4.1 Corner Solutions We have noticed already in our graphs that, for certain combinations of wages and prices, it is optimal for producers to shut down and produce nothing. Our calculus method of finding optimal solutions, however, implicitly assumes a positive level of output is optimal and searches for a tangency between isoprofit curves and the production function. Just as in the consumer model, it will be the case that *if the true optimal solution involves an “interior solution”* (i.e., a positive level of production) then the calculus previously described will indeed find that solution.

Consider, however, the production function depicted in Graph 11.12a with price p and wage w forming isoprofit curves with slopes as depicted in the graph. If I now set the optimization problem up as in expression (11.9) or (11.10) and use any of the calculus-based solution methods we have introduced in this text, the production plan A will be offered as the optimal solution, suggesting production of x^A using labor input ℓ^A . If I then proceed to calculate my profit $\pi = px^A - w\ell^A$, however, I would discover that $\pi < 0$ (as indicated in the graph by the negative vertical intercept). Thus, the corner solution B , which yields zero profit, is better than the production plan A (as indicated by the fact that B lies on a higher isoprofit curve).

GRAPH 11.12 Non-Convexities in Producer Choice Sets and Negative Profits at Tangencies

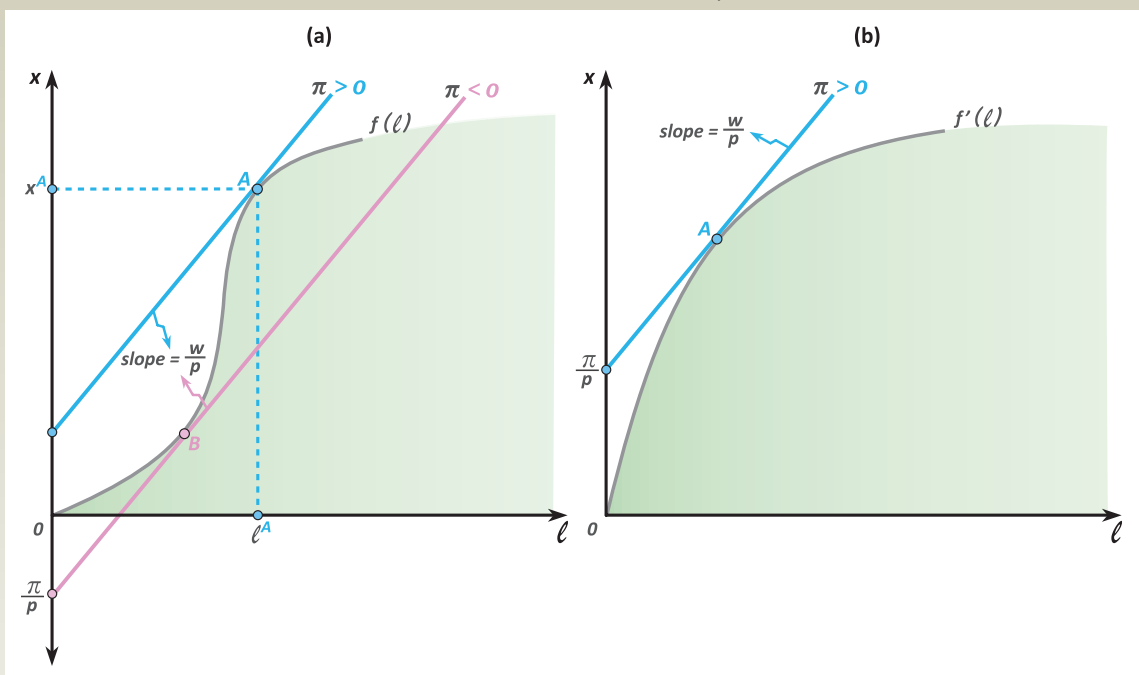

“Shutting down” is a corner solution.

When calculating solutions to profit-maximization problems, it is then important to be sure that the solutions suggested by our methods are not dominated by corner solutions, especially by the corner solution that implies shutting down. Put differently, before claiming that a particular production plan is profit maximizing, we should check to make sure that profits under that production plan are at least zero. Otherwise, we know that shutting down dominates producing. However, one case in which we do not have to check whether profit for a solution emerging from a tangency between isoprofit and the production function arises is when the producer choice set is convex (as in panel (b) of Graph 11.12).

EXERCISE 11B.7 Consider a production function that gives rise to increasing marginal product of labor throughout (beginning with the first labor hour). *True or False:* In this case, the mathematical optimization problem will unambiguously lead to a “solution” for which profit is negative.

11B.4.2 Distinguishing a Minimum from Maximum Profit A second technical problem that could emerge from using our calculus-based solution methods to profit maximization involves the appearance of multiple “candidate” optimal solutions. Consider for instance the production function and isoprofit curves depicted in Graph 11.13a. Recall that our calculus methods identify production plans where the slopes of isoprofit curves w/p are tangent to the production function. In the case depicted here, this method would identify two such plans, A and B , but it is clear from the picture that A is the true optimal production plan (and B in fact generates negative profits).

GRAPH 11.13 Non-Convexities in Production Sets and Multiple “Solutions”

Once again, the culprit of this multiplicity of tangencies lies in the non-convexity of the producer choice set, and when such non-convexities disappear (as in panel (b) of Graph 11.13), the calculus-based optimization methods we use in this text yields a single optimal solution. While more complicated methods for calculating the true optimum in profit maximization problems exist, we can navigate around such methods by being aware of exactly what type of problem we are dealing with (i.e., where are the non-convexities?) and then checking to make sure our calculated optima are truly optimal. Using equation (11.13), for instance, we derived “optimal” labor demand for the production function in equation (11.3) when $w = 20$ and $p = 5$ as $\ell = 22$ and $\ell = 78$. Using Graph 11.6, we realized that the math gave us one incorrect solution because it gave the level of labor where w intersects MRP_ℓ on the upward-sloping portion as well as when it intersects on the downward-sloping part. This is exactly analogous to point B in Graph 11.13a, with the real optimum lying at A .

Consider a production function that gives rise to increasing marginal product of labor throughout (beginning with the first labor hour). *True or False:* In this case, the mathematical optimization problem will give a single solution, albeit one that minimizes rather than maximizes profit.

EXERCISE 11B.8

11B.4.3 Necessary and Sufficient Conditions for Profit Maximization The general point illustrated in Section 11B.4.1 is that the *first order condition* (in equation (11.11)) is a *necessary condition* that must be satisfied for profit-maximizing producers so long as the true profit-maximizing plan does not lie at a corner of the producer choice set. There are two such “corners”—one at which production is zero and another at which it is infinite. As long as the true profit-maximizing plan does not lie at one of these corners, the actual profit-maximizing plan must *necessarily* satisfy the first order condition (11.11).

Give an example of a producer choice set and economic conditions such that infinite production would be “optimal.”

EXERCISE 11B.9

Do you think the scenario you outlined in the previous within-chapter exercise makes sense under the assumption of “price-taking” behavior by producers?

EXERCISE 11B.10

In Section 11B.4.2, however, we showed that a production plan satisfying the first order condition (11.11) does not mean it is the true profit-maximizing production plan even if none of the “corners” is optimal; that is, there may be several production plans that satisfy the first order condition, with some yielding more profit than others. The first order conditions are only *sufficient* for us to conclude a production plan is profit maximizing if the producer choice set is convex. Such convexity automatically rules out the potential for corner solutions, and it ensures that there are not multiple production plans that satisfy the first order conditions. Thus, the first order condition from which we derive labor demand and output supply functions is *both necessary and sufficient* for profit maximization so long as the underlying producer choice set is convex.

Our calculus method of profit maximizing is guaranteed to yield a single correct solution only if the producer choice set is convex.

11B.5 Two-Step Profit Maximization

As we argued in part A, there is a second way to derive the profit-maximizing plan for producers: by splitting profit maximizing into two parts. The first part is concerned simply with how much it costs to produce different output levels; the second part then asks how much we should produce given the costs and given the price at which we can sell the goods in the market.

Cost minimization in a single-input production process is trivial because there exists only one technologically efficient way of producing any level of output: by using the input level that lies on the production frontier for the desired level of output. (Once we have two inputs, this problem will not be nearly as “trivial” because we will then have many different ways in which we can combine labor and capital to produce the same level of output.) We illustrated this one-input cost minimization in Graph 11.10 where the cost of producing x^A of the output required ℓ^A input and thus cost $w\ell^A$. More formally, all we did in going from panel (a) to panel (d) of the graph was to take the inverse of the production function $f(x)$ to get

$$\ell(x) = f^{-1}(x). \quad (11.17)$$

This tells us how many units of labor are required for each level of output. Then, in going from panel (d) to (e), we simply multiplied this function by the cost of labor w to get a cost function

$$C(w, x) = w\ell(x). \quad (11.18)$$

That tells us the total cost of production for any level of output. In fact, panel (e) of Graph 11.10 is a “slice” of the cost function $C(w, x)$ that holds w fixed. From this, we can then derive marginal cost and average cost functions

$$MC(w, x) = \frac{\partial C(w, x)}{\partial x} \quad \text{and} \quad AC(w, x) = \frac{C(w, x)}{x} \quad (11.19)$$

and derive the output supply curve as the portion of the MC curve above the AC curve. More precisely, the supply curve we derived is an inverse “slice” of the more general supply function $x(p, w)$ that tells us how much a producer supplies in any economic environment characterized by some output price p and wage w . To derive this supply function, we recognize that, so long as price is above the lowest point on the AC curve, a price-taking producer will produce until price equals marginal cost; that is, he or she will produce such that

$$p = MC(w, x) \quad \text{if} \quad p \geq \min_x \{AC(w, x)\}. \quad (11.20)$$

We can then solve the equation $p = MC(w, x)$ for x to get the supply function $x(p, w)$ that lies above AC , with supply equal to zero below that; that is,

$$x(p, w) = MC^{-1}(p, w) \quad \text{if} \quad p \geq \min_x \{AC(w, x)\} \\ 0 \quad \text{if} \quad p < \min_x \{AC(w, x)\}, \quad (11.21)$$

where MC^{-1} simply signifies the inverse of the MC function with respect to price. We can furthermore derive the input demand function for labor $\ell(p, w)$ by simply substituting $x(p, w)$ into the inverse production function $\ell(x)$ from equation (11.17).

11B.5.1 Relationship of MC and AC Having derived mathematical expressions for total, marginal, and average cost, we can also now easily demonstrate mathematically what we concluded intuitively about the relationship between average and marginal costs. In particular, we concluded that the MC curve crosses the AC curve at its lowest point; that is, where the derivative of the AC with respect to x is equal to zero. Using the expression for AC from equation (11.19) and taking the derivative with respect to x , we get

$$\frac{\partial AC(w, x)}{\partial x} = \frac{\partial C(w, x)/\partial x}{x} - \frac{C(w, x)}{x^2} = \frac{MC(w, x)}{x} - \frac{C(w, x)}{x^2}. \quad (11.22)$$

Multiplying by x , this gives

$$\frac{\partial AC(w, x)}{\partial x} x = MC(w, x) - \frac{C(w, x)}{x} = MC(w, x) - AC(w, x). \quad (11.23)$$

The cost curve is a slice (that holds input prices fixed) of the cost function.

When the derivative of AC with respect to x is zero, this can be written as

$$MC(w, x) - AC(w, x) = 0 \text{ or just } MC(w, x) = AC(w, x). \quad (11.24)$$

Thus, when AC reaches its minimum, $MC(w, x) = AC(w, x)$.

11B.5.2 Two Ways of Profit Maximizing: An Example with Strictly Diminishing MP_ℓ

Because of the complexity of production functions with initially increasing and eventually decreasing MP_ℓ (such as the one in equation (11.3)), we have thus far foregone calculating the exact supply and demand functions but have merely indicated the two methods by which these can be calculated. To provide an illustration of these methods in a setting where calculations are more manageable, we will now conclude the chapter by offering an example in which we do not have to worry about corner solutions or multiple potential solutions because we assume from the outset a producer choice set that is strictly convex. Several of the end-of-chapter exercises allow you to investigate the same general methods for more complex production functions.

Suppose the producer choice set and the production frontier are defined by the production function

$$f(\ell) = A\ell^\alpha. \quad (11.25)$$

What has to be true about α in order for this production function to exhibit diminishing marginal product of labor?

EXERCISE 11B.11

Setting up the profit-maximization problem, our first way of calculating input demands and output supplies, we get

$$\max_{x, \ell} \pi = px - w\ell \text{ subject to } x = A\ell^\alpha, \quad (11.26)$$

or, with the constraint placed into the objective function,

$$\max_{\ell} \pi = pA\ell^\alpha - w\ell. \quad (11.27)$$

Taking the first derivative with respect to ℓ , we get the first order condition

$$\alpha Ap\ell^{\alpha-1} - w = 0, \quad (11.28)$$

and solving this for ℓ , we find the labor demand function

$$\ell(p, w) = \left(\frac{w}{\alpha Ap} \right)^{1/(\alpha-1)}. \quad (11.29)$$

Suppose $0 < \alpha < 1$ and $A > 0$. Holding price fixed, is the labor demand function downward sloping in the wage? Holding wage fixed, is it upward or downward sloping in price? Can you graphically illustrate why your answers hold?

EXERCISE 11B.12

The output supply function is then simply the production function evaluated at $\ell(p, w)$

$$x(p, w) = f(\ell(p, w)) = A \left(\frac{w}{\alpha Ap} \right)^{\alpha/(\alpha-1)}. \quad (11.30)$$

Suppose $0 < \alpha < 1$ and $A > 0$. Holding wage fixed, is the supply function upward sloping in price? Holding price fixed, is the supply function upward sloping in wage? Can you graphically illustrate why your answers hold?

EXERCISE 11B.13

EXERCISE 11B.14* How do your answers to the previous two exercises change when $\alpha > 1$? Can you make sense of what is going on? (*Hint:* Graph the production function and illustrate the tangencies of isoprofits for different wages and prices.)

Now consider the two-step method: cost minimization on the way to profit maximization. We begin by taking the inverse of the production function to get $\ell(x)$ as in equation (11.17) and then multiply it by w to get the cost function as in equation (11.18). This gives us

$$\ell(x) = \left(\frac{x}{A}\right)^{1/\alpha} \quad \text{and} \quad C(w, x) = w\left(\frac{x}{A}\right)^{1/\alpha}. \quad (11.31)$$

The marginal and average cost functions then are

$$\begin{aligned} MC(w, x) &= \frac{\partial C(w, x)}{\partial x} = \left(\frac{w}{\alpha A^{1/\alpha}}\right) x^{(1-\alpha)/\alpha} \quad \text{and} \\ AC(w, x) &= \frac{C(w, x)}{x} = \left(\frac{w}{A^{1/\alpha}}\right) x^{(1-\alpha)/\alpha}. \end{aligned} \quad (11.32)$$

Notice that, in this case, $MC(w, x) = AC(w, x)$ when $x = 0$, and, whenever $0 < \alpha < 1$, $MC(w, x) > AC(w, x)$ for all $x > 0$. Thus, the lowest point of the AC curve occurs at $x = 0$ for this production function when α lies between zero and 1. As a result, we can simply set price equal to MC and solve for x to get (as in equation (11.21)),

$$x(p, w) = \left(\frac{\alpha A^{1/\alpha} p}{w}\right)^{\alpha/(1-\alpha)} A \left(\frac{\alpha A p}{w}\right)^{\alpha/(1-\alpha)} = A \left(\frac{w}{\alpha A p}\right)^{\alpha/(\alpha-1)}. \quad (11.33)$$

Note that this is precisely the supply function we calculated in equation (11.30) when we solved the profit-maximization problem for the same production function directly rather than solving first for the cost function and then finding the profit-maximizing supply function by setting price equal to marginal cost. Similarly, if we now plug $x(p, w)$ into the function $\ell(x)$ in equation (11.31), we get

$$\ell(p, w) = \left(\frac{w}{\alpha A p}\right)^{1/(\alpha-1)}, \quad (11.34)$$

just as we did in the profit-maximization problem that resulted in equation (11.29).

EXERCISE 11B.15 Graphically illustrate the way we have just derived the output supply function assuming α lies between 0 and 1. What changes when $\alpha > 1$?

CONCLUSION

This chapter has explored profit-maximizing behavior in the simplest possible producer model: a model in which a single input “labor” is turned into a single output. A production plan is then defined as a plan for converting input into output, and a production frontier divides the set of all production plans into those that are technologically feasible and those that are not. Thus, the production frontier, expressed mathematically as the production function, is the technological constraint under which production occurs. Producers then search for that production plan on the production frontier that results in the highest possible profit, a process we graphed by illustrating a producer’s indifference map as a map of isoprofit lines with slopes given by the ratio of input to output prices. We then explored how profit-maximizing choices change as the economic environment—prices and wages—change. This analysis leads to the derivation of labor demand

curves (and functions), as well as output supply curves (and functions). Finally, we illustrated that we can also think of profit maximization as a two-step process where the first step involves a focus on determining the cost of producing and the second step brings in the revenue potential of different output levels. This will become useful in the next chapter.

Much of the intuition behind the producer model emerges from this very simple setting, but some important subtleties are overlooked. Most important among these is the choice producers must make between different inputs like capital and labor. Put differently, given that we have assumed only a single input so far, it was always quite clear how a producer would go about producing a particular quantity of output: he or she would simply take the least amount of labor required to get the job done. But once we introduce a second possible input—like machinery, for instance—the producer must not only choose how much to produce but also with what combination of inputs. We therefore next expand our producer model to focus on issues surrounding this complication.

END-OF-CHAPTER EXERCISES

11.1[†] Throughout part A of the text, we used the technology we called more “realistic” in panel (b) of Graph 11.1.

- A.** Suppose now that the producer choice set was instead strictly convex everywhere.
- Illustrate what such a technology would look like in terms of a production frontier.
 - Derive the output supply curve with price on the vertical and output on the horizontal axis (in graphs analogous to those in Graph 11.9) for this technology.
 - Derive the labor demand curve for such a technology.
 - Now suppose the technology were instead such that the marginal product of labor is always increasing. What does this imply for the shape of the producer choice set?
 - How much should the firm produce if it is maximizing its profits in such a case? (*Hint: Consider corner solutions.*)
- B.** Suppose that the production function a firm faces is $x = f(\ell) = 100\ell^\alpha$.
- For what values of α is the producer choice set strictly convex? For what values is it non-convex?
 - Suppose $\alpha = 0.5$. Derive the firm’s output supply and labor demand function.
 - How much labor will the firm hire, and how much will it produce if $p = 10$ and $w = 20$?
 - How does labor demand and output supply respond to changes in w and p ?
 - Suppose that $\alpha = 1.5$. How do your answers change?

11.2 In the following, we will investigate the profit-maximizing choice in the two steps that first involve a strict focus on the cost side.

- A.** Consider again (as in the previous exercise) a production process that gives rise to a strictly convex producer choice set.
- Derive the cost curve from a picture of the production frontier.
 - Derive the marginal and average cost curves from the cost curve.
 - Illustrate the supply curve on your graph. How does it change if the wage rate increases?
 - Now suppose the production process gives rise to increasing marginal product of labor throughout. Derive the cost curve and from it the marginal and average cost curves.
 - Can you use these curves to derive a supply curve?
 - The typical production process is one that has increasing marginal product initially but eventually turns to one where marginal product is diminishing. Can you see how the two cases considered in this exercise combine to form the typical case?
- B.** Consider again (as in the previous problem) the production function $x = f(\ell) = 100\ell^\alpha$.
- Derive the firm’s cost function.
 - Derive the marginal and average cost functions, and determine how their relationship to one another differs depending on α .

*conceptually challenging

**computationally challenging

[†]solutions in Study Guide

- c. What is the supply function for this firm when $\alpha = 0.5$? What is the firm’s labor demand function?
- d. How do your answers change when $\alpha = 1.5$?

11.3[†] Consider a profit-maximizing firm.

- A.** Explain whether the following statements are true or false:
 - a. For price-taking, profit-maximizing producers, the “constraint” is determined by the technological environment in which the producer finds him- or herself, whereas the “tastes” are formed by the economic environment in which the producer operates.
 - b. Every profit-maximizing producer is automatically cost minimizing.
 - c. Every cost-minimizing producer is automatically profit maximizing.
 - d. Price-taking behavior makes sense only when marginal product diminishes at least at some point.
- B.** Consider the production function $x = f(\ell) = \alpha \ln(\ell + 1)$.
 - a. Does this production function have increasing or decreasing marginal product of labor?
 - b. Set up the profit-maximization problem and solve for the labor demand and output supply functions.
 - c. Recalling that $\ln x = y$ implies $e^y = x$ (where $e \approx 2.7183$ is the base of the natural log), invert the production function and derive from this the cost function $C(w, x)$.
 - d. Determine the marginal and average cost functions.
 - e. Derive from this the output supply and labor demand functions. Compare them to what you derived directly from the profit-maximization problem in part (b).
 - f. In your mathematical derivations, what is required for a producer to be cost minimizing? What, in addition, is required for her to be profit maximizing?

11.4 In this exercise, we will explore how changes in output and input prices affect output supply and input demand curves.

- A.** Suppose your firm has a production technology with diminishing marginal product throughout.
 - a. With labor on the horizontal axis and output on the vertical, illustrate what your production frontier looks like.
 - b. On your graph, illustrate your optimal production plan for a given p and w . *True or False:* As long as there is a production plan at which an isoprofit curve is tangent, it is profit maximizing to produce this plan rather than shut down.
 - c. Illustrate what your output supply curve looks like in this case.
 - d. What happens to your supply curve if w increases? What happens if w falls?
 - e. Illustrate what your marginal product of labor curve looks like and derive the labor demand curve.
 - f. What happens to your labor demand curve when p increases? What happens when p decreases?
- B.** Suppose that your production process is characterized by the production function $x = f(\ell) = 100 \ln(\ell + 1)$. For purposes of this problem, assume $w > 1$ and $p > 0.01$.
 - a. Set up your profit-maximization problem.
 - b. Derive the labor demand function.
 - c. The labor demand curve is the inverse of the labor demand function with p held fixed. Can you demonstrate what happens to this labor demand curve when p changes?
 - d. Derive the output supply function.
 - e. The supply curve is the inverse of the supply function with w held fixed. What happens to this supply curve as w changes? (*Hint:* Recall that $\ln x = y$ implies $e^y = x$, where $e \approx 2.7183$ is the base of the natural log.)
 - f. Suppose $p = 2$ and $w = 10$. What is your profit-maximizing production plan, and how much profit will you make?

11.5*† When we discussed optimal behavior for consumers in Chapter 6, we illustrated that there may be two optimal solutions for consumers whenever there are non-convexities in either tastes or choice sets. We can now explore conditions under which multiple optimal production plans might appear in our producer model.

- A.** Consider only profit-maximizing firms whose tastes (or isoprofits) are shaped by prices.
- Consider first the standard production frontier that has initially increasing marginal product of labor and eventually decreasing marginal product of labor. *True or False:* If there are two points at which isoprofits are tangent to the production frontier in this model, the lower output quantity cannot possibly be part of a truly optimal production plan.
 - Could it be that neither of the tangencies represents a truly optimal production plan?
 - Illustrate a case where there are two truly optimal solutions where one of these does not occur at a tangency.
 - What would a production frontier have to look like in order for there to be two truly optimal production plans that both involve positive levels of output? (*Hint:* Consider technologies that involve multiple switches between increasing and decreasing marginal product of labor.)
 - True or False:* If the producer choice set is convex, there can only be one optimal production plan.
 - Where does the optimal production plan lie if the production frontier is such that the marginal product of labor is always increasing?
 - Finally, suppose that the marginal product of labor is constant throughout. What production plans might be optimal in this case?
- B.** In the text, we used a cosine function to illustrate a production process that has initially increasing and then decreasing marginal product of labor. In some of the end-of-chapter exercises, we will instead use a function of the form $x = f(\ell) = \beta\ell^2 - \gamma\ell^3$ where β and γ are both greater than zero.
- Illustrate how the profit-maximization problem results in two “solutions.” (Use the quadratic formula to solve for these.)
 - Which of your two “solutions” is unambiguously *not* the actual profit-maximizing solution?
 - What else would you have to check to be sure that the other “solution” is profit maximizing?
 - Now consider instead a production process characterized by the equation $x = A\ell^\alpha$. Suppose $\alpha < 1$. Determine the profit maximizing production plan.
 - What if $\alpha > 1$?
 - What if $\alpha = 1$?

11.6 This exercise explores in some more detail the relationship between production technologies and marginal product of labor.

- A.** We often work with production technologies that give rise to initially increasing marginal product of labor that eventually decreases.
- True or False:* For such production technologies, the marginal product of labor is increasing so long as the slope of the production frontier becomes steeper as we move toward more labor input.
 - True or False:* The marginal product of labor becomes negative when the slope of the production frontier begins to get shallower as we move toward more labor input.
 - True or False:* The marginal product of labor is positive so long as the slope of the production frontier is positive.
 - True or False:* If the marginal product of labor ever becomes zero, we know that the production frontier becomes perfectly flat at that point.
 - True or False:* A negative marginal product of labor necessarily implies a downward-sloping production frontier at that level of labor input.
- B.** We have thus far introduced two general forms for production functions that give rise to initially increasing and eventually decreasing marginal product.
- ** The first of these was given as an example in the text and took the general form $f(\ell) = \alpha(1 - \cos(\beta\ell))$ for all $\ell \leq \pi/\beta \approx 3.1416/\beta$ and $f(\ell) = 2\alpha$ for all $\ell > \pi/\beta \approx 3.1416/\beta$, with α and β assumed to be greater than 0. Determine the labor input level at which the marginal product of labor begins to decline. (*Hint:* Recall that the cosine of $\pi/2 \approx 1.5708$ is equal to zero.)

- b. Does the marginal product of labor ever become negative? If so, at what labor input level?
- c. In light of what you just learned, can you sketch the production function given in (a)? What does the marginal product of labor for this function look like?
- d. The second general form for such a production function was given in exercise 11.5 and took the form $f(\ell) = \beta\ell^2 - \gamma\ell^3$. Determine the labor input level at which the marginal product of labor begins to decline.
- e. Does the marginal product of labor ever become negative? If so, at what labor input level?
- f. Given what you have learned about the function $f(\ell) = \beta\ell^2 - \gamma\ell^3$, illustrate the production function when $\beta = 150$ and $\gamma = 1$. What does the marginal product of labor look like?
- g. In each of the two previous cases, you should have concluded that the marginal product of labor eventually becomes zero and/or negative. Now consider the following new production technology: $f(\ell) = \alpha/(1 + e^{-(\ell-\beta)})$ where $e \approx 2.7183$ is the base of the natural logarithm. Determine the labor input level at which the marginal product of labor begins to decline.
- h. Does the marginal product of labor ever become negative? If so, at what labor input level?
- i. Given what you have discovered about the production function $f(\ell) = \alpha/(1 + e^{-(\ell-\beta)})$, can you sketch the shape of this function when $\alpha = 150$ and $\beta = 5$? What does the marginal product of labor function look like?

11.7[†] We have shown that there are two ways in which we can think of the producer as maximizing profits: Either directly, or in a two-step process that begins with cost minimization.

- A.** This exercise reviews this equivalence for the case where the production process initially has increasing marginal product of labor but eventually reaches decreasing marginal product. Assume such a production process throughout.
 - a. Begin by plotting the production frontier with labor on the horizontal and output on the vertical axis. Identify in your graph the production plan $A = (\ell^A, x^A)$ at which increasing returns turn to decreasing returns.
 - b. Suppose wage is $w = 1$. Illustrate in your graph the price p_0 at which the firm obtains zero profit by using a profit-maximizing production plan B . Does this necessarily lie above or below A on the production frontier?
 - c. Draw a second graph next to the one you have just drawn. With price on the vertical axis and output on the horizontal, illustrate the amount the firm produces at p_0 .
 - d. Suppose price rises above p_0 . What changes on your graph with the production frontier, and how does that translate to points on the supply curve in your second graph?
 - e. What if price falls below p_0 ?
 - f. Illustrate the cost curve on a graph below your production frontier graph. What is similar about the two graphs—and what is different—around the point that corresponds to production plan A .
 - g. Next to your cost curve graph, illustrate the marginal and average cost curves. Which of these reaches its lowest point at the output quantity x^A ? Which reaches its lowest point at x^B ?
 - h. Illustrate the supply curve on your graph and compare it with the one you derived in parts (c) and (d).
- B.**** Suppose that you face a production technology characterized by the function $x = f(\ell) = \alpha/(1 + e^{-(\ell-\beta)})$.
 - a. Assuming labor ℓ costs w and the output x can be sold at p , set up the profit-maximization problem.
 - b. Derive the first order condition for this problem.
 - c. Substitute $y = e^{-(\ell-\beta)}$ into your first order condition and, using the quadratic formula, solve for y . Then, recognizing that $y = e^{-(\ell-\beta)}$ implies $\ln y = -(\ell - \beta)$, solve for the two implied labor inputs and identify which is profit maximizing (assuming that an interior production plan is optimal).
 - d. Use your answer to solve for the supply function (assuming an interior solution is optimal).
 - e. Now use the two-step method to verify your answer. Begin by solving the production function for ℓ to determine how much labor is required for each output level assuming none is wasted.

- f. Use your answer to derive the cost function and the marginal cost function.
- g. Set price equal to marginal cost and solve for the output supply function (assuming an interior solution is optimal). Can you get your answer into the same form as the supply function from your direct profit-maximization problem?
- h. Use the supply function and your answer from part (e) to derive the labor input demand function (assuming an interior solution is optimal). Is it the same as what you derived through direct profit maximization in part (c)?

11.8 Everyday Application: Workers as Producers of Consumption: We can see some of the connections between consumer and producer theory by reframing models from consumer theory in producer language.

- A. Suppose we modeled a worker as a “producer of consumption” who can sell leisure of up to 60 hours per week at a wage w .
 - a. On a graph with “labor” as the input on the horizontal axis and “consumption” as the output on the vertical, illustrate what the producer choice set faced by such a “producer” would look like.
 - b. How is this fundamentally different from the usual producer case where the producer choice set has nothing to do with prices in the economy?
 - c. What does the marginal product of labor curve look like for this “producer”?
 - d. On the graph you drew for part (a), illustrate what “producer tastes” for this producer would look like assuming the worker’s tastes over consumption and leisure satisfy the usual five assumptions for tastes we developed in Chapter 4. How is this fundamentally different from the usual producer case where the producer’s indifference curves are formed by prices in the economy?
- B. Suppose the worker’s tastes over consumption and leisure are Cobb–Douglas with equal weights on the two variables in the utility function.
 - a. Derive an expression for the production function in this model.
 - b. Set up the worker’s optimization problem similar to a profit-maximization problem for producers.
 - c. Derive the “output supply” function; that is, the function that tells us how much consumption the worker will “produce” for different economic conditions.

11.9[†] Everyday Application: Studying for an Exam: Consider the problem you face as a student as you determine how much to study for an exam by modeling yourself as a “producer of an exam score” between 0 and 100.

- A. Suppose that the marginal payoff to studying for the initial hours you study increases but that this marginal payoff eventually declines as you study more.
 - a. Illustrate, on a graph with “hours studying for the exam” as an input on the horizontal axis and “exam score” (ranging from 0 to 100) as an output on the vertical axis, what your production frontier will look like.
 - b. Now suppose that your tastes over leisure time (i.e., non-study time) and exam scores satisfies the usual assumptions about tastes that we outlined in Chapter 4. What will your producer tastes look like? (Be careful to recognize that the producer picture has “hours studying” and not leisure hours on the horizontal axis.)
 - c. Combining your production frontier with graphs of your indifference curves, illustrate the optimal number of hours you will study.
 - d. Suppose that you and your friend differ in that your friend’s marginal rate of substitution at every possible “production plan” is shallower than yours. Who will do better on the exam?
 - e. Notice that the same model can be applied to anything we do where the amount of effort is an input and how well we perform a task is the output. As we were growing up, adults often told us: “Anything worth doing is worth doing well.” Is that really true?
- B. Now suppose that you and your friends Larry and Daryl each face the same “production technology” $x = 3\ell^2 - 0.2\ell^3$ where x is the exam grade and ℓ is the number of hours of studying. Suppose further that each of you has tastes that can be captured by the utility function $u(\ell, x) = x - \alpha\ell$.
 - a. Calculate your optimal hours of studying as a function of α .
 - b. Suppose the values for α are 7, 10, and 13 for you, Larry, and Daryl respectively. How much time will each of you study?

- c. What exam grades will each of you get?
- d. If each of you had 10 hours available that you could have used to study for the exam, could you each have made a 100? If so, why didn't you?

**BUSINESS
APPLICATION**

11.10 Business Application: *Optimal Response to Labor Regulations:* Governments often impose costs on businesses in direct relation to how much labor they hire. They may, for instance, require that businesses provide certain benefits like health insurance or retirement plans.

- A.** Suppose we model such government regulations as a cost c per worker hour in addition to the wage w that is paid directly to the worker. Assume that you face a production technology that has the typical property of initially increasing marginal product of labor that eventually diminishes.
 - a. Illustrate the isoprofits for this firm and include both the explicit labor cost w as well as the implicit cost c of the regulation.
 - b. Illustrate the profit-maximizing production plan.
 - c. Assuming that it continues to be optimal for your firm to produce, how does your optimal production plan change as c increases?
 - d. Illustrate a case where an increase in c is sufficiently large to cause your firm to stop producing.
 - e. *True or False:* For firms that make close to zero profit, additional labor regulations might cause large changes in behavior.
- B.** Suppose that your production technology can be represented by the production function $x = 100/(1 + e^{-(\ell-5)})$ where e is the base of the natural logarithm.
 - a. Suppose $w = 10$ and $p = 1$. Set up your profit-maximization problem and explicitly include the cost of regulation.
 - b.** Calculate the optimal labor demand and output supply as a function of c . (*Hint:* Solving the first order condition becomes considerably easier if you substitute $y = e^{-(\ell-5)}$ and solve for y using the quadratic formula. Once you have a solution for y , you know this is equal to $e^{-(\ell-5)}$. You can then take natural logs of both sides, recalling that $\ln e^{-(\ell-5)} = -(\ell - 5)$. This follows the steps in exercise 11.7 where we used an almost identical production function.)
 - c. What is the profit-maximizing production plan when $c = 0$?
 - d. How does your answer change when $c = 2$?
 - e. What if $c = 3$? (*Hint:* Check to see what happens to profit.)

**BUSINESS
APPLICATION**

11.11[†] Business Application: *Technological Change in Production:* Suppose you and your friend Bob are in the business of producing baseball cards.

- A.** Both of you face the same production technology, which has the property that the marginal product of labor initially increases for the first workers you hire but eventually decreases. You both sell your cards in a competitive market where the price of cards is p , and you hire in a competitive labor market where the wage is w .
 - a. Illustrate your profit-maximizing production plan assuming that p and w are such that you and Bob can make a positive profit.
 - b. Now suppose you find a costless way to improve the technology of your firm in a way that unambiguously expands your producer choice set. As a result, you end up producing more than Bob (who has not found this technology). Illustrate how the new technology might have changed your production frontier.
 - c. Can you necessarily tell whether you will hire more or less labor with the new technology?
 - d. Can you say for sure that adopting the new technology will result in more profit?
 - e. Finally, suppose p falls. Illustrate how it might now be the case that Bob stops producing but you continue to stay in the business.
- B.** You and Bob initially face the production technology $x = 3A\ell^2 - 0.1\ell^3$, and you can sell your output for p and hire workers at a wage w .
 - a. Derive the marginal product of labor and describe its properties.
 - b. Calculate the profit-maximizing number of baseball cards as a function of A assuming output price is given by p and the wage is $w = 20$. (Use the quadratic formula.)

- How much will you each produce if $A = 1$ and $p = 1$, and how much profit do each of you earn?
- Now suppose you find a better technology, one that changes your production function from one where $A = 1$ to one where $A = 1.1$. How do your answers change?
- Now suppose that competition in the industry intensifies and the price of baseball cards falls to $p = 0.88$. How will you and Bob change your production decisions?

11.12 Policy Application: Politicians as Producers of “Good Feelings”: Consider a politician who has to determine how much effort to exert in his or her reelection campaign.

- We can model such a politician as a “producer of good feelings among voters.”
 - Begin with a graph that puts “effort” on the horizontal axis and the “good voter feelings” on the vertical axis. Assume that the marginal payoff from exerting effort initially increases with additional effort but eventually declines. Illustrate this politician’s feasible “production plans.”
 - Suppose that the politician dislikes expending effort but likes the higher probability of winning reelection that results from good voter feelings. Assume that tastes are rational, continuous, and convex. Illustrate what indifference curves for this politician will look like.
 - Combining your two graphs, illustrate the optimal level of effort expended by a politician during the reelection campaign.
 - Now suppose that the politician’s opponent in the campaign has the same “production technology.” Suppose further that, at any “production plan” in the model, the opponent’s indifference curve has a shallower slope than the incumbent’s. Assuming the candidate who has produced more good voter feelings will win, will the incumbent or the challenger win this election?
- Let effort be denoted by ℓ and “good voter feelings” by x . Suppose that a politician’s tastes are defined by $u(x, \ell) = x - \alpha\ell$, and suppose that the production frontier for producing “good feelings” among voters is given by $x = \ell^2 - 0.25\ell^3$.
 - When effort ℓ is on the horizontal and x is on the vertical, what is the marginal rate of substitution for this politician?
 - What does your answer imply for the shape of indifference curves?
 - Setting this up similar to a profit-maximization problem, solve for the politician’s optimal level of effort.
 - Compare the optimal effort level for the politician for whom $\alpha = 1$ and the politician for whom $\alpha = 0.77$.
 - Which one will win the election? Explain how this makes sense intuitively.

11.13⁺ Policy Application: Determining Optimal Class Size: Public policy makers are often pressured to reduce class size in public schools in order to raise student achievement.

- One way to model the production process for student achievement is to view the “teacher/student” ratio as the input. For purposes of this problem, let t be defined as the number of teachers per 1,000 students; that is, $t = 20$ means there are 20 teachers per 1,000 students. Class size in a school of 1,000 students is then equal to $1000/t$.
 - Most education scholars believe that the increase in student achievement from reducing class size is high when class size is high but diminishes as class size falls. Illustrate how this translates into a production frontier with t on the horizontal axis and average student achievement a on the vertical.
 - Consider a school with 1,000 students. If the annual salary of a teacher is given by w , what is the cost of raising the input t by 1; that is, what is the cost per unit of the input t ?
 - Suppose a is the average score on a standardized test by students in the school, and suppose that the voting public is willing to pay p for each unit increase in a . Illustrate the “production plan” that the local school board will choose if it behaves analogously to a profit-maximizing firm.
 - What happens to class size if teacher salaries increase?
 - How would your graph change if the voting public’s willingness to pay per unit of a decreases as a increases?

- f. Now suppose that you are analyzing two separate communities that fund their equally sized schools from tax contributions by voters in each school district. They face the same production technology, but the willingness to pay for marginal improvements in a is lower in community 1 than in community 2 at every production plan. Illustrate how the isoprofit maps differ for the two communities.
 - g. Illustrate how this will result in different choices of class size in the two communities.
 - h. Suppose that the citizens in each of the two communities were identical in every way except that those in community 1 have a different average income level than those in community 2. Can you hypothesize which of the two communities has greater average income?
 - i. Higher-level governments often subsidize local government contributions to public education, particularly for poorer communities. What changes in your picture of a community’s optimal class size setting when such subsidies are introduced?
- B.** Suppose the production technology for average student achievement is given by $a = 100t^{0.75}$, and suppose again that we are dealing with a school that has 1,000 students.
- a. Let w denote the annual teacher salary in thousands of dollars and let p denote the community’s marginal willingness to pay for an increase in student achievement. Calculate the “profit-maximizing” class size.
 - b. What is the optimal class size when $w = 60$ and $p = 2$?
 - c. What happens to class size as teacher salaries change?
 - d. What happens to class size as the community’s marginal willingness to pay for student achievement changes?
 - e. What would change if the state government subsidizes the local contribution to school spending?
 - f. Now suppose that the community’s marginal willingness to pay for additional student achievement is a function of the achievement level. In particular, suppose that $p(a) = Ba^{\beta-1}$ where $\beta \leq 1$. For what values of β and B is the problem identical to the one you just solved?
 - g. Solve for the optimal t given the marginal willingness to pay of $p(a)$. What is the optimal class size when $B = 3$ and $\beta = 0.95$ (assuming again that $w = 60$.)
 - h. Under the parameter values just specified, does class size respond to changes in teacher salaries as it did before?

CHAPTER
12

Production with Multiple Inputs

In Chapter 11, we developed some of the basic building blocks of the competitive producer model, but we limited ourselves to the case of a single input being used to produce a single output.¹ From the outset, we did not hide the fact that such simple production processes rarely exist in the world, except perhaps in the short run where producers can vary only one of their inputs. But restricting ourselves to such short-run settings allowed us to depict the building blocks of the producer model. We did this in two-dimensional graphs of production plans, with producer choice sets forming the technological constraint faced by producers, and with isoprofit curves depicting their “tastes” for profit. We also demonstrated an alternative two-step approach to profit maximization, one in which producers first investigate the cost side of their operations before bringing revenues into the analysis.

We will now focus on how we can extend the model to multiple inputs. This will allow us to ask not just how much a competitive firm will produce at different prices but also what *mix of inputs* it will employ. In the short-run model of Chapter 11, we did not have to think about such questions because, so long as firms did not waste inputs, there was only a single way to produce a given output level. But when the firm is using multiple inputs like workers *and* machines, there are typically many different ways of combining these inputs (without wasting any) to produce a particular output level. I can buy a fancy robot to print up my economist cards and fire all my workers, or I can get rid of all the printing presses and have lots of workers stamp the images on the cards by hand, or I can find some in-between solution that uses some machines and some workers. Once we know how to model production processes with such multiple inputs, we can think of how an economist might advise me to choose between these options, or, in my case, how I will advise myself as I hold one of my imaginary discussions between me and myself.²

We will find out quickly that the direct “profit maximization” method first employed in Chapter 11 becomes graphically cumbersome, and, in fact, you may skip straight to Section 12A.2 if you already believe me on this point after looking at the daunting Graph 12.1. It is

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

¹Chapter 11 is required reading for this chapter. No material from chapters prior to Chapter 11 is directly used in this chapter. However, as with Chapter 11, this chapter contains frequent analogies to the consumer model and particularly to material covered in Chapter 2, as well as Chapters 4 through 6. The final part of the B section also draws analogies to Chapter 10.

²But, as my wife would say, I am probably revealing too much about myself when I mention the voices in my head. Too much sharing, she tells me. Save it for the therapist, she says.

in part for this reason that we will quickly move on to implementing the two-step approach to profit maximization, the approach that starts by first looking at just costs and only afterward brings revenues into the picture. As you will see, this approach, even with multiple inputs, ends up looking a lot like the approach developed at the end of Chapter 11 and will be relied on extensively throughout the rest of the book. It is an approach we rely on in part because it lends itself to a more manageable graphical exposition for thinking about competitive firms, but it also gives us a series of *cost curves* that we can use for *all* firms whether they are competitive or not. This is because cost curves are the result of firms thinking about how to produce different levels of output in the least cost way, and that part of the producer problem does not depend on whether the firm is a perfectly competitive price taker in the output market. *All* profit-maximizing firms, whether competitive or not, seek to minimize their costs, and the development of cost curves (and functions) therefore builds a basis for our current thinking about price-taking firms as well as our later thinking (in Chapters 23 and 25 through 26) about firms that exercise market power.

12A

AN INTUITIVE DEVELOPMENT OF THE TWO-INPUT MODEL

The basic building block of the producer model extends straightforwardly from the single input to the two-input case. *Production plans*, previously defined as points in two dimensions that indicate how much labor ℓ the plan calls for to produce a certain level of output x , are now defined as points in three dimensions, indicating how much of each of the *two* inputs the plan proposes to use in the production of a certain level of output x . For convenience, we will once again call one input “labor” (denoted ℓ), and we will usually call the other input “capital” (denoted k). Clearly, we are still simplifying the real world a lot, leaving out such important inputs as “land” or “entrepreneurial talent” and neglecting to distinguish between different types of labor and capital.

A production plan A , previously defined as a point (ℓ^A, x^A) , is therefore now defined as a point (ℓ^A, k^A, x^A) . We will continue to talk about the labor input ℓ as expressed in “hours of labor input” and can thus continue to express its price in the labor market as the hourly wage rate w . Similarly, we can express the output x in terms of those units in which the output is sold, whether as “packets of economist cards” or “bags of oranges” or “computers.” This allows us to interpret the output price p as simply the price of a unit of the good that is sold to customers in the output market. Finally, we are left with the input k that is introduced for the first time here and has already been referred to as “capital.” In some ways, it is harder to clearly identify a natural unit of measurement for this input, partly because the nature of “capital” will differ across different firms and industries. In some contexts, capital will simply refer to machines such as copiers, as if for instance, we were to analyze the production of photocopies by Kinkos. In other cases, “capital” might lump together all types of nonlabor investments the firm makes in plant and equipment, and might therefore best be thought of as “dollars of capital employed in production.” In either case, we will denote the price of a unit of capital as the “rental rate” r .

This *rental rate* of capital is defined as the *opportunity cost of using capital in current production*. To understand what it means intuitively, we have to ask “what is the producer giving up by employing a particular form of capital?” For instance, suppose again that we consider photocopiers at Kinkos, and suppose Kinkos rents all its photocopiers (but pays for its own maintenance, ink, and paper). Then the rental rate is the rent (per week, per day, per hour, or whatever time interval we are trying to model) that Kinkos has to pay for each copier because this is what Kinkos is giving up by employing a photocopier. It gets a little more complicated if we assume that Kinkos has purchased its own photocopiers. What is Kinkos then giving up by employing these copiers? Actually, it is giving up the opportunity to rent the copiers to other users in the same rental market, and thus the rental rate is exactly the same as if Kinkos were renting

The price of a unit of capital is the rental rate r .

the photocopier from someone else. If, on the other hand, “capital” simply represents nonlabor investments in current production, then the rental rate of the financial capital required to make these investments is the interest rate the firm has to pay in order to make use of the capital during the period over which we are studying the firm’s production.

Suppose we are modeling all nonlabor investments as capital. Is the rental rate any different depending on whether the firm uses money it already has or chooses to borrow money to make its investments?

EXERCISE
12A.1

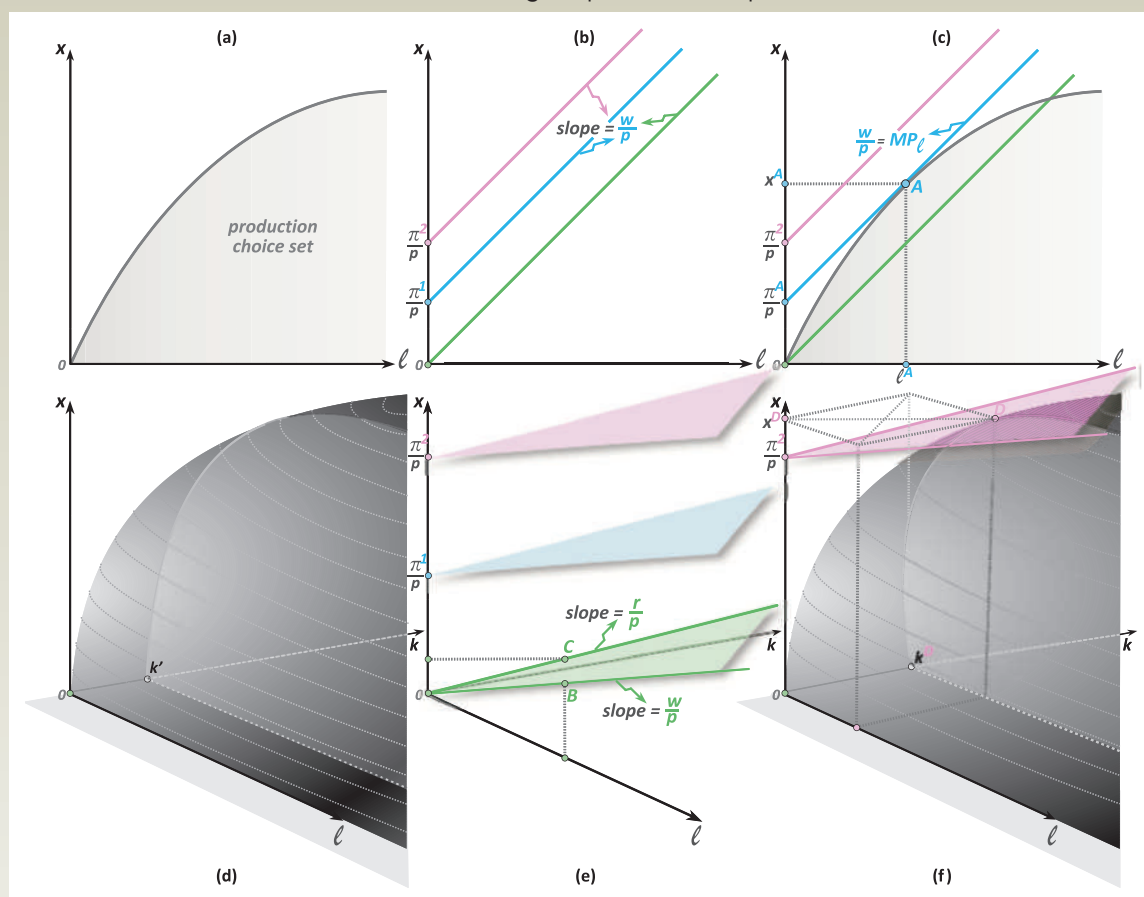

12A.1 Profit Maximization with Two-Input Producer Choice Sets

Direct profit maximization in our one-input/one-output model of Chapter 11 essentially involved three parts: First, we had to identify the technologically feasible production plans known as the producer choice set and its boundary, the production frontier. Second, we had to know the market output price and wage to construct the map of isoprofit curves. Finally, we had to locate the highest possible isoprofit curve that contained at least 1 technologically feasible production plan from the production frontier.

Panels (a) through (c) of Graph 12.1 replicate these three steps for a convex producer choice set, with the notation π used to denote “profit.” This is simply what we did in Chapter 11. Panels (d) through (f) then illustrate the exact same steps for a similarly convex producer choice set in the more complicated two-input case. You may choose to skip forward to Section 12A.2; all I mean to present is an illustration of how the “direct” profit maximization method would look with two inputs. The rest of our development of producer theory, however, relies primarily on material beginning in Section 12A.2.

12A.1.1 Producer Choice Sets and Production Frontiers with Two Inputs Since production plans with two inputs are points with the three components ℓ , k , and x , the set of technologically feasible production plans is now a three-dimensional set such as the set of points that lie underneath the production frontier graphed in panel (d) of Graph 12.1. The particular production frontier in this graph is analogous to the two-dimensional production frontier in panel (a) in the sense that it too gives rise to a convex production set (because the line connecting any two production plans in the set is fully contained in the same set). Furthermore, when we hold capital fixed at some level such as k' , the two-dimensional “slice” of the three-dimensional production set becomes a two-dimensional producer choice set such as the one depicted in panel (a). If capital is fixed at k' in the short run, then this slice becomes a one-input production model that can be used to analyze short-run labor demand and output supply decisions by a producer. Thus, even though we stated at the outset of Chapter 11 that most production processes require multiple inputs, the single-input model could still be a useful model in that it might adequately represent the short-run production environment faced by a firm that can vary its multiple inputs only in the long run.

12A.1.2 Isoprofit Curves (or Planes) with Two Inputs Next, consider what the set of production plans that all yield the same level of profit would look like in this three-dimensional space. Suppose, for instance, we wanted to find all production plans that would generate zero profit when the output price is p and the input prices are w and r . In the one-input model, such production plans simply lie on a line emanating from the origin with slope w/p (depicted as the lowest of the three isoprofit curves in panel (b)). When we restrict ourselves to production plans that make use of no capital in panel (e), we end up with precisely the same isoprofit curve: The line that contains production plan B lies on the two-dimensional plane that holds k fixed at zero and has a slope w/p for precisely the same reasons as in panel (b). It contains all zero profit production plans that make no use of capital. The line emanating from the origin and containing

GRAPH 12.1 Profit Maximization in the Single-Input and Two-Input Models

plan C , on the other hand, lies in the two-dimensional plane that holds labor input fixed at zero and represents all zero profit production plans that make no use of labor. This is then once again analogous to the isoprofit curves in the single input model, except that now the slope of the line is r/p since the price of capital is r . Finally, you can imagine forming a three-dimensional plane that contains these two line segments and that contains those production plans that make use of both capital and labor and yield zero profit at wage rate w , rental rate r , and output price p . This plane represents the three-dimensional isoprofit “curve” of zero profit production plans. The plane has a vertical intercept at the origin (indicating zero profit when no capital and no labor are used to produce no output), a slope of w/p on any “slice” that holds capital fixed, and a slope of r/p on any “slice” that holds labor fixed.

Just as in the single-input case, we can then think of planes parallel to the zero profit isoprofit plane. When such a parallel plane of production plans lies above the zero profit plane, it results in positive profit; when it lies below, it represents production plans that give rise to negative profits.

EXERCISE 12A.2 Explain why the vertical intercept on a three-dimensional isoprofit plane is π/p (where π represents the profit associated with that isoprofit plane).

12A.1.3 Profit Maximization The production frontier in panel (d) and the isoprofits of panel (e) are then combined in panel (f), which graphs the highest possible isoprofit plane that contains at least 1 production plan (D) that is technologically feasible (just as panel (c) did for the single-input case with production plan A). The profit-maximizing production plan D lies at a point where an isoprofit plane is tangent to the three-dimensional frontier just as the profit-maximizing production plan A in the single input case lies at a point where the isoprofit curve is tangent to the two-dimensional production frontier. If we then look at the “slice” of panel (f) that holds capital input fixed at its optimal level k^D , we notice that this slice is a two-dimensional picture that looks just like panel (c) of Graph 12.1; that is, we get a two-dimensional graph in which the slope of the line from the isoprofit plane is tangent to the slope of the short-run (single-input) production frontier (that fixes capital at k^D). The slope of the tangent line is w/p , and the slope of the slice of the production frontier is the marginal product of labor *given that capital is k^D and given that we are currently employing ℓ^D hours of labor*. Thus, just as in the single-input case, $w/p = MP_\ell$ at the profit-maximizing production plan. Similarly, if we were to look at the “slice” of the picture with labor held fixed at ℓ^D , we would conclude that the *marginal product of capital (MP_k)* is exactly equal to r/p at the profit-maximizing production plan. We can then conclude that

$$\text{Profit Maximization implies } MP_\ell = \frac{w}{p} \text{ and } MP_k = \frac{r}{p}. \quad (12.1)$$

We have just concluded that $MP_k = r/p$ at the profit-maximizing bundle. Another way to write this is that the marginal revenue product of capital $MRP_k = pMP_k$ is equal to the rental rate. Can you explain intuitively why this makes sense?

**EXERCISE
12A.3**

Suppose capital is fixed in the short run but not in the long run. *True or False:* If the firm has its long run optimal level of capital k^D (in panel (f) of Graph 12.1), then it will choose ℓ^D labor in the short run. And if ℓ^D in panel (c) is not equal to ℓ^D in panel (f), it must mean that the firm does not have the long-run optimal level of capital as it is making its short-run labor input decision.

**EXERCISE
12A.4**

We can of course also write the expression (12.1) in terms of the marginal revenue products of labor and capital,

$$\text{Profit Maximization implies } MRP_\ell = pMP_\ell = w \text{ and } MRP_k = pMP_k = r, \quad (12.2)$$

a simple extension of our conclusion that $MRP_\ell = pMP_\ell = w$ in the single-input model of Chapter 11 and panel (c) of Graph 12.1. The nice result from the admittedly complicated lower panels of the graph is then that our profit-maximizing conditions from the single-input production model fully generalize to the multi-input production model. The obvious drawback of this depiction of profit maximization is of course that it is exceedingly difficult for most of us to draw three-dimensional graphs in a way that leads to sound economic analysis.

Fortunately, it turns out that we do not have to do this. Rather, we can develop an alternative graphical approach to profit maximization analogous to the two-step process that begins with “cost minimization” first introduced in Chapter 11. This will enable us to picture the process more easily in two dimensions. Section 12A.3 of the chapter will develop this alternative approach. First, however, we need to do a little more work in exploring what the different shapes of production choice sets tell us about the underlying technology a firm is using when it employs two inputs.

Profit maximization implies that the marginal revenue product of each input is equal to that input's price.

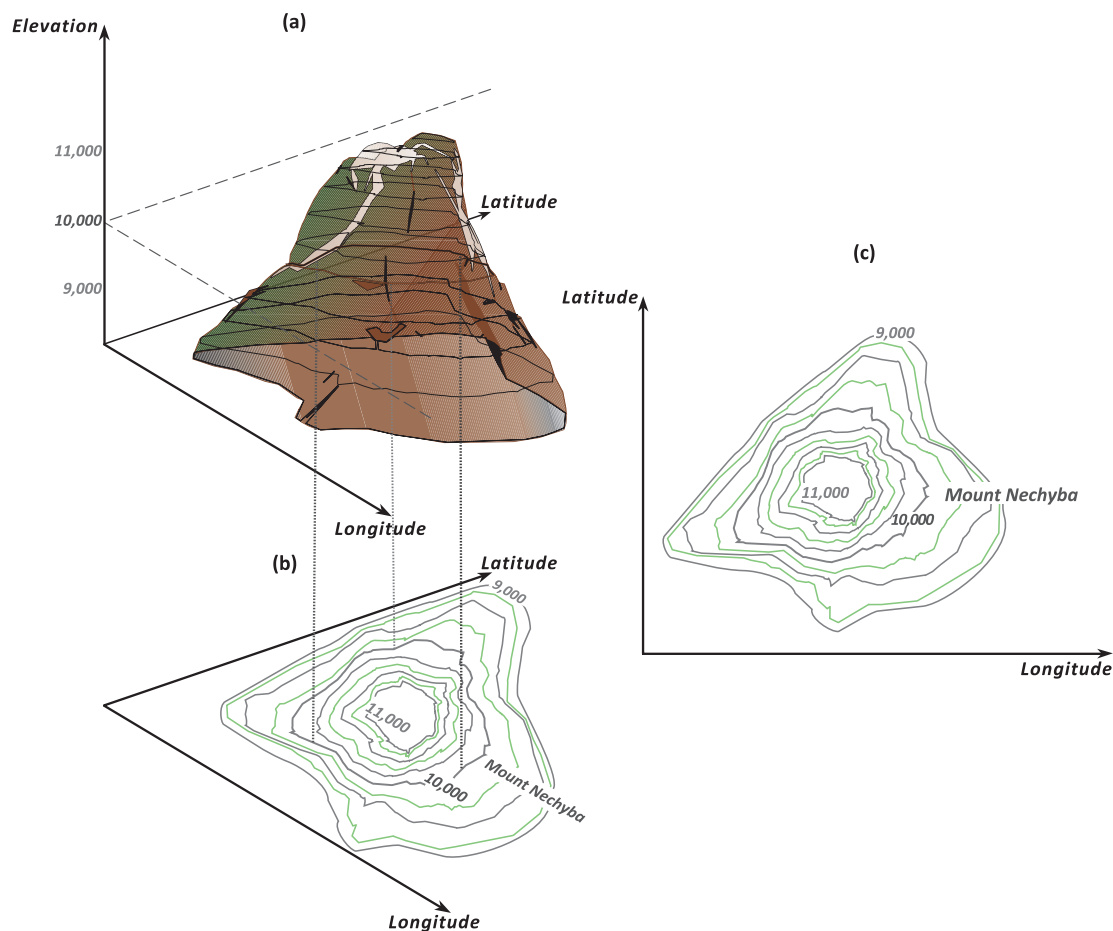

12A.2 Two-Input Production Sets: Isoquants and Returns to Scale

When firms use both labor and capital, production frontiers—as we already saw in Graph 12.1—are three-dimensional. Given that our artistic abilities tend to fail us when we draw in more than two dimensions, this is not very convenient. Fortunately, we already became implicitly familiar with graphing three-dimensional objects in two dimensions when we learned how to graph

indifference curves for consumers. In fact, we pointed out in Chapter 4 that our way of drawing indifference curves is a simple extension of how you learned to graph three-dimensional mountains in your grade-school studies of geography, and we now repeat this argument more explicitly here (than we did in part A of Chapter 4) in the context of production frontiers.³

Think back to your geography classes where you learned to read two-dimensional maps depicting mountains that are three-dimensional objects. The two-dimensional map provided you with an easy way to represent longitude and latitude but not the vertical elevation of the mountain. So, instead of resorting to three-dimensional graphs, geographers map the elevations (or “levels”) of mountains as rings that get smaller and smaller as one approached the peak of the mountain. For instance, Graph 12.2 depicts the shape of a mountain—cleverly named after myself—at different elevations in a three-dimensional picture in panel (a) but then brings those shapes down into a two-dimensional space (with just longitude and latitude on the axes) by

GRAPH 12.2 Two-Dimensional Level Curves from a Three-Dimensional “Mount Nechyba”

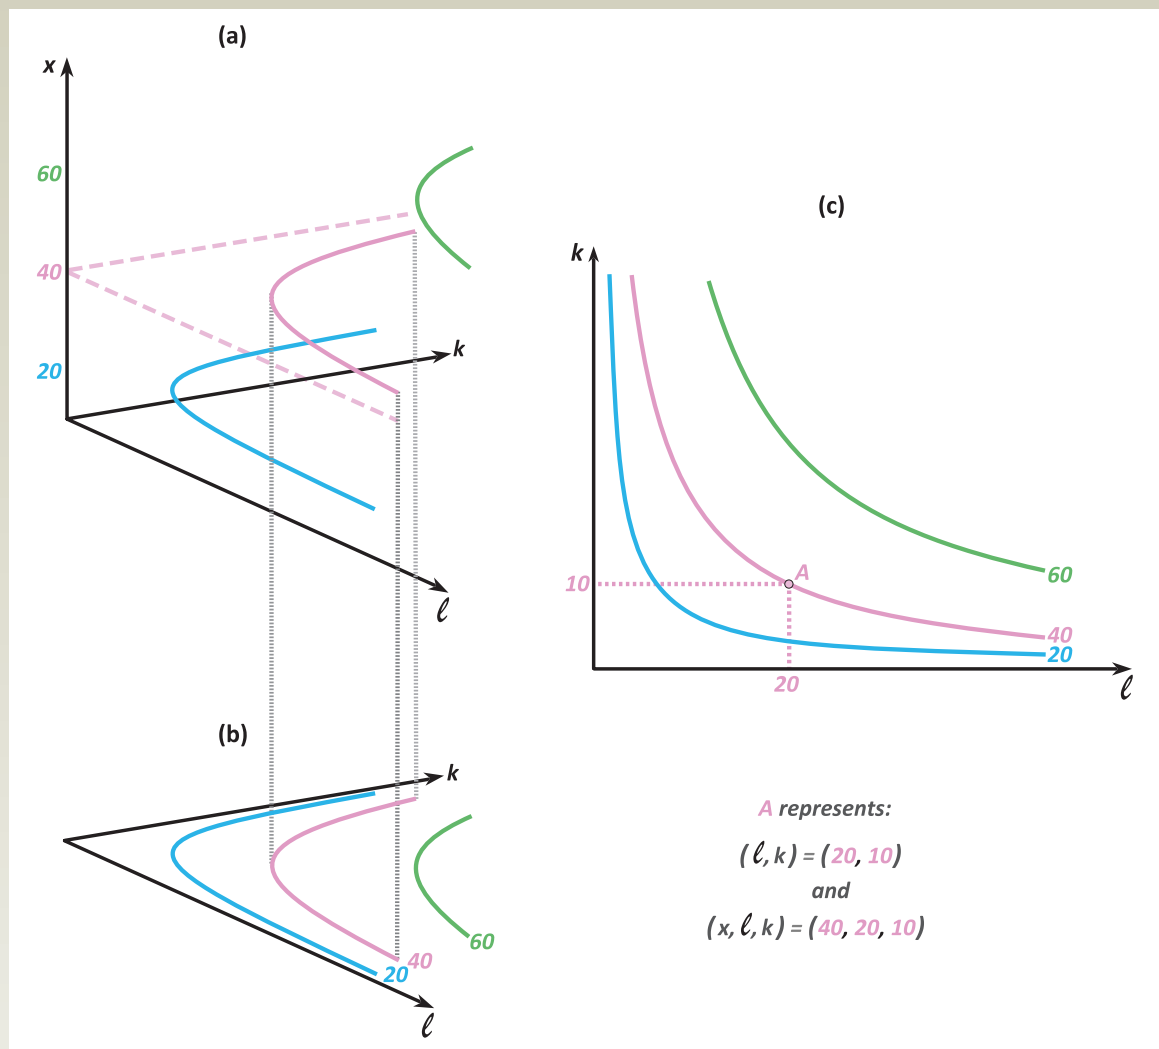

³If you have read part B of Chapter 4, you have already seen the argument in the next few paragraphs.

mapping out the levels of the mountain and labeling them with the relevant elevation. Moving the axes of panel (b) somewhat, we can then depict the mountain in the two-dimensional picture in panel (c) of Graph 12.2. When we graphed indifference curves, curves that represent “levels” of a three-dimensional “utility mountain” that has no peak (since more is always assumed to yield higher utility), we did exactly the same thing as we just did with our geographical mountain.

In the case of producer theory, we can now do the same with the three-dimensional production frontier in Graph 12.1d. Panel (a) of Graph 12.3 begins by drawing some of the levels of such a three-dimensional production frontier. These levels are then mapped into two dimensions in panel (b), with the axes turned into the usual position in panel (c). The final picture then looks a lot like indifference curves, but each curve, now called an *isoquant*, is interpreted in the context production. More precisely, *an isoquant for some output level x is the set of all*

Isoquants are horizontal slices of three-dimensional production frontiers.

GRAPH 12.3 Deriving Two-Dimensional Isoquants from a Three-Dimensional Production Frontier

combinations of input levels (k and ℓ) that result in this output level assuming no input is wasted in the process. Points in the two-dimensional isoquant graph can then be interpreted as *input bundles* or, together with the number associated with the isoquant output, as a production plan. Point A in Graph 12.3c, for instance, represents the input bundle $(\ell, k) = (20, 10)$, and it also represents the production plan $(x, \ell, k) = (40, 20, 10)$.

EXERCISE 12A.5 Apply the definition of an isoquant to the single-input producer model. What does the isoquant look like there? (*Hint:* Each isoquant is typically a single point.)

Given the similarity of the “look” of isoquants to indifference curves, it is worthwhile to recall at the outset that their economic interpretation is quite different in some important ways. First, isoquants arise from production frontiers, which are the technological *constraint* faced by producers. Indifference curves, on the other hand, represent *tastes*, not constraints, in the consumer choice problem. Second, we made a point in our discussion of consumer theory that utility (or happiness) itself was not measurable in any objective way, and therefore there was no objective interpretation to the numbers accompanying indifference curves other than the ordering of indifference curves that they signify. In fact, we said that one can change the numbers associated with indifference curves on an indifference map arbitrarily so long as one does not change their order and be left with what a modern economist would consider to be exactly the same tastes as before. This is decidedly not true for isoquants that represent input bundles that yield a particular level of *output*, not happiness. Output is something we can objectively measure, and taking the same isoquant map but relabeling the isoquants changes the three-dimensional production technology in economically meaningful ways. For instance, while doubling all the values associated with a consumer indifference map leaves us with the same tastes as before, doubling the values associated with isoquants alters the production technology, with the new technology producing twice as much output from any bundle of inputs.

EXERCISE 12A.6 Why do you think we have emphasized the concept of marginal product of an input in producer theory but not the analogous concept of marginal utility of a consumption good in consumer theory?

12A.2.1 TRS and Marginal Product While the economic interpretation of isoquants is thus in many ways different than the economic interpretation of indifference curves, there is also much that we have learned in our study of indifference curves that is directly applicable to our understanding of isoquants. We begin with the interpretation of the slope of isoquants, known as the *marginal technical rate of substitution* or just the *technical rate of substitution*. A slope of -3 on an isoquant (as, for instance, in panel (b) of the upcoming Graph 12.4) indicates that 3 units of capital could be traded for 1 unit of labor with overall production remaining roughly constant. The technical rate of substitution thus tells us at each input bundle how many units of the input on the vertical axis I could substitute for 1 unit of the input on the horizontal axis and maintain a constant level of output. Notice that I could phrase the definition of marginal rates of substitution in consumer theory almost identically by saying that they “tell us for each consumption bundle how many units of the good on the vertical axis I could substitute for 1 of the goods on the horizontal axis and maintain a constant level of utility.” Since it is a mouthful to say “marginal technical rate of substitution,” we will generally stick with just “technical rate of substitution” and abbreviate it as *TRS*. Furthermore, since we have adopted the convention of always putting labor on the horizontal and capital on the vertical axis in our isoquant graphs, we will simply call the slope of an isoquant the *TRS* without always having to add the phrase “of labor with respect to capital.”

The technical rate of substitution (*TRS*) at a production plan is equal to the slope of the isoquant at that production plan.

GRAPH 12.4 Relatively More or Less Substitutability of Capital for Labor

In addition, we can now identify a property of isoquants that we did not emphasize for indifference curves: The relationship between the TRS and the marginal products of inputs. We have thus far defined these terms separately, with marginal product representing the slope of a slice of the production frontier along which *one of the inputs* is held fixed and the TRS representing the slope of an isoquant along which *output* is held fixed. We will make use later of the following relationship, which is not an assumption but rather a logical implication of the definitions of these concepts:

The TRS is the (negative) ratio of the marginal products of the two inputs.

$$TRS = - \frac{MP_{\ell}}{MP_k} \quad (12.3)$$

After a little reflection, this should make intuitive sense: Suppose, for instance, you were currently using the input bundle (ℓ, k) to produce $x = 100$ on the isoquant for 100 units of output, and suppose that $MP_{\ell} = 4$ and $MP_k = 2$ at that input bundle. This implies that, at your current input bundle, a unit of labor is twice as productive as a unit of capital. If you were then given 1 additional unit of labor, you could let go of approximately 2 units of capital and thereby keep your total output roughly constant at 100 units. But this is just the definition of $TRS = -2$ at this input bundle; we can replace two units of capital on the vertical axis with one additional unit of labor on the horizontal while keeping production constant. Thus, $TRS = (-MP_{\ell}/MP_k) = -4/2 = -2$.

Repeat this reasoning for the case where $MP_{\ell} = 2$ and $MP_k = 3$.

EXERCISE 12A.7

Is there a relationship analogous to equation (12.3) that exists in consumer theory and, if so, why do you think we did not highlight it in our development of consumer theory?

EXERCISE 12A.8

12A.2.2 Technical Similarities between Isoquants and Consumer Indifference Curves

We can then point out a few more technical similarities between isoquants and consumer indifference curves. First, we assume (1) “more is better” (monotonicity) in the sense that more inputs yield more outputs; (2) “averages are better than extremes” (convexity) in the sense that, when two extreme input bundles result in the same output level, an average of these extreme bundles produces at least as much (but typically more) output; and (3) “no sudden jumps

in production” (continuity) when very small amounts of additional input are used in production. These assumptions seem at least as intuitively plausible in the producer context as they are in the consumer context, and they then lead to isoquant maps that look very much like indifference maps. In particular, the convexity assumption implies *diminishing TRS* along an isoquant just as it implied diminishing *MRS* in the consumer model, and the monotonicity assumption implies that isoquants to the northeast will have higher output numbers associated with them than isoquants to the southwest.⁴

Second, the rate of change of the *TRS* along an isoquant is an indication of the degree of substitutability of the inputs in the production process just as the rate of change of the *MRS* along an indifference curve is an indication of the degree of substitutability between goods in a consumer’s tastes. Graph 12.4, for instance, begins in panel (a) with a production frontier whose isoquants are almost straight lines and thus indicate that capital and labor can easily be substituted for one another, continues in panel (b) with isoquants representing a production process in which labor and capital are less substitutable, and ends in panel (c) with a production process in which the inputs are almost perfect complements in production.

The curvature of isoquants is related to the degree of substitutability of labor for capital in production.

EXERCISE 12A.9

In the “old days,” professors used to handwrite their academic papers and then have secretaries type them up. Once the handwritten scribbles were handed to the secretaries, there were two inputs into the production process: secretaries (labor) and typewriters (capital). If one of the production processes in Graph 12.4 represents the production for academic papers, which would it be?

Finally, we discussed (in Chapter 5) relationships between indifference curves, defining in particular the concepts of quasilinear and homothetic tastes. Recall that we said tastes were quasilinear in the good on the horizontal axis if and only if the *MRS* was the same along any vertical line drawn through the indifference map, and tastes were homothetic if the *MRS* remained constant along any ray emanating from the origin. We can define the very same concepts for maps of isoquants in exactly analogous ways, although homothetic maps of isoquants are more commonly used by economists in producer theory than are quasilinear ones. Just as in consumer theory, the homotheticity property allows for production processes that range from having no substitutability between inputs to those allowing perfect substitutability and thus allows for a wide range of different types of production processes (as illustrated by the three homothetic production processes in Graph 12.4.) We will assume throughout that production processes are homothetic because this allows us to most easily define the very useful new concept known as *returns to scale*, a concept we turn to next.

EXERCISE 12A.10

What would isoquant maps with no substitutability and perfect substitutability between inputs look like? Why are they homothetic?

There are three economically meaningful ways of slicing two-input production frontiers.

12A.2.3 Returns to Scale: A Third Way of Slicing Production Frontiers In Graph 12.1d, we illustrated a vertical slice of the three-dimensional production frontier—the *vertical* slice that holds capital fixed at a certain level k' . This, in essence, gives us a short-run production frontier along which only labor can vary, with the slope of this short-run production frontier equal to the marginal product of labor. (We could similarly hold labor fixed at some level and

⁴We of course implicitly also assume completeness and transitivity; that is, the production frontier can tell me for every combination of inputs the maximum amount of output that is technologically feasible; and if an input bundle *A* leads to greater output than a second input bundle *B* which in turn leads to greater output than a third input bundle *C*, then the input bundle *A* also leads to greater production than *C*. In the producer context, these statements are so trivial that they often are not even stated explicitly.

create a vertical slice along which only capital varies, and the slope of that slice would be the marginal product of capital.) Then, in Graph 12.3, we illustrated a second way of slicing three-dimensional production frontiers, this time holding output fixed and slicing the frontier *horizontally* to obtain isoquants. The shape of these horizontal slices then tells us something about the degree of substitutability between capital and labor. We now turn to a third and final way of slicing the three-dimensional production frontier, and this time the shape of this slice will tell us something about the *returns to scale* of the production process.

Consider a three-dimensional frontier similar to the one graphed in Graph 12.1 but with two goods on the horizontal axes and utility on the vertical. Why would we not think that vertical slices like the one in 12.1d are meaningful in this case?

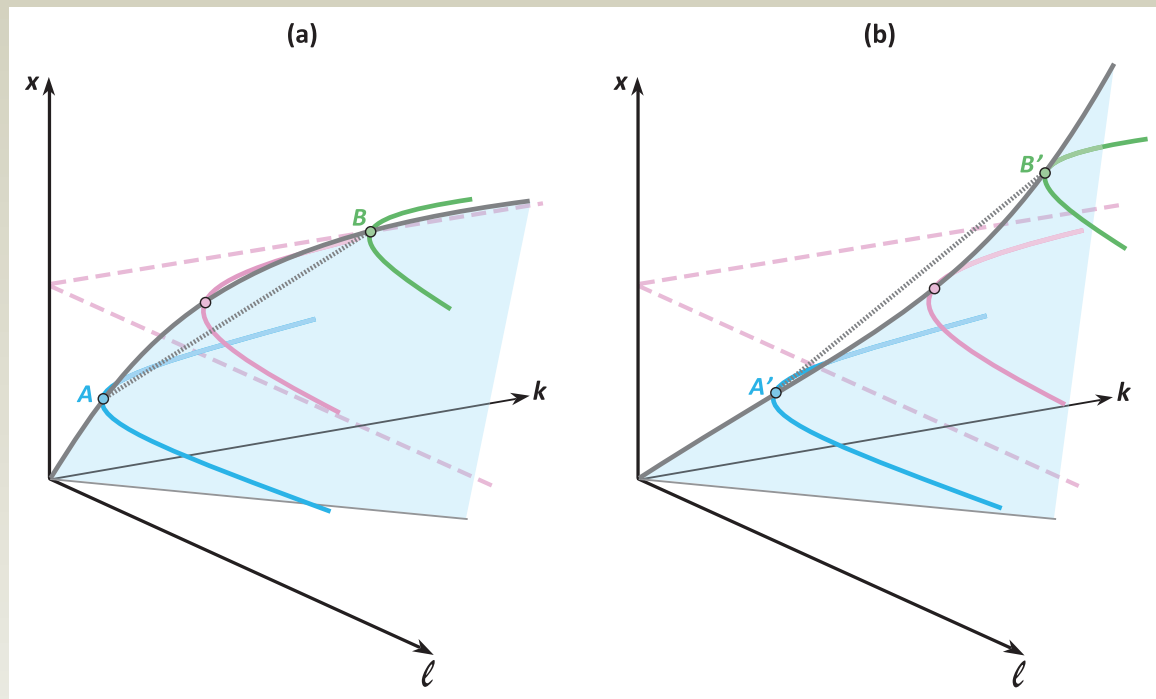

EXERCISE 12A.11

Consider the same utility frontier described in the previous exercise. What would the horizontal slices analogous to those in Graph 12.3 be in consumer theory? Why are they meaningful when the vertical slices in Graph 12.1 are not?

EXERCISE 12A.12

To be more precise, we will now look at *vertical* slices of the production frontier that hold the ratio of capital to labor fixed. Graphically, this implies that we are slicing the production frontier along rays from the origin in the lower plane that measures the inputs capital and labor. For instance, Graph 12.5 illustrates such slices along the 45-degree line for two different three-dimensional production frontiers, with the shaded slice in panel (a) forming a convex set while that in panel (b) forms a non-convex set. An alternative and equivalent way of saying this is that the darkened boundary of the slice in panel (a) is a concave function (giving rise to a convex

GRAPH 12.5 Producer Choice Sets with (a) Decreasing and (b) Increasing Returns to Scale

set underneath) while the darkened boundary of the slice in panel (b) is a convex function (that gives rise to a non-convex set underneath).

EXERCISE 12A.13*

Consider a real-world mountain and suppose that the shape of any horizontal slice of this mountain is a perfect (filled in) circle. I have climbed the mountain from every direction, and I have found that the climb typically starts off easy but gets harder and harder as I approach the top because the mountain gets increasingly steep. If I take a vertical slice of this mountain, will the outer boundary of that slice be a concave or convex function?

EXERCISE 12A.14*

Is the vertical slice described in the previous section (including all the points inside the mountain that lie on the slice) a convex set?

A production process has increasing returns to scale when output increases at an increasing rate as inputs rise in proportion to one another, and it has decreasing returns to scale when output increases at a decreasing rate as inputs rise in proportion to one another.

The following should now be easy to see in Graph 12.5: As we increase capital and labor by the same proportion (thus holding the ratio of capital to labor fixed) along the ray of the slice in panel (a), production is increasing at a slower and slower rate. Put differently, in panel (a) it is getting harder and harder to produce more as we increase both capital and labor proportionately. This is what we will mean by *decreasing returns to scale*. In panel (b), on the other hand, production is increasing at a faster and faster rate as we increase capital and labor by the same proportion along the ray, and this is what we mean by *increasing returns to scale*. A *constant returns to scale* production process would be the borderline case between these two—with the boundary of the slice taking on the shape of a straight line.

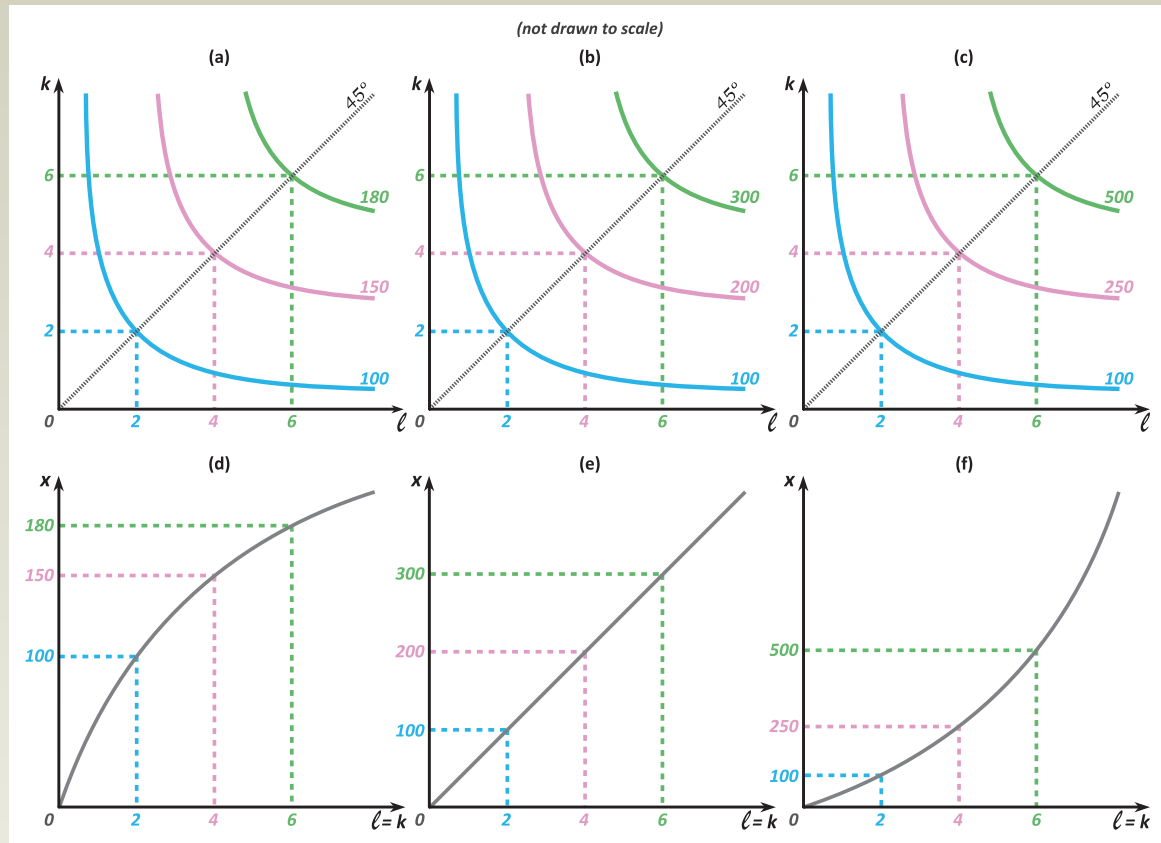

Now consider the homothetic isoquant map graphed three times in the upper three panels of Graph 12.6. The only difference between the three panels lies in the labels of the magenta and green isoquants, labels that indicate the “height” of the isoquant in the underlying three-dimensional production frontier. In the middle panel (b), for instance, doubling the input levels (that is, moving out twice the distance from the origin) results in an exact doubling of the output level, and a tripling of all input levels results in an exact tripling of the output level. This is the *constant returns to scale* case. In panel (a), on the other hand, a doubling of the inputs leads to less than double the output, the *decreasing returns to scale* case, and in panel (c) a doubling of inputs leads to more than twice the output, the *increasing returns to scale* case. More generally, we will define a homothetic production process as constant returns to scale whenever multiplying inputs by a factor t results in a t -fold change in output, as decreasing returns to scale whenever multiplying inputs by a factor t results in less than a t -fold change in output, and as increasing returns to scale whenever multiplying inputs by a factor t results in more than a t -fold change in output.

EXERCISE 12A.15

Consider a single-input production process with increasing marginal product. Does this production process exhibit increasing returns to scale? What about the production process in Graph 11.10?

Now consider what the three-dimensional producer choice sets look like for the upper three panels of Graph 12.6. Consider first panel (b) where the production frontier has constant returns to scale. Imagine taking a “vertical” slice of the three-dimensional production frontier (from which these isoquants are derived) along the 45-degree line in the isoquant picture of panel (b). This slice is graphed in panel (e) immediately below panel (b) with ℓ and k both represented on the horizontal axis (since they are equal to one another on the 45-degree line in panel (b)). Because this production frontier has the feature that multiplying inputs along the 45-degree line by a factor t results in a t -fold increase in output no matter where we start, this lower panel indicates that production increases along a straight line on this slice. The same would be true for any other vertical

GRAPH 12.6 Homothetic Isoquant Maps Can Represent Increasing, Constant, or Decreasing Returns to Scale Production Processes

Go to MindTap to interact with this graph.

slice of the production frontier along a ray from the origin. In panel (a), on the other hand, the same slice would have the concave shape in panel (d). Finally, the reverse is true in panel (f) for the production frontier from panel (c). If you imagine these producer choice sets as three-dimensional “mountains,” the first would be a mountain that is initially hard to climb but that becomes easier and easier to climb as we walk up the mountain, while the last producer choice set is a mountain that is initially easy to climb but becomes harder and harder to scale as we approach the top. Put differently, the underlying producer choice set in panel (a) looks like the first picture in Graph 12.5, while the producer choice set in (c) looks like the second picture in Graph 12.5.

True or False: Homothetic production frontiers can have increasing, decreasing, or constant returns to scale.

EXERCISE 12A.16

If the three panels of Graph 12.6 represented indifference curves for consumers, would there be any meaningful distinction between them? Can you see why the concept of “returns to scale” is not meaningful in consumer theory?

EXERCISE 12A.17

12A.2.4 Returns to Scale and Diminishing Marginal Product At this point, I have found that students are often unclear about the difference between decreasing returns to scale and diminishing marginal product. The marginal product of an input is defined as the additional output generated from hiring one more unit of the input *holding all other inputs fixed*. To say that the marginal product of all inputs is diminishing then implies that, as we hire additional units of a particular input *holding all other inputs fixed*, each additional unit of input will (at least eventually) add less to my total output than the previous unit. Diminishing marginal product of labor, for instance, implies that, holding the level of capital fixed, additional labor hours will eventually lead to smaller and smaller additions to total output; and diminishing marginal product of capital implies that, holding labor hours fixed, additional machines (or other forms of capital) will eventually result in smaller and smaller additions to output. Because all other inputs are held fixed as we define marginal product of a particular input, *marginal product is measured as the slope of a slice of the production frontier that holds all other inputs constant, and diminishing marginal product implies that this slice eventually has diminishing slope*. Graph 12.1f illustrates such a slice as it holds k fixed at k^D .

This is quite different from the property of decreasing returns to scale, which is, as we discussed in Section 12A.2.3, a property of slices of the production frontier that emanate from the origin and keep the ratio of l and k fixed (as in Graph 12.5 and the lower panels of Graph 12.6). This is because, for a production process to satisfy decreasing returns to scale, we have said that a t -fold increase in *all inputs* must lead to a less than t -fold increase in output. Unlike the definition of diminishing marginal product, the definition of decreasing returns to scale does not hold any input fixed but explicitly defines what happens to output when *all* input levels are adjusted in proportion to one another. While there is thus a logical relationship between returns to scale and marginal product in the single-input model (where increasing *all* inputs is the same as increasing one input), that relationship becomes more complex in the two-input model.

Would it be possible, for instance, to have decreasing marginal product of all inputs *and* increasing returns to scale? Your first reaction, I am sure, is no. But now let me ask the same question differently: If I tell you that it's *not* possible to double your output by *just* doubling the amount of labor you hire, and it's *not* possible to double your output by *just* doubling the amount of capital you hire—does that preclude the possibility that it might be possible to double (or more than double) your output by doubling *both labor and capital*? I think you can see that it might just be possible to more than double output by doubling both labor and capital even though you can't double it by doubling only labor or only capital. But that's exactly the same as saying that you can have decreasing marginal product of both labor and capital and still have increasing returns to scale.

While they are similar in the one-input case, increasing returns to scale and increasing marginal product are different concepts in the two-input case, just as decreasing returns to scale and diminishing marginal product are different concepts.

EXERCISE 12A.18 *True or False:* If you have decreasing marginal product of all inputs, you might have decreasing, constant, or increasing returns to scale.

Or here is another brain teaser: Suppose you have a production process with many inputs, and only one of those inputs has increasing marginal product and all the others have decreasing marginal product. Does this necessarily imply that the production process has increasing returns to scale? Again, your initial reaction is probably to say no, not necessarily. But now let me rephrase the question again: Suppose that you can more than double your output by doubling *just one input*. Does that mean that you will necessarily be able to more than double your output by doubling *all inputs*? Of course it does—if you can more than double output by doubling just one input, you can surely do it by doubling all inputs! But that's exactly equivalent to saying that increasing marginal product of just one input implies increasing returns to scale.

True or False: In the two-input model, decreasing returns to scale implies decreasing marginal product of all inputs.

EXERCISE
12A.19

True or False: In the two-input model, increasing returns to scale implies increasing marginal product of at least one input.

EXERCISE
12A.20*

With the tools developed in this section, we are now ready to illustrate how to identify the economically efficient production plans along an isoquant of many technologically efficient plans, and then to show how we can infer profit-maximizing choices from resulting cost curves (as first developed in Section 11A.5 for the single-input model).

12A.3 Cost Minimization on the Way to Profit Maximization

When we derived the total cost curve in the single-input model in Section 11A.5, we were graphically solving a quite trivial problem. In essence, we identified the cheapest possible or *economically most efficient* way to produce each output level (given the input price w) as simply the one production plan on the production frontier that produces this output level in the *technologically efficient way*; that is, without wasting any resources. In the two-input model, finding the economically efficient way to produce a given output level is not that trivial because *now there are many ways of producing a given output level in a technologically efficient way* as indicated by the many possible input bundles that lie on an isoquant that represents all the ways this output level can be produced without wasting inputs.

In the two-input model, a technologically efficient production plan is not necessarily economically efficient.

12A.3.1 Isocosts and Cost Minimization Suppose, for instance, we are interested in finding the cheapest possible way of producing 100 units of output in Graph 12.7a. The isoquant in the graph gives us all the technologically efficient input bundles that can result in 100 units of output (with no input going to waste). Given that different inputs are associated with different prices, however, it is not sufficient for a production plan to be *technologically efficient* (in the sense of not wasting inputs) to conclude that the production plan is *economically efficient* (in the sense of being the cheapest).

True or False: In the single-input model, each isoquant is composed of a single point, which implies that all technologically efficient production plans are also economically efficient.

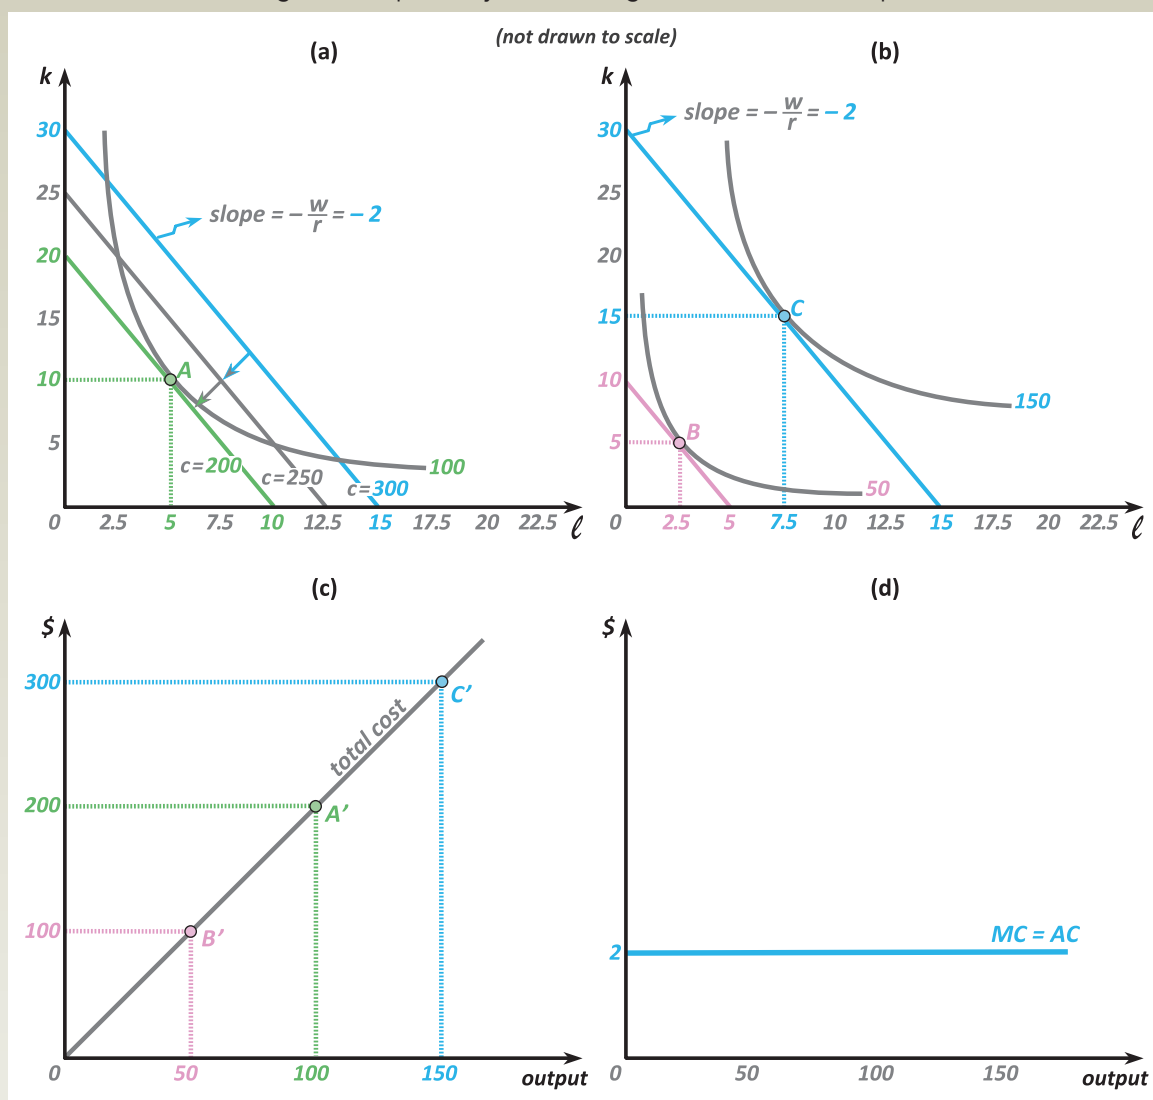

EXERCISE
12A.21

True or False: In the two-input model, every economically efficient production plan must be technologically efficient but not every technologically efficient production plan is necessarily economically efficient.

EXERCISE
12A.22

We can then imagine giving the producer a “budget” to work with, a budget with which to buy labor (ℓ) and capital (k) at an hourly wage rate w and a rental rate r . This hypothetical budget is exactly like the budgets we drew for consumers: if, for instance, the wage rate is \$20 per hour and the rental rate is \$10 per unit of capital, the producer’s hypothetical budget could be represented by the blue line in Graph 12.7a if we give the producer a total of \$300 to work with. This type of hypothetical budget for producers is called an *isocost curve*, which *represents all the combinations of inputs that cost the same at input prices (w, r)*. While the blue isocost curve certainly makes it possible for this producer to produce 100 units of output, we could reduce the amount of money we give to the producer, thus moving the isocost curve inward. For instance,

GRAPH 12.7 Finding the Cheapest Way of Producing Different Units of Output

Cost
minimization
implies
 $TRS = -w/r$.

we could give the producer only \$250 to work with, which would put us on the grey isocost curve, but this would still be more than the producer needs to produce 100 units of output. We could thus keep reducing the producer's hypothetical budget until we get to the green isocost curve that represents all input combinations that cost exactly \$200. This last isocost curve then contains exactly 1 input bundle—bundle A with 5 hours of labor and 10 units of capital—that can produce 100 units of output. Any less of a hypothetical budget would imply that the producer would not be able to buy sufficiently many inputs to produce 100 units of output. The input bundle A then represents *the least cost way of producing 100 units of output when input prices are \$20 for labor and \$10 for capital*. Put differently, the production plan $(\ell, k, x) = (5, 10, 100)$ represented by A is the economically efficient way to produce 100 output units given these input

prices. Since the slope of the isoquant must equal the slope of the isocost at this cost-minimizing input bundle, we can conclude that

$$\text{Cost Minimization implies } -TRS = \frac{MP_\ell}{MP_k} = \frac{w}{r}. \quad (12.4)$$

True or False: We have to know nothing about prices, wages, or rental rates to determine the technologically efficient ways of producing different output levels, but we cannot generally find the economically efficient ways of producing any output level without knowing these.

EXERCISE 12A.23

12A.3.2 Cost Curves with Multiple Inputs We can then imagine doing this for each possible isoquant; that is, for each possible output level. For instance, in panel (b) of Graph 12.7, we illustrate the least cost input bundle B for producing 50 units of output as well as the least cost input bundle C for producing 150 units of output. Finally, panel (c) of the graph translates the three production plans represented by the input bundles A , B , and C and their respective isoquants into a new graph illustrating the cost of producing 50, 100, and 150 units of output with output on the horizontal axis and dollars on the vertical. For instance, since the least cost input bundle for producing 100 units of output at input prices $w = 20$ and $r = 10$ involves using 5 labor hours (costing a total of \$100) and 10 units of capital (costing an additional \$100), the total cost of producing 100 units of output is \$200 (point A'). Similarly, the total cost of producing 50 units is \$100 (point B') and the total cost of producing 150 units is \$300 (point C'). Connecting these points in panel (c) then gives an estimate of the (total) *cost curve*, which is the curve illustrating the cost of producing different quantities of output in the economically most efficient way given $w = 20$ and $r = 10$.

The cost curve is derived from the economically efficient production plans.

Notice that the underlying technology here has constant returns to scale; that is, it has the characteristic that multiplying inputs by a factor t leads to a t -fold increase in output. It is for this reason that each additional unit of output always adds exactly the same additional cost to our total cost of production, causing the marginal cost of production to be constant (and equal to \$2 per unit of output) and exactly equal to the average cost of producing. Panel (d) of Graph 12.7 then illustrates this with constant MC at \$2 that is equal to AC .

Suppose the numbers associated with the isoquants in Graphs 12.7a and (b) had been 50, 80, and 100 instead of 50, 100, and 150. What would the total cost, MC , and AC curves look like? Would this be an increasing or decreasing returns to scale production process, and how does this relate to the shape of the cost curves?

EXERCISE 12A.24

How would your answer to the previous question change if the numbers associated with the isoquants were 50, 150, and 300 instead?

EXERCISE 12A.25

We implicitly assumed in Graph 12.7 that the underlying production technology is homothetic. If we are then faced with a particular wage w and rental rate r , we immediately know where *all* the economically efficient production plans are as soon as we know where *one* such production plan is because all such cost-minimizing production plans will lie on the same vertical ray from the origin. This is true regardless of whether the production technology has constant returns to scale (as in Graph 12.7) or whether it has some other returns to scale. For instance, consider the homothetic isoquant map in panel (a) of Graph 12.8 and suppose again that $w = 20$ and $r = 10$. If we know that an isocost with slope $-w/r = -2$ is tangent at D , we know that using 20 units of capital and 10 units of labor is the economically efficient way of producing

When technologies are homothetic, all economically efficient production plans lie on the same ray from the origin in the isoquant graph.

GRAPH 12.8 Cost Curves of "Typical" Production Processes

Go to MindTap to interact with this graph.

140 units of output. But we also know that the slope of *all* the isoquants is -2 along the ray that emanates from the origin and passes through *D*, and thus we know that *all* the tangencies of isocosts with slope -2 will occur along this ray. Thus, *A* is the economically efficient input bundle for producing 10 output units, *B* is the economically efficient input bundle for producing 40 output units, and so on.

EXERCISE 12A.26 If w increases, will the economically efficient production plans lie on a steeper or shallower ray from the origin (in the isoquant graph)? What if r increases?

The production technology represented by the isoquant map in Graph 12.8 differs from the constant returns to scale technology in Graph 12.7 in that it has one additional feature we often think holds in real-world firms: It initially has increasing returns to scale but eventually assumes decreasing returns. You can tell that this is the case by simply looking at how quickly the labels on the isoquants increase; initially they increase at an increasing rate but eventually they increase at a decreasing rate. Just as for the typical single-input production process we illustrated in Chapter 11, we therefore have an example of a production technology where increased production initially becomes easier and easier but eventually becomes harder and harder.

We can now derive the shape of the (total) cost curve from the points *A* through *F* in panel (a) of the graph by simply calculating the cost of the inputs required to reach each of the isoquants, just as we did in Graph 12.7. For instance, panel (a) of the graph tells us that the least cost way of producing 140 units of output when $w = 20$ and $r = 10$ is to use the input bundle *D* that contains 20 units of capital and 10 units of labor. The cost of that input bundle is $10w + 20r = 10(20) + 20(10) = 400$. In panel (b) of the graph, we therefore plot *D'* with 140 units of output (measured on the horizontal axis) costing \$400 (measured on the vertical). Repeating this for each of the isoquants in panel (a), we can derive the shape of the (total) cost curve as one that initially increases at a decreasing rate but eventually increases at an increasing rate. This is precisely the shape we derived in Chapter 11 for single-input production processes that have the analogous feature of production initially getting easier and easier but eventually harder and harder.

Returns to scale can be inferred from the shape of the cost curve.

What is the shape of such a production process in the single-input case? How does this compare to the shape of the vertical slice of the three-dimensional production frontier along the ray from the origin in our graph?

EXERCISE
12A.27

From this (total) cost curve we can then calculate average and marginal cost curves in exactly the same way we developed in Chapter 11. The AC curve in panel (c) arises from plotting the average cost of producing the six different quantities of output, and we can infer the approximate shape of the MC curve by knowing that MC curves must logically begin where the AC curve begins and lie below the AC until the AC reaches its lowest point (see the discussion in Section 11A.5.3).

Just as in the one-input model, the supply curve contains the portion of MC that lies above AC .

12A.3.3 Profit Maximizing with Cost Curves Finally, the same logic that led us to conclude that profit-maximizing producers in the single-input model will produce where price is equal to MC (so long as MC lies above AC) holds here once again. Rather than repeat this reasoning, you can simply refer to Section 11A.5.3. No step in this argument differs in the two-input case from the argument we already made in the single-input case. As a result, we can derive the producer's output supply curve (for a given set of input prices) directly from the MC and AC picture and do not need to resort to the three-dimensional graphs of Section 12A.1. For the production frontier illustrated in panel (a) of Graph 12.8, and for the input prices $w = 20$ and $r = 10$, the resulting output supply curve is then graphed in the last panel of Graph 12.8.

True or False: If a producer minimizes costs, he or she does not necessarily maximize profits, but if the producer maximizes profits, he or she also minimizes costs. (*Hint:* Every point on the cost curve is derived from a producer minimizing the cost of producing a certain output level.)

EXERCISE
12A.28

In filling in the output supply curve in Graph 12.8, we have recognized that the producer will end up at an interior solution (that is, he or she will produce a positive amount) when the output price is sufficiently high (that is, above the lowest point of AC), and we have implicitly recognized that the producer will end at a corner solution (that is, produce nothing) if the output price falls too low (that is, below the lowest point of AC). However, there is one additional theoretical possibility that does not emerge when we are working with the type of production frontier that has initially increasing and eventually decreasing returns to scale, which is the theoretical possibility that a producer's optimal choice is to produce an infinite amount of output.

I recognize that this sounds absurd, but bear with me for one minute. Suppose we have a production frontier that has increasing returns throughout. You can verify for yourself that the resulting MC curve will always lie below the AC curve, which implies that the part of the MC curve that lies above AC and usually becomes the output supply curve does not exist. Does this mean that a producer for whom it is getting easier and easier to produce should never produce? The answer is no, the producer's optimal choice is to produce either nothing or an infinite amount of the good. You can see this in Graph 12.9 where the MC and AC curves for a production process that has increasing returns to scale is graphed. Here, both the MC and AC curves approach (but never quite reach) p^* . If the output price is below p^* , the price always lies below AC regardless of how much the producer sends to the market, implying a negative profit no matter how much is produced. In this case, the producer would simply not produce. But if the price rises above p^* , then, although she will make a loss on the initial output she produces, the producer can make a positive profit by producing an infinite amount.

GRAPH 12.9 *MC and AC under Increasing Returns to Scale Production*

EXERCISE 12A.29* Suppose a production process begins initially with increasing returns to scale and eventually assumes constant returns to scale but never has decreasing returns. Would the *MC* curve ever cross the *AC* curve?

Increasing returns to scale throughout the production process is not compatible with price-taking behavior.

So, do production processes like this exist? Consider the production of operating systems for personal computers. An enormous amount of effort goes into just producing the first operating system and then into getting all the bugs out as one learns where they are. But eventually, producing additional operating systems is just a matter of burning a CD or putting it on a Web site for people to download, which is virtually costless. Such a production process would give rise to *MC* and *AC* curves similar to those in Graph 12.9, perhaps with *MC* actually reaching p^* (the cost of burning a CD) at some point. So yes, such production processes do exist. However, the decisions by producers that face such production processes are not properly modeled with the assumption that such producers are “price takers.” Examples of such producers include firms like Microsoft that have substantial market power and can influence price. We will therefore postpone further discussion of the profit-maximizing behavior of such producers to Chapter 23 where we will relax the “price-taking” assumption. It is worth noting here, however, that the cost-minimization part of profit maximization will be exactly the same for such producers; it is only the second step of profit maximization that will differ when producers have market power and no longer take price as given.

EXERCISE 12A.30 Another special case is the one graphed in Graph 12.7. What are the profit-maximizing supply choices for such a producer as the output price changes?

EXERCISE 12A.31 Illustrate the output supply curve for a producer whose production frontier has decreasing returns to scale throughout (such as the case illustrated in Graph 12.1).

12A.4 Bringing Cost Minimization and Profit Maximization Together

We have covered a lot in this section, and before moving on, it might pay to pause and take stock of some “bottom lines” that will show up crisply in the math of Section B and will then play an important role in Chapter 13. In particular, it is useful to step back and summarize how profit maximization and cost minimization differ.

A producer that only minimizes costs pays no attention to output prices; all he or she does is determine, for a given set of input prices (w, r), the least cost (or economically efficient) way of producing different levels of output. In our graphical development of the two-input model, this implied that a cost-minimizing producer uses input bundles where the slope of the isoquants is equal to the slope of isocosts (assuming an interior solution is in fact economically efficient); that is, $TRS = -w/r$. Since we know from Section 12A.2.1 that $TRS = (-MP_\ell/MP_k)$ we can equivalently say that, so long as the least cost production bundle involves at least some of each input,

$$\text{Cost Minimization implies } -TRS = \frac{MP_\ell}{MP_k} = \frac{w}{r}. \quad (12.5)$$

A *profit-maximizing* producer, on the other hand, also thinks about output price and produces where the marginal revenue product of each input is equal to that input's price. In the two-step profit maximization method that begins with cost minimization, this involves comparing marginal costs to marginal revenues, with the latter simply equal to the output price (when producers are price takers). Competitive profit-maximizing firms therefore (1) minimize costs and (2) produce where $p = MC$. But this is equivalent to the one-step profit maximization we discussed in Section 12A.1 where we argued that profit-maximizing firms will produce where the isoprofit planes are tangent to the production frontier, which implied that $MP_\ell = w/p$ and $MP_k = r/p$; that is,

$$\text{Profit Maximization implies } MRP_\ell = pMP_\ell = w \text{ and } MRP_k = pMP_k = r \quad (12.6)$$

so long as the true profit maximum occurs at an interior solution (and not at output of zero or infinity).

Dividing the equations in expression (12.6) by one another, we see that profit maximization implies that $MP_\ell/MP_k = w/r$, which is precisely what cost minimization implies. Thus *profit-maximizing producers are implicitly cost minimizing*. The reverse, however, is not true because $MP_\ell/MP_k = w/r$ does *not* imply that $pMP_\ell = w$ and $pMP_k = r$.⁵ Thus, cost-minimizing producers become profit maximizers only when they set output level such that $p = MC$ (as long as MC is greater than or equal to AC), which turns out to be the same as saying that profit maximizers produce where marginal revenue products are equal to input prices.

Profit maximization implies cost minimization but not vice versa.

12B

THE MATHEMATICS BEHIND THE MULTIPLE-INPUT MODEL

Section A essentially began with an illustration of the technical complexity of graphing profit maximization when production technologies have more than one input and then set up an alternative graphical method that uses cost minimization as a first step to finding the profit-maximizing

⁵For instance, if $pMP_\ell > w$ and $pMP_k > r$, MP_ℓ/MP_k could still be equal to w/r . Consider the following case: $p = 1$, $MP_\ell = 20$, $MP_k = 10$, $w = 10$ and $r = 5$. Then

$$\frac{w}{r} = 2 = \frac{pMP_\ell}{pMP_k} = \frac{MP_\ell}{MP_k} \quad (12.7)$$

but $pMP_\ell = 20 > 10 = w$ and $pMP_k = 10 > 5 = r$.

choices made by price-taking producers. When we take a more mathematical approach, the complexity of solving for profit-maximizing choices directly is not as overwhelming and thus the need for an alternative approach is less compelling. However, we will find that the alternative cost minimization approach provides us with a method that is almost identical to the expenditure minimization problem in consumer theory, and it allows us ultimately to derive a “duality” picture such as the one we derived in consumer theory. Cost minimization furthermore builds the basis for deriving the cost functions that apply to *all* producers, whether they are competitive “price takers” or whether they can in fact exercise market power (as will be assumed in chapters beginning with Chapter 23).

12B.1 Producer Choice Sets and Production Functions

In the single-input case of Chapter 11, we represented production frontiers mathematically with production functions of the form $f: \mathbb{R}_+^1 \rightarrow \mathbb{R}_+^1$. Production functions in the multiple-input case are then just straightforward extensions, with a production process that uses n inputs represented by a function $f: \mathbb{R}_+^n \rightarrow \mathbb{R}_+^1$. For the case in which labor ℓ and capital k represent the only two inputs, for instance, the function $f: \mathbb{R}_+^2 \rightarrow \mathbb{R}_+^1$ tells us the quantity of output $f(\ell, k)$ that can be produced from any input bundle (ℓ, k) assuming no inputs are wasted. The producer choice set is then defined (just as in Chapter 11) as the set of production plans (x, ℓ, k) that are technologically feasible; that is,

$$C(f: \mathbb{R}_+^2 \rightarrow \mathbb{R}_+^1) = \{(x, \ell, k) \in \mathbb{R}^3 \mid x \leq f(\ell, k)\}. \quad (12.8)$$

In principle, not only could such a choice set contain some arbitrary number n of inputs but it could also result in a number m of different outputs (x_1, x_2, \dots, x_m) , with a function $f: \mathbb{R}_+^n \rightarrow \mathbb{R}_+^m$ generating the relevant production frontier. Production processes with multiple outputs may be of two different types: First, it may be the case that a producer *intentionally* uses a given set of inputs to *jointly* produce several different outputs to sell on the market. For instance, the owner of an apple orchard might use the inputs “apple trees” and “bees” (required for cross-pollination) to produce outputs “apples” and “honey” to be sold in the output market. Second, a producer might *unintentionally* produce goods that he or she does not (or is not able to) sell on the market but that impact the lives of others. The apple orchard owner might, for instance, unintentionally provide “cross-pollination” services to a neighboring peach orchard, or the processing of honey might produce the output “water pollution” in a neighboring river. Such unintentionally produced outputs will be referred to as “production externalities” in later chapters. For now, however, we will restrict ourselves to production processes that yield a single, intentionally produced output x .

12B.1.1 Marginal Product and TRS Now consider once again the definition of the marginal product of an input, which is the increase in total output from hiring one more unit of the input while holding all other inputs fixed. This translates directly into the mathematical definition of marginal product as *the partial derivative of the production function with respect to the input*, or

$$MP_\ell = \frac{\partial f(\ell, k)}{\partial \ell} \quad \text{and} \quad MP_k = \frac{\partial f(\ell, k)}{\partial k} \quad (12.9)$$

for the case where the inputs are labor ℓ and capital k . Since k is held fixed in the partial derivative that defines MP_ℓ , this implies that the marginal product of labor is simply the slope of the “slice” of the production function that holds k fixed, while the marginal product of capital is the slope of the “slice” that holds labor input fixed. Examples of such slices are depicted graphically in Graph 12.1.

The marginal product of an input is given by the derivative of the production function with respect to that input.

Just as we can take the partial derivative of a production function with respect to one of the inputs (and call it the “marginal product of the input”), we could take the partial derivative of a utility function with respect to one of the consumption goods (and call it the “marginal utility from that good”). Why is the first of these concepts economically meaningful but the second is not?

EXERCISE
12B.1

As already discussed extensively in Section A, we can also explore the properties of production functions by considering the horizontal slices of these functions, slices that are known as *isoquants*. In Section A, we argued that it is reasonable to assume that such isoquants will have properties similar to consumer indifference curves (which are just horizontal slices of utility rather than production functions). The slope of an isoquant derived from a production function $f(\ell, k)$, the (marginal) *technical rate of substitution (TRS)*, is then given by

$$TRS = -\left(\frac{\partial f(\ell, k)/\partial \ell}{\partial f(\ell, k)/\partial k}\right), \quad (12.10)$$

which can be derived exactly as the formula for *MRS* in Chapter 4 was derived.

Using the same method employed to derive the formula for *MRS* from a utility function, derive the formula for *TRS* from a production function $f(\ell, k)$.

EXERCISE
12B.2*

Given the expressions for marginal product in equation (12.9), the technical rate of substitution can then also be expressed as the fraction of the marginal products of the inputs

$$TRS = -\frac{MP_\ell}{MP_k}, \quad (12.11)$$

as we already derived intuitively in Section 12A.2.1.

12B.1.2 “Averages Are Better than Extremes” and Quasiconcavity A particularly important assumption we typically make about producer choice sets is that “averages are better than extremes” in the sense that an input bundle formed as the average of two input bundles on the same isoquant will produce at least as much (but typically more) than the more extreme bundles. When we made the same assumption in consumer theory, we called it “convexity” because it gives rise to convex upper contour sets of indifference curves. As it turns out, assuming convexity of upper contour sets is equivalent to assuming that the underlying production function is *quasiconcave*. Consider the definition of quasiconcavity of a function: A function $f: \mathbb{R}_+^2 \rightarrow \mathbb{R}^1$ is *quasiconcave* if and only if, for any two points $A = (x_1^A, x_2^A)$ and $B = (x_1^B, x_2^B)$ in \mathbb{R}_+^2 and any $\alpha \in (0, 1)$,

$$\min \{f(x_1^A, x_2^A), f(x_1^B, x_2^B)\} \leq f(\alpha x_1^A + (1 - \alpha)x_1^B, \alpha x_2^A + (1 - \alpha)x_2^B). \quad (12.12)$$

Now suppose we pick 2 input bundles $A = (\ell^A, k^A)$ and $B = (\ell^B, k^B)$ on an isoquant of the quasiconcave production function $f(\ell, k)$. Since they lie on the same isoquant, we know that $f(\ell^A, k^A) = f(\ell^B, k^B)$, and from our definition of quasiconcavity, we can infer that the output of any weighted average of input bundles A and B will be at least as much as is produced on the isoquant from which A and B were drawn. Thus, quasiconcave production functions represent production processes under which average input bundles produce more than extremes. Similarly, you can convince yourself that, whenever averages are better than extremes in the sense we have defined this, only quasiconcave functions can represent such production processes. As a result,

Quasiconcave production functions give rise to isoquants that satisfy the “averages are better than extremes” property, and isoquant maps that have this property can only be represented by quasiconcave production functions.

we can conclude that *quasiconcave production functions give rise to isoquants with convex upper contour sets, and production processes in which isoquants have convex upper contour sets must arise from quasiconcave production functions*. Since all the utility functions we worked with in our development of consumer theory had the “averages are better than extremes” feature, we then immediately know that all these utility functions were also quasiconcave.

EXERCISE 12B.3 True or False: Producer choice sets whose frontiers are characterized by quasiconcave functions have the following property: All horizontal slices of the choice sets are convex sets.

We can note immediately, however, that this does not imply that production (or utility) functions that have the “averages are better than extremes” feature must be *concave*, only that they must be *quasiconcave*. We can clarify this by first stating the definition of a concave function with two inputs: A function $f: \mathbb{R}_+^2 \rightarrow \mathbb{R}^1$ is *concave* if and only if, for any two points $A = (x_1^A, x_2^A)$ and $B = (x_1^B, x_2^B)$ in \mathbb{R}_+^2 and any $\alpha \in (0, 1)$,

$$\alpha f(x_1^A, x_2^A) + (1 - \alpha)f(x_1^B, x_2^B) \leq f(\alpha x_1^A + (1 - \alpha)x_1^B, \alpha x_2^A + (1 - \alpha)x_2^B). \quad (12.13)$$

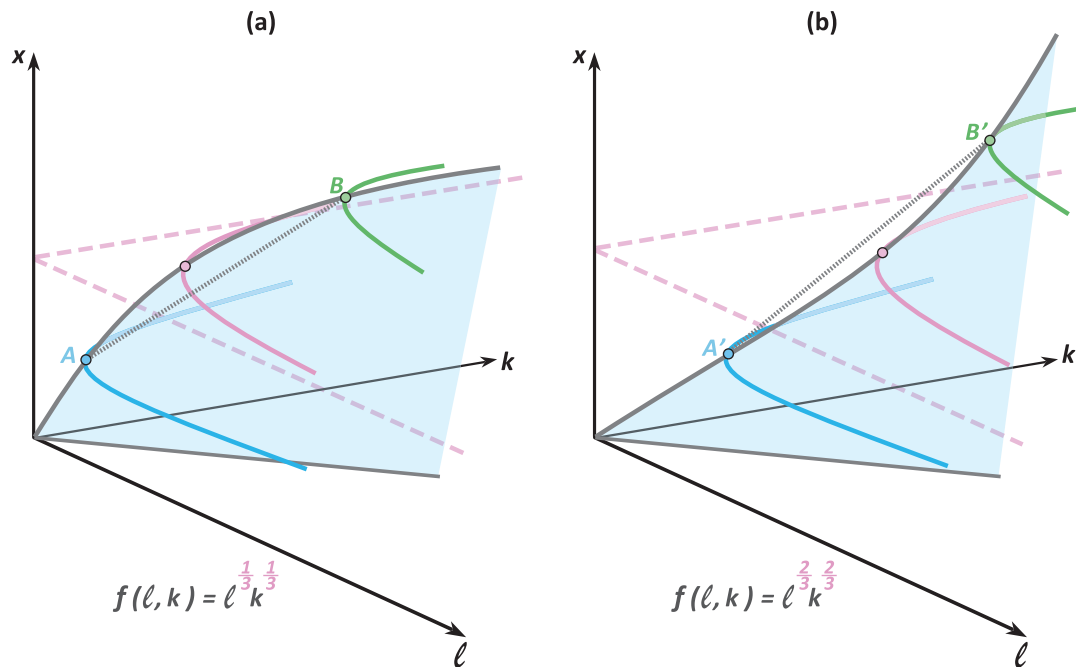

It is easy to see that every concave function is also quasiconcave by noting that, for any $A = (x_1^A, x_2^A)$ and $B = (x_1^B, x_2^B)$ and any $\alpha \in (0, 1)$, it is always true that

$$\min \{f(x_1^A, x_2^A), f(x_1^B, x_2^B)\} \leq \alpha f(x_1^A, x_2^A) + (1 - \alpha)f(x_1^B, x_2^B) \quad (12.14)$$

as long as f satisfies (12.13). If f is concave, then equations (12.13) and (12.14) together imply that equation (12.12) holds; that is, f being concave implies f is quasiconcave.

The reverse, however, does not hold. And it is in exploring this through an example that we can get some intuition for the difference between quasiconcavity and concavity of a function. Consider, for instance, the Cobb–Douglas production function $f(\ell, k) = \ell^{1/3}k^{1/3}$, which is graphed in panel (a) of Graph 12.10. The production plans A and B fall on the vertical slice of

GRAPH 12.10 Quasiconcave Functions Can Be Concave (a) but Don’t Have to Be (b)

this function that lies on the 45-degree line in the (ℓ, k) plane. Since the slope on this slice of the function starts out large and declines, the dotted line connecting A and B lies below the function. Points on this dotted line correspond to the left-hand side of equation (12.13), while points on the boundary of the slice correspond to the right-hand side of equation (12.13). The fact that the former falls below the latter then formally satisfies the definition of concavity. Panel (b) of Graph 12.10, on the other hand, illustrates the same function squared; that is, $f(\ell, k) = \ell^{2/3}k^{2/3}$, but this time the dotted line connecting A' and B' lies above the function, which implies that the definition of concavity is not satisfied.

Therefore, panel (a) of Graph 12.10 represents a production function that is concave while panel (b) represents a production function that is not concave. You can immediately see that this is equivalent to saying that the producer choice set in panel (a) is a convex set, while the producer choice set in panel (b) is a non-convex set. Concave production functions therefore represent convex producer choice sets. At the same time, the shape of the same-colored isoquants in the two panels is identical since, as we learned in the development of consumer theory, a transformation of a function (such as squaring it) does not change the shape of the levels projected into two dimensions even though it does change the three-dimensional function. And these shapes of isoquants give rise to convex upper contour sets, indicating that both functions are quasiconcave.

All concave functions are quasiconcave, but not all quasiconcave functions are concave.

True or False: All quasiconcave production functions, but not all concave production functions, give rise to convex producer choice sets.

EXERCISE
12B.4

True or False: Both quasiconcave and concave production functions represent production processes for which the “averages are better than extremes” property holds.

EXERCISE
12B.5

12B.1.3 Returns to Scale and Concavity Our discussion of concavity of production functions then relates directly to the concept of returns to scale. In Section A, we defined a homothetic production process as having *decreasing returns to scale* if multiplying inputs by a factor t will lead to less than t times as much output, *constant returns to scale* if it leads to t times as much output, and *increasing returns to scale* if it leads to more than t times as much output. Notice that the production function graphed in panel (a) of Graph 12.10 has the feature that any vertical slice of the function along a ray from the origin (such as the one that is pictured) has a slope that gets shallower and shallower, implying that multiplying inputs along the ray by a factor t will result in less than t times as much output. The reverse is true for the production function in panel (b) where the slope of the function along any vertical slice emanating from the origin becomes steeper and steeper. Thus, the same feature of homothetic production functions that makes them either concave or not concave determines whether or not they have decreasing returns to scale. Put differently, when isoquant maps are homothetic, *the boundary of convex producer choice sets is represented by a concave production function that has decreasing returns to scale*. Increasing returns to scale, on the other hand, imply a non-convexity in the producer choice set and thus a non-concavity in the production function.

Concave production functions have decreasing returns to scale while convex production functions have increasing returns to scale.

We can, in fact, be even more precise about what returns to scale mean mathematically for the production function if the function is homogeneous. First, recall that all homogeneous functions are homothetic, and a function is homogeneous of degree k if and only if

$$f(t\ell, tk) = t^k f(\ell, k). \quad (12.15)$$

Since a production function is defined to have constant returns to scale when a t -fold increase in inputs causes a t -fold increase in output, it follows that *constant returns to scale production functions are homogeneous of degree 1*. Similarly, *decreasing returns to scale production functions that are homogeneous are homogeneous of degree less than 1*, and *increasing returns to scale production functions that are homogeneous are homogeneous of degree greater than 1*.

Cobb–Douglas functions have decreasing returns to scale if the exponents sum to less than 1 and increasing returns to scale if they sum to greater than 1.

In the case of two-input Cobb–Douglas production functions, for instance, this implies that the production function is decreasing returns to scale if the exponents sum to less than 1, constant returns to scale if the exponents sum to 1, and increasing returns to scale if they sum to greater than 1. Note, however, that not all homothetic production functions are homogeneous. You could, for instance, have a homothetic production function that has initially increasing and eventually decreasing returns to scale (as will be explored in some end-of-chapter exercises).

EXERCISE 12B.6

Verify the last statement regarding two-input Cobb–Douglas production functions.

12B.1.4 Returns to Scale and Diminishing Marginal Product Finally, we can return to our discussion from Section 12A.2.4 in which we argued intuitively that diminishing marginal product of inputs is conceptually quite different from decreasing returns to scale because the first concept holds all inputs but one fixed while the latter varies all inputs in proportion to one another. We can get some further intuition by illustrating the concepts using the homothetic (and homogeneous) Cobb–Douglas production function $f(\ell, k) = \ell^\alpha k^\beta$, which has marginal product of labor and capital equal to

$$MP_\ell = \alpha \ell^{\alpha-1} k^\beta \quad \text{and} \quad MP_k = \beta \ell^\alpha k^{\beta-1}. \quad (12.16)$$

The production function has diminishing MP if and only if the derivative of MP is negative, where

$$\frac{\partial MP_\ell}{\partial \ell} = \alpha(\alpha - 1)\ell^{\alpha-2} k^\beta \quad \text{and} \quad \frac{\partial MP_k}{\partial k} = \beta(\beta - 1)\ell^\alpha k^{\beta-2}. \quad (12.17)$$

So long as the exponents α and β are positive (as they always are in Cobb–Douglas production functions), this implies that marginal product of labor and capital will be diminishing only if each exponent is less than 1. That’s because only when the exponent on the input is less than 1 will the derivative of marginal product in (12.17) be negative.

Graph 12.11 then illustrates two increasing returns to scale Cobb–Douglas production functions, one with diminishing marginal product and the other with increasing marginal product. In particular, panel (a) replicates the production function $f(\ell, k) = \ell^{2/3} k^{2/3}$ from Graph 12.10b but now illustrates the shape of the slice of the production function that holds labor fixed at ℓ^A . Panel (b) of Graph 12.11 then does the same for the production function $f(\ell, k) = \ell^{4/3} k^{4/3}$. From equation (12.17), we would expect the production function in panel (a) to exhibit diminishing marginal product of each input since the exponents on each input in the production function are less than 1, and we would expect the production function in panel (b) to exhibit increasing marginal product since the same exponents are larger than 1. This is precisely what the shapes of the slices of these functions indicate, with $f(\ell^A, k)$ exhibiting a diminishing slope in panel (a) (and thus diminishing MP_k) and an increasingly steep slope in panel (b) (and thus increasing MP_k).

The marginal product of an input in a Cobb–Douglas function is diminishing if the exponent on that input is less than 1 and increasing if it is greater than 1.

EXERCISE 12B.7

Can you give an example of a Cobb–Douglas production function that has increasing marginal product of capital and decreasing marginal product of labor? Does this production function have increasing, constant, or decreasing returns to scale?

EXERCISE 12B.8

True or False: It is not possible for a Cobb–Douglas production process to have decreasing returns to scale and increasing marginal product of one of its inputs.

GRAPH 12.11 Increasing Returns to Scale with (a) Diminishing MP and (b) Increasing MP

12B.2 Isoprofit Planes and Profit Maximization

In Graph 12.1, we briefly illustrated profit maximization with two-input production frontiers as the tangency of an “isoprofit plane” with the production frontier. Just as in the case of the single-input model in Chapter 11, the production frontier represents the technological constraint faced by producers, and the isoprofit curves represent the “tastes” for profit that arise from the economic environment that the producer takes as given. We will now illustrate the graphical profit maximization of Graph 12.1 mathematically by first defining isoprofits formally and then setting up and solving the full profit maximization problem.

12B.2.1 Isoprofit Curves with Multiple Inputs As we already discussed extensively in Chapter 11, we assume that “tastes” for producers are generally quantified straightforwardly in terms of profit. Profit, in turn, is expressed simply as the difference between economic revenue (generated from the sale of goods and services) and economic costs (incurred as inputs are purchased for producing outputs). In the two-input case with labor ℓ and capital k , profit π at a production plan (x, ℓ, k) is then simply

$$\pi = px - w\ell - rk, \quad (12.18)$$

where the economic environment is characterized by the output price p and the input prices (w, r) , all of which our price-taking producer takes as given. An “indifference curve” for price-taking producers, the isoprofit curve P , was then defined in Chapter 11 as the set of production plans that yield the same amount of profit in a given economic environment (p, w, r) . This can be defined more formally as

$$P(\pi, p, w, r) = \{(x, \ell, k) \in \mathbb{R}^3 \mid \pi = px - w\ell - rk\}. \quad (12.19)$$

EXERCISE 12B.9 In a three-dimensional graph with x on the vertical axis, can you use equation (12.18) to determine the vertical intercept of an isoprofit curve $P(\pi, p, w, r)$? What about the slope when k is held fixed?

EXERCISE 12B.10 Define profit and isoprofit curves for the case where land L is a third input and can be rented at a price r_L .

12B.2.2 Profit Maximization with Multiple Inputs The movement to the highest possible isoprofit plane on the three-dimensional production function graphed in Graph 12.1f is then formalized mathematically as the solution to the profit maximization problem

$$\max_{x, \ell, k} \pi = px - w\ell - rk \quad \text{subject to } x = f(\ell, k). \quad (12.20)$$

This problem could be read as “pick the production plan that lies on the highest isoprofit plane while remaining technologically feasible.” It can also be written as an unconstrained maximization problem by substituting the constraint into the objective function and writing

$$\max_{\ell, k} \pi = pf(\ell, k) - w\ell - rk. \quad (12.21)$$

The first order conditions are then simply the partial derivatives of π (with respect to the two choice variables) set to zero; that is,

$$\begin{aligned} \frac{\partial \pi}{\partial \ell} &= p \frac{\partial f(\ell, k)}{\partial \ell} - w = 0, \\ \frac{\partial \pi}{\partial k} &= p \frac{\partial f(\ell, k)}{\partial k} - r = 0, \end{aligned} \quad (12.22)$$

which can also be written as

$$w = p \frac{\partial f(\ell, k)}{\partial \ell} \quad \text{and} \quad r = p \frac{\partial f(\ell, k)}{\partial k}, \quad (12.23)$$

or simply

$$w = pMP_{\ell} = MRP_{\ell} \quad \text{and} \quad r = pMP_k = MRP_k. \quad (12.24)$$

These are of course precisely the conditions that emerge in Graph 12.1f: At the profit-maximizing production plan A , the slope of the “slice” of the production frontier that holds capital fixed at k^D is equal to the slope of the corresponding “slice” of the isoprofit plane that also holds capital fixed at k^D ($w/p = MP_{\ell}$); and the slope of the “slice” of the production frontier that holds labor fixed at ℓ^D is equal to the corresponding “slice” of the isoprofit plane that also holds labor fixed at ℓ^D ($r/p = MP_k$).

EXERCISE 12B.11 Demonstrate that the problem as written in (12.20) gives the same answer.

Input demand functions emerge as the solutions to the profit-maximization problem and can be used to derive the output supply function.

The two equations in (12.23) can then be solved to give the input demand functions that tell us how much labor and capital the producer will hire in any economic environment (p, w, r) that he or she might face; that is,

$$\ell(p, w, r) \quad \text{and} \quad k(p, w, r) \quad (12.25)$$

are the *labor and capital demand functions* for this producer. Plugging these into the production function, we can then derive (the *output supply function*)

$$x(p, w, r) = f(\ell(p, w, r), k(p, w, r)) \quad (12.26)$$

that tells me how much output the producer will supply in any economic environment (p, w, r) he or she might face.

12B.2.3 An Example of Profit Maximization Suppose, for instance, that the technology available to me as a producer can be represented by the function $f(\ell, k) = 20\ell^{2/5}k^{2/5}$. We can then set up the profit maximization problem

$$\max_{x, \ell, k} \pi = px - w\ell - rk \quad \text{subject to } x = 20\ell^{2/5}k^{2/5}, \quad (12.27)$$

which can also be written as

$$\max_{\ell, k} \pi = p(20\ell^{2/5}k^{2/5}) - w\ell - rk. \quad (12.28)$$

The first order conditions are then

$$\begin{aligned} \frac{\partial \pi}{\partial \ell} &= 8p\ell^{-3/5}k^{2/5} - w = 0, \\ \frac{\partial \pi}{\partial k} &= 8p\ell^{2/5}k^{-3/5} - r = 0, \end{aligned} \quad (12.29)$$

which can be written as

$$w = 8p\ell^{-3/5}k^{2/5} \quad \text{and} \quad r = 8p\ell^{2/5}k^{-3/5}. \quad (12.30)$$

Solving the second of these two equations for k and plugging it into the first, we get the labor demand function

$$\ell(p, w, r) = \frac{(8p)^5}{r^2w^3}, \quad (12.31)$$

and plugging this in for ℓ in the second equation, we get the capital demand function

$$k(p, w, r) = \frac{(8p)^5}{w^2r^3}. \quad (12.32)$$

Finally, we can derive the output supply function by plugging equations (12.31) and (12.32) into the production function $f(\ell, k) = 20\ell^{2/5}k^{2/5}$ to get

$$x(p, w, r) = 20 \frac{(8p)^4}{(wr)^2} = 81920 \frac{p^4}{(wr)^2}. \quad (12.33)$$

Demonstrate that solving the problem as defined in equation (12.27) results in the same solution.

**EXERCISE
12B.12**

Suppose, for instance, the economic environment is characterized by an output price of \$5 for each good I produce, and that I have to pay \$20 per hour for labor and \$10 per hour for the capital equipment I use. Plugging these values into equations (12.31), (12.32), and (12.33), we get that I will choose a production plan that hires 128 worker hours and 256 units of capital to produce 1,280 units of the output. We could then illustrate different “slices” of these functions by varying one price at a time and plotting the resulting economic relationships. For instance, we might be interested to know how output supply responds to output price, in which case we could hold w and r fixed at \$20 and \$10 and plot the function $x(p, 20, 10)$. Or we might be interested in how labor demand responds to changes in the wage rate and plot $\ell(5, w, 10)$, or

how labor demand responds to output price changes ($\ell(p, 20, 10)$) or changes in the rental rate ($\ell(5, 20, r)$). The relationships between output supply and price as well as input demand and each input’s price are graphed in Graph 12.12. These are commonly known as output supply and input demand curves, and they represent the inverse of the “slices” $x(p, 20, 10)$, $\ell(5, w, 10)$, and $k(5, 20, r)$.

EXERCISE 12B.13*

Each panel of Graph 12.12 illustrates one of three inverse “slices” of the respective function through the production plan ($x = 1280, \ell = 128, k = 256$). What are the other two slices for each of the three functions? Do they slope up or down?

12B.3 Cost Minimization on the Way to Profit Maximization

So far, we have treated the mathematics of the producer’s problem by solving it in one shot as a single profit maximization problem. In deriving the cost curves we used in Section A to illustrate profit maximization, however, we instead imagined that a producer first determines how much it would cost to produce each output level in an economically efficient way and then uses this information to find the profit-maximizing output quantity (by setting price equal to marginal cost). We first illustrated this two-step method of profit-maximizing in Section 11A.5 for the single-input case and then showed in part A of this chapter how to extend the logic to the two-input case. The defining difference between the single-input and two-input cases was found in the fact that technologically efficient production plans are by default economically efficient in the single-input model but not in the two-input model because when there are two inputs, there are typically many technologically efficient ways of producing each output level, only one of which is usually economically efficient given the relevant prices for labor and capital. We will now show this mathematically.

12B.3.1 Extending Cost Minimization to Multiple Inputs For the single-input case, we illustrated the steps involved in calculating the output supply function in equations (11.17) through (11.21). The sequence of steps for accomplishing the same in the multiple-input case

GRAPH 12.12 Inverse of (a) $x(p, 20, 10)$, (b) $\ell(5, w, 10)$, and (c) $k(5, 20, r)$ when $f(\ell, k) = 20\ell^{2/5}k^{2/5}$

differs only up to the derivation of the cost function in equation (11.18), with the remaining steps essentially the same. This is analogous to what we concluded graphically in Graph 12.8 where we developed a new way of deriving the (total) cost curve in panel (b) but then derived the supply curve in panel (c) exactly as we would have had the cost curve represented a single-input production process.

More precisely, since there are now many different technologically efficient ways of producing any output level, the derivation of the cost function now requires us to determine the economically most efficient input bundle on each isoquant (rather than simply inverting the production function as we did in Chapter 11 for the single-input case). The process we described in Section A for accomplishing this graphically had us imagine that we try to determine the smallest possible budget under which a producer could produce each level of output; or, in the language of our graphical development, the lowest isocost to reach each isoquant. Put into mathematical language, we can express this process as a constrained minimization problem in which we are attempting to ascertain the minimum cost necessary to reach each of the isoquants from our production function; that is,

$$\min_{\ell, k} C = w\ell + rk \text{ subject to } x = f(\ell, k). \quad (12.34)$$

The Lagrange function is then given by

$$\mathcal{L}(\ell, k, \lambda) = w\ell + rk + \lambda(x - f(\ell, k)), \quad (12.35)$$

with first order conditions

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \ell} &= w - \lambda \frac{\partial f(\ell, k)}{\partial \ell} = 0, \\ \frac{\partial \mathcal{L}}{\partial k} &= r - \lambda \frac{\partial f(\ell, k)}{\partial k} = 0, \\ \frac{\partial \mathcal{L}}{\partial \lambda} &= x - f(\ell, k) = 0. \end{aligned} \quad (12.36)$$

Taking the negative terms in the first two equations to the other side and dividing the two equations by each other, we get

$$\frac{w}{r} = \frac{\partial f(\ell, k) / \partial \ell}{\partial f(\ell, k) / \partial k} = -TRS \text{ or } TRS = -\frac{w}{r}, \quad (12.37)$$

precisely what we concluded intuitively in Graph 12.7a where we graphically illustrated the process of minimizing the cost of producing 100 units of output and concluded that the economically efficient input bundle *A* had the property that the slope of the isoquant (or the technical rate of substitution (*TRS*)) is equal to the slope of the isocost ($-w/r$).

From the three equations in (12.36), we can now calculate the amount of labor and capital input that a cost-minimizing producer will purchase under different economic environments in the input market (w, r) conditional on the level of output x the producer wants to reach. Put differently, we can derive the functions

$$\ell(w, r, x) \text{ and } k(w, r, x) \quad (12.38)$$

that are known as *conditional input demand functions*. The name derives from the fact that these functions tell us how much labor and capital a producer will hire at prevailing wage and rental rates conditional on producing x units of the output. In Graph 12.8a, for instance, the conditional labor and capital input demands for producing 40 units of the output when $w = 20$ and $r = 10$ are given by the input bundle *B*: 5 labor hours and 10 units of capital. A full graphical derivation of conditional input demand is not, however, included in part A of this chapter but is provided in Chapter 13 in Graph 13.2.

The conditional input demand functions that emerge from cost minimization tell us the least cost input bundle for any level of output.

EXERCISE 12B.14* Did we calculate a “conditional labor demand” function when we did cost minimization in the single-input model?

EXERCISE 12B.15 Why are the conditional input demand functions not a function of output price p ?

The cost function is derived directly from the conditional input demand functions that emerged from the cost-minimization problem.

It is then easy to calculate the lowest possible cost at which a producer can produce 40 units of output at these input prices: simply multiply the input quantities demanded by their respective prices and add up the total expenses for labor and capital. This then gives us a cost of \$200 and one point on the cost curve in Graph 12.8b. More generally, if we know the conditional input demand functions, we can similarly derive the (total) cost function $C(w, r, x)$ that tells us the minimum cost of producing any output level for any set of input prices:

$$C(w, r, x) = w\ell(w, r, x) + rk(w, r, x). \quad (12.39)$$

Once we know the cost function, we can proceed exactly as in the single-input case to calculate the marginal cost function $MC(w, r, x)$ and the average cost function $AC(w, r, x)$ and derive the output supply $x(p, w, r)$ by setting price equal to marginal cost when price is above average cost. Finally, by then plugging this supply function back into the conditional input demands, we can derive the actual (rather than the conditional) input demand functions.

12B.3.2 An Example Continued Consider, for example, the same production function $f(\ell, k) = 20\ell^{2/5}k^{2/5}$ that we used in Section 12B.2.3 to derive output supply and input demand directly from the profit maximization problem. Using the cost minimization approach, we first define the problem as in equation (12.34)

$$\min_{\ell, k} c = w\ell + rk \text{ subject to } x = 20\ell^{2/5}k^{2/5}. \quad (12.40)$$

The Lagrange function is then given by

$$\mathcal{L}(\ell, k, \lambda) = w\ell + rk + \lambda(x - 20\ell^{2/5}k^{2/5}), \quad (12.41)$$

with first order conditions

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \ell} &= w - 8\lambda\ell^{-3/5}k^{2/5} = 0, \\ \frac{\partial \mathcal{L}}{\partial k} &= r - 8\lambda\ell^{2/5}k^{-3/5} = 0, \\ \frac{\partial \mathcal{L}}{\partial \lambda} &= x - 20\ell^{2/5}k^{2/5} = 0. \end{aligned} \quad (12.42)$$

Taking the negative terms in the first two equations to the other side and dividing the equations by one another, we get

$$\frac{w}{r} = \frac{k}{\ell} \text{ or just } k = \frac{w}{r}\ell. \quad (12.43)$$

Substituting the latter into the third first-order condition and solving for ℓ , we then get the conditional labor demand function

$$\ell(w, r, x) = \left(\frac{r}{w}\right)^{1/2} \left(\frac{x}{20}\right)^{5/4}, \quad (12.44)$$

and substituting this back into (12.43), we can solve for the conditional capital demand function

$$k(w, r, x) = \left(\frac{w}{r}\right)^{1/2} \left(\frac{x}{20}\right)^{5/4}. \quad (12.45)$$

Suppose you are determined to produce a certain output quantity \bar{x} . If the wage rate goes up, how will your production plan change? What if the rental rate goes up?

EXERCISE 12B.16

The cost function is then simply the sum of the conditional input demands multiplied by input prices, or

$$C(w, r, x) = w\ell(w, r, x) + rk(w, r, x) = 2(wr)^{1/2} \left(\frac{x}{20}\right)^{5/4}. \quad (12.46)$$

Once we have a cost function, we can easily calculate marginal and average costs as

$$MC(w, r, x) = \frac{\partial C(w, r, x)}{\partial x} = \frac{(wr)^{1/2}}{8} \left(\frac{x}{20}\right)^{1/4} \quad \text{and} \quad (12.47)$$

$$AC(w, r, x) = \frac{C(w, r, x)}{x} = \frac{(wr)^{1/2}}{10} \left(\frac{x}{20}\right)^{1/4}.$$

Since the Cobb–Douglas production function we used has decreasing returns to scale, $MC = AC$ when $x = 0$ and $AC < MC$ for all $x > 0$, which implies that both MC and AC curves emanate from the origin and slope up, with MC always lying above AC . Setting MC equal to price and solving for x , we then get

$$x(p, w, r) = 20 \frac{(8p)^4}{(wr)^2} = 81920 \frac{p^4}{(wr)^2} \quad (12.48)$$

just as we did in equation (12.33) from the direct profit maximization problem. Similarly, when we now plug $x(p, w, r)$ from equation (12.48) into the conditional input demands in equations (12.44) and (12.45), we get

$$\ell(p, w, r) = \frac{(8p)^5}{r^2 w^3} \quad \text{and} \quad k(p, w, r) = \frac{(8p)^5}{w^2 r^3}, \quad (12.49)$$

which we had previously derived as the actual input demand functions in equations (12.31) and (12.32). As expected, the two-step approach that first minimizes costs and then sets price equal to marginal cost yields the same output supply and input demand functions as the one-step profit maximization problem.

Two-step profit maximization (via cost minimization) leads to the same input demand and output supply functions as one-step profit maximization.

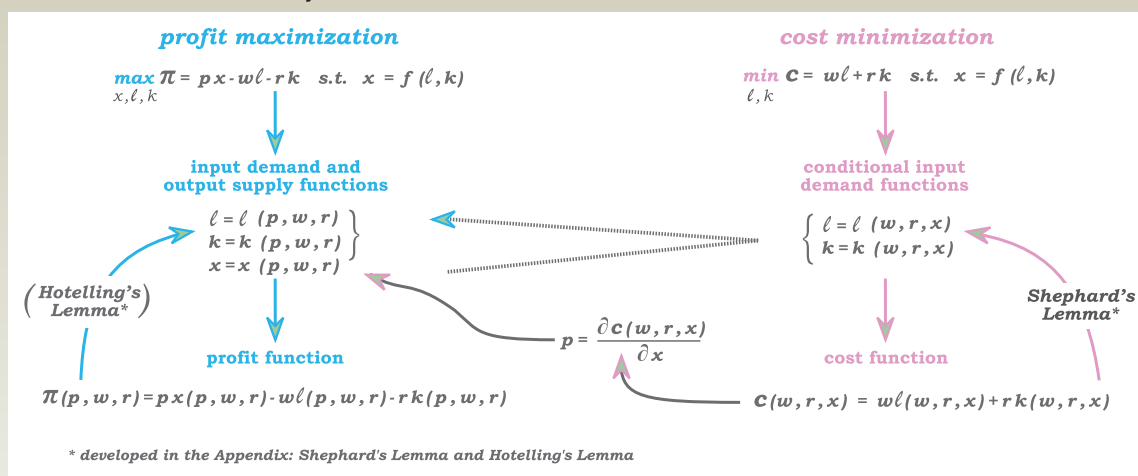

12B.4 Duality in Producer Theory

At this point, it has probably become obvious to you that there is a “duality” picture that emerges in producer theory just as there was in consumer theory in Chapter 10. In the case of consumers, the picture (Graph 10.12) had the utility maximization problem on the left-hand side and the expenditure minimization problem on the right. In the producer case, the duality picture presented in Graph 12.13 has profit maximization on the left-hand side and cost minimization on the right.

In comparing the consumer duality picture with the producer duality picture, a striking similarity emerges on the right-hand side: *the consumer expenditure minimization problem is identical to the producer cost minimization problem*, with goods prices (p_1, p_2) replaced by input prices (w, r) , the consumer goods bundle (x_1, x_2) replaced by the producer input bundle (ℓ, k) , and the utility function u replaced by the production function f . Notice that the

Cost minimization for producers is exactly analogous to expenditure minimization for consumers.

GRAPH 12.13 "Duality" of Profit Maximization and Cost Minimization

compensated (or Hicksian) demand functions in consumer theory are analogous to conditional input demand functions in producer theory, with the former telling us the consumption bundle a consumer would buy at different output prices assuming he or she always has just enough money to reach a given indifference curve (or utility level) and the latter telling us the input bundle a producer would buy at different input prices assuming he or she always has just enough money to reach a given isoquant (or output level). Similarly, the expenditure function in consumer theory is exactly analogous to the cost function in producer theory, with the former telling us the minimum expenditure necessary at different output prices for a consumer always to reach utility level u and the latter telling us the minimum cost necessary at different input prices for a producer always to reach output level x .

The left-hand side of the duality picture for producers differs, however, from what we developed for consumers. We have now stated the fundamental difference repeatedly: The utility function in consumer theory is the objective function under utility maximization while the production function in producer theory is the constraint under profit maximization. On the right-hand side of the picture, we demonstrated in our development of consumer theory that compensated demand curves incorporated only substitution effects. Since the right-hand side is identical for producers, we will see in the next chapter similar substitution effects for conditional input demands. In addition, consumer theory is complicated by income effects on the left-hand side of the picture, but these only arise because the utility function is maximized subject to a budget constraint. Producers face no such budget constraints; if they can make a profit by producing, the revenues pay for the costs. Thus, income effects will not appear in our discussion of producer theory as these do not emerge on the left-hand side of the producer duality picture.

Substitution effects analogous to those in consumer theory emerge for firms, but there is no income effect in producer theory.

CONCLUSION

In this chapter, we have moved from single-input production processes to technologies that permit two (or, in terms of the mathematics, multiple) inputs. Just as in Chapter 11, firms are still assumed to choose production plans with the goal of maximizing profit, but, with more than one input, they now face trade-offs between labor and capital depending on how much each costs.

Each level of output can now be produced through many different combinations of labor and capital, a fact we depicted graphically in the three-dimensional producer choice set. And we showed that there are three economically meaningful ways of “slicing” the three-dimensional production frontier:

1. Vertical slices that hold one input fixed give rise to short-run production frontiers, with marginal product of the input emerging as the slope;
2. Horizontal slices that hold output fixed give rise to isoquants, with the technical rate of substitution emerging as the slope; and
3. Vertical slices along rays from the origin give rise to slices along which cost-minimizing production plans lie, with the shape of the slices illustrating returns to scale.

The one-step profit maximization problem becomes graphically challenging with multiple inputs, but the two-step approach we introduced from Chapter 11 extends naturally to the two-input case. This second method for analyzing profit-maximizing choices by producers views producers as first finding the minimum cost of producing various levels of output and then choosing how much to produce in part based on the results from cost minimization and in part based on the level of output prices. The two methods—direct profit maximization and profit maximization via cost minimization—were also developed mathematically, and we demonstrated that these methods will result in the same ultimate behavioral predictions of what producers will do under different circumstances. Along the way, we developed ways of modeling multi-input production technologies in graphs of isoquants that have much in common with consumer indifference curves but that also have some quite different economic interpretations associated with them. Concepts like marginal product and returns to scale were not meaningful properties of utility functions and consumer indifference curves while they do become meaningful for production functions and isoquants. We will next proceed to a more careful look at how producer choices change as economic circumstances change.

APPENDIX: PROPERTIES OF EXPENDITURE AND PROFIT FUNCTIONS

In our development of the duality picture for producers in Graph 12.13, we have already noted that the right-hand side of this picture is identical (aside from notation) to the right-hand side of the consumer duality picture in Graph 10.12. As a result, the properties of compensated demand functions in consumer theory are identical to the properties of conditional input demand functions in producer theory, and the properties of the expenditure function in consumer theory are identical to the properties of the cost function in producer theory. Thus, the application of the Envelope Theorem to expenditure minimization in the Appendix to Chapter 10 could be repeated almost verbatim here, but we will leave this as an exercise. We can simply note that we know from our work in the Appendix to Chapter 10 that *Shephard's Lemma* holds in producer theory and can be expressed as

$$\frac{\partial C(w, r, x)}{\partial w} = \ell(w, r, x) \quad \text{and} \quad \frac{\partial C(w, r, x)}{\partial r} = k(w, r, x). \quad (12.50)$$

We furthermore know by analogy to the consumer expenditure minimization problem that the cost function $C(w, r, x)$ is concave in w and r . As a result, we know that conditional input demands always slope down; that is,

$$\frac{\partial \ell(w, r, x)}{\partial w} \leq 0 \quad \text{and} \quad \frac{\partial k(w, r, x)}{\partial r} \leq 0. \quad (12.51)$$

Can you replicate the graphical proof of the concavity of the expenditure function in the Appendix to Chapter 10 to prove that the cost function is concave in w and r ?

**EXERCISE
12B.17***

What is the elasticity of substitution between capital and labor if the relationships in equation (12.51) hold with equality?

**EXERCISE
12B.18***

The left-hand sides of the duality pictures for consumers and producers, however, are different, which means we cannot simply apply what we know from utility maximization to profit maximization.

The Profit Function and Hotelling’s Lemma

We can, however, apply the Envelope Theorem once again to prove a relationship analogous to Roy’s Identity from the consumer duality picture. Applying this theorem (as we did twice in the Appendix to Chapter 10) to the profit maximization problem on the left side of Graph 12.13 leads to the following, known as *Hotelling’s Lemma*:

$$\frac{\partial \pi(p, w, r)}{\partial p} = x(p, w, r), \quad \frac{\partial \pi(p, w, r)}{\partial w} = -\ell(p, w, r) \quad \text{and} \quad \frac{\partial \pi(p, w, r)}{\partial r} = -k(p, w, r), \quad (12.52)$$

where $\pi(p, w, r)$ is the *profit function* that tells us, for any set of prices, how much profit will be made by a profit-maximizing price taker. (This profit function, as the one defined in Chapter 11, is simply $\pi = px(p, w, r) - w\ell(p, w, r) - rk(p, w, r)$.)

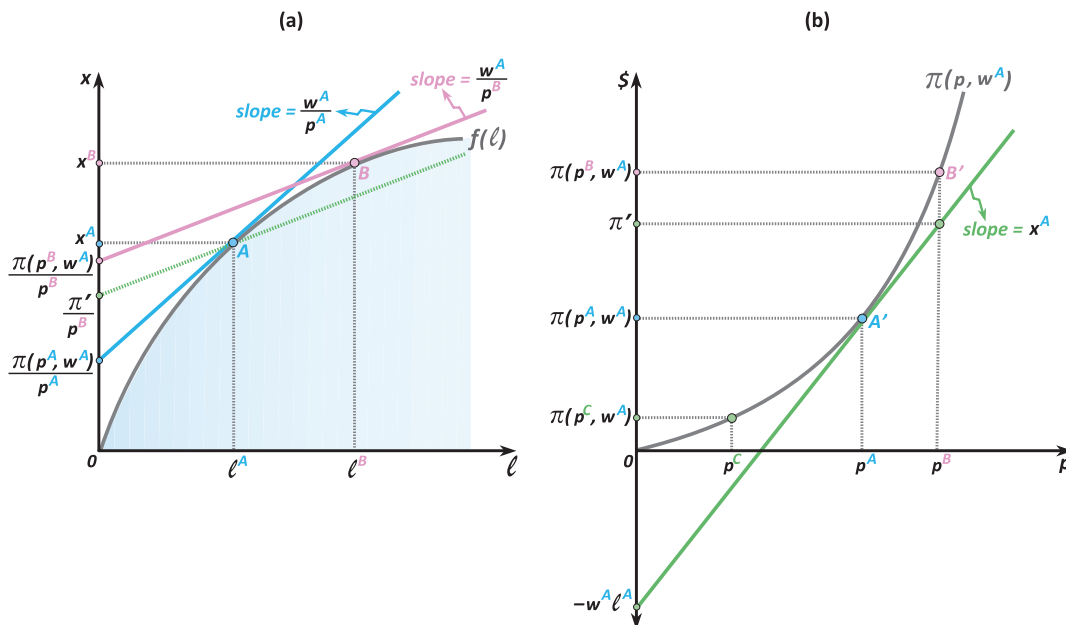

EXERCISE 12B.19*

Demonstrate how these indeed result from an application of the Envelope Theorem.

As we did in the case of expenditure functions, we can get some of the intuition for why these equations hold from some graphical development. It is easiest to do this in the context of the single-input model, but the same logic holds when there are multiple inputs.

Suppose, for instance, we know that, when I face the economic environment (p^A, w^A) , my optimal production plan is (x^A, ℓ^A) , giving me profit $\pi(p^A, w^A) = p^A x^A - w^A \ell^A$. In panel (a) of Graph 12.14, we illustrate this using an underlying production function $f(\ell)$, with the optimal production plan A illustrated as the tangency of the (blue) isoprofit containing price p^A and wage w^A with the production function. In panel (b) of the graph, the point A' then represents one point on the “slice” of the profit function $\pi(p, w^A)$ that holds wage fixed at w^A .

GRAPH 12.14 Convexity (in Output Price) of the Profit Function and Hotelling’s Lemma

Now suppose that the price rises to p^B . If I do not alter my production plan and stick with the plan (x^A, ℓ^A) , my profit will be $\pi' = p^B x^A - w^A \ell^A$, which lies on a line (represented by the green line in panel (b) of the graph) with intercept $(-w^A \ell^A)$ and slope x^A . As a producer who is not responding to the changes in my economic environment, I therefore experience an increase in my profit from $\pi(p^A, w^A)$ to π' simply by being able to sell my output at a higher price than before. In addition, however, panel (a) of the graph shows that my profit-maximizing production plan does *not* stay the same when the output price rises from p^A to p^B —it changes from (x^A, ℓ^A) to (x^B, ℓ^B) , which results in profit $\pi(p^B, w^A) > \pi'$. Thus, at p^B , $\pi(p^B, w^A)$ lies above the green line in panel (b) of Graph 12.14.

How can you tell from panel (a) of the graph that $\pi(x^B, \ell^B) > \pi' > \pi(x^A, \ell^A)$?

EXERCISE
12B.20*

You can similarly show that, when price falls to p^C , $\pi(x^C, \ell^C)$ is greater than the profit indicated by the green line in panel (b) of Graph 12.14, which represents a producer who does not respond to the price change but continues to produce at the original production plan (x^A, ℓ^A) .

The shape of the slice of the profit function $\pi(p, w^A)$ (which holds wage fixed at w^A) that emerges from this analysis is that of a convex function, letting us conclude that *the profit function is convex in the output price*. Furthermore, the slope of this function at p^A is $x^A = x(p^A, w^A)$, or, put differently,

$$\frac{\partial \pi(p^A, w^A)}{\partial p} = x(p^A, w^A), \tag{12.53}$$

exactly consistent with Hotelling’s Lemma. The same argument holds more generally for multi-input production processes where we can show that the “slice” $\pi(p, w^A, r^A)$ must be convex in p because producers who respond to changes in price will always make more profit than producers who do not (and whose profit can be illustrated on a line such as the green line in Graph 12.14b).

You can furthermore demonstrate that slices of the profit function $\pi(p^A, w)$ that hold output price constant and vary w are also convex, although, unlike the slice that varies output price (as in Graph 12.14b), $\pi(p^A, w)$ is downward sloping. Suppose again that the economic environment is described by (p^A, w^A) and that the optimal production plan in this environment is (x^A, ℓ^A) , giving a profit of $\pi(p^A, w^A) = p^A x^A - w^A \ell^A$. In Graph 12.15, point A' is the same point as A' in Graph 12.14b but viewed from a different angle (with w rather than p on the horizontal axis). Now suppose that wage increases to w^B and the producer does not change behavior. Then profit will be $\pi'' = p^A x^A - w^B \ell^A$, which lies on the blue line in the graph, a

GRAPH 12.15 Convexity (in Input Prices) of the Profit Function and Hotelling’s Lemma

line with intercept $p^A x^A$ and slope $-\ell^A$. A producer who responds to changes in the economic environment will make at least as much profit as one who does not (but typically will make more profit). Thus, $\pi(p^A, w^B) \geq \pi^n$. The same logic applied to a wage decrease to w^C suggests that $\pi(p^A, w^C)$ will also lie above the blue line. As a result, the slice of the profit function that holds price constant and varies w is a downward-sloping and convex function, with

$$\frac{\partial \pi(p^A, w^A)}{\partial w} = -\ell(p^A, w^A), \quad (12.54)$$

as suggested by Hotelling’s Lemma. Again, the logic extends straightforwardly to multiple inputs.

EXERCISE 12B.21*

Use a graph similar to that in panel (a) of Graph 12.14 to motivate Graph 12.15.

END-OF-CHAPTER EXERCISES

- 12.1†** In our development of producer theory, we have found it convenient to assume that the production technology is homothetic.
- A.** In each of the following, assume that the production technology you face is indeed homothetic. Suppose further that you currently face input prices (w^A, r^A) and output price p^A , and that, at these prices, your profit-maximizing production plan is $A = (\ell^A, k^A, x^A)$.
- On a graph with ℓ on the horizontal and k on the vertical, illustrate an isoquant through the input bundle (ℓ^A, k^A) . Indicate where all cost-minimizing input bundles lie given the input prices (w^A, r^A) .
 - Can you tell from what you know whether the shape of the production frontier exhibits increasing or decreasing returns to scale along the ray you indicated in (a)?
 - Can you tell whether the production frontier has increasing or decreasing returns to scale around the production plan $A = (\ell^A, k^A, x^A)$?
 - Now suppose that wage increases to w' . Where will your new profit-maximizing production plan lie relative to the ray you identified in (a)?
 - In light of the fact that supply curves shift to the left as input prices increase, where will your new profit-maximizing input bundle lie relative to the isoquant for x^A ?
 - Combining your insights from (d) and (e), can you identify the region in which your new profit-maximizing bundle will lie when wage increases to w' ?
 - How would your answer to (f) change if wage fell instead?
 - Next, suppose that, instead of wage changing, the output price increases to p' . Where in your graph might your new profit-maximizing production plan lie? What if p decreases?
 - Can you identify the region in your graph where the new profit-maximizing plan would lie if instead the rental rate r fell?
- B.** Consider the Cobb–Douglas production function $f(\ell, k) = A\ell^\alpha k^\beta$ with $\alpha, \beta > 0$ and $\alpha + \beta < 1$.
- ** Derive the demand functions $\ell(w, r, p)$ and $k(w, r, p)$ as well as the output supply function $x(w, r, p)$.
 - ** Derive the conditional demand functions $\ell(w, r, x)$ and $k(w, r, x)$.
 - Given some initial prices (w^A, r^A, p^A) , verify that all cost-minimizing bundles lie on the same ray from the origin in the isoquant graph.
 - If w increases, what happens to the ray on which all cost-minimizing bundles lie?
 - What happens to the profit-maximizing input bundles?

*conceptually challenging

**computationally challenging

†solutions in Study Guide

- f. How do your answers change if w instead decreases?
- g. If instead p increases, does the ray along which all cost-minimizing bundles lie change?
- h. Where on that ray will the profit-maximizing production plan lie?
- i. What happens to the ray on which all cost-minimizing input bundles lie if r falls? What happens to the profit-maximizing input bundle?

12.2 We have said that economic profit is equal to economic revenue minus economic cost, where cash inflows or outflows are not “real” economic revenues or costs unless they are in fact impacted by the economic decisions of the firm. Suppose that a firm uses both labor ℓ and capital k in its production of x , and that no output can be produced without at least some of each input.

- A.** In the short run, however, it can only change the level of labor input because it has already committed to a particular capital input level for the coming months. Assume that the firm’s homothetic production process is one that has initially increasing but eventually decreasing returns to scale, and that the marginal product of each input is initially increasing but eventually decreasing. (The full production frontier would then look something like what we have plotted in Graph 12.16.)
 - a. Suppose the firm is currently implementing the profit-maximizing production plan $A = (\ell^A, k^A, x^A)$. Given input prices w and r and output price p , what is the expression for the profit this firm earns?
 - b. Now consider the short run where capital is fixed at k^A . Graph the short-run production function for this firm.
 - c. Add to this graph the slice of the isoprofit plane that is tangent to the production frontier at A . Indicate its slope and vertical intercept.
 - d. Given that we learned in Chapter 11 that the vertical intercept of the isoprofit is equal to profit (along that isoprofit) divided by output price, what does the vertical intercept in your graph suggest is the profit for this firm when viewed from the short-run perspective?
 - e. Explain why the short-run perspective of economic profit differs in this case from the long-run perspective.
 - f. *True or False:* It is possible for a firm to be earning zero profit in the long run but positive profit when viewed from a short-run perspective.

GRAPH 12.16 Production Frontier with Two Inputs

- B.** Suppose that, instead of the production process described in part A, the production frontier is characterized by the Cobb–Douglas production function $x = f(\ell, k) = A\ell^\alpha k^\beta$ with $\alpha + \beta < 1$ and A , α , and β all greater than zero.
- Does this production process have increasing, decreasing, or constant returns to scale?
 - Set up the profit maximization problem.
 - ** Solve this for the optimal production plan.
 - Now consider the short-run profit maximization problem for the firm that is currently employing \bar{k} of capital. Write down the firm’s short-run production function and its short-run profit maximization problem.
 - * Solve for the short-run labor demand and output supply functions.
 - * Suppose that the short-run fixed capital is equal to the long-run optimal quantity you calculated in part (c). Demonstrate that the firm would then choose the same amount of labor in the short run as it does in the long run.
 - Finally, illustrate that profit is larger from the short-run perspective than the long-run perspective.

12.3[†] Consider again the two ways in which we can view the producer’s profit maximization problem.

- A.** Suppose a homothetic production technology involves two inputs, labor and capital, and that its producer choice set is fully convex.
- Illustrate the production frontier in an isoquant graph with labor on the horizontal axis and capital on the vertical.
 - Does this production process have increasing or decreasing returns to scale? How would you be able to see this on an isoquant graph like the one you have drawn?
 - For a given wage w and rental rate r , show in your graph where the cost-minimizing input bundles lie. What is true at each such input bundle?
 - On a separate graph, illustrate the vertical slice (of the production frontier) that contains all these cost-minimizing input bundles.
 - Assuming output can be sold at p^A , use a slice of the isoprofit plane to show the profit-maximizing production plan. What, in addition to what is true at all the cost-minimizing input bundles, is true at this profit-maximizing plan?
 - If output price changes, would you still profit maximize on this vertical slice of the production frontier? What does the supply curve (which plots output on the horizontal and price on the vertical) look like?
 - Now illustrate the (total) cost curve (with output on the horizontal and dollars on the vertical axis). How is this derived from the vertical slice of the production frontier that you have drawn before?
 - Derive the marginal and average cost curves and indicate where in your picture the supply curve lies.
 - Does the supply curve you drew in part (f) look similar to the one you drew in part (h)?
- B.**** Suppose that the production technology is fully characterized by the Cobb–Douglas production function $x = f(\ell, k) = A\ell^\alpha k^\beta$ with $\alpha + \beta < 1$ and A , α , and β all greater than zero.
- Set up the profit maximization problem (assuming input prices w and r and output price p). Then solve for the input demand and output supply functions. (Note: This is identical to parts B(b) and (c) of exercise 12.2, so if you have solved it there, you can simply skip to part (b) here.)
 - Now set up the cost minimization problem and solve for the first order conditions.
 - Solve for the conditional labor and capital demands.
 - Derive the cost function and simplify the function as much as you can. (*Hint:* You can check your answer with the cost function given for the same production process in exercise 12.4.) Then derive from this the marginal and average cost functions.
 - Use your answers to derive the supply function. Compare your answer with what you derived in (a).
 - Finally, derive the (unconditional) labor and capital demands. Compare your answers with those in (a).

12.4 In upcoming chapters, we will often assume that the average cost curve is U-shaped.

- A.** Indicate for each of the following statements whether you believe that the description of the firm's situation would lead to a U-shaped average cost curve.
- The firm's production frontier initially exhibits increasing returns to scale but, beginning at some output quantity \bar{x} , it exhibits decreasing returns to scale.
 - The firm's production frontier initially exhibits decreasing returns to scale but, beginning at some output quantity \bar{x} , it exhibits increasing returns to scale.
 - The firm's production process initially has increasing returns to scale, then, in some interval from \underline{x} to \bar{x} , it has constant returns to scale, followed by decreasing returns to scale.
 - The firm's production process initially has increasing returns to scale, then, in some interval from \underline{x} to \bar{x} , it has constant returns to scale, followed by once again increasing returns to scale.
 - The production process for the firm has decreasing returns to scale throughout, but, before ever producing the first unit of output, the firm incurs annually a fixed cost FC (such as a large license fee) that must be paid if production is to occur.
 - The firm incurs the same annual FC as in (e), but its production process initially has increasing returns to scale before eventually switching to decreasing returns to scale.
- B.** We will explore production processes with initially increasing and eventually decreasing returns to scale in exercises 12.5 and 12.6. Here, we instead focus on exploring the impact of recurring fixed costs (like annual license fees) on the shape of cost curves. Consider, as we did in exercises 12.2 and 12.3, the Cobb–Douglas production function $x = f(\ell, k) = A\ell^\alpha k^\beta$. In exercise 12.3B(d), you should have concluded that the cost function for this production process is

$$C(w, r, x) = (\alpha + \beta) \left(\frac{xw^\alpha r^\beta}{A\alpha^\alpha \beta^\beta} \right)^{1/(\alpha + \beta)}. \quad (12.55)$$

- In problem 12.3, this cost function was derived for the case where $\alpha + \beta < 1$ and A , α , and β are all greater than zero. Is the cost function still valid for the case where $\alpha + \beta \geq 1$?
 - Are marginal and average cost curves for this production process upward or downward sloping? What does your answer depend on?
 - Suppose that the firm incurs a fixed cost FC that has to be paid each period before production starts. How does this change the (total) cost function, the marginal cost function, and the average cost function?
 - Suppose that $\alpha + \beta < 1$. What is the relationship between MC and AC now?
 - How does your answer differ if $\alpha + \beta \geq 1$? What if $\alpha + \beta = 1$?
- 12.5†** In the absence of recurring fixed costs (such as those in exercise 12.4), the U-shaped cost curves we will often graph in upcoming chapters presume some particular features of the underlying production technology when we have more than one input.
- A.** Consider the production technology depicted in Graph 12.16 where output is on the vertical axis (that ranges from 0 to 100) and the inputs capital and labor are on the two horizontal axes. (The origin on the graph is the left-most corner.)
- Suppose that output and input prices result in some profit-maximizing production plan A (that is not a corner solution). Describe in words what would be true at A relative to what we described as an isoprofit plane at the beginning of this chapter.
 - Can you tell whether this production frontier has increasing, constant, or decreasing returns to scale?
 - Illustrate what the slice of this graphical profit maximization problem would look like if you held capital fixed at its optimal level k^A .
 - How would the slice holding labor fixed at its optimal level ℓ^A differ?
 - What two conditions that have to hold at the profit-maximizing production plan emerge from these pictures?
 - * Do you think there is another production plan on this frontier at which these conditions hold?

- g.* If output price falls, the profit-maximizing production plan changes to once again meet the conditions you derived. Might the price fall so far that no production plan satisfying these conditions is truly profit maximizing?
- h.* Can you tell in which direction the optimal production plan changes as output price increases?

B.** Suppose your production technology is characterized by the production function

$$x = f(\ell, k) = \frac{\alpha}{1 + e^{-(\ell-\beta)} + e^{-(k-\gamma)}} \quad (12.56)$$

where e is the base of the natural logarithm. Given what you might have learned in one of the end-of-chapter exercises in Chapter 11 about the function $x = f(\ell) = \alpha/(1 + e^{-(\ell-\beta)})$, can you see how the shape in Graph 12.16 emerges from this extension of this function?

- Set up the profit maximization problem.
- Derive the first order conditions for this optimization problem.
- Substitute $y = e^{-(\ell-\beta)}$ and $z = e^{-(k-\gamma)}$ into the first order conditions. Then, with the first order conditions written with w and r on the right-hand sides, divide them by each other and derive from this an expression $y(z, w, r)$ and the inverse expression $z(y, w, r)$.
- Substitute $y(z, w, r)$ into the first order condition that contains r . Then manipulate the resulting equation until you have it in the form $az^2 + bz + c$ (where the terms a , b , and c may be functions of w , r , α , and p). (*Hint:* It is helpful to multiply both sides of the equation by r .) The quadratic formula then allows you to derive two “solutions” for z . Choose the one that uses the negative rather than the positive sign in the quadratic formula as your “true” solution $z^*(\alpha, p, w, r)$.
- Substitute $z(y, w, r)$ into the first order condition that contains w and then solve for $y^*(\alpha, p, w, r)$ in the same way you solved for $z^*(\alpha, p, w, r)$ in the previous part.
- Given the substitutions you did in part (c), you can now write $e^{-(\ell-\beta)} = y^*(\alpha, p, w, r)$ and $e^{-(k-\gamma)} = z^*(\alpha, p, w, r)$. Take natural logs of both sides to solve for labor demand $\ell(w, r, p)$ and capital demand $k(w, r, p)$ (which will be functions of the parameters α , β , and γ).
- How much labor and capital will this firm demand if $\alpha = 100$, $\beta = \gamma = 5 = p$, $w = 20 = r$? (It might be easiest to type the solutions you have derived into an Excel spreadsheet in which you can set the parameters of the problem.) How much output will the firm produce? How does your answer change if r falls to $r = 10$? How much profit does the firm make in the two cases.
- Suppose you had used the other “solutions” in parts (d) and (e), the ones that emerge from using the quadratic formula in which the square root term is added rather than subtracted. How would your answers to (g) be different, and why did we choose to ignore this “solution”?

12.6 We will now reconsider the problem from exercise 12.5 but will focus on the two-step optimization method that starts with cost minimization.

- A.** Suppose again that you face a production process such as the one depicted in Graph 12.16.
- What do the horizontal slices—the map of isoquants—of this production process look like? Does this map satisfy our usual notion of convexity as “averages better than extremes”?
 - From this map of isoquants, how would you be able to infer the vertical shape of the production frontier? Do you think the producer choice set is convex?
 - Suppose this production frontier is homothetic. For a given set of input prices (w, r) , what can you conclude about how the cost-minimizing input bundles in your isoquant map will be related to one another.
 - What can you conclude about the shape of the cost curve for a given set of input prices?
 - What will the average and marginal cost curves look like?
 - Suppose again that $A = (\ell^A, k^A, x^A)$ is a profit-maximizing production plan at the current prices (and suppose that A is not a corner solution). Illustrate the isoquant that represents the profit-maximizing output quantity x^A . Using the conditions that have to hold for this to be a profit maximum, can you demonstrate that these imply the producer is cost minimizing at A ?
 - Where else does the cost-minimizing condition hold? Do the profit-maximizing conditions hold there as well?

- h. What happens to output as p falls? What happens to the ratio of capital to labor in the production process (assuming the production process is indeed homothetic)?

B.** Consider the same production function as the one introduced in part B of exercise 12.5.

- Write down the problem you would need to solve to determine the least cost input bundle to produce some output level x .
- Set up the Lagrange function and derive the first order conditions for this problem.
- To make the problem easier to solve, substitute $y = e^{-(\ell-\beta)}$ and $z = e^{-(k-\gamma)}$ into the first order conditions and solve for y and z as functions of w, r, x (and α).
- Recognizing that y and z were placeholders for $e^{-(\ell-\beta)}$ and $e^{-(k-\gamma)}$, use your answers now to solve for the conditional input demands $\ell(w, r, x)$ and $k(w, r, x)$.
- Derive from your answer the cost function for this firm; that is, derive the function that tells you the least it will cost to produce any output quantity x for any set of input prices. Can you guess the shape of this function when α, β, γ, w , and r are held fixed?
- Derive the marginal cost function. Can you guess its shape when α, w , and r are held fixed?
- Use your expression of the marginal cost curve to derive the supply function. Can you picture what this looks like when it is inverted to yield a supply curve (with input prices held fixed)?
- In (g) of exercise 12.5, you were asked to calculate the profit-maximizing output level when $\alpha = 100, \beta = \gamma = 5 = p$, and $w = r = 20$. You did so using the input demand functions calculated from the profit maximization problem. You can now use the supply function derived from the cost minimization problem to verify your answer (which should have been 91.23 units of output). Then verify that your answer is also the same as it was before (93.59) when r falls to 10.

12.7[†] Everyday Application: To Study or to Sleep?: Research suggests that successful performance on exams requires preparation (that is, studying) and rest (that is, sleep). Neither by itself produces good exam grades, but in the right combination they maximize exam performance.

- A.** We can then model exam grades as emerging from a production process that takes hours of studying and hours of sleep as inputs. Suppose this production process is homothetic and has decreasing returns to scale.
- On a graph with hours of sleep on the horizontal axis and hours of studying on the vertical, illustrate an isoquant that represents a particular exam performance level x^A .
 - Suppose you are always willing to pay \$5 to get back an hour of sleep and \$20 to get back an hour of studying. Illustrate on your graph the least cost way to get to the exam grade x^A .
 - Since the production process is homothetic, where in your graph are the cost-minimizing ways to get to the other exam grade isoquants?
 - Using your answer to (c), can you graph a vertical slice of the production frontier that contains all the cost-minimizing sleep/study input bundles?
 - Suppose you are willing to pay $\$p$ for every additional point on your exam. Can you illustrate on your graph from (d) the slice of the “isoprofit” that gives you your optimal exam grade? Is this necessarily the same as the exam grade x^A from your previous graph?
 - What would change if you placed a higher value on each exam point?
 - Suppose a new caffeine/ginseng drink comes on the market, and you find it makes you twice as productive when you study. What in your graphs will change?
- B.** Suppose that the production technology described in part A can be captured by the production function $x = 40\ell^{0.25}s^{0.25}$, where x is your exam grade, ℓ is the number of hours spent studying, and s is the number of hours spent sleeping.
- Assume again that you’d be willing to pay \$5 to get back an hour of sleep and \$20 to get back an hour of studying. If you value each exam point at p , what is your optimal “production plan”?
 - Can you arrive at the same answer using the Cobb–Douglas cost function (given in problem 12.4)?
 - What is your optimal production plan when you value each exam point at \$2?
 - How much would you have to value each exam point in order for you to put in the effort and sleep to get a 100 on the exam.

- e. What happens to your optimal production plan as the value you place on each exam point increases?
- f. What changes if the caffeine/ginseng drink described in A(g) is factored into the problem?

12.8 Everyday and Business Application: *Fast Food Restaurants and Grease*: Suppose you run a fast food restaurant that produces only greasy hamburgers using labor that you hire at wage w . There is, however, no way to produce the hamburgers without also producing lots of grease that has to be hauled away. In fact, the only way for you to produce a hamburger is to also produce 1 ounce of grease. You therefore also have to hire a service that comes around and picks up the grease at a cost of q per ounce.

- A.** Since we are assuming that each hamburger comes with 1 ounce of grease that has to be picked up, we can think of this as a single-input production process (using only labor) that produces two outputs, hamburgers and grease, in equal quantities.
- a. On a graph with hours of labor on the horizontal axis and hamburgers on the vertical, illustrate your production frontier assuming decreasing returns to scale. Then illustrate the profit-maximizing plan assuming for now that it does not cost anything to have grease picked up (that is, assume $q = 0$.)
 - b. Now suppose $q > 0$. Can you think of a way of incorporating this into your graph and demonstrating how an increase in q changes the profit-maximizing production plan?
 - c. Illustrate the marginal cost curves with and without q and then illustrate again how the cost of having grease picked up (that is, $q > 0$) alters the profit-maximizing production choice.
 - d. With increasing fuel prices, the demand for hybrid cars that run partially on gasoline and partially on used cooking grease has increased. As a result, fast food chains report that they no longer have to pay to have grease picked up; in fact, they are increasingly being paid for their grease. (In essence, one of the goods you produce used to have a negative price but now has a positive price.) How does this change how many hamburgers are being produced at your fast food restaurant?
 - e. We have done all our analysis under the assumption that labor is the only input into hamburger production. Now suppose that labor and capital were both needed in a homothetic, decreasing returns to scale production process. Would any of your conclusions change?
 - f. We have also assumed throughout that producing 1 hamburger necessarily entails producing exactly 1 ounce of grease. Suppose instead that more or less grease per hamburger could be achieved through the purchase of fattier or less fatty hamburger meat. Would you predict that the increased demand for cooking grease in hybrid vehicles will cause hamburgers at fast food places to increase in cholesterol as higher gasoline prices increase the use of hybrid cars?
- B.** Suppose that the production function for producing hamburgers x is $x = f(\ell) = A\ell^\alpha$ where $\alpha < 1$. Suppose further that for each hamburger that is produced, 1 ounce of grease is also produced.
- a. Set up the profit maximization problem assuming that hamburgers sell for price p and grease costs q (per ounce) to be hauled away.
 - b. Derive the number of hours of labor you will hire as well as the number of hamburgers you will produce.
 - c. Determine the cost function (as a function of w , q , and x).
 - d. Derive from this the marginal cost function.
 - e. Use the marginal cost function to determine the profit-maximizing number of hamburgers and compare your answer with what you got in (b).
 - f. How many hours of labor will you hire?
 - g. How does your production of hamburgers change as grease becomes a commodity that people will pay for (rather than one you have to pay to have hauled away)?

12.9*† Business and Policy Application: *Investing in Smokestack Filters under Cap-and-Trade*: On their own, firms have little incentive to invest in pollution-abating technologies such as smokestack filters. As a result, governments have increasingly turned to “cap-and-trade” programs. Under these programs, discussed in more detail in Chapter 21, the government puts an overall “cap” on the amount of permissible pollution and firms are permitted to pollute only to the extent to which they own sufficient numbers of pollution permits or “vouchers.” If a firm does not need all of its vouchers, it can sell them at a market price p_v to firms that require more.

EVERYDAY APPLICATION

BUSINESS APPLICATION

BUSINESS APPLICATION

POLICY APPLICATION

- A.** Suppose a firm produces x using a technology that emits pollution through smokestacks. The firm must ensure that it has sufficient pollution vouchers v to emit the level of pollution that escapes the smokestacks, but it can reduce the pollution by installing increasingly sophisticated smokestack filters s .
- Suppose that the technology for producing x requires capital and labor and, without considering pollution, has constant returns to scale. For a given set of input prices (w, r) , what does the marginal cost curve look like?
 - Now suppose that relatively little pollution is emitted initially in the production process, but as the factory is used more intensively, pollution per unit of output increases, and thus more pollution vouchers have to be purchased per unit absent any pollution-abating smokestack filters. What does this do to the marginal cost curve assuming some price p_v per pollution voucher and assuming the firm does not install smokestack filters?
 - Considering carefully the meaning of “economic cost,” does your answer to (b) depend on whether the government gives the firm a certain amount of vouchers or whether the firm starts out with no vouchers and has to purchase whatever quantity is necessary for its production plan?
 - Suppose that smokestack filters are such that initial investments in filters yield high reductions in pollution, but as additional filters are added, the marginal reduction in pollution declines. You can now think of the firm as using two additional inputs, pollution vouchers and smokestack filters, to produce output x legally. Does the overall production technology now have increasing, constant, or decreasing returns to scale?
 - Next, consider a graph with “smokestack filters” s on the horizontal and “pollution vouchers” v on the vertical axis. Illustrate an isoquant that shows different ways of reaching a particular output level \bar{x} legally; that is, without polluting illegally. Then illustrate the least cost way of reaching this output level (not counting the cost of labor and capital) given p_v and p_s .
 - If the government imposes additional limits on pollution by removing some of the pollution vouchers from the market, p_v will increase. How much will this affect the number of smokestack filters used in any given firm assuming output does not change? What does your answer depend on?
 - What happens to the overall marginal cost curve for the firm (including all costs of production) as p_v increases? Will output increase or decrease?
 - Can you tell whether the firm will buy more or fewer smokestack filters as p_v increases? Do you think it will produce more or less pollution?
 - True or False:* The cap-and-trade system reduces overall pollution by getting firms to use smokestack filters more intensively and by causing firms to reduce how much output they produce.
- B.** Suppose the cost function (not considering pollution) for a firm is given by $C(w, r, x) = 0.5w^{0.5}r^{0.5}x$, and suppose that the trade-off between using smokestack filters s and pollution vouchers v to achieve legal production is given by the Cobb–Douglas production technology $x = f(s, v) = 50s^{0.25}v^{0.25}$.
- In the absence of cap-and-trade policies, does the production process have increasing, decreasing, or constant returns to scale?
 - Ignoring for now the cost of capital and labor, derive the cost function for producing different output levels as a function of p_s and p_v , the price of a smokestack filter and a pollution voucher. (You can derive this directly or use the fact that we know the general form of cost functions for Cobb–Douglas production functions from what is given in problem 12.4.)
 - What is the full cost function $C(w, r, p_s, p_v, x)$? What is the marginal cost function?
 - For a given output price p , derive the supply function.
 - Using Shephard’s Lemma, can you derive the conditional smokestack filter demand function?
 - Using your answers, can you derive the (unconditional) smokestack filter demand function?
 - Use your answers to illustrate the effect of an increase in p_v on the demand for smokestack filters holding output fixed as well as the effect of an increase in p_v on the profit-maximizing demand for smokestack filters.

12.10 Policy Application: Taxes on Firms: There are several ways in which governments tax firms, including taxes on labor, capital, or profits. As we will see in Chapter 19, it is not at all immediately clear whether taxes on labor or capital are paid by firms even when tax laws specify that firms will pay them. For now, we will simply assume that we know that some share of taxes on inputs are real costs to firms. It is also

**POLICY
APPLICATION**

not clear that governments can easily identify economic profit of firms, or that price-taking firms usually make such profits (as we will see in Chapter 14). Again, we will simply assume these issues away for now.

- A.** Suppose a firm employs labor ℓ and capital k to produce output x using a homothetic, decreasing returns to scale technology.
- Suppose that, at the current wage w , rental rate r and output price p , the firm has identified $A = (x^A, \ell^A, k^A)$ as its profit-maximizing production plan. Illustrate an isoquant corresponding to x^A and show how (ℓ^A, k^A) must satisfy the conditions of cost minimization.
 - Translate this to a graph of the cost curve that holds w and r fixed, indicating where in your isoquant graph the underlying input bundles lie for this cost curve.
 - Show how x^A emerges as the profit-maximizing production level on the marginal cost curve that is derived from the cost curve you illustrated in (b).
 - Now suppose that the government taxes labor, causing the cost of labor for the firm to increase to $(1 + t)w$. What changes in your pictures, and how will this effect the profit-maximizing production plan?
 - What happens if the government instead imposes a tax on capital that raises the real cost of capital to $(1 + t)r$?
 - What happens if instead the government imposes a tax on both capital and labor, causing the cost of capital and labor to increase by the same proportion (that is, to $(1 + t)w$ and $(1 + t)r$)?
 - Now suppose the government instead taxes economic profit at some rate $t < 1$. Thus, if the firm makes pretax profit π , the firm gets to keep only $(1 - t)\pi$. What happens to the firm's profit maximizing production plan?
- B.** Suppose your firm has a decreasing returns to scale, Cobb–Douglas production function of the form $x = A\ell^\alpha k^\beta$ for which you may have previously calculated input, and output demands as well as the cost function. (The latter is also given in problem 12.4.)
- If you have not already done so, calculate input demand and output supply functions. (You can do so directly using the profit maximization problem, or you can use the cost function given in problem 12.4 to derive these.)
 - Derive the profit function for this firm and check that it is correct by checking whether Hotelling's Lemma works.
 - If you have not already done so, derive the conditional input demand functions. (You can do so directly by setting up the cost minimization problem, or you can employ Shephard's Lemma and use the cost function given in problem 12.4.)
 - Consider a tax on labor that raises the labor costs for firms to $(1 + t)w$. How does this affect the various functions in the duality picture for the firm?
 - Repeat for a tax on capital that raises the capital cost for the firm to $(1 + t)r$.
 - Repeat for simultaneous taxes on labor and capital that raise the cost of labor and capital to $(1 + t)w$ and $(1 + t)r$.
 - Repeat for a tax on profits as described in part A(g).

CHAPTER
13

Production Decisions in the Short and Long Run

Suppose you are happily profit maximizing in your firm that produces economist cards using labor and capital.¹ Suddenly you realize that a new government regulation has increased your cost of employing workers. If capital is fixed in the short run, then you now find yourself in the world of Chapter 11, making decisions along a short-run production frontier that has output changing solely with the number of workers you employ. As we have seen in Chapter 11, you will now employ fewer workers and will therefore produce fewer economist cards. But as time passes, your firm will have a chance to make some more decisions because it will have the opportunity to change the amount of capital it is using, and then to reevaluate whether it wants to hire more or fewer workers. Now you begin to find yourself in the world of Chapter 12, where both labor and capital can be adjusted to meet the new economic conditions in the labor market. Your firm's short-run problem, it turns out, is a "slice" of the more complex long-run problem you eventually face as time passes. Between this and the next chapter, our focus now turns to how your firm will transition from the short run (of Chapter 11) to the long run (of Chapter 12) as underlying conditions change.

More generally, we will ask how changes in the *economic* environment will affect the decisions by producers over time. By the "economic environment," we will continue to mean the output and input prices that price-taking producers take as given as they try to do the best they can. In the short run, we will typically assume that capital is fixed and labor is variable, but of course this mirrors an analysis where labor is fixed in the short run and capital is variable. And, we will begin to introduce a new type of "fixed" cost for firms, a cost that is not associated with an input like labor or capital. (We actually first encountered such a "recurring fixed cost" in end-of-chapter exercise 12.4.) Our main focus in this chapter, however, remains on a firm's economic response to changing input and output prices, whereas the next chapter will consider the underlying causes of such changes in prices within a competitive industry.

¹This chapter contains some of the most challenging material in the text, and instructors may wish to be selective about which part(s) to use. Chapters 11 and 12 are necessary reading for this chapter. Analogies to substitution effects in the consumer model (Chapter 7) also appear. Upcoming chapters make use mainly of material in Section 13A.1. Sections 13A.2 and 13A.3 both have intuitive introductory sections that may be sufficient without the more detailed parts of the sections that follow.

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

13A

CHANGES IN PRODUCER BEHAVIOR AS CONDITIONS CHANGE

We have already seen that it is often convenient to view profit-maximizing firms initially as cost minimizers that then use information on output prices to determine the production plan at which the difference between revenues and costs is greatest. As we begin to consider how price-taking firms adapt to changing circumstances in both the short and long run, we will therefore often consider how such changes impact the cost curves of firms. We will also find that insights about cost curves will continue to be important as we move through much of the rest of the book, and we therefore begin here (in Section 13A.1) by spending a bit of time on how cost curves are affected in changing environments. In the remainder of the chapter, we will then proceed to illustrate more directly how changes in prices impact decisions. Upcoming chapters, however, build primarily on the material in Section 13A.1.

13A.1 Different Types of Costs and Expenses in the Short and Long Run

Since we will often use changes in cost curves to arrive at conclusions about a firm’s supply responses, it is essential to understand what affects these cost curves in the short and the long run. *If we define costs correctly, then it will always be the case that a price-taking firm’s supply curve is that part of the marginal cost curve that lies above its average cost curve, regardless of whether we are talking about the short run or the long run.* The most important insight we will have to keep in mind, however, is that only true *economic* costs can affect a firm’s behavior, even if we are tempted to call something a cost when it really isn’t one. And “what counts” as a cost will differ depending on whether we are thinking about the short or long run. Section 13A.1.1 therefore explores the distinction between “costs” and “expenditures” and how this distinction relates to short- and long-run cost curves for firms. It is only after gaining some clarity on this that we can then explore the different types of costs (and expenditures) and the impact that changing costs and expenditures have on the firm’s short- and long-run supply of output.

If we define costs correctly, then the firm’s supply curve is always that portion of MC that lies above AC —both in the short and long run.

13A.1.1 Costs versus Expenses Consider again your economist card business and the increased labor costs that you are experiencing from some new labor regulation. Suppose we would like to use the picture of your short-run cost curves to determine what you will do immediately in response to the increased labor costs. We know that you have committed to a certain amount of capital, say $k = 100$, in the short run, which means you will have to write a check for $\$100r$ to pay for this capital. There is no doubt that you’d prefer not to have to write this check, but the question we have to confront as we decide whether to include $\$100r$ as a cost in our analysis is not whether you like writing checks. The question is whether writing this particular check is at all impacted by your decision of whether to produce more or less (or not at all). And the answer is that once you have committed to rent the 100 units of capital in the short run, you have to write the check for $\$100r$ *regardless* of what decisions you make in your firm, even if you decide not to use any of the capital. This means that your expense on the 100 units of capital is *not* a real cost of doing business in the short run; it is not an *economic* cost that affects your short run decisions in any way. For this reason it is often called a “*sunk* cost,” “sunk” in the sense that you have to pay it no matter what you do.

Sunk costs are expenses that firms incur no matter what production plan they choose or whether they choose to produce at all.

There is much confusion that arises in microeconomics courses because we often slip into the bad habit of using the term “cost” when we don’t actually mean “economic cost.” We will try to avoid this confusion by adopting the following convention: Whenever the expenses we refer to are 100% true economics costs (such as the short-run cost of labor in our example), we will

call them “costs.” But if the expenses include sunk “costs” (such as the check you write for the capital you committed to in our example), we will call them “expenditures” or “expenses” (even if some fraction of them represents real costs). Sometimes, textbooks will differentiate between “economic” and “accounting” costs, with “accounting costs” being similar to what we simply call expenses that are not economic costs.

So let’s return to our example where your current capital is fixed at $k = 100$ but labor can be adjusted as you are free to hire and fire workers in the short run. Panel (a) of Graph 13.1 illustrates the short-run *cost* curve $C_{k=100}$ that is relevant for the short-run decisions your firm makes when it cannot vary the level of capital it is using. If we want to illustrate the total checks you write in your firm, including the wages you pay to your workers as well as the expense of renting the capital, we can do so by showing the fixed expense on capital $FE_{k=100} = \$100r$ on the vertical axis. Even if the firm produces nothing, it will incur this expense, and the expense does not change as you start producing. The rest of the total expenditure curve $TE_{k=100}$ then simply lies exactly $\$100r$ above the $C_{k=100}$ curve, and it includes real economic costs as well as (sunk)

GRAPH 13.1 Short-Run Expenditure and Cost Curves

expenditures. For this reason, we call it an “expenditure curve” because it is polluted by expenses that are not real economic costs in the short run and are therefore “sunk” or “irrelevant” as you make short-run decisions.²

Panel (b) of Graph 13.1 then translates these curves into marginal and average cost (and expenditure) curves. Since the fixed expenditures have to be paid even if we produce no output, they are never an *additional* cost (or expense) incurred from producing one more unit of the output. The marginal cost curve $MC_{k=100}$, defined as the *additional* cost incurred from producing additional units of output when capital is fixed at 100, thus does *not* include the fixed expenditure of renting the 100 units of capital. It is simply the slope of the $C_{k=100}$ curve (just as it was in previous chapters). Similarly, the *average cost curve* ($AC_{k=100}$) that begins at roughly the intercept of the marginal cost curve represents only true economic costs given that capital is fixed at 100. Finally, the *average expenditure curve* ($AE_{k=100}$), derived from the $TE_{k=100}$ curve in panel (a), has an intercept that lies $FE_{k=100}$ above the intercept of the other two curves because at the first unit of output, the difference between the average cost and the average expenditure is exactly equal to the difference between true cost and total expenditure. As production increases, however, the $AE_{k=100}$ curve gets closer and closer to the $AC_{k=100}$ curve because the *average* fixed expenditure declines as output increases. At the output level x^A , for instance, the *average* fixed expenditure per unit of output is equal to the vertical distance between point A and A' and can be mathematically represented simply as $FE_{k=100}/x^A = \$100r/x^A$. When we then multiply this average fixed expenditure by the output level x^A , the shaded area in the graph is equal to $FE_{k=100} = \$100r$ just as the similarly labeled distance at the intercept.

EXERCISE 13A.1 Can you find similar rectangular areas that are equal to $FE_{k=100}$ for other output levels? Given that these rectangular areas have to be equal to one another, can you see why the AC and AE curves must be getting closer and closer as output rises?

EXERCISE 13A.2 Can you explain why the MC curve intersects both the AC and the AE curves at their lowest points?

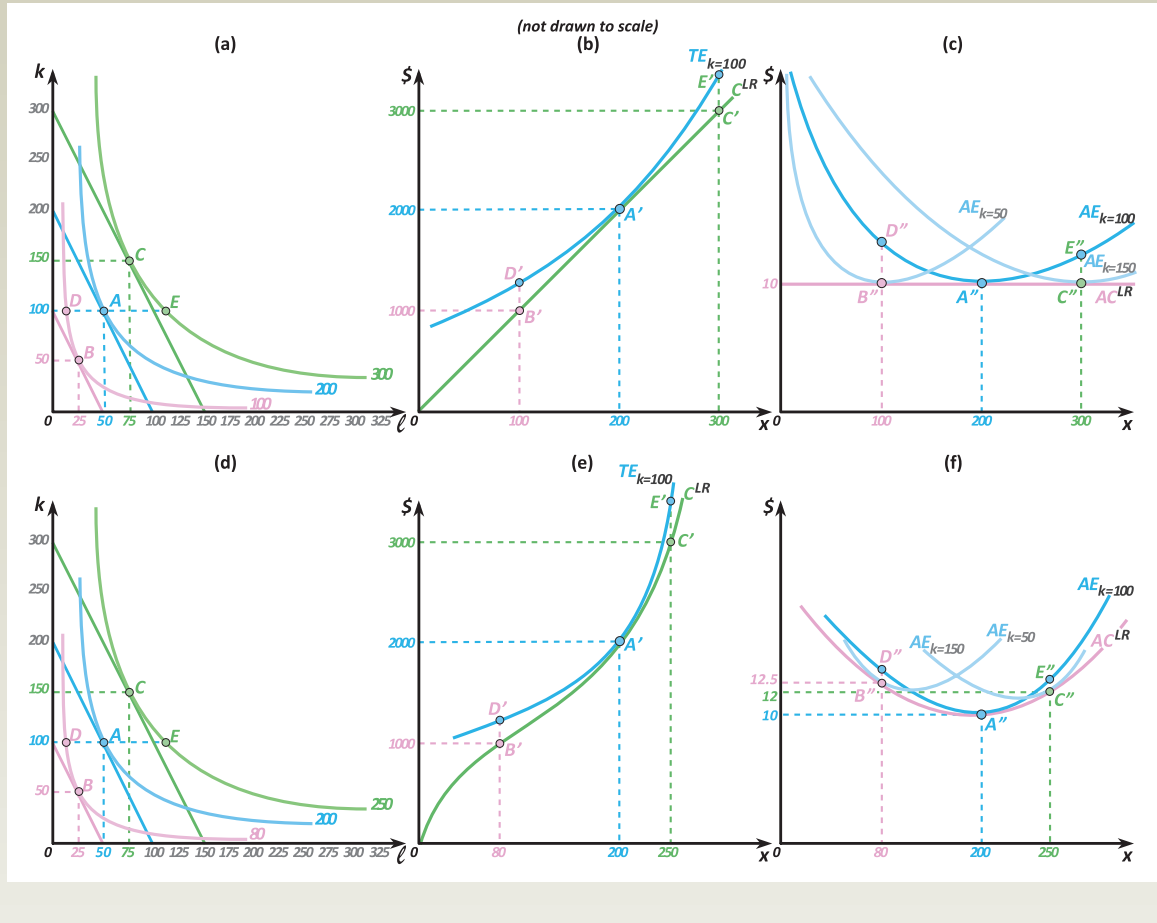

EXERCISE 13A.3 Where in the graph would you locate the “marginal expenditure” curve (derived from the total expenditure curve)?

13A.1.2 Short-Run Expenditure and Long-Run Cost Curves Since the difference between the short run and the long run is that firms have more opportunities to adjust the input bundles in the long run, it would seem intuitive that costs might be higher in the short run due to less flexibility in choosing the right mix of inputs. This is true in the sense that the total *expenditures* on inputs will indeed never be lower in the short run than the long-run *cost* of production.

To see this, consider the case where I face the production technology represented by the isoquants in Graph 13.2a and suppose again that capital is my fixed input in the short run while labor hours can be varied easily. Suppose further that I again just signed a lease for $k^A = 100$ units of capital equipment, committing me to pay a weekly rental rate of $r = 10$ per unit for the next year. At the time I signed this lease, I intended to produce 200 units of output per week, and I picked the units of capital I am renting to give me the least cost input bundle (together with $\ell^A = 50$ labor

²Other textbooks refer to the fixed expenditures as “fixed costs” even though they are sunk in the short run, and they call our TE expenditure curve a “total cost” curve even though it includes sunk costs. To differentiate such “total costs” from the real economic costs, such treatments then call the real cost curve a “variable cost curve.”

GRAPH 13.2 Short-Run Expenditure versus Long-Run Cost Curves

hours) for producing 200 output units assuming a wage rate of $w = 20$. This is graphed in panel (a) of Graph 13.2 as the input bundle A on the (blue) isoquant for 200 units of output.

Now suppose that I change my mind and want to produce 100 instead of 200 units of output. Ideally, I would like to reduce both my labor and capital inputs to reach the least cost way of producing 100 units of output as represented by input bundle B, and in the long run that is precisely what I will do. But in the short run, I have already committed to rent 100 units of capital, which implies that I will use the input bundle D instead of B in the short run. Similarly, if I change my mind again and want to produce 300 units of the output instead, I will choose input bundle E in the short run even though I will choose input bundle C in the long run. Notice that I am constrained in the short run to operate on the slice of my isoquant picture that keeps capital fixed at 100 units.

In panel (b) of the graph, we then plot the costs and expenditures necessary to pay for the input bundles labeled in panel (a) while continuing to assume that the rental rate of capital is \$10 and the wage rate is \$20. The input bundle A, for instance, employs 50 hours of labor and 100 units of capital costing a total of \$2,000. Since the input bundle A results in output of 200, panel (b) of the graph plots the total long-run cost of producing 200 units of output as \$2,000. We can

similarly derive the total long-run cost of producing 100 units of output using the input bundle B and 300 units of output using the input bundle C . Since the input bundles A , B , and C all represent the least cost ways of producing different quantities of the output *assuming we can adjust both labor and capital*, the corresponding points A' , B' , and C' in panel (b) represent points on the long-run (total) cost curve.

EXERCISE 13A.4 Can you tell from the shape of the long-run (total) cost curve whether the production process has increasing, decreasing, or constant returns to scale?

The short-run expense of producing a given level of output can never be lower—and is usually higher—than the long-run cost of producing that output level.

In the short run, however, I have exactly the right quantity of capital to produce 200 units of output in the least costly way, which means I will incur a greater overall *expense* for the inputs labor and capital if I try to produce more or less than 200 units of output. You can see this immediately in panel (a) of Graph 13.2 by noticing that the input bundle D (which uses 100 units of capital to produce 100 units of output) lies above the isocost line containing input bundle B and thus requires a greater overall “budget” to produce 100 units of output than is necessary in the long run. The same is true for input bundle E . As a result, if I have exactly 100 units of capital in the short run, I will incur higher expenditures on inputs in the short run than in the long run unless I produce exactly 200 units of output. Panel (c) then shows the same for the average cost and expenditure curves, with the long-run AC curve below the short-run $AE_{k=100}$ curve when capital is held fixed at 100 units.

I could, of course, derive short-run total and average expenditure curves assuming some other fixed level of capital, and in each case I would conclude that the short-run expense of production will be higher than the long-run cost except for the level of output for which the fixed level of capital is exactly the “right” level in the long run. The lighter-colored average expenditure curves in panel (c) illustrate this for the case when capital is fixed at 50 and 150 units.

The lower set of panels of Graph 13.2 then repeat the same derivation of short-run expenditure and long-run cost curves from a production technology that has the same shapes but different labeling of isoquants. The new labels turn the previous constant returns to scale production process in panel (a) into a production process that initially exhibits increasing but eventually decreasing returns to scale.

EXERCISE 13A.5 Verify the derivation of cost curves in panels (e) and (f) in Graph 13.2. In what sense is the relationship between short-run expenditure and long-run cost curves similar in this case to the case we derived in the top panels of the graph for constant returns to scale production processes?

EXERCISE 13A.6 Where would you find the long-run marginal cost curve in panel (f) of the Graph?

EXERCISE 13A.7* A textbook author (not me!) once told his publisher to produce a graph such as panel (f) of Graph 13.2 and explained that he wanted the short-run average expenditure curves corresponding to different levels of fixed capital to each be tangent at their lowest point to the U-shaped long-run average cost curve. The graphics artist (who knew nothing about economics) came back to the author and sheepishly explained that such a graph cannot logically be drawn. What was wrong in the author’s instructions?

13A.1.3 To Be or Not to Be: Shutting Down versus Exiting the Industry Using the graphs we have developed so far, we can now determine how low an output price a firm is willing to tolerate and still produce, and at what point the price has just fallen so far that it is not worth going on because profit would be negative. The answer will differ a bit depending on whether we are thinking about the short or the long run because a firm cannot actually disappear entirely in the short run since it is stuck for some period with a fixed level of capital. We will therefore say that a firm “shuts down” production if it stops producing in the short run, and it “exits the industry” if it ceases production in the long run. You can picture “shutting down” as locking the doors of the factory and nailing the sign “Closed for Business” on them, while “exiting the industry” means you have sold the factory (or not renewed your lease) and thus all evidence of your firm has disappeared.

We will see shortly that a firm’s “shut down price” is lower than the “exit price” because the firm can more easily cover its economic costs in the short run since these don’t include the fixed expense of capital that has to be paid regardless of what the firm does. You may already know that you won’t renew the lease to your factory once the lease comes up for renewal, but it may still be worth it to produce in the meantime until you get a chance to unload the factory by not renewing the lease. You’ll often see this with new restaurants that try to break into the local restaurant market: Within a few weeks of opening, some restaurants are buzzing with activity and others attract few customers. You can tell pretty quickly which restaurants won’t be around a year from now, but often the restaurants continue to stay open for some period even though it is clear that not enough people show up for the restaurant to remain viable. Do the restaurant owners not see what you can see—that their restaurant just isn’t going to make it? Probably not; rather, the owner probably had to sign a lease for 6 months or a year and can’t get out of the lease, which makes the lease an expense the owner does not have to cover in the short-run in order to justify staying open. Put differently, short-run profit may be positive even though long-run profit is negative, which implies that it is economically rational to remain open in the short run but not to renew the lease in the long run.

In terms of our graphs, we can identify the “shut down” and “exit” prices by simply locating the lowest point of the average cost curves in the short and long run because it is *always* the case that a firm produces so long as price is not below its average cost curve (assuming we have not included expenses that aren’t really costs). In the short-run picture of Graph 13.1, this lowest point lies on the $AC_{k=100}$ curve; in our long-run picture of Graph 13.2, it lies on the AC^{LR} curves of panels (c) and (f). We can then combine the insights of the short-run picture (Graph 13.1) and the long-run curves (of Graph 13.2) to see the relationship between the short-run “shut down” price and the long-run “exit” price.

In particular, consider Graph 13.3. In this graph, we assume that the firm is currently producing 200 units of output using the input bundle A from panel (d) of Graph 13.2, precisely the cost-minimizing input bundle for this output level. This implies that the (short-run) average expenditure curve $AE_{k=100}$ touches the long-run average cost curve AC^{LR} at the output level 200 but exceeds it at every other output level (as first derived in panel (f) of Graph 13.2). From our short-run picture in Graph 13.1, we also know that the short-run average cost curve $AC_{k=100}$ lies below the short-run $AE_{k=100}$ curve (because it does not include the fixed expenditure on capital), and we can now include this short-run average *cost* curve as well as the short-run marginal cost ($MC_{k=100}$) curve in Graph 13.3. The bolded portion of the $MC_{k=100}$ curve is then the short-run supply curve, which clearly extends below the lowest point of the AC^{LR} curve. Thus, the short-run “shut down” price \bar{p} lies below the long-run “exit” price (which is \$10 in the graph). If the output price falls into the range from \bar{p} to \$10, the firm will therefore stay open in the short run but will exit in the long run.

If output price falls too low, a firm might “shut down” in the short run and “exit the industry” in the long run.

The “shut down price” lies at the lowest point of short-run AC , and the “exit price” lies at the lowest point of long-run AC .

Demonstrate that the firm’s (long-run) profit is zero when $p = 10$.

EXERCISE
13A.8

GRAPH 13.3 "Shut Down" versus "Exit" Price

Go to MindTap to interact with this graph.

To see a bit more clearly how a firm (like those new restaurants that just don't draw much business) can stay open in the short run but exit in the long run, consider Graph 13.4, which largely replicates the short-run cost and expenditure curves we derived in Graph 13.1b and that are contained in Graph 13.3. Suppose that the price of the output is p^* . If this firm produces at all, it will produce x^* where the additional cost of producing one more unit of output is just equal to the additional revenue from selling that unit. This would generate total revenue of p^*x^* , the shaded blue rectangle in the graph. At the output level x^* , the firm would incur average costs exactly equal to p^* ,

GRAPH 13.4 Output Supply in the Short Run

Go to MindTap to interact with this graph.

giving total (short-run) costs equal to the same blue rectangle. Thus, the firm is making enough revenues to cover exactly its short-run economic costs. It does not, however, make enough to cover its fixed expenditure $FE_{k=100}$ (represented by the magenta area) for the fixed amount of capital it has to rent in the short run. But since the firm has to pay $FE_{k=100}$ regardless of whether or not it produces, it does not have to recover $FE_{k=100}$ in the short run in order to produce. Put differently, it has to write the check for $FE_{k=100}$ whether it produces or not, and so it's no more necessary that you cover this expense with your short-run revenues than it is that you cover your grocery bill with those revenues. It is for this reason that we have said the fixed expenditures associated with inputs that are fixed in the short run are not economic costs: They do not impact economic decisions of the firm in the short run. Since *economic profit* is defined as the difference between economic revenues and economic costs, economic profit is equal to exactly zero in the short run when the output price falls to the lowest point of the short-run $AC_{k=100}$ curve.

Can you illustrate that short-run economic profits will be positive when price falls between the lowest points of the $AC_{K=100}$ and the AC^{LR} curves even though total expenditures exceed total revenues? What will long-run economic profits be in that price range?

EXERCISE
13A.9

In many beach resorts on the East Coast of the United States, business is brisk in the summers but slow in the winters. In summers, resort rentals are sold out at high weekly rates, but in winters they are only partially rented at much lower rates. If you were to calculate expenses and revenues on a monthly basis, you would almost certainly find these resorts with revenues greater than expenses in the summers and expenses greater than revenues in the winters. How come these resorts don't just shut down in winters?

EXERCISE
13A.10

13A.1.4 (Long-Run) Recurring Fixed Costs In the short run, we have made a point of using the term “fixed expenditures (FE)” for the “cost” of fixed inputs that become variable in the long run. Such fixed expenditures are not true economic costs as long as they have to be paid regardless of any choices the firm makes and thus have no impact on short-run economic behavior. And, since they arise from inputs that can be varied as time goes by, these expenses cease to be “fixed” when they become real economic costs in the long run. Thus, fixed *expenditures* on inputs that cannot be varied in the short run do not become fixed *costs* in the long run so long as these inputs can in fact be varied in the long run. Such costs are then referred to as (long-run) *variable costs* since they “vary with output” in the long run. And all the economic costs we have dealt with so far, including the costs associated with variable labor input, have been of this type. As such, changes in such costs affect both the long-run marginal and average cost curves. There are, however, certain expenses a firm might incur that are “fixed” (in the sense that they do not vary with the level of output) but that actually represent real economic costs that could be avoided in the long run if the firm chose not to produce at all. We will call such costs *fixed costs that are avoidable only by exiting the industry* or simply *long-run or recurring fixed costs*, and it is because they are avoidable by exiting the industry that they are real economic costs in the long run.

Suppose, for instance, the government requires an annual payment for a license to produce some output. The license simply allows the firm to produce, but the amount charged for the license does not depend on how much is produced. When you get your hair cut, for instance, you might have noticed your hairdresser's beautician license prominently displayed. Your auto mechanic might have to have a license to do car inspections, and your taxi driver in New York needs to have a license called a medallion to give you a ride. Such licenses are typically renewable on an annual basis, with a license fee charged on, for instance, January 1 of each year. In some instances (like the taxi cab medallions), the cost of such licenses can be quite substantial.

Once you have paid for (or committed to pay for) such an annual license in your business, the expense of the license becomes a sunk “cost.” But as January 1 approaches each year, you have

Expenses on inputs that are fixed in the short run become variable costs in the long run.

Recurring fixed costs (like annual license fees) are (sunk) expenses in the short run but fixed costs in the long run.

a real economic decision to make: Will you renew the license and stay in business next year, or will you exit the business and stop producing? As you make this decision, you will want to look at all your economic costs including the cost of the license. But the only way to avoid paying the license is to abandon your business and stop producing; thus, we have a *recurring fixed cost avoidable only by exiting*. As you approach your decision of whether to renew your license, you will then face cost curves for the coming year that look like those in Graph 13.5, with the AC curve having a different intercept than the MC curve because of the fixed license fee. The dashed green curve is the average cost curve *excluding* the fixed cost of the license fee, labeled AVC for “average variable cost.” It is dashed in the graph because it is not a curve of any real relevance for the firm’s long-run decision because the firm will produce (as always) along MC as long as output price lies above the lowest point of its true average cost curve (which is AC in this case).

EXERCISE 13A.11 Compare Graphs 13.4 and 13.5. Why is the supply curve beginning at the higher average curve in 13.5 and on the lower one in 13.4?

Another example of a recurring fixed cost in the real world is the cost associated with an input that always remains fixed, in both the short and long run. Different entrepreneurs may, for instance, possess different levels of “entrepreneurial skill” as they manage the various inputs in their firm. Facing the same technology, some producers are simply better at figuring out how to motivate workers or get other organizational objectives accomplished. Yet that entrepreneurial skill, unlike the number of labor hours or units of capital hired by the producer, is in fixed supply within the firm. Bill Gates can double the number of workers in Microsoft and double the equipment and facility space as he increases production, but he cannot replicate himself. His leadership or entrepreneurial skill is a fixed input for Microsoft, and the opportunity cost of hiring this fixed input is a recurring fixed cost. If there is such an input that is simply always fixed as long as the firm is in production, it thus becomes a recurring fixed cost just like the license fee, with Bill Gates having to decide each year whether to stay in production and employ his talents in Microsoft or to close shop and employ his talents elsewhere. Most real-world production processes probably have some such fixed input, and it is for this reason that it is usually (although

GRAPH 13.5 Long-Run Output Supply with Fixed Cost

TABLE 13.1 Examples of Costs and Expenses

Example	Impact on Firm		Effect on MC and AC	
	Short Run	Long Run	Short Run	Long Run
Annual license fee	Fixed expense	Fixed cost	None	AC
Cost of capital	Fixed expense	(Variable) cost	None	AC, MC
Cost of labor	(Variable) cost	(Variable) cost	AC, MC	AC, MC

not always) not possible for a firm simply to keep doubling all its inputs to produce twice as much output.³

13A.1.5 Overview of Cost and Expense Types Keeping track of the different types of cost and expenditure changes that might impact firm behavior can get confusing, but in essence, we have really identified only three types of costs that will change what firms do. Table 13.1 identifies examples of each. The first example is the annual license fee that we just discussed in the previous section. It is a fixed *expense* in the short run because there is nothing the firm can do to avoid paying it right now, but it becomes a recurring fixed *cost* in the long run as the firm gets to decide whether to stay in business and renew the license or to exit the industry. Thus, the only cost curves that can possibly be affected by the license fee are those in the long run, but among those, the *MC* curve does not change because the license fee does not actually change the cost of producing additional output, only the cost of staying in business and beginning production. This is illustrated in panel (a) of Graph 13.6; an increase in the license fee raises the long-run average cost curve from *AC* to *AC'* without impacting the (long-run) marginal cost curve. As a result, the long-run supply curve for the firm does not move; it simply becomes “shorter” as the dashed portion disappears.

GRAPH 13.6 Three Types of Cost Changes

³ Since I am writing these words on a Mac and not a Windows-based PC, I should probably have used Tim Cook as an example instead of Bill Gates. But Mac folks are generous folks, and occasionally we pretend that there is actual value in the Microsoft world.

The second type of cost listed in the table is the cost of capital, an input we are assuming is fixed in the short run. As we argued in Section 13A.1.1, this is not a real cost in the short run. The only cost curves that can be affected are therefore those in the long run, but this time, the MC curve is affected in addition to the (total) cost curve C and the average cost curve AC . This is because, unlike the license fee, the amount we have to pay for capital will increase as we produce more when capital is variable in the long run. An increase in the cost of capital is then illustrated in panel (b) of Graph 13.6, with the long-run AC curve shifting up and the MC curve shifting as well.

Finally, the table lists the cost of labor, an input that is assumed to be variable in both the short and long run. Since the amount we must pay for labor depends on how much we produce in both the short and long run, it is always a real cost, with all the cost curves affected in the short and long run. This is illustrated for the short run in panel (c) of Graph 13.6 for an increase in labor costs. (The long-run cost curves are similarly changed.) Whether the lowest point of the long-run AC curve shifts to the left or the right will depend on the underlying technology, and the degree to which the firm can substitute capital and labor. We will explore this a bit further in the next section.

EXERCISE 13A.12 Can we say for sure that the lowest point of the long-run AC curve will shift to the right when the license fee increases?

13A.2 Output Supply in the Short and Long Run

In our discussion of short- and long-run cost curves, we have already begun to illustrate how changes in input and output prices affect output supply across time by focusing on the difference between “shutting down” and “exiting.” We’ll now think about this a bit more directly, first investigating the short- and long-run impact of changes in output prices on supply and then turning toward the impact of input prices on supply in the short and long run. In Sections 13A.2.1 and 13A.2.2, we will work through some of the details of this, but you already have all the tools to understand the bottom line of these sections. So before going into the details, let’s use what we already know.

In panel (f) of Graph 13.2, we illustrated the relationship between short-run average expenditure curves and long-run AC curves. Because the picture was already cluttered enough, we did not include the short-run MC curves (corresponding to each fixed level of capital) nor the long-run MC . But you can look back at the picture and see exactly where these would fall: Each short-run MC curve (for a fixed level of capital) would have an upward sloping part that passes through the lowest point of the AE curve that has the same level of fixed capital, and the long-run MC curve would have an upward sloping part that passes through the lowest point of the long-run AC curve. So you would end up with one long-run MC curve that has lots of short-run MC curves crossing for different levels of fixed capital—and those would form the basis for short- and long-run supply curves that end up looking exactly like panel (c) of Graph 13.7 in the next section. The conclusion from that graph is that *output responds more in the long run than in the short run to changes in output price*. If you start with price p^2 in Graph 13.7c and price increases to p^3 , you would initially increase output along the short-run magenta curve (that holds capital fixed) and then, when you can adjust capital, increase output further to get back to the long-run supply curve. Similarly, if price falls from p^2 to p^1 , you would initially lower output along the short-run magenta curve and then lower it further in the long run to get back to your long-run supply curve. This should make intuitive sense: *Since capital is fixed in the short run, you can’t change output as much as you want (when output price changes) until you can adjust capital in the long run.*

In the isoquant graph, you can see the same effect: Initially, you produce along some cost-minimizing ray from the origin (where isocosts are tangent to isoquants) at the production plan that maximizes profit. *If output price increases*, the slopes of your isocost curves do not change, which implies that *the cost minimizing ray from the origin has not changed*. Thus, when price increases, you will want to remain on that initial ray from the origin in the long run but you will want to produce more (and thus move up along that ray). In the short run, however, your level of capital is fixed—and so you can't yet do as much as you would like. Thus you'll increase your output in the short run by less than in the long run.

When input prices change, on the other hand, the slopes of the isocost curves do change—which implies that your new cost-minimizing ray (that has isocosts tangent to isoquants) will change. When the input price change makes isocosts shallower (because either wage falls or the rental rate increases), the new cost-minimizing ray will become shallower; and when the input price change makes isocosts steeper (because either wage increases or the rental rate falls), the new cost-minimizing ray will become steeper. This is entirely due to a *substitution effect away from the input that has become more expensive and toward the input that has become cheaper*. For instance, if the wage increases, you will substitute away from labor and toward capital in order to lessen the increase in costs you will incur for any level of output that you might choose to produce. As a result, your long-run *MC* curve—and thus your long-run supply curve, will shift up by less than it would have had you not substituted away from labor and toward capital.

The next two sections illustrate all of this more precisely. You may decide to skip these if you are sufficiently comfortable with the underlying intuition we just covered and want to avoid some of the more technical underlying details.

13A.2.1 Output Price and Supply Over Time⁴ Suppose that a producer is currently facing the economic environment (w^A, r^A, p^A) and is producing at his or her long-run profit-maximizing production plan $A = (\ell^A, k^A, x^A)$. This is illustrated in panel (a) of Graph 13.7 as point A on the isoquant x^A with the slope of the isocost $(-w^A/r^A)$ equal to the TRS^A . Now suppose that the output price rises to p' . We know from our previous work that this will cause *an increase in output* and thus a movement to a higher isoquant, both in the short and long run. But in the short run, the producer cannot vary capital away from its current input level k^A and must therefore operate with input bundles lying on the horizontal line emanating from k^A on the vertical axis of the graph. Suppose that it is optimal for the producer to pick the input bundle B in the short run.

True or False: $p'MP_\ell^B = w^A$.

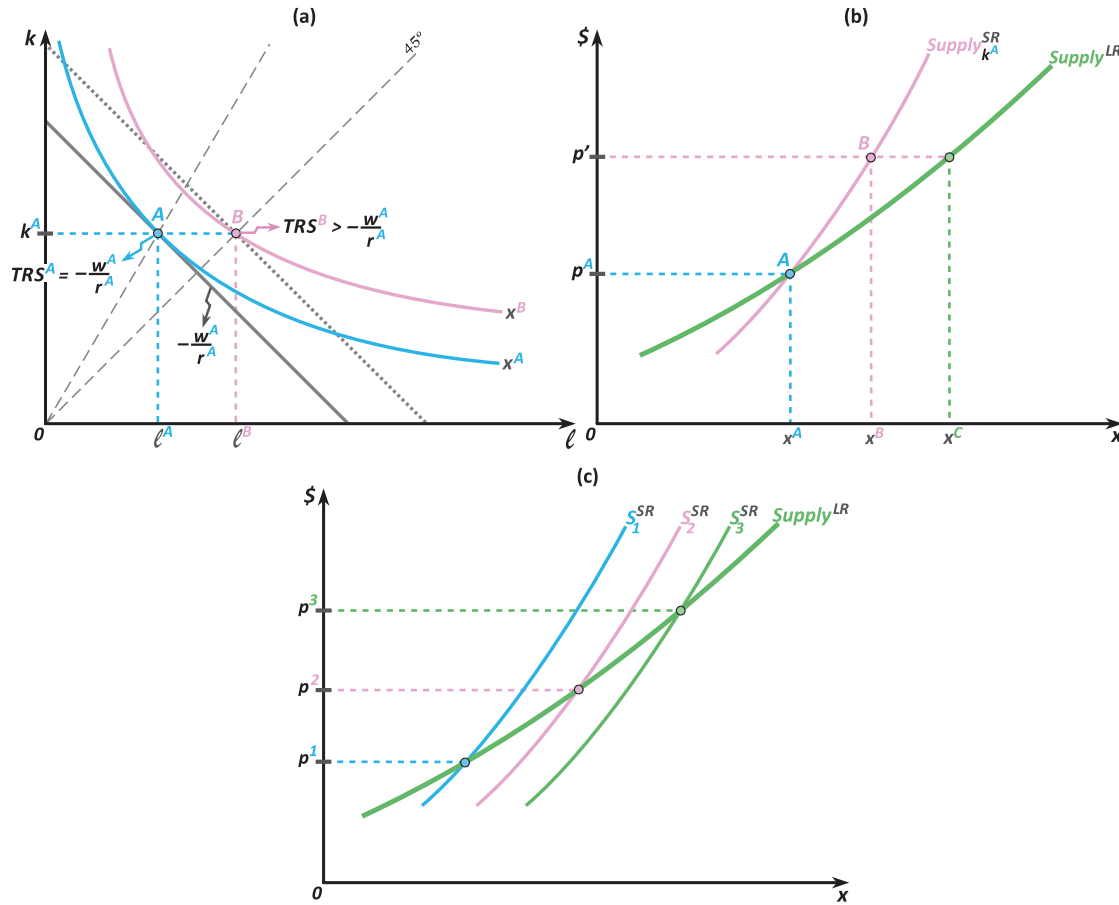

EXERCISE
13A.13

Since we are assuming that the underlying production technology is homothetic, we know that any input bundle to the right of the diagonal connecting to the origin has a shallower isoquant slope than the slope of the isoquant at A (which is equal to $-w^A/r^A$). Thus,

$$TRS^B > -\frac{w^A}{r^A} \quad (13.1)$$

⁴ This section can be skipped if the intuition from the introductory part of Section 13A.2 is sufficient.

GRAPH 13.7 Short-Run versus Long-Run Supply Curves

or, given that $-TRS = (MP_\ell/MP_k)$,

$$\frac{MP_\ell^B}{MP_k^B} < \frac{w^A}{r^A}. \quad (13.2)$$

Multiplying the denominator and numerator of (MP_ℓ/MP_k) by p' leaves the fraction unchanged, which implies that we can also write what we have concluded as

$$\frac{p' MP_\ell^B}{p' MP_k^B} < \frac{w^A}{r^A}. \quad (13.3)$$

At the same time, since B is the short-run optimum when labor is fully variable, the marginal revenue product of labor at B must be equal to the wage w^A , or $p' MP_\ell^B = w^A$. Thus, the inequality (13.3) can hold only if $p' MP_k^B > r^A$; that is, the marginal revenue product of capital at B is greater than the rental rate. Put differently, *at the short run optimum B , the producer can hire additional capital at a cost that is less than the additional revenue this capital will produce.*

When the producer is able to adjust capital in the long run, he or she will therefore hire more of it, causing an increase in output in the long run that goes beyond the short-run increase. This is reflected in panel (b) of Graph 13.7 in a (green) long-run supply curve that is shallower than the (magenta) short-run supply curve. In particular, the graph shows the relationship between the short-run supply curve that holds capital fixed at k^A and the long-run supply curve that allows capital to vary. The two curves intersect at x^A because that is precisely the output level for which k^A is the correct long-run quantity of capital given the current wage and rental rates. Of course, we could have started out at some other initial price and the corresponding initial profit-maximizing input bundle and derived a similar relationship between the short-run supply curve that holds capital fixed at that initial input level and the long-run supply curve that allows capital to vary. Panel (c) of Graph 13.7 illustrates this for three initial output prices p^1 , p^2 , and p^3 . Thus, *long-run supply curves are shallower than short-run supply curves, indicating that producers will respond more to changes in output price in the long run than in the short run.*

Output supply is more responsive to price in the long run than in the short run.

If the marginal product of labor increases as additional capital is hired in the long run, can you tell whether the producer will hire additional labor (beyond ℓ^B) in the long run?⁵ Can you then identify the minimum distance above A on the ray through A the long-run optimal isoquant in Graph 13.7a will lie?

EXERCISE 13A.14

13A.2.2 Long-Run Supply and Input Prices: Substitution Effects in Production⁶ While changes in output prices will cause producers to alter their production behavior *along supply curves*, changes in input prices will *shift supply curves* because such changes cause shifts in cost curves. These shifts are complicated by the fact that, as the relative prices of inputs change, producers will (at least in the long run) adjust the ratio of capital to labor that they use to produce any given level of output. This was an issue that did not arise in the single-input model since there was only a single technologically efficient way of producing any level of output without wasting inputs. Now, however, we have a whole isoquant of possible input combinations that all represent technologically efficient ways of producing a given output level. Which of these technologically efficient input bundles is economically efficient then depends on the relative prices of the inputs, and this implies that the economically efficient input bundle for producing any given level of output will typically change as input prices change.

Suppose, for instance, that we initially face the input prices $w = 20$ and $r = 10$ and the production frontier is represented by the isoquant map in Graph 13.8a (which is the same map we first introduced in Graph 12.8a). Since the isoquant map is homothetic, the economically efficient ratio of inputs will be the same for any output level and can be located along a ray from the origin where isocosts with slope $-w/r = -2$ are tangent to each isoquant. Now suppose that the wage rate falls to $w' = 10$. The new economically efficient input bundles on each of the isoquants in the graph would then lie at tangencies with isocosts that have a slope of -1 rather than -2 , causing us to slide down to a new input bundle on each of the isoquants with economically efficient input bundles again lying on a ray from the origin. Put differently, a change in input prices will cause us to *substitute away from the input that has become relatively more expensive and toward the input bundle that has become relatively cheaper.*

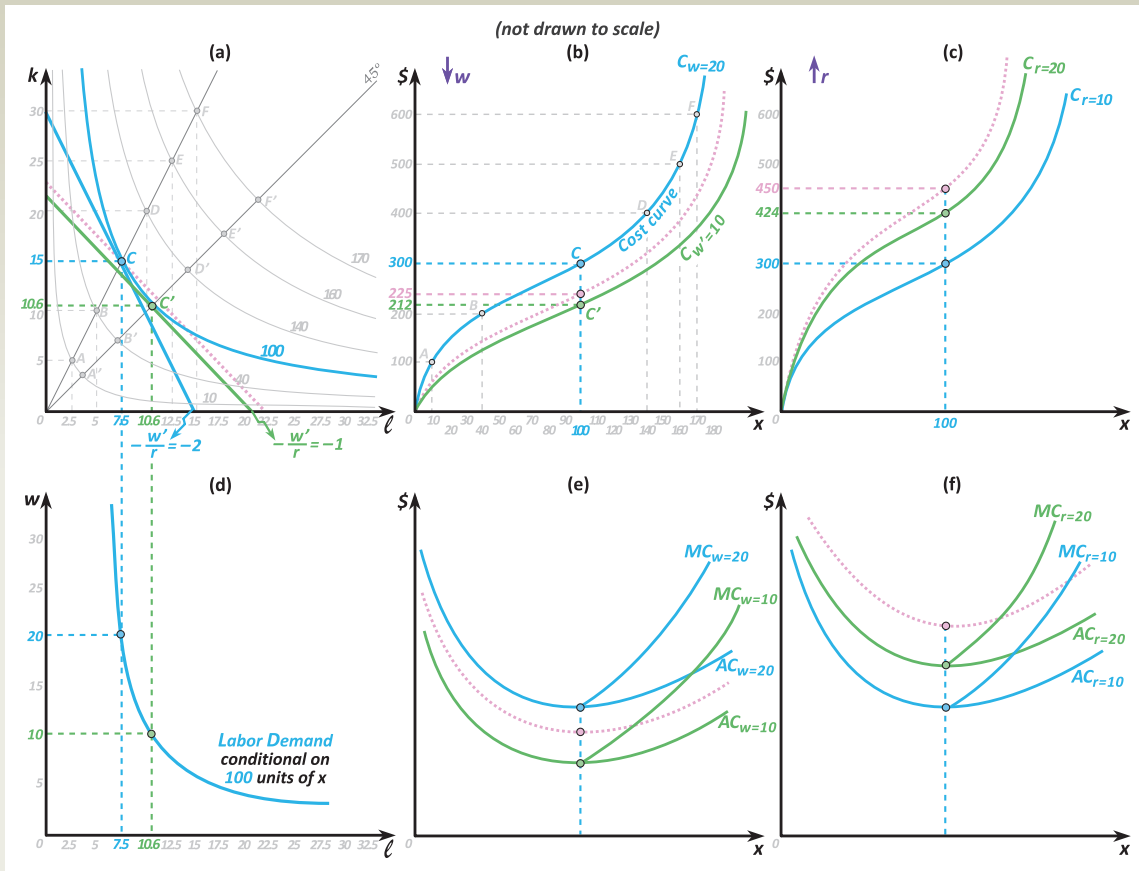

Changes in input prices give rise to substitution effects that result in a new ray of cost-minimizing production plans.

The change in isocosts when w falls from \$20 to \$10 is represented in panel (a) of Graph 13.8 along the isoquant labeled 100 as a change in the tangency at the initial isocost at input bundle

⁵ At the end of the chapter, we will show that the marginal product of labor does not necessarily increase as more capital is hired. Whether it does or does not depends on the substitutability of capital and labor in production.

⁶ This section can be skipped if the intuition from the introductory part of Section 13A.2 is sufficient.

GRAPH 13.8 Costs and Input Substitution Effects

C to the tangency at the new isocost at bundle C' , with all other economically efficient input bundles for other isoquants lying on the ray connecting the origin with bundle C' . Each of the new input bundles is now cheaper, both because the wage has fallen *and* because we have substituted away from capital and toward the cheaper labor. This is represented in a change in the (total) long-run cost curve in panel (b) from the initial blue curve (which is identical to the one derived in Graph 12.8b) to the final green cost curve. The dotted magenta curve in between represents the change in total costs that would have occurred had the producer not changed input bundles but simply experienced lower costs because the wage had fallen, with the remaining drop in total costs due to the substituting behavior induced by the change in relative input prices.

EXERCISE 13A.15 Can you see in panel (a) of Graph 13.8 the cost of not substituting from C to C' ? Can you verify that the numbers in panel (b) are correct?

Just as in consumer theory, the size of the input substitution effect depends on the degree of substitutability of the two inputs in the production process. One way to represent this is in what is called a *conditional input demand curve that tells us, conditional on a given level of output, how the producer's demand for the input changes with the input price*. (We already derived the mathematical counterpart to this—the conditional labor demand curve—in part B of Chapter 12.) Panel (d) of the graph, for example, illustrates the conditional labor demand curve given an output level of 100 units. It shows that, as the wage drops from \$20 to \$10, the producer substitutes away from capital and toward labor when he or she produces 100 units of x . This conditional labor demand curve is therefore derived solely from the isoquant representing 100 units of output and the tangencies of isocosts as w changes. As such, it incorporates a pure substitution effect induced solely by the change in the opportunity cost of labor, just as the compensated demand curve in consumer theory illustrates a pure substitution effect from changes in the opportunity costs of goods. And just as the slope of compensated demand curves depends on the substitutability of goods in consumption along an indifference curve, the slope of the conditional labor demand curve depends on the substitutability of inputs in production along an isoquant.

The size of input substitution effects depends on the degree of substitutability between capital and labor.

Suppose, for instance, that the two inputs were perfect complements in production. Then the substitution effect would disappear, with C and C' both falling on the corner of the same isoquant, and the conditional labor demand curve would be perfectly vertical. As a result, the (total) long-run cost curve would fall only to the magenta line in panel (b) of the graph since the entire reduction in the cost of producing 100 units (or any other quantity) of output derives from the direct effect of the current input bundle costing less and not from the indirect benefit a producer gets from substituting toward the input that has become cheaper. The more substitutable the two inputs, the greater will be the substitution effect, the flatter will be the conditional labor demand curves, and the farther the green long-run cost curve in panel (b) will lie below the magenta curve.

Are these long-run or short-run cost curves?

EXERCISE 13A.16

Once we have derived the change in the long-run cost curve, we can derive the change in long run AC and MC and then identify the shift in the long-run output supply curve when w falls. Panel (e) illustrates the shift in these curves such that the lowest point of the AC curve remains at the same output level, and thus the portion of the MC curve that is the supply curve begins at the same output level (although at a different price). This is a special case, and there is no particular reason that the lowest point of the long-run AC curve should typically remain at the same output level as input prices change. Depending on the underlying technology, it may be that the lowest point shifts to either the right or the left. Regardless, however, for a fixed price level, the quantity supplied will increase as wage falls because the new (green) supply curve lies to the right of the original (blue) one.

Now suppose that instead of wages falling from \$20 to \$10, the rental rate had increased from \$10 to \$20. In both cases, the ratio w/r changes from -2 to -1 , indicating that the slopes of isocosts change in exactly the same way as in Graph 13.8a. Now, however, one of the input prices has gone up, which means that the long-run total cost of producing any quantity of output must be higher than it was originally. This is graphed in panels (c) and (f) of Graph 13.8 as a change in the (total) cost, the AC , and the MC curves from the initial blue to the final green curve. The dotted magenta curves represent how much total and average costs would have increased had the producer not substituted away from capital and toward labor. The conclusion in panel (f) is then that *as the rental rate increases, output supply decreases*.

EXERCISE
13A.17

Can you verify that the numbers in panel (c) are correct?

EXERCISE
13A.18*

Assuming the original cost-minimizing input bundle remains C , which of the three curves graphed in Graph 13.8c would be different (and how would it be different) if the inputs in panel (a) of the graph were more substitutable? How would the graph change if the two inputs were perfect complements in productions?

In the short run, of course, the substitution effects in Graph 13.8 will not occur when capital is held fixed (just as substitution effects did not arise in the single-input model of Chapter 11). The short-run supply curve then simply appears as the MC curve above short-run average cost (as in Graph 13.4), and a change in the price of the variable input simply shifts the short-run MC and short-run AC as production of any given output level is undertaken with production plans that hold capital constant. It can be shown, however, that *output responses for changes in input prices are at least as large in the long run as in the short run*.

13A.3 Input Demand and Changes in the Economic Environment

Since the distinguishing characteristic of the short run in the two-input model is that one of the inputs is fixed, it must be true (just as in the single-input model of Chapter 11) that the *short-run* labor demand decision occurs simply along the marginal revenue product (of labor) curve as wage changes. As we discussed in detail in Chapter 11, *some portion of the declining part of the MRP_ℓ curve (with capital held fixed at its short-run quantity) is therefore the short-run labor demand curve*. Similarly, short-run labor demand varies with output price as described for the single-input model in Chapter 11, with changes in p causing the labor demand curve to shift just as changes in p shift the MRP_ℓ curve (see Graph 11.8). In the long run, however, both ℓ and k can be adjusted, which implies that the long-run labor demand curve will be different from the short-run labor demand curve that lies on the MRP_ℓ curve. In the following, we therefore explore how labor demand changes in the long run as input and output prices change.

EXERCISE
13A.19*

In Graph 13.8d, we already derived conditional labor demand curves along which capital is allowed to adjust. Explain why these are not long-run labor demand curves.

If an input price change causes isocosts to become steeper, the substitution effect will lead to a steeper cost-minimizing ray from the origin, and the reverse is true if isocosts become shallower.

We will again develop the ideas in this section under the assumption that production technologies are homothetic. As demonstrated in part B of the chapter, these ideas hold more generally, but the homotheticity assumption simplifies the graphical approach a bit by giving us a convenient way to narrow the region within the isoquant space where new *cost-minimizing* input bundles will lie as relative input prices change. Suppose, for instance, that the input bundle $A = (\ell^A, k^A)$ in Graph 13.9 is the cost-minimizing way of producing x^A at input prices (w^A, r^A) . If input prices change such that isocosts become steeper, then the new cost-minimizing input bundles must lie on a steeper ray to the *left* of the ray connecting A to the origin because only in that region could there be a tangency between an isoquant and one of the new (steeper) isocosts. Similarly, if input prices change such that isocosts become shallower, the new cost-minimizing input bundles must lie on a shallower ray to the *right* of the same ray. This is entirely due to the substitution effect we discussed in the previous section.

GRAPH 13.9 Changes in Input Prices and New Long-Run Profit-Maximizing Input Bundles

Go to MindTap to interact with this graph.

Can you tell from just seeing the tangency at (ℓ^A, k^A) of the isocost with the isoquant whether the production plan $A = (\ell^A, k^A, x^A)$ is profit maximizing at prices (w^A, r^A, p^A) ?

EXERCISE
13A.20

Identifying where the new profit-maximizing production plan lies in this isoquant picture when input prices change, however, requires more than identifying where the substitution effect has placed the new cost-minimizing ray. In addition, we have to know whether the input price change causes the profit-maximizing firm to produce more or less on that ray—an effect we will call the *scale effect*. Suppose, for instance, that the production plan $A = (\ell^A, k^A, x^A)$ is not only cost-minimizing at input prices (w^A, r^A) but is also long run profit-maximizing given the output price p^A . Now suppose that w decreases. This implies that the long-run MC curve will shift down, resulting in an *increase* in the profit-maximizing output level where p^A intersects MC . The scale effect is therefore positive: Output will increase above the isoquant x^A in addition to lying on the shallower cost-minimizing ray from the substitution effect toward the input

An increase in input price will cause a negative scale effect while a decrease in input price will cause a positive scale effect.

that has become relatively cheaper. Putting the substitution effect together with the scale effect, we can then conclude that the new profit-maximizing production plan will lie in the shaded blue region when wage falls—that is, the intersection of the region that contains bundles on a shallower ray from the origin with the region that contains more output than was originally produced. If instead the rental rate r increased, the substitution effect would again suggest a more labor-intensive production process along a shallower cost-minimizing ray from the origin, but this time the long-run MC curve shifts up. This implies that p^A intersects MC at a lower output level than x^A —giving us a negative scale effect. As a result, we can conclude that the new profit-maximizing production plan when r increases will lie in the shaded magenta region of Graph 13.9.

Similarly, we can conclude that an increase in w or a decrease in r (both of which cause iso-costs to become steeper) will lead to substitution effects that result in a steeper cost-minimizing ray from the origin (to the left of the original ray through A). An increase in w will furthermore cause an upward shift in long-run MC and therefore a negative scale effect, placing the new profit-maximizing plan in the shaded green region of Graph 13.9. A decrease in r , on the other hand, will cause a downward shift in long-run MC and therefore a positive scale effect, placing the new profit-maximizing plan in the shaded gray region.

EXERCISE 13A.21* Do you see from Graph 13.9 that long-run demand curves for labor (with respect to wage) must slope down, as must long-run demand curves for capital (with respect to the rental rate)?

EXERCISE 13A.22* Does Graph 13.9 tell us anything about whether the cross-price demand curve for labor (with the rental rate on the vertical axis) slopes up or down in the long run?

The shaded regions in Graph 13.9 thus tell us where our new long-run production plan might lie as different input prices change assuming that A was the profit-maximizing plan prior to the change in input prices. In the short run, however, we are constrained to keep capital at its current level k^A —which raises the question of how short-run firm choices relate to long-run firm choices as these input prices change. A lot will depend on the degree of substitutability between capital and labor, as we will see next.

Suppose, for instance, we run a company that employs labor and capital, and the wage we have to pay our workers goes up. First, note again what we know from our work in Chapter 11: in the short run when capital is fixed, we will simply hire fewer workers, which moves us up the MRP_ℓ curve. Thus, once we have chosen the new short-run optimal number of workers, the marginal product of labor (MP_ℓ) will be higher than it was before the wage increase. This should make sense: since labor has become more expensive, we will only hire workers so long as their output justifies the higher cost. But what will we do once we can adjust capital? Will we hire more capital or less? The shaded green area in Graph 13.9 suggests both are possible. And what does that in turn imply for whether we’ll let even more workers go in the long run? The answers, it turns out, depend on whether the capital employed in our firm is more like robots or more like computers.

EXERCISE 13A.23* Where in Graph 13.9 will our new production plan fall after we have made our short-run labor adjustment?

First, suppose our firm is one that employs both robots and workers to produce cars. In this case, it may be that capital and labor are very substitutable if robots can do many of the same tasks as workers. Since we know that the MP_ℓ has gone up as a result of our decision to have fewer workers in the short run, it would then also be the case that the MP_k has increased. After all,

if workers are a lot like robots in our firm, then what happens to the marginal product of one should be roughly equal to what happens to the marginal product of the other. But if the MP_k has increased, that means we'll want to hire more robots (that have *not* become any more expensive), and we should let go of more workers (that *have* become more expensive) once we can replace them with robots in the long run. Thus, it is because robots and workers are substitutable that we know the MP_k must have increased when we hired fewer workers in the short run, which in turn means we'll want to hire more robots and replace additional workers with robots in the long run. Our labor demand response is therefore greater in the long run than in the short run, all because we will *increase* capital in the long run due to its substitutability with labor.

When labor and capital are relatively substitutable, an increase in wage causes a long-run increase in capital.

We know that we will decrease output in the short run as w increases because we hire fewer workers. In the case of robots and workers, do you think that we will increase or decrease output once we can hire more robots in the long run?

EXERCISE 13A.24*

Next, suppose that capital and labor were instead quite complementary in production, as perhaps in the case of a computer animations firm that hires computers as capital and computer graphics artists as labor. If the firm we own is of that type, then an increase in w will initially cause a decrease in labor for the same reasons as before. But now labor and capital are more complementary (and less substitutable) because the computer is not of much use without a computer graphics artist. Thus, when we decrease our labor in the short run, the MP_k falls (even as the MP_ℓ increases). When I can adjust my capital in the long run, I will therefore let go of some of the computers, which will reduce the marginal product of my workers further and cause me to let go of even more of them. Thus, it is because computers and graphic artists are relatively complementary that we know the MP_k falls as graphics artists are let go in response to an increase in their wage, which in turn causes a reduction in the number of computers and with it a further reduction in the number of workers. As in the case where labor and capital were substitutable, we therefore again conclude that the long-run reduction in labor exceeds the short-run reduction, but this time it is accompanied by a long-run *reduction* of capital.

When labor and capital are relatively complementary, an increase in wage causes a long-run decrease in capital.

The two examples illustrate that regardless of how substitutable capital and labor are in production, the long-run labor demand response to wage changes is always greater than the short-run response. The long-run capital demand response to a wage change, on the other hand, depends on the substitutability of capital and labor. Of course an in-between special case also exists: the case where capital and labor are neither too substitutable nor too complementary, and, as a result, the firm does not change its capital as w increases even when it can in the long run. In that special case, as we will see, the firm's long-run labor demand response is equal to its short-run labor demand response. It is therefore more accurate to restate our conclusion about the long-run labor demand response slightly: *Regardless of how substitutable or complementary capital and labor are in production, the long-run labor response to wage changes will be at least as large as the short-run response.*

The decrease in the amount of labor demanded as wage increases is at least as great in the long run as it is in the short run.

Section 13A.3.1 goes on to illustrate what we have just derived intuitively in a more formal way. This section can be skipped if you are happy with the intuition derived from our example of robots and computers. Section 13A.3.2 then explores the analogous case of the rental rate (rather than the wage) increasing. Since capital is fixed in the short run, only the long-run change in firm behavior is relevant. For reasons exactly analogous to what we just discussed for an increase in the wage, an increase in the rental rate would cause firms to hire more labor in the long run if capital and labor are relatively substitutable, and it would cause firms to hire less labor in the long run if capital and labor are relatively complementary. Section 13A.3.2 can similarly be skipped if this intuition is clear and you are not looking for a further, more formal, demonstration.

13A.3.1 Demand for Labor and Capital as w Changes⁷ We can now demonstrate this a little more formally by applying the fact that two main conditions must hold in order for a producer to be maximizing profits in the short and long run: first, each input’s marginal revenue product must equal its price, and second, the negative TRS (which is equal to MP_ℓ/MP_k) must equal the ratio of input prices (w/r) in the long run (thus getting us to a new tangency between isocost and isoquant). (Note that the second condition follows logically from the first, but we will proceed in this section as if they were distinct conditions.) Suppose again (as we did in Graph 13.9) that a producer is currently operating at a production plan $A = (\ell^A, k^A, x^A)$ that is his or her long-run profit-maximizing production plan in the economic environment (w^A, r^A, p^A) . We then know that

$$p^A MP_\ell^A = w^A, p^A MP_k^A = r^A \text{ and } -TRS^A \left(= \frac{MP_\ell^A}{MP_k^A} \right) = \frac{w^A}{r^A}. \quad (13.4)$$

This production plan is depicted as point A in panels (a), (b), and (c) of Graph 13.10.

Now suppose the wage rises to w' , thus causing all isocosts to become steeper and implying that the new long-run optimal input bundle C will lie to the left of the ray connecting the origin to A and below the isoquant containing A (as illustrated in Graph 13.9). In the short run, however, the producer cannot adjust capital and therefore must operate with an input bundle B that lies on the horizontal line that holds capital at k^A .

Panel (b) of Graph 13.10 illustrates the special case where the new long-run optimal input bundle C has exactly the same level of capital input as the original input bundle A . In this case, there is nothing to keep the producer from implementing the new long-run optimum even in the short run, which implies that the short-run optimal input bundle B is the same as the long-run optimal bundle C , and the long-run labor and capital demand responses are exactly the same as the short-run responses. Since labor is variable in the short run, $p^A MP_\ell^B = w'$ as the firm adjusts its labor input in exactly the way described in the single-input model of Chapter 11. Since the new isocost happens to be tangent to the isoquant at B ,

$$\frac{MP_\ell^B}{MP_k^B} = \frac{w'}{r^A} \text{ or, equivalently, } \frac{p^A MP_\ell^B}{p^A MP_k^B} = \frac{w'}{r^A}. \quad (13.5)$$

But, since $p^A MP_\ell^B = w'$, this implies $p^A MP_k^B = r^A$, which, given that $p^A MP_k^A = r^A$, implies $MP_k^A = MP_k^B$. Thus, the fact that we have graphed the new isocost tangent to the isoquant at B implies that we have graphed a technology where the short-run reduction in labor input has left the marginal product of capital unchanged. This in turn implies that the producer reaches his or her long-run optimum in the short-run, causing the short- and long-run labor demand curves to coincide in panel (e) and the cross-price relationship between w and k to be vertical as in panel (h).

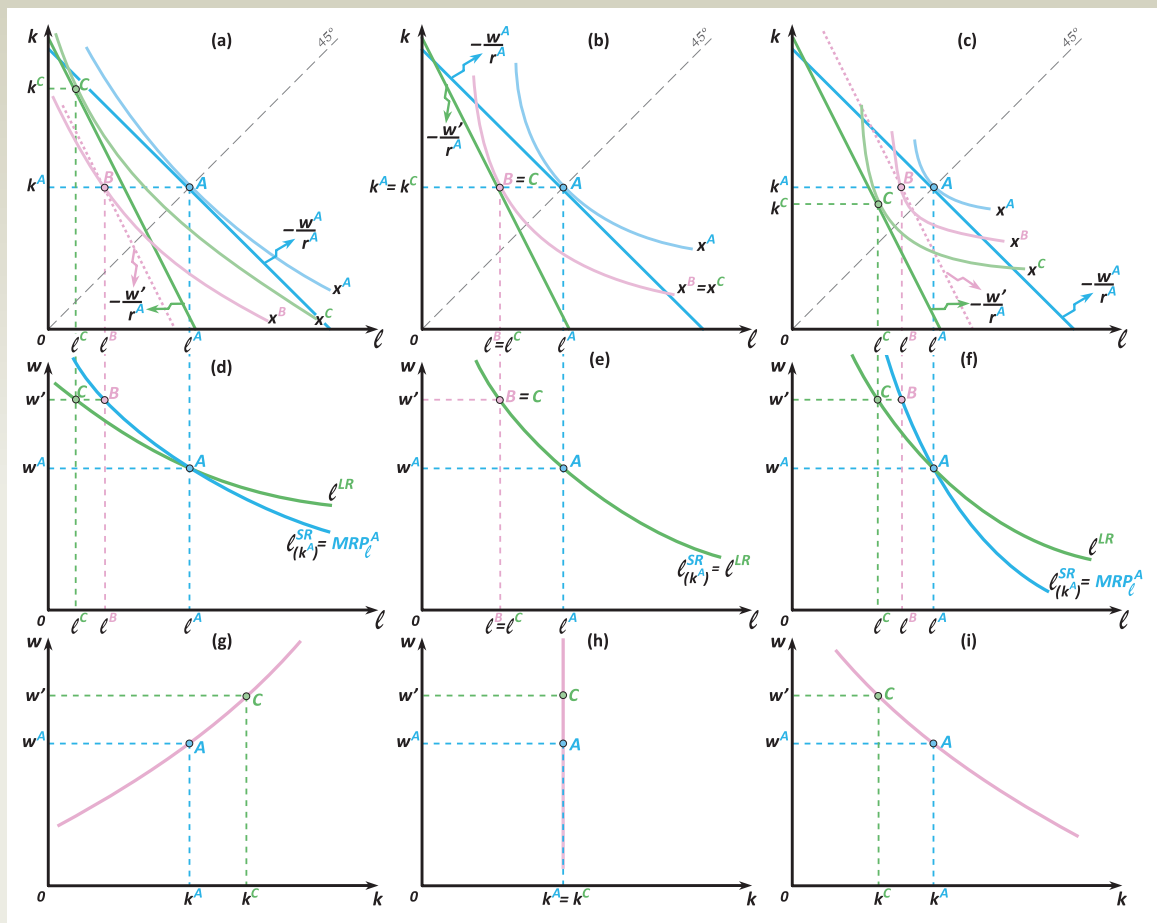

Now consider the technology graphed in panel (a). Here, the new optimal input bundle C contains more capital input than the original bundle A , which implies that the producer cannot immediately switch to the long-run optimum when capital is fixed in the short run. Rather, in the short run the producer switches to input bundle B , which has the characteristic that the isocost containing B cuts the isoquant containing B from above; that is, $TRS^B > -w'/r^A$ or equivalently

$$\frac{MP_\ell^B}{MP_k^B} < \frac{w'}{r^A}, \text{ which implies } \frac{p^A MP_\ell^B}{p^A MP_k^B} < \frac{w'}{r^A}. \quad (13.6)$$

In the short run, we know the firm will adjust labor until $p^A MP_\ell^B = w'$. The previous equation then implies that $p^A MP_k^B > r^A$ and thus (since $p^A MP_k^A = r^A$) that $MP_k^B > MP_k^A$. Capital is therefore more productive at the margin at B than at A , which causes producers to substitute away from labor and toward capital, causing a decline in labor input beyond the initial decline from ℓ^A to ℓ^B all the way to ℓ^C . This leads the labor demand curve in panel (d) to be shallower

⁷This section can be skipped if the intuition from the introductory part of Section 13A.3 is sufficient.

GRAPH 13.10 Short- and Long-Run Input Demand Responses when w Increases

in the long run than in the short run and the cross-price relationship between w and k to be upward sloping. As suggested by the relatively flat shape of isoquants in panel (a), this occurs when capital and labor are relatively substitutable in production (as in our example of robots and workers), and when an increase in the cost of labor thus leads to a lot of substitution into capital.

Finally, panel (c) illustrates the opposite case where the producer adjusts to less capital in the long run as wage increases from w^A to w' . Since the producer finds it optimal to adjust capital that is fixed in the short run, his or her long-run response to the wage increase will therefore again differ from his or her short-run response. In the short run, he or she switches to input bundle B where the isocost containing B cuts the isoquant containing B from below. Using steps analogous to those in the previous paragraph, this allows us to conclude that $MP_k^B < MP_k^A$; that is, capital has become less productive at the margin when labor input was adjusted in the short run. As a result, the producer reduces the capital input in the long run and further reduces labor input as well, which leads again to a long-run labor demand curve that is shallower than in the short run (panel (f)) but a cross-price relationship between w and k that is downward sloping (panel (i)). Notice that this is derived from panel (c) where isoquants represent inputs that are relatively complementary (as in our example of computers and workers), and thus an increase in the cost of labor results in less use of both labor and its complementary input capital.

EXERCISE 13A.25* Suppose labor and capital were perfect complements in production. What would the analogous graph for an increase in w look like?

EXERCISE 13A.26* Demonstrate that $MP_k^B < MP_k^A$ in panel (c) of Graph 13.10.

EXERCISE 13A.27* How is the long-run response in output related to the short-run response in output as w increases? What does your answer depend on? (*Hint:* You should be able to see the answer in Graph 13.10.)

We can therefore conclude that, except for the special case in panel (b) of the graph, *the long-run labor demand response to changes in w is larger than the short run labor demand response* (just as we concluded earlier in the chapter that the long-run output supply response to a change in output price is larger in the long run than in the short run). The underlying reasoning is somewhat subtle: In the case where labor and capital are relatively substitutable in production in panel (a) (analogous to our example of capital as “robots”), the marginal product of capital *increases* because of the short-run drop in labor when w increases. As a result, the firm will hire more capital when it can and reduce labor further because capital and labor are relatively substitutable. But in the case where labor and capital are relatively complementary in production in panel (c) (analogous to our example of capital as “computers”), the marginal product of capital *falls* as a result of the short-run drop in labor when w increases. This causes the firm to reduce its capital when it can in the long run, and, because labor and capital are relatively complementary, it will then reduce the labor it hires beyond the short-run reduction. Whether labor and capital are relatively substitutable or relatively complementary, the long-run labor demand response therefore exceeds the short-run response—albeit for somewhat different reasons—and the demand for capital either increases or decreases depending on the degree of substitutability between capital and labor.

13A.3.2 Demand for Labor and Capital as r Changes⁸ An analogous set of steps can lead us to an analogous set of conclusions regarding the long-run change in the demand for labor and capital when r rather than w rises. Since we are assuming throughout that capital is fixed in the short run, however, an increase in the cost of capital is a sunk “cost” in the short run and thus does not affect production decisions with respect to labor, capital, or output in the short run.

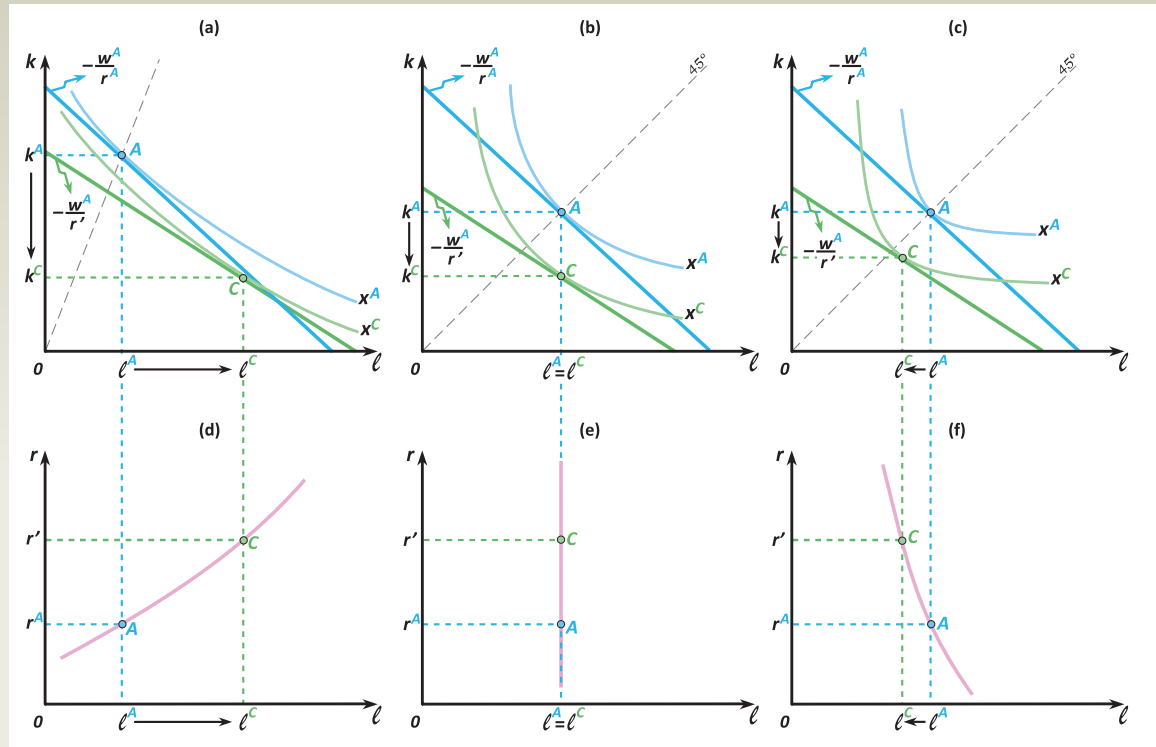

Suppose again that a producer is currently operating at a production plan $A = (\ell^A, k^A, x^A)$ that is his or her long-run profit-maximizing production plan in the economic environment (w^A, r^A, p^A) . Now suppose that r increases, which makes isocosts shallower. We know from our work in Graph 13.9 that this will lead to a new profit-maximizing input bundle that lies below the isoquant containing A and to the right of the ray connecting A to the origin. Graph 13.11 then illustrates three possibilities, with panel (a) once again representing a production process in which capital and labor are relatively substitutable and panel (c) representing the case where capital and labor are relatively complementary in production.

Since capital falls in all three scenarios as r increases, we can conclude that *the long-run demand curve for capital is downward sloping (with respect to r)*. The cross-price relationship between r and ℓ , however, may slope up when labor and capital are relatively substitutable or down when labor and capital are relatively complementary in production as demonstrated by panels (d) through (f) in Graph 13.11. This happens for reasons exactly analogous to those cited for the potentially upward- or downward-sloping cross-price relationship between w and k in Graph 13.10.

⁸This section can be skipped if the intuition from the introductory part of Section 13A.3 is sufficient.

An increase in the rental rate will cause a long-run increase in labor demanded if capital and labor are relatively substitutable and a long-run decrease in labor demanded if they are relatively complementary.

GRAPH 13.11 Long-Run Labor Demand Responses when r Increases

Can you arrive at these conclusions intuitively using again the examples of robots and computers?

EXERCISE 13A.28

13A.3.3 Demand for Labor and Capital as p Changes⁹

Finally, we know from our previous work that output supply curves slope up (because the relevant portion of MC curves slope up), which implies that output increases when the output price p rises. Since a change in output price by itself does not alter the slope of isocosts (which is equal to $-w/r$), this implies that increases in output price do not give rise to substitution effects. They do, however, give rise to a positive scale effect, implying that the new profit-maximizing production plan will lie on the original cost-minimizing ray but on a higher isoquant.

Output price changes cause no substitution effects, only scale effects.

In the short run, however, capital may be fixed, which implies that the increase in output in the short run results entirely from additional labor being hired. Whether the increase in labor demand is higher or lower in the short run then again depends on the relative substitutability of capital and labor in production. Consider, for instance, the case of capital and labor being perfect complements in production, as illustrated in Graph 13.12a where once again A is the initial

⁹This section is optional. No other part of the text builds on it.

GRAPH 13.12 Input Demand Responses when p Increases

An increase in output price will result in short- and long-run increases in the quantity of labor demanded, but whether the short-run increase is larger or smaller than the long-run increase depends on the degree of substitutability of capital and labor.

profit-maximizing input bundle before the price of the output rises. Since it is impossible in this case to produce additional output without adjusting both capital and labor, the producer would have no choice but to keep output unchanged in the short run as long as capital is fixed, resulting in $A = B$. Thus, when capital and labor are very complementary in production, there will be little or no change in labor demand in the short run as output price rises, and the bulk of the increase in production happens in the long run as both labor and capital can be adjusted in the same proportion.

Now consider the opposite extreme, the case where capital and labor are perfect substitutes in production as illustrated in Graph 13.12b. Suppose that capital is relatively cheaper than labor, which implies that the producer is using only capital and no labor at the original input bundle A . When output price increases without a change in input prices, the producer will end up producing more output with an increase in capital in the long run (bundle C), but in the short run he or she cannot change the level of capital in production. As a result, the producer may well hire some labor in the short run (taking him or her to input bundle B) before being able to adjust capital. In this case, then, there is a temporary increase in labor demand in the short-run as output price increases, but this increase vanishes in the long run.

From these extremes, we can conclude that *the short-run labor demand response from a change in output price might be larger or smaller than the long-run response depending on the degree of substitutability between capital and labor in production.* We will illustrate this more mathematically in Section B.

EXERCISE 13A.29*

In panel (a) of Graph 13.7, we determined that the firm will once again end up on the steeper ray once it can adjust capital. Call the new (long-run) input bundle at the higher output price C . Can you now tell what will determine whether C lies to the right or left of B ?

13B

TRANSITIONING FROM SHORT- TO LONG-RUN MATHEMATICALLY

In the duality picture in Graph 12.13, the profit maximization problem on the left-hand side yields output supply and input demand functions

$$x(p, w, r), \ell(p, w, r), \text{ and } k(p, w, r). \quad (13.7)$$

These functions tell us, purely as a function of the economic environment (p, w, r) , the profit-maximizing production plan (x, ℓ, k) . As we explore the change in the profit-maximizing production plan when the economic environment changes, we are interested in the partial derivatives of these functions with respect to the output and input prices, and we are interested in distinguishing the signs and magnitudes of these in the short and long run. Some of our analysis in this section will draw on the results developed in the Appendix of Chapter 12, which we will state (but not prove) when we use them.

13B.1 Expenses and Costs

In part A of this chapter, we spent a considerable amount of time discussing the difference between what we called short-run “expenses” that are sunk and real economic costs that impact the economic behavior of firms. We ended up distinguishing in Table 13.1 between three types of expenditures for the firm: (1) A short-run fixed expenditure that becomes a long-run recurring fixed cost avoidable only by exiting (such as a recurring license fee); (2) a short-run fixed expenditure associated with a fixed input (such as capital) that becomes variable in the long run, and thus becomes a variable cost as time passes; and (3) a variable cost associated with an input that is variable in both the short and long run (like labor).

13B.1.1 Short-Run Expenses and Long-Run Costs Without Fixed Costs Suppose, for instance, that k^A is the economically efficient level of capital to employ when input prices are (w^A, r^A) if one wants to produce the output level x^A . If capital is fixed at that level in the short-run, the short-run cost-minimizing input bundle for producing any given level of output x is then $(\ell_{k^A}(x), k^A)$, where $\ell_{k^A}(x)$ is just the minimum amount of labor necessary to produce output x given that capital is fixed at k^A . We would arrive at this in exactly the same way that we used in Chapter 11, with the relevant production function in the short run simply being the slice of the long-run production function that holds capital fixed at k^A . We can denote this slice as $f_{k^A}(\ell)$. For instance, if the full (long-run) production function is $f(\ell, k) = A\ell^\alpha k^\beta$, the short-run production function when the firm is restricted to keep capital at k^A is $x = f_{k^A} = [A(k^A)^\beta]\ell^\alpha$, with the term in brackets being treated as a constant. To find the cost-minimizing labor input level for producing x in the short run, we would simply invert this to get

$$\ell_{k^A}(x) = \left(\frac{x}{[A(k^A)^\beta]} \right)^{1/\alpha}. \quad (13.8)$$

Suppose the long-run production function were a function of three inputs, labor, capital, and land, and suppose that both labor and capital were variable in the short run but land is only variable in the long run. How would we now calculate the short-run cost-minimizing labor and capital input levels conditional on some (short-run) fixed level of land?

EXERCISE 13B.1

When input prices are (w^A, r^A) , the short-run *expense* associated with producing x is then

$$E_{k^A}(x, w^A, r^A) = w^A \ell_{k^A}(x) + r^A k^A \quad (13.9)$$

while the short run *cost* is

$$C_{k^A}(x, w^A) = w^A \ell_{k^A}(x). \quad (13.10)$$

EXERCISE 13B.2 Can you use these expressions to justify the difference in the (total) cost and total expenditure curves in panel (a) of Graph 13.1 as well as the difference between AC and AE in panel (b) of that graph?

The long-run cost, however, is derived from solving the cost minimization problem

$$\min_{\ell, k} w\ell + rk \text{ subject to } x = f(\ell, k) \quad (13.11)$$

with the underlying assumption that both capital and labor can be adjusted. As we saw in Chapter 12 (and in the intuitive exposition of Graph 13.2), this results in conditional input demands $\ell(x, w, r)$ and $k(x, w, r)$ and the long-run cost function $C(x, w, r) = w\ell(x, w, r) + rk(x, w, r)$. When input prices are (w^A, r^A) , the long-run cost is therefore

$$C(x, w^A, r^A) = w^A \ell(x, w^A, r^A) + r^A k(x, w^A, r^A). \quad (13.12)$$

Saying that x^A is the output level for which k^A is the long-run optimal quantity of capital is then the same as saying $k^A = k(x^A, w^A, r^A)$. If the firm starts with k^A in the short run and decides to produce x^A , it can then set labor (which is variable in the short run) to its (long-run) cost-minimizing level, resulting in $\ell_{k^A}(x^A) = \ell(x^A, w^A, r^A)$, which implies that the firm's short-run expenses are equal to its long-run costs; that is, $E_{k^A}(x^A, w^A, r^A) = C(x^A, w^A, r^A)$. For any other output level, however, k^A is not generally the long-run optimal level, which implies that

$$E_{k^A}(x, w^A, r^A) \geq C(x, w^A, r^A) \quad (13.13)$$

with the expression holding with equality only when $x = x^A$. This is precisely what we showed graphically in Graph 13.2.

EXERCISE 13B.3 Can you derive from this the relationship between long-run average cost and short-run average expenses as illustrated graphically in Graph 13.2?

The short-run supply curve would then be calculated by setting price equal to short-run marginal cost derived from $C_{k^A}(x, w^A)$ while the long-run supply curve would be calculated by setting price equal to long-run marginal cost derived from $C(x, w^A, r^A)$.

EXERCISE 13B.4 In the case of U-shaped average cost curves, how can you use the previous mathematical expressions to argue that the short-run "shut down" price is lower than the long-run "exit" price?

13B.1.2 An Example Consider, for instance, our example of a decreasing returns to scale production process modeled by the production function $f(\ell, k) = 20\ell^{2/5}k^{2/5}$. In Chapter 12 (equations (12.44) and (12.45)), we derived the conditional input demands for this production function as

$$\ell(w, r, x) = \left(\frac{r}{w}\right)^{1/2} \left(\frac{x}{20}\right)^{5/4} \quad \text{and} \quad k(w, r, x) = \left(\frac{w}{r}\right)^{1/2} \left(\frac{x}{20}\right)^{5/4}, \quad (13.14)$$

and the (long-run) cost function (in equation (12.46)) as

$$C(w, r, x) = w\ell(w, r, x) + rk(w, r, x) = 2(wr)^{1/2} \left(\frac{x}{20}\right)^{5/4}. \quad (13.15)$$

If we were to produce 1,280 units of output at input prices $(w, r) = (20, 10)$, for instance, these functions imply that we would want to choose the cost-minimizing input bundle $(\ell, k) = (128, 256)$ incurring a (long-run) cost of \$5,120.

Verify that these numbers are correct.

**EXERCISE
13B.5**

Suppose this is the current input bundle employed by a producer facing input prices $(w, r) = (20, 10)$, and the producer now considers producing a different level of output. In the long run, the cost of producing other levels of output at these input prices is given by the cost function in equation (13.15) with $w = 20$ and $r = 10$ plugged into the equation, which results in

$$C(x, 20, 10) = 0.66874x^{5/4}. \quad (13.16)$$

In the short run, however, demand for labor is given by the inverse of the short-run production function $f_{k^A=256} = [20(256)^{2/5}]^{2/5}\ell^{2/5}$, which is

$$\ell_{k^A=256}(x) = \left(\frac{x}{20(256)^{2/5}}\right)^{5/2} = \frac{x^{5/2}}{20^{5/2}(256)}. \quad (13.17)$$

This gives a short-run expenditure function of

$$E_{k^A=256}(x, 20, 10) = 20\ell_{k^A=256}(x) + (10)256 = \frac{x^{5/2}}{20^{3/2}256} + 2,560. \quad (13.18)$$

What is the short-run cost (as opposed to expenditure) function?

**EXERCISE
13B.6**

The cost function in equation (13.16) and the short-run expense function in equation (13.18) are then graphed in panel (a) of Graph 13.13, with panel (b) graphing the corresponding average cost and expense functions. As we concluded intuitively, these functions are related in that average short-run expenses are never lower than average long-run costs.

GRAPH 13.13 Long-Run Cost and Short-Run Expense Curves when $f(\ell, k) = 20\ell^{2/5}k^{2/5}$ and $k^A = 256$ **EXERCISE 13B.7**

Verify that when $x = 1,280$, the short-run expense is equal to the long-run cost.

13B.1.3 Adding a (Long-Run) Recurring Fixed Cost So far, we have included in our analysis the expenses and costs associated with inputs, with the expense on fixed inputs not showing up as an economic cost in the short run and showing up as a variable cost in the long run. In part A of the chapter, we also introduced a new type of cost that we called a “fixed cost avoidable only by exiting” or a “recurring fixed cost.” We gave two examples of such a cost: the cost associated with recurring license fees that do not vary with the level of output and the cost associated with an input (such as the management skills of the firm’s CEO) that remains fixed even in the long run. These are fixed expenses in the short run and therefore do not affect short-run costs (and thus short-run supply decisions), but they are real economic costs in the long run. We can include them in our usual cost function $C(x, w, r)$ by simply adding them as a fixed cost FC term. Thus, the new cost function becomes

$$\bar{C}(x, w, r) = C(x, w, r) + FC = w\ell(x, w, r) + rk(x, w, r) + FC. \quad (13.19)$$

You can then see immediately that the addition of such a fixed cost has no impact on the marginal cost function because, when we take the derivative of $\bar{C}(x, w, r)$ with respect to x , the FC term simply drops out. The average cost function, however, changes to

$$AC(x, w, r) = \frac{C(x, w, r)}{x} + \frac{FC}{x} = AVC(x, w, r) + \frac{FC}{x} \quad (13.20)$$

where AVC denotes the average *variable* cost associated with the variable inputs of capital and labor. Since the term FC/x declines as x increases, the new average cost AC converges to the average variable cost as illustrated in Graph 13.5. This implies that the long-run supply curve

is not shifted by the addition of such a fixed cost; it merely becomes “shorter” because its starting point (at the lowest point of AC) moves up with an upward shift in the AC curve.

Does the inclusion of a fixed cost cause any change in conditional input demands? What about unconditional input demands?

EXERCISE
13B.8

Does the inclusion of a fixed cost change either the (short-run) “shut down” price or the (long-run) “exit” price?

EXERCISE
13B.9

13B.2 Output Supply and Changes in the Economic Environment

We now turn more directly to the output supply function $x(p, w, r)$, asking why it slopes up and how short- and long-run supply curves relate to one another (as we did graphically in Graph 13.7). We then proceed to investigate how changes in input prices shift these supply curves. Note that a “supply curve” is simply an inverse “slice” of the supply function $x(p, w, r)$ that holds the input prices (w, r) fixed and illustrates how output supply changes with output price p .

13B.2.1 Supply Curves Always Slope Up In the Appendix to Chapter 12, we developed two concepts relating to output supply that we will simply take as given in this chapter. First, part of what we called Hotelling’s Lemma in equation (12.52) states that

$$\frac{\partial \pi(p, w, r)}{\partial p} = x(p, w, r), \quad (13.21)$$

and one of our conclusions from Graph 12.14 was that the profit function $\pi(p, w, r)$ in our duality picture is convex in p ; that is,

$$\frac{\partial^2 \pi(p, w, r)}{\partial p^2} \geq 0. \quad (13.22)$$

Combining these two equations, we get

$$\frac{\partial x(p, w, r)}{\partial p} = \frac{\partial^2 \pi(p, w, r)}{\partial p^2} \geq 0; \quad (13.23)$$

Both short-run and long-run supply curves slope up.

that is, the output supply curve is upward sloping in price. Since Hotelling’s Lemma holds for production functions of any number of inputs, it also holds for short-run production functions (in which some inputs are held fixed); thus *all output supply curves, both in the short and long run, slope up*. Notice furthermore that none of this requires assumptions like homotheticity, which we used in part A of the chapter simply for convenience.

13B.2.2 Short-Run Supply Curves Are Steeper than Long-Run Supply Curves Next, suppose that capital is fixed at quantity k^A in the short-run (as it was in our development of Graph 13.7). Then, while our long-run supply function is $x(p, w, r)$, our short-run supply function $x_{k^A}(p, w)$ is derived from the single-input production function that is given by the “slice” of the two-input production function which holds capital fixed at k^A . For instance, as we already discussed in the example of Section 13B.1.2, if the long-run

production function is $f(\ell, k) = 20\ell^{2/5}k^{2/5}$, the short-run production function with capital fixed at k^A is $f_{k^A}(\ell) = [20(k^A)^{2/5}]^{2/5}\ell^{2/5}$ where the bracketed term is simply a constant parameter. While $x(p, w, r)$ is derived from the profit maximization problem using the function $f(\ell, k)$, $x_{k^A}(p, w)$ is derived from the profit maximization problem using $f_{k^A}(\ell)$. As will become clear in a minute, the short-run supply function will then not be a function of r because the expense on the fixed amount of capital k^A is not an economic cost in the short run.

To be more precise, the short-run profit maximization problem is

$$\max_{x, \ell} px - w\ell \quad \text{such that } x = f_{k^A}(\ell) \quad (13.24)$$

which can be written as the unconstrained optimization problem

$$\max_{\ell} pf_{k^A}(\ell) - w\ell. \quad (13.25)$$

EXERCISE 13B.10 Would including the fixed expense rk^A in the short-run profit maximization problem (so that the objective function becomes $px - w\ell - rk^A$) make any difference as the problem is solved?

Solving this exactly as we solved the single-input profit maximization problem in Chapter 11, we then get the short-run labor demand function $\ell_{k^A}(p, w)$, and plugging this back into the short-run production function, we get the short-run output supply function $x_{k^A}(p, w)$. At this short-run optimum, the marginal revenue product of labor is equal to the wage, but the marginal revenue product of capital is not typically equal to the rental rate because we are unable to adjust capital away from its fixed quantity k^A in the short run. The short-run profit function is equal to $\pi_{k^A}(p, w) = px_{k^A}(p, w) - w\ell_{k^A}(p, w)$, which does not include a term rk^A for the expense on capital because this expense is a sunk “cost” in the short run.

Now suppose that input and output prices are such that k^A happens to be equal to the long-run optimal quantity of capital; that is, suppose that we happen to have just the right quantity of capital that results in the marginal revenue product of capital being equal to the rental rate. In that case, the short-run profit *minus* the expense on fixed capital is exactly equal to the long-run profit, which takes the cost of capital as a real economic cost; that is, $\pi(p, w, r) = \pi_{k^A}(p, w) - rk^A$. This emerges directly from the insight that the short-run total *expenditure* is exactly equal to the (total) *cost* in the long-run when capital is at its long-run optimum, an insight we first developed in Graph 13.2 and then developed mathematically in Section (13B.1.1). But if k^A is not equal to the long-run optimal level of capital, the short-run profit *minus* rk^A must be less than the long-run profit because in the long run we would adjust capital to the optimal quantity. This again emerges directly from Graph 13.2 and from equation (13.13) where we showed that the short-run total *expenditure* exceeds the long-run (total) cost whenever capital is not at its long-run optimal level. We can therefore conclude that

$$\pi(p, w, r) \geq \pi_{k^A}(p, w) - rk^A, \quad (13.26)$$

with this equation holding with equality only when k^A is in fact at its long-run optimal level.

Suppose next that the input prices are currently fixed at (w^A, r^A) . We can then define $g(p)$ as the difference between long-run profit and short-run profit adjusted for the expense on capital; that is,

$$g(p) = \pi(p, w^A, r^A) - \pi_{k^A}(p, w^A) + r^A k^A, \quad (13.27)$$

and we know from what we have concluded so far that $g(p)$ will be equal to zero when k^A is the long-run optimal level of capital for the output price p , but $g(p)$ is greater than zero when this is

GRAPH 13.14 Graph of $g(p) = \pi(p, w^A, r^A) - \pi_{k^A}(p, w^A) + r^A k^A$

not the case. This function is sketched out in Graph 13.14 where p^A is the price at which k^A is the long-run optimal quantity of capital (when input prices are held at (w^A, r^A)).

As is apparent from this graph, $g(p)$ attains its minimum at p^A , which implies that the second derivative of g is positive at p^A . Thus,

$$\frac{\partial^2 g(p^A)}{\partial p^2} = \frac{\partial^2 \pi(p^A, w^A, r^A)}{\partial p^2} - \frac{\partial^2 \pi_{k^A}(p^A, w^A)}{\partial p^2} \geq 0. \tag{13.28}$$

Hotelling’s Lemma is valid for both short-run and long-run profit functions, and so, when we apply Hotelling’s Lemma to both these profit functions in equation (13.28), we can rewrite the equation as

$$\frac{\partial x(p^A, w^A, r^A)}{\partial p} - \frac{\partial x_{k^A}(p^A, w^A)}{\partial p} \geq 0, \tag{13.29}$$

or simply

$$\frac{\partial x(p^A, w^A, r^A)}{\partial p} \geq \frac{\partial x_{k^A}(p^A, w^A)}{\partial p}. \tag{13.30}$$

This then simply states what we showed graphically in Graph 13.7: the long-run supply response is larger than the short-run supply response from a change in output price. Note that, while we showed this for homothetic production processes in our graphical development, the mathematical proof again required no such restrictions on production. Thus, the result holds generally for all production processes.

Long-run supply responds more than short-run supply when output price changes.

Equation (13.30) can also be read as “the slope of the long-run output supply function is larger than the slope of the short-run output supply function (with respect to price).” But the long-run supply curve in Graph 13.7 appears to have a shallower (and thus smaller) slope than that of the short-run supply curve. How can you reconcile what the math and the graphs seem to be telling us?

EXERCISE 13B.11

13B.2.3 An Example (continued) In our example of the long-run production function $f(\ell, k) = 20\ell^{2/5}k^{2/5}$, for instance, we determined in Chapter 12 that the long-run output supply and input demand functions are

$$x(p, w, r) = 81,920 \frac{p^4}{(wr)^2}, \ell(p, w, r) = 32,768 \frac{p^5}{r^2w^3} \text{ and } k(p, w, r) = 32,768 \frac{p^5}{w^2r^3}. \quad (13.31)$$

Suppose the economic environment is given by $(p, \ell, r) = (5, 20, 10)$ for which we concluded in Chapter 12 that the long-run optimal production plan is $(x, \ell, k) = (1280, 128, 256)$. Now suppose capital is fixed at 256 in the short run. The short-run production function is then given by $f_{k=256}(\ell) = 20(256^{2/5})\ell^{2/5} = 183.79\ell^{2/5}$. When this production function is used to define the short-run profit maximization problem

$$\max_{\ell} p(183.79\ell^{2/5}) - w\ell, \quad (13.32)$$

the resulting short-run output supply and input demand functions are

$$x_{k=256}(p, w) = 3,225 \left(\frac{p}{w}\right)^{2/3} \text{ and } \ell_{k=256}(p, w) = 1,290 \left(\frac{p}{w}\right)^{5/3}. \quad (13.33)$$

EXERCISE 13B.12 Verify that these are truly the short-run output supply and input demand functions by checking to see if the short-run functions give the same answers as the long-run functions when $(p, w, r) = (5, 20, 10)$.

Taking derivatives of the long-run and short-run output supply functions with respect to p , we get

$$\frac{\partial x(p, w, r)}{\partial p} = 327,680 \frac{p^3}{(wr)^2} \text{ and } \frac{\partial x_{k=256}(p, w)}{\partial p} = \frac{2,150}{p^{1/3}w^{2/3}}. \quad (13.34)$$

Evaluated at the $(p, w, r) = (5, 20, 10)$, this gives a partial derivative of the long-run supply function of 1,024 and a partial derivative of the short-run supply function of 170.67, indicating the predicted larger change in output in the long run than in the short run when we begin at a production plan that is long-run profit-maximizing and experience a change in output price. If p , for instance, were to rise from \$5.00 to \$7.50, the long-run profit-maximizing production plan given by equations (13.31) would go from $(x, \ell, k) = (1280, 128, 256)$ to $(x, \ell, k) = (6480, 972, 1944)$, but the new short-run production plan (holding k fixed at 256) would be given by equations (13.33) as $(x, \ell, k) = (1677, 252, 256)$, implying that production will rise from 1,280 to 1,677 output units in the short run and to 6,480 in the long run when capital can be adjusted.

13B.2.4 Substitution Effects in Production In Graph 13.8, we illustrated that, as input prices fall, the cost of production falls both because the *direct effect* of current cost-minimizing input bundles becoming cheaper and because of the *substitution effect* leading to less intensive use of relatively more expensive inputs. We can illustrate this with our example of a production process represented by the production function $f(\ell, k) = 20\ell^{2/5}k^{2/5}$ for which we have calculated the various functions in our producer duality picture. In particular, we recall again the conditional input demands (from equation (13.14))

$$\ell(w, r, x) = \left(\frac{r}{w}\right)^{1/2} \left(\frac{x}{20}\right)^{5/4} \text{ and } k(w, r, x) = \left(\frac{w}{r}\right)^{1/2} \left(\frac{x}{20}\right)^{5/4}, \quad (13.35)$$

which explicitly incorporate the substitution effect, with the slice of the conditional labor demand curve in Graph 13.8d derived explicitly from a single isoquant. The corresponding cost

function, previously given in equation (13.15), then incorporates both the direct and the substitution effect from input price changes and is given by

$$C(w, r, x) = 2(wr)^{1/2} \left(\frac{x}{20} \right)^{5/4}. \tag{13.36}$$

Suppose we begin with input prices of $(w, r) = (20, 10)$ and w falls to \$10. Then the slice of the cost function at the original input prices is $C(x, 20, 10) = 0.66874x^{5/4}$ while the slice at the new input prices becomes $C(x, 10, 10) = 0.47287x^{5/4}$. Thus the (total) long-run cost curve shifts down by $0.19587x^{5/4}$. Taking the derivative of these functions with respect to x , we can also calculate the corresponding marginal cost curves $MC(x, 20, 10) = 0.83593x^{1/4}$ and $MC(x, 10, 10) = 0.59109x^{1/4}$, and dividing the total cost curves by x we can calculate the average cost curves $AC(x, 20, 10) = 0.66874x^{1/4}$ and $AC(x, 10, 10) = 0.47287x^{1/4}$. The shift in the total and marginal cost curves are illustrated in Graph 13.15 as a shift from blue to green curves.

Now let's suppose we isolate the direct effect of an input price change by assuming that the producer does not substitute away from capital and into labor when w falls from \$20 to \$10. When input prices are $(20, 10)$, the conditional labor demand for different output levels x is given by $\ell(20, 10, x) = 0.01672x^{5/4}$ and $k(20, 10, x) = 0.03344x^{5/4}$. If the producer does not alter his or her behavior as a result of a decline in the wage to \$10, this would imply that his or her (total) costs are given by $10\ell(20, 10, x) + 10k(20, 10, x) = 0.5016x^{5/4}$, which is higher than the (total) cost including the substitution effect ($C(x, 10, 10) = 0.47287x^{5/4}$) we calculated. The magenta curves in Graph 13.15 represent the change in cost curves that is due to this direct effect, with the remainder due to the substitution effect.

Panels (a) and (b) of Graph 13.15 are analogous to panels (b) and (e) of Graph 13.8. Now calculate the relevant curves and graph them for the case that is analogous to panels (c) and (f) of Graph 13.8 where, instead of wage falling from \$20 to \$10, the rental rate of capital rises from \$10 to \$20.

EXERCISE 13B.13

GRAPH 13.15 Change in Cost Curves as w Falls when $f(\ell, k) = 20\ell^{2/5}k^{2/5}$

TABLE 13.2 Declining Substitution Effects with Declining Substitutability (as w falls from 10 to 5)

Producing 5,000 Units of Output when w Falls and $f(\ell, k) = 100(0.5\ell^{-\rho} + 0.5k^{-\rho})^{-0.5/\rho}$					
ρ	$\ell(5, 10, 5000)$	$k(5, 10, 5000)$	Change in Cost	Direct Effect	Substitution Effect
-1.00	5,000	0	-\$25,000	-\$12,500	-\$12,500
-0.90	5,388	5	-\$23,004	-\$12,500	-\$10,504
-0.75	5,384	336	-\$19,715	-\$12,500	-\$7,215
-0.50	4,444	1,111	-\$16,667	-\$12,500	-\$4,167
0.00	3,536	1,768	-\$14,645	-\$12,500	-\$2,145
1.00	3,018	2,134	-\$13,572	-\$12,500	-\$1,072
5.00	2,617	2,379	-\$12,855	-\$12,500	-\$365
25.00	2,538	2,472	-\$12,582	-\$12,500	-\$82
∞	2,500	2,500	-\$12,500	-\$12,500	\$0

It should be clear to you by this point that the size of the substitution effect is captured in the downward slope of the conditional input demands.¹⁰ Thus, as the elasticity of substitution in production increases, the input demand curves become flatter causing the substitution effect to become relatively more important. Table 13.2 illustrates this with an example in which the production function is a generalized CES production function with decreasing returns to scale. The general form of this function is

$$f(\ell, k) = A(\alpha\ell^{-\rho} + (1 - \alpha)k^{-\rho})^{-\beta/\rho}, \quad (13.37)$$

where, as in the case of CES utility functions, ρ can take on values between -1 and ∞ with the elasticity of substitution given by $1/(1 + \rho)$. Thus, when $\rho = -1$, the isoquants are straight lines with perfect substitutability between labor and capital, while when $\rho = \infty$, labor and capital are perfect complements in production. The only difference between this family of CES production functions and the family of CES utility functions we defined in Chapter 5 is that we have included the additional β and A terms in the producer version, terms we will see used later in this chapter. For now we can simply note that β indicates the returns to scale of the function (with $\beta < 1$ indicating decreasing returns to scale, $\beta > 1$ indicating increasing returns to scale), and A scaling the function up or down. We will explore the properties of this family of production functions in some more detail at the end of the chapter.¹¹

¹⁰ In the Appendix to Chapter 10, we proved formally that compensated demand curves always slope down in consumer theory, and, since we have seen that compensated demand curves are exactly analogous to conditional input demand curves in producer theory, the same argument can be used to prove formally that conditional input demand curves slope down; that is, the substitution effect always points in the same direction.

¹¹ While it is algebraically tedious, you can calculate the various functions in the duality picture that arise from the generalized CES function. For instance, the input demand and output supply functions are

$$\ell(\rho, w, r) = \left(\frac{w + r\gamma}{\beta A \rho (\alpha + (1 - \alpha)\gamma^{-\rho})^{-(\beta/\rho)}} \right)^{1/(\beta-1)}, \quad (13.38)$$

$$k(\rho, w, r) = \gamma \left(\frac{w + r\gamma}{\beta A \rho (\alpha + (1 - \alpha)\gamma^{-\rho})^{-(\beta/\rho)}} \right)^{1/(\beta-1)},$$

$$x(\rho, w, r) = (A\rho)^{-1/(\beta-1)} \left(\frac{w + r\gamma}{\beta (\alpha + (1 - \alpha)\gamma^{-\rho})^{-(\beta/\rho)}} \right)^{\beta/(\beta-1)} (\alpha + (1 - \alpha)\gamma^{-\rho})^{-\beta/\rho},$$

where

$$\gamma = \left(\frac{(1 - \alpha)w}{\alpha r} \right)^{1/(\rho+1)}. \quad (13.39)$$

If the generalized CES function was used as a utility function instead of the version where A and β are set to 1, would the underlying tastes represented by that function be changed?

EXERCISE
13B.14

The particular version of this production function selected for the derivation of results in Table 13.2 has the property that, when w and r are set to \$10 and p is set to \$20, the profit-maximizing production plan is $(x, \ell, k) = (5000, 2500, 2500)$ regardless of what value ρ takes. Table 13.2 then presents the conditional input demand for labor and capital when wage drops to \$5 and production remains at 5,000 units of output, and it reports the overall change in the cost of producing 5,000 units of output as well as the portion of the overall drop in costs that is due to the direct effect and the portion that is due to the substitution effect. Notice that, as the production process becomes one of declining substitutability between capital and labor (as one goes down the table), the direct effect of the drop in w on cost (equivalent to moving from the blue to the magenta curves in our graphs) remains constant while the effect due to the substitution effect (equivalent to moving from the magenta to the green curves in our graphs) declines dramatically.

Explain why the direct effect in the table does not depend on the degree of substitutability between capital and labor in production.

EXERCISE
13B.15

13B.3 Input Demand and Changes in the Economic Environment

In Section A, we demonstrated that input demand curves slope down and that short-run input demand curves are steeper than long-run input demand curves. We also showed that the “cross-price” relationship between one input’s price and demand for another input is ambiguous and depends on the relative substitutability of the inputs in production. Similarly, we showed that short-run and long-run labor responses to output price changes may differ with the relative substitutability of the inputs. In this section, we will demonstrate some of these results mathematically and illustrate others by using specific production functions.

13B.3.1 Input Demand Curves Slope Down In Graph 13.10 (and implicitly in Graphs 13.9 and 13.11), we illustrated the impact of input price changes on input demand and for both labor and capital found that the *own price input demand curves slope down*; that is, the quantity of labor demanded falls with increases in w and the quantity of capital demanded falls with increases in r . While our graphical illustrations were for the case of homothetic production processes, the result turns out to hold more generally, with no possibility of upward-sloping input demand curves (unlike in consumer theory where a sufficiently large income effect—absent from producer theory—could lead to upward-sloping consumer demand curves). And like our proof that output supply curves slope down (in Section 13B.2.1), this can be illustrated quickly from Hotelling’s Lemma and the fact that profit functions are convex (as developed in the Appendix to Chapter 12). First, Hotelling’s Lemma states that

$$\frac{\partial \pi(p, w, r)}{\partial w} = -\ell(p, w, r) \quad \text{and} \quad \frac{\partial \pi(p, w, r)}{\partial r} = -k(p, w, r). \quad (13.40)$$

The convexity of the profit function implies that

$$\frac{\partial^2 \pi(p, w, r)}{\partial w^2} \geq 0 \quad \text{and} \quad \frac{\partial^2 \pi(p, w, r)}{\partial r^2} \geq 0. \quad (13.41)$$

All labor and capital (own-price) demand curves slope down.

Combining these, we can conclude that

$$\frac{\partial \ell(p, w, r)}{\partial w} = -\frac{\partial^2 \pi(p, w, r)}{\partial w^2} \leq 0 \quad \text{and} \quad \frac{\partial k(p, w, r)}{\partial r} = -\frac{\partial^2 \pi(p, w, r)}{\partial r^2} \leq 0; \quad (13.42)$$

that is, labor and capital demand curves slope down with respect to their own prices. Since the properties of profit functions and Hotelling’s Lemma apply regardless of how many inputs a production function has when the optimization problem is solved, this implies that the result holds for both short-run and long-run input demand curves (since short-run supply curves are derived simply from smaller dimensional slices of larger dimensional production frontiers).

EXERCISE 13B.16 Show that the short- and long-run input demand curves calculated for the production function $f(\ell, k) = 20\ell^{2/5}k^{2/5}$ in equation (13.33) and (13.31) are downward sloping.

13B.3.2 Labor Demand Curves Are Steeper in the Long Run than in the Short Run

Next, we illustrated in Graph 13.10 that short-run labor demand curves are steeper than long-run labor demand curves; or, put differently, as wage changes, the quantity of labor adjusts more in the long run than in the short run. This result is similar to the result in Section 13B.2.2 that output supply is more responsive in the long run than in the short run. In fact, the steps are virtually identical to those in equations (13.26) through (13.30), except that derivatives are with respect to w rather than p . I will therefore leave it to you as an end-of-chapter exercise to demonstrate that labor demand responses to wage changes are stronger in the long run than in the short run.

13B.3.3 Substitutability of ℓ and k and Slopes of Cross-Price Input Demand

In some of the same Graphs (particularly Graphs 13.10 and 13.11), we also demonstrated that cross-price input demand relationships may be upward or downward sloping depending on the substitutability of capital and labor in production. More specifically, we showed that demand for capital may increase or decrease with the wage rate, and demand for labor may increase or decrease with the rental rate of capital. And we demonstrated that *a positive cross-price input demand relationship emerges when inputs are relatively substitutable, while a negative relationship emerges when they are relatively complementary.*

We will forego demonstrating this formally but will rather return to our example of a generalized CES production function $f(\ell, k) = A(\alpha\ell^{-\rho} + (1 - \alpha)k^{-\rho})^{-\beta/\rho}$. Specifically, we will again let $A = 100$, $\alpha = 0.5$, and $\beta = 0.5$ and present in Table 13.3 how input demands change as the substitutability of the inputs (captured by the parameter ρ) changes. And, as in the previous table, we begin in the economic environment $(p, w, r) = (20, 10, 10)$. For this particular configuration of economic and technological parameters, the profit-maximizing production plan is invariant to changes in ρ , with $(x, \ell, r) = (5000, 2500, 2500)$ optimal for all degrees of substitutability of inputs.¹²

Beginning with the economic environment $(p, w, r) = (20, 10, 10)$, we then ask how the behavior of the producer changes in the short and long run as w increases from 10 to 11. In particular, Table 13.3 reports the new short- and long-run labor demand, the new long-run demand for capital, and the new short- and long-run output supply for this wage increase as we vary the

¹²This is very much a special case, with optimal production plans ordinarily varying a great deal with the degree of input substitutability. The special case arises from the fact that we have set α equal to 0.5 and because we have set the initial wage and rental rates to be equal to one another. You should be able to convince yourself that $\alpha = 0.5$ implies that all isoquants have slope -1 along the 45-degree line. Similarly, isocosts have slope -1 when wages and rental rates are equal to one another. Thus, all cost-minimizing bundles lie on the 45-degree line, and changing ρ simply changes the curvature of isoquants without changing the slope along the 45-degree line. Furthermore, changing ρ does not alter the vertical slice of the production choice set along the 45-degree line, which implies that the cost-minimizing bundle that is also profit-maximizing will remain unchanged by changes in ρ . We will explore this in some more detail in one of the end-of-chapter exercises that employs a computer simulation.

TABLE 13.3 Cross-Price Input Demands when w Increases (from 10 to 11) and $\bar{k} = 2,500$

SR and LR Production Plans when w Increases and $f(\ell, k) = 100(0.5\ell^{-\rho} + 0.5k^{-\rho})^{-1/\rho}$						
ρ	$\ell(20, 10, 10)$	$\ell_{\bar{k}}(20, 11, 10)$	$\ell(20, 11, 10)$	$k(20, 11, 10)$	$x_{\bar{k}}(20, 11, 10)$	$x(20, 11, 10)$
-0.99	2,500	1,652	0.36	4,965	4,556	4,965
-0.80	2,500	1,891	1,767	2,845	4,681	4,789
-0.60	2,500	2,021	2,016	2,558	4,749	4,775
-0.50	2,500	2,066	2,066	2,500	4,773	4,773
-0.25	2,500	2,147	2,133	2,422	4,815	4,769
0.00	2,500	2,201	2,167	2,384	4,843	4,767
0.50	2,500	2,271	2,200	2,345	4,880	4,766
1.00	2,500	2,314	2,217	2,326	4,902	4,765
5.00	2,500	2,425	2,250	2,287	4,961	4,763
50.00	2,500	2,490	2,266	2,270	4,995	4,762

input substitutability (as captured by ρ) beginning with virtually perfect substitutes in the first row to virtually perfect complements in the final row. First, notice that labor demand falls (from the initial 2,500), both in the short run and the long run, for all rows, and it always falls more in the long run than in the short run. This is consistent with our conclusions about labor demand thus far.

Can you make sense of the fact that the demand for labor falls less (both in the short and long run) the more complementary labor and capital are in production?

**EXERCISE
13B.17**

Second, consider the column that illustrates demand for capital at the higher wage ($k(20, 11, 10)$) and recall that the optimal production plan before w increased contained 2,500 units of capital. When ρ lies between -1 and -0.5 and the inputs are therefore relatively substitutable, demand for capital increases as wage increases, whereas when ρ rises above -0.5 and inputs become less substitutable, demand for capital falls when wage increases. This is precisely the result we derived intuitively in Graph 13.10 where the relationship between capital and wage was upward sloping in panel (g) when it was derived from relatively flat isoquants in panel (a), while the relationship was downward sloping in panel (i) when it was derived from isoquants with relatively little substitutability in panel (c). Panel (h) of Graph 13.10 then gives the “in between case” where the quantity of capital demanded as the wage changes is the same as the original quantity at the initial wage. In this special case, the producer is therefore able to go immediately to the long-run profit-maximizing production plan because there is no need to change how much capital is used.

What value of ρ , and what implied elasticity of substitution between capital and labor, corresponds to the “in between case”?

**EXERCISE
13B.18**

Lastly, notice one other feature of Table 13.3: While output always falls, both in the short and long run, from the 5,000 units of output before the wage increased, it *increases* from the short to the long run when labor and capital are relatively substitutable and *decreases* from the short to the long run when labor and capital are relatively complementary. This, too, is consistent with Graph 13.10 where long-run output x^C falls on a higher isoquant than short-run output x^B in panel (a) but not in panel (c). The dividing line between these two cases is once again the case where capital input remains unchanged as w rises, with short-run and long-run production plans coinciding in panel (b).

13B.3.4 Demand for Labor as ρ Changes Finally, we used two extreme sets of isoquants in Graph 13.12 to argue that the relationship between the short- and long-run labor demand response to changes in output price also depends on the relative substitutability of labor and capital. The intuition behind this result is relatively straightforward. Whenever output price rises, we know from our results on output supply curves that producers will want to produce more in the short run and even more in the long run. Suppose capital and labor are relatively substitutable and capital is relatively cheap compared to labor. Then producers would rely primarily on capital in their production processes, but if capital is fixed in the short run, they might initially hire additional labor to increase production in response to an output price increase. In the long run, however, they would substitute away from this additional labor and into more capital. Thus, it may well be the case that labor demand increases in the short run with an increase in output price but that some of that increased labor is laid off as the producer enters the long run. At the same time, if capital and labor are relatively more complementary, short-run increases in labor may be supplemented with additional increases in labor as capital is adjusted in the long run.

We again illustrate this with the CES production function we previously used in Table 13.3 and with an initial economic environment $(p, w, r) = (20, 10, 10)$. Table 13.4 then once again varies ρ

TABLE 13.4 Substitutability and Responses to a Change in p (from 20 to 25) when $\bar{k} = 2,500$

SR and LR Production Plans when ρ Increases and $f(\ell, k) = 100(0.5\ell^{-\rho} + 0.5k^{-\rho})^{-0.5\rho}$						
ρ	$\ell(20, 10, 10)$	$\ell_{\bar{k}}(25, 10, 10)$	$\ell(25, 10, 10)$	$k(25, 10, 10)$	$x_{\bar{k}}(25, 10, 10)$	$x(25, 10, 10)$
-0.99	2,500	5,270	3,906	3,906	6,230	6,250
-0.80	2,500	4,584	3,906	3,906	5,925	6,250
-0.60	2,500	4,088	3,906	3,906	5,707	6,250
-0.50	2,500	3,906	3,906	3,906	5,625	6,250
-0.25	2,500	3,579	3,906	3,906	5,480	6,250
0.00	2,500	3,366	3,906	3,906	5,386	6,250
0.50	2,500	3,116	3,906	3,906	5,275	6,250
1.00	2,500	2,975	3,906	3,906	5,212	6,250
5.00	2,500	2,666	3,906	3,906	5,074	6,250
50.00	2,500	2,520	3,906	3,906	5,009	6,250

in the first column, going from virtually perfect substitutes in the first row to virtually perfect complements in the last row. The table differs from Table 13.3 in that now we are changing the output price from 20 to 25 rather than changing the wage. Note that since the ratio of wage to rental rate therefore does not change in this table, the long-run profit-maximizing input bundle will have the same ratio of labor to capital at any output price, but in the short run this ratio changes as we hold capital fixed.

Can you identify in Table 13.4 the relationship of the substitutability of capital and labor to the degree of short-versus long-run response in labor demand from an increase in output price? Is this consistent with what emerges in Graph 13.12?

EXERCISE
13B.19

CONCLUSION

This chapter concludes our treatment of production by a price-taking firm in isolation. We began the chapter by tracing out the impact of changes in input prices on cost curves, and we emphasized that care must be taken to include in these curves only those expenditures by the firm that are true economic costs. When we do this correctly, it is *always* the case that the price-taking firm's supply curve, whether in the short or long run, is equal to the portion of the marginal cost curve that lies above average cost. Because some expenses (such as those on inputs that are fixed in the short run) are not real economic costs in the short run, we found that firms will often stay open in the short run even if they have decided that they will exit the industry in the long run. This is because short-run profit can be positive even when long-run profit is negative when certain long-run costs are not real economic costs in the short run, and it implies that the short-run supply curve extends "below" the long run supply curve. We furthermore found that output supply responses to price changes are greater in the long run than in the short run, and that labor demand responses to wage changes are similarly greater in the long run than in the short run.

Much of the remainder of the chapter focused on the role of substitution effects and scale effects in production. When one input price changes relative to another, we found that firms will, conditional on producing some output quantity, substitute away from the input that has become relatively more expensive and toward the input that has become relatively cheaper, and they will "scale up" production if the input price falls and "scale down" production when the input price rises. The degree of substitutability between inputs in the production process was then found to determine whether "cross-price" input demands slope up or down—whether long-run labor demand increases or decreases with an increase in the price of capital, and whether long-run capital demand increases or decreases with an increase in the price of labor. We similarly determined that the degree of substitutability of inputs determines whether changes in labor demand are greater or less in the short run than in the long run when output price changes.

We will now leave behind some of the details we uncovered in this chapter and move toward discussing the interaction of the demand and supply sides of markets. This implies that we will combine the insights from consumer theory with those from producer theory, putting consumer demand together with producer supply in output markets, and combining consumer supply and producer demand in input markets. Put differently, we will now move from the world of "optimization" where we consider an individual's choices in isolation toward the world of "equilibrium" where we investigate the aggregate implications of individual optimizing behavior. What happens when lots of price-taking individuals who try to do the best they can on all sides of a market interact with one another? And how does our answer to this change when underlying conditions change?

END-OF-CHAPTER EXERCISES

- 13.1[†]** The following problem explores the relationship between maximizing profit in the short and long run when capital is fixed in the short run.
- A.** Suppose you have a homothetic production technology and you face output price p and input prices (w, r) .
- On a graph with labor ℓ on the horizontal and capital k on the vertical axis, draw an isoquant and label a point on that isoquant as $(\bar{\ell}, \bar{k})$.
 - Suppose that the point in your graph represents a profit-maximizing production plan. What has to be true at this point?
 - In your graph, illustrate the slice along which the firm must operate in the short run.
 - Suppose that the production technology has decreasing returns to scale throughout. If p falls, can you illustrate all the possible points in your graph where the new profit-maximizing production plan might lie in the long run? What about the short run?
 - What condition that is satisfied in the long run will typically not be satisfied in the short run?
 - What qualification would you have to make to your answer in (d) if the production process had initially increasing but eventually decreasing returns to scale?
- B.** Consider the Cobb–Douglas production function $x = f(\ell, k) = A\ell^\alpha k^\beta$.
- ** For input prices (w, r) and output price p , calculate the long-run input demand and output supply functions assuming $0 < \alpha, \beta \leq 1$ and $\alpha + \beta < 1$.
 - How would your answer change if $\alpha + \beta \geq 1$?
 - Suppose that capital is fixed at \bar{k} in the short run. Calculate the short-run input demand and output supply functions.
 - What has to be true about α and β for these short-run functions to be correct?
 - Suppose $\bar{k} = k(w, r, p)$ (where $k(w, r, p)$ is the long-run capital demand function you calculated in part (a)). What is your optimal short-run labor demand and output supply in that case?
 - How do your answers compare to the long-run labor demand function $\ell(w, r, p)$ and the long-run supply function $x(w, r, p)$ you calculated in part (a)? Can you make intuitive sense of this?
- 13.2** The following problem explores issues similar to those in exercise 13.1, but instead of thinking directly about profit maximization, we will think about cost minimization on the way to profit maximization.
- A.** Suppose you have a homothetic production technology and you face input prices (w, r) .
- On a graph with labor ℓ on the horizontal and capital k on the vertical axis, illustrate a ray along which all cost-minimizing production plans might lie for a given set of input prices. Does your answer depend on whether the production technology has increasing or decreasing returns to scale (or some combination of these)?
 - Illustrate in your graph an isoquant corresponding to some output level \bar{x} . What has to be true at the intersection of the ray and the isoquant?
 - Show what happens to the ray of cost-minimizing input bundles if w increases to w' . Then illustrate how you would derive the conditional labor demand curve for producing \bar{x} .
 - From this point forward, suppose that the production technology has decreasing returns to scale. Illustrate how you would derive the firm’s long-run cost curve for the original input prices.
 - What happens to the cost curve when w increases to w' ?

*conceptually challenging

**computationally challenging

[†]solutions in Study Guide

- f. Suppose that you are initially producing at the intersection of your original isoquant (corresponding to \bar{x}) and the original ray. If w remained unchanged, where would your (short-run) expenditure curve fall on your graph with the long-run cost curve?
 - g. Translate your cost/expenditure curve graph to a graph with the average (long-run) cost and average (short-run) expenditure curves.
 - h. How does the average (long-run) cost curve change when w increases to w' ? If you also graphed a cost curve that removed the substitution effect, where would it generally lie relative to the original and final cost curve? What would its precise location depend on?
 - i. Now suppose that instead of wage increasing, the rental rate on capital r fell to r' . What happens to the conditional labor demand curve that you graphed in part (c)?
 - j. Repeat (h) for the change in the rental rate.
- B.** Suppose again (as in exercise 13.1) that the production process is defined by the Cobb–Douglas production function $x = f(\ell, k) = A\ell^\alpha k^\beta$.
- a.** For input prices (w, r) , calculate the long-run conditional input demand functions.
 - b. Do you need to assume $0 < \alpha, \beta \leq 1$ and $\alpha + \beta < 1$ in order for these to be valid?
 - c. Derive the long-run total, marginal, and average cost functions.
 - d. Suppose output price is p . Use your answer to derive the firm's (long-run) profit-maximizing output supply function. Do you need to assume $0 < \alpha, \beta \leq 1$ and $\alpha + \beta < 1$ for this to be valid? (If you have done exercise 13.1, check to make sure your answer agrees with what you concluded in part (a) of that exercise.)
 - e. From your answer, derive the firm's profit-maximizing long-run labor and capital demand functions. (You can again check your answers with those you derived through direct profit maximization in exercise 13.1.)
 - f. Now suppose capital is fixed in the short-run at \bar{k} . Derive the short-run conditional input demand for labor.
 - g. Derive the short-run (total) cost function as well as the short-run marginal and average cost functions.
 - h. Derive the short-run supply curve.
 - i. *True or False:* As long as the production function has decreasing returns the scale, the (short-run) average expenditure curve will be U-shaped even though the short-run average cost curve is not.
 - j. What is the shape of the long-run average cost curve? Can the Cobb–Douglas production function yield U-shaped long-run average cost curves?

13.3[†] In this exercise, we add a (long-run) fixed cost to the analysis.

- A.** Suppose the production process for a firm is homothetic and has decreasing returns to scale.
- a. On a graph with labor ℓ on the horizontal and capital k on the vertical axis, draw an isoquant corresponding to output level \bar{x} . For some wage rate w and rental rate r , indicate the cost-minimizing input bundle for producing \bar{x} .
 - b. Indicate in your graph the slice of the production frontier along which all cost-minimizing input bundles lie for this wage and rental rate.
 - c. In two separate graphs, draw the (total) cost curve and the average cost curve with the marginal cost curve.
 - d. Suppose that, in addition to paying for labor and capital, the firm has to pay a recurring fixed cost (such as a license fee). What changes in your graphs?
 - e. What is the firm's exit price in the absence of fixed costs? What happens to that exit price when a fixed cost is added?
 - f. Does the firm's supply curve shift as we add a fixed cost?
 - g. Suppose that the cost-minimizing input bundle for producing \bar{x} that you graphed in part (a) is also the profit-maximizing production plan before a fixed cost is considered. Will it still be the profit-maximizing production plan after we include the fixed cost in our analysis?

- B.** As in exercises 13.1 and 13.2, suppose the production process is again characterized by the production function $x = f(\ell, k) = A\ell^\alpha k^\beta$ with $0 < \alpha, \beta \leq 1$ and $\alpha + \beta < 1$.
- If you have not already done so in a previous exercise, derive the (long-run) cost function for this firm.
 - Now suppose that, in addition to the cost associated with inputs, the firm has to pay a recurring fixed cost of FC . Write down the cost minimization problem that includes this FC . Will the conditional input demand functions change as a result of the FC being included?
 - Write down the new cost function and derive the marginal and average cost functions from it.
 - What is the shape of the average cost curve? How does its lowest point change with changes in the FC ?
 - Does the addition of a FC term change the (long-run) marginal cost curve? Does it change the long-run supply curve?
 - How would you write out the profit maximization problem for this firm including fixed costs? If you were to solve this problem, what role would the FC term play?
 - Considering not just the math but also the underlying economics, does the addition of the FC have any implications for the input demand and output supply functions?

13.4 Repeat exercise 13.3 assuming increasing rather than decreasing returns to scale. What changes in the analysis, and what does not change?

13.5[†] We will often assume that a firm’s long-run average cost curve is U-shaped. This shape may arise for two different reasons that we explore in this exercise.

- A.** Assume that the production technology uses labor ℓ and capital k as inputs, and assume throughout this problem that the firm is currently long-run profit-maximizing and employing a production plan that is placing it at the lowest point of its long-run AC curve.
- Suppose first that the technology has decreasing returns to scale but that, in order to begin producing each year, the firm has to pay a fixed license fee F . Explain why this causes the long-run AC curve to be U-shaped.
 - Draw a graph with the U-shaped AC curve from the production process described in part (a). Then add to this the short-run MC and AC curves. Is the short-run AC curve also U-shaped?
 - Next, suppose that there are no fixed costs in the long run. Instead, the production process is such that the marginal product of each input is initially increasing but eventually decreasing, and the production process as a whole has initially increasing but eventually decreasing returns to scale. (A picture of such a production process was given in Graph 12.16 of the previous chapter.) Explain why the long-run AC curve is U-shaped in this case.
 - Draw another graph with the U-shaped AC curve. Then add the short-run MC and AC curves. Are they also U-shaped?
 - * Is it possible for short-run AC curves to *not* be U-shaped if the production process has initially increasing but eventually decreasing returns to scale?
- B.** Suppose first that the production process is Cobb–Douglas, characterized by the production function $x = f(\ell, k) = A\ell^\alpha k^\beta$ with $\alpha, \beta > 0$ and $\alpha + \beta < 1$.
- In the absence of fixed costs, you should have derived in exercise 13.2 that the long-run cost function for this technology is given by

$$C(w, r, x) = (\alpha + \beta) \left(\frac{w^\alpha r^\beta x}{A\alpha^\alpha \beta^\beta} \right)^{1/(\alpha + \beta)}. \quad (13.43)$$

If the firm has long-run fixed costs F , what is its long-run average cost function? Is the average cost curve U-shaped?

- What is the short-run cost curve for a fixed level of capital \bar{k} ? Is the short-run average cost curve U-shaped?
- Now suppose that the production function is still $f(\ell, k) = A\ell^\alpha k^\beta$ but now $\alpha + \beta > 1$. Are long-run average and marginal cost curves upward or downward sloping? Are short-run average cost curves upward or downward sloping? What does your answer depend on?

d.** Next, suppose that the production technology were given by the equation

$$x = f(\ell, k) = \frac{\alpha}{1 + e^{-(\ell-\beta)} + e^{-(k-\gamma)}} \quad (13.44)$$

where e is the base of the natural logarithm. (We first encountered this in exercises 12.5 and 12.6.) If capital is fixed at \bar{k} , what is the short-run production function and what is the short-run cost function?

e.** What is the short-run marginal cost function?

f. You should have concluded in exercise 12.6 that the long-run MC function is $MC(w, r, x) = \alpha(w + r)/(x(\alpha - x))$ and demonstrated that the MC curve (and thus the long-run AC curve) is U-shaped for the parameters $\alpha = 100$, $\beta = 5 = \gamma$ when $w = r = 20$. Now suppose capital is fixed at $\bar{k} = 8$. Graph the short-run MC curve and use the information to conclude whether the short-run AC curve is also U-shaped.

g. What characteristic of the this production function is responsible for your answer in part (f)?

13.6* In Graph 13.3, we illustrated the relationship between short-run average expenditure AE_k , short-run average cost AC_k , and long-run average cost AC^{LR} curves for a particular level of capital. The particular level of capital chosen in Graph 13.3 is that level that makes the AE_k curve tangent to the AC^{LR} at its lowest point.

- A.** Consider a firm whose technology has decreasing returns to scale throughout and who faces a recurring fixed cost. Denote the level of capital chosen in the long run at the lowest point of the long run AC as k^* .
- Replicate the short-run MC and long-run AC curves from Graph 13.3. Where in your graph does the long-run MC curve lie?
 - Draw a separate graph with the AC^{LR} curve. Suppose that $k < k^*$ in the short run. Illustrate where the AE_k must now lie.
 - Next illustrate where the AC_k and MC_k curves lie. Is the long-run MC curve now different than in part (a)?
 - On a separate graph, repeat (b) and (c) for $k' > k^*$.
 - Illustrate the short-run MC curves you drew in parts (c) and (d) in the graph you first drew in part (a). How is this graph similar to Graph 13.7 in the text?
 - True or False:* The MC_k curve crosses the AC^{LR} curve at the lowest point of the AE_k curve *only* if $k = k^*$.
 - How would your answer to (f) change if the sentence had started with the words “If the production technology has constant returns to scale and there are no fixed costs, ...”?
 - True or False:* Unless the production technology has constant returns to scale and no long-run fixed costs, the short-run AE curves are tangent at the lowest point of the long-run AC curve only if $k = k^*$.
- B.** Suppose that a firm’s production function is $x = f(\ell, k) = A\ell^\alpha k^\beta$ with $\alpha, \beta > 0$ and $\alpha + \beta < 1$. Suppose further that the firm incurs a recurring (long-run) fixed cost FC .
- In equation (13.43) from exercise 13.5, we already provided the long-run cost function for such a firm in the absence of fixed costs. What are this firm’s long-run marginal and average cost functions?
 - Derive the output level x^* at which the lowest point of the long-run average cost curve occurs.
 - From here on, suppose that $\alpha = 0.2$, $\beta = 0.6$, $A = 30$, $w = 20$, $r = 10$, and $FC = 1,000$. Given these values, what is x^* ? How much capital k^* does the firm hire to produce x^* ? (Note: The conditional input demand functions for a Cobb–Douglas production process are given in equation (13.46) of exercise 13.7.)
 - What is the long-run marginal cost of production at x^* ? What about the long-run average cost? Interpret your answer.
 - For a fixed level of capital k , what are the short-run MC , AC , and AE functions?
 - What is the short-run AE , AC , and MC for $x = x^*$ when capital is fixed at k^* ? How do these compare to long-run AC and MC of producing x^* ?
 - Now suppose capital is fixed in the short run at $k = 200$. How does your answer to (f) change? What if capital were instead fixed at $k = 400$? Interpret your answer.

13.7*† Business Application: Switching Technologies: Suppose that a firm has two different homothetic, decreasing returns to scale technologies it could use, but one of these is patented and requires recurring license payments F to the owner of the patent. In this exercise, assume that all inputs, including the choice of which technology is used, are viewed from a long-run perspective.

- A.** Suppose further that both technologies take capital k and labor ℓ as inputs but that the patented technology is more capital intensive.
- Draw two isoquants, one from the technology representing the less capital intensive and one representing the more capital intensive technology. Then illustrate the slice of each map that a firm will choose to operate on assuming the wage w and rental rate r are the same in each case.
 - Suppose that the patented technology is sufficiently advanced such that, for any set of input prices, there always exists an output level \bar{x} at which it is (long-run) cost effective to switch to this technology. On a graph with output x on the horizontal and dollars on the vertical, illustrate two cost curves corresponding to the two technologies and then locate \bar{x} . Then illustrate the cost curve that takes into account that a firm will switch to the patented technology at \bar{x} .
 - What happens to \bar{x} if the license cost F for using the patented technology increases? Is it possible to tell what happens if the capital rental rate r increases?
 - At \bar{x} , which technology must have a higher marginal cost of production? On a separate graph, illustrate the marginal cost curves for the two technologies.
 - At \bar{x} , the firm is cost-indifferent between using the two technologies. Recognizing that the marginal cost curves capture all costs that are not fixed and that total costs excluding fixed costs can be represented as areas under marginal cost curves, can you identify an area in your graph that represents the recurring fixed license fee F ?
 - Suppose output price p is such that it is profit-maximizing *under the nonpatented technology* to produce \bar{x} . Denote this as \bar{p} . Can you use marginal cost curves to illustrate whether you would produce more or less if you switched to the patented technology?
 - Would profit be higher if you used the patented or nonpatented technology when output price is \bar{p} . (*Hint:* Identify the total revenues if the firm produces at \bar{p} under each of the technologies. Then identify the total cost of using the nonpatented technology as an area under the appropriate marginal cost curve and compare it to the total costs of using the patented technology as an area under the other marginal cost curve and add to it the fixed fee F .)
 - True or False:* Although the total cost of production is the same under both technologies at output level \bar{x} , a profit-maximizing firm will choose the patented technology if price is such that \bar{x} is profit maximizing under the nonpatented technology.
 - Illustrate the firm’s supply curve. (*Hint:* The supply curve is not continuous, and the discontinuity occurs at a price below \bar{p} .)
- B.** Suppose that the two technologies available to you can be represented by the production functions $f(\ell, k) = 19.125\ell^{0.4}k^{0.4}$ and $g(\ell, k) = 30\ell^{0.2}k^{0.6}$, but technology g carries with it a recurring fee of F .
- In exercise 13.2, you derived the general form for the two-input Cobb–Douglas conditional input demands and cost function.¹³ Use this to determine the ratio of capital to labor (as a function of w and r) used under these two technologies. Which technology is more capital intensive?
 - Determine the cost functions for the two technologies (and be sure to include F where appropriate).
 - Determine the output level \bar{x} (as a function of w , r and F) at which it becomes cost effective to switch from the technology f to the technology g . If F increases, is it possible to tell whether \bar{x} increases or decreases? What if r increases?
 - Suppose $w = 20$ and $r = 10$. Determine the price \bar{p} (as a function of F) at which a firm using technology f would produce \bar{x} .

¹³ For the Cobb–Douglas production function $x = f(\ell, k) = A\ell^\alpha k^\beta$, you should have derived the conditional input demands

$$\ell(w, r, x) = \left(\frac{\alpha r}{\beta w}\right)^{\beta/(\alpha+\beta)} \left(\frac{x}{A}\right)^{1/(\alpha+\beta)} \quad \text{and} \quad k(w, r, x) = \left(\frac{\beta w}{\alpha r}\right)^{\alpha/(\alpha+\beta)} \left(\frac{x}{A}\right)^{1/(\alpha+\beta)}. \quad (13.45)$$

The cost function was previously provided in equation (13.43).

- e. How much would the firm produce with technology g if it faces \bar{p} ? Can you tell whether, regardless of the size of F , this is larger or smaller than \bar{x} (which is the profit-maximizing quantity when the firm uses technology f and faces \bar{p})?
- f. The (long-run) profit function for a Cobb–Douglas production function $f(\ell, k) = A\ell^\alpha k^\beta$ is

$$\pi(w, r, p) = (1 - \alpha - \beta) \left(\frac{Ap\alpha^\alpha\beta^\beta}{w^\alpha r^\beta} \right)^{1/(1-\alpha-\beta)}. \quad (13.46)$$

Can you use this to determine (as a function of p , w and r) the highest level of F at which a profit-maximizing firm will switch from f to g ? Call this $\bar{F}(w, r, p)$.

- g. From your answer to (f), determine (as a function of w , r and F) the price p^* at which a profit-maximizing firm will switch from technology f to technology g .
- h. Suppose again that $w = 20$, $r = 10$. What is p^* (as a function of F)? Compare this to \bar{p} you calculated in part (d) and interpret your answer in light of what you did in A(i).
- i. Suppose (in addition to the values for parameters specified so far) that $F = 1,000$. What is \bar{p} and p^* ? At the price at which the profit-maximizing firm is indifferent between using technology f and technology g , how much does it produce when it uses f and how much does it produce when it uses g ?¹⁴
- j. Continuing with the values we have been using (including $F = 1,000$), can you use your answer to (a) to determine how much labor and capital the firm hires at p^* under the two technologies? How else could you have calculated this?
- k. Use what you have calculated in (i) and (j) to verify that profit is indeed the same for a firm whether it uses the f or the g technology when price is p^* (when the rest of the parameters of the problem are as we have specified them in (i) and (j)). (Note: If you rounded some of your previous numbers, you will not get exactly the same profit in both cases, but if the difference is small, it is almost certainly just a rounding error.)

13.8* Business Application: Switching Technologies: Short Run versus Long Run: In exercise 13.7, we viewed all inputs (including the technology that is chosen) as variable, which is to say we viewed these inputs from a long-run perspective.

- A.** Now consider the same set-up as in exercise 13.7 but assume throughout that labor is instantaneously variable, that capital is fixed in the short run and variable in the *intermediate* run, and that the choice of technology is fixed in the short and intermediate run but variable in the long run.
- Suppose you are currently long-run profit-maximizing. Graph the (long-run) supply curve you derived in part A(i) of exercise 13.7 and indicate a price p and quantity x combination that is consistent with using the nonpatented technology.
 - Next suppose that output price increases to \bar{p} and that this increase is sufficient for you to wish that you in fact had rented the patented technology instead. Illustrate how your output level will adjust in the intermediate run to x^{IR} .
 - In the short run, your firm cannot change its level of capital. Where would your short-run optimal output level x^{SR} (at the new \bar{p}) lie relative to x and x^{IR} ? How is your answer impacted by the relative substitutability of capital and labor in the nonpatented technology?
 - In the long run, where will your optimal output level x^{LR} lie?
 - Suppose price had fallen to \underline{p} instead of rising to \bar{p} . Indicate where your short-, intermediate-, and long-run output levels would lie.
 - On a new graph, illustrate the short-, intermediate-, and long-run supply curves for your firm given you started at the original price p and the original optimal output level x .
 - What would your last graph look like if you had originally started at price \bar{p} and had originally produced at the long-run optimal output level x^{LR} ?

¹⁴ Recall from your previous work in exercise 13.1 that the supply function for a Cobb–Douglas production process $f(\ell, k) = A\ell^\alpha k^\beta$ is

$$x(w, r, p) = \left(\frac{Ap^{(\alpha+\beta)}\alpha^\alpha\beta^\beta}{w^\alpha r^\beta} \right)^{1/(1-\alpha-\beta)}.$$

- B.** Suppose, as in exercise 13.7, that the two technologies available to you can be represented by the production functions $f(\ell, k) = 19.125\ell^{0.4}k^{0.4}$ and $g(\ell, k) = 30\ell^{0.2}k^{0.6}$, but technology g carries with it a recurring fee of F . Suppose further that $w = 20$, $r = 10$, and $F = 1,000$.
- If $p = 2.25$ and the firm is currently long-run optimizing, how much does it produce? (You can use what you learned from exercise 13.7 and employ equation (13.45).)
 - Now suppose the output price increases from 2.25 to 2.75. How much will the firm adjust output in the short run (where neither capital nor technology can be changed)?¹⁵
 - How much will it increase output in the intermediate run (where capital can adjust but technology remains fixed)?
 - How much will it adjust output in the long run?
 - What happens to the quantity of labor and capital hired in the short, intermediate, and long run?
 - Suppose that instead of increasing, the output price had fallen from 2.25 to 2.00. What would have happened to output in the short, intermediate, and long run?
 - Suppose that the firm has fully adjusted to the higher output price of 2.75. Then price falls to 2.25. What happens to output in the short, intermediate, and long run?

13.9*† Business and Policy Application: Fixed Amount of Land for Oil Drilling: Suppose that your oil company is part of a competitive industry and is using three rather than two inputs—labor ℓ , capital k , and land L —to produce barrels of crude oil denoted by x . Suppose that the government, due to environmental concerns, has limited the amount of land available for oil drilling, and suppose that it has assigned each oil company \bar{L} acres of such land. Assume throughout that oil sells at a market price p ; labor, at a market wage of w ; and capital, at a rental rate r , and these prices do not change as government policy changes.

- A.** Assume throughout that the production technology is homothetic and has constant returns to scale.
- Suppose that, once assigned to an oil company, the company is not required to pay for using the land to drill for oil (but it cannot do anything else with it if it chooses not to drill). How much land will your oil company use?
 - While the three-input production frontier has constant returns to scale, can you determine the effective returns to scale of production once you take into account that available land is fixed?
 - What do average and marginal cost curves look like for your company over the time frame when both labor and capital can be varied?
 - Now suppose that the government begins to charge a per-acre rental price q for use of land that is assigned to your company, but an oil company that is assigned \bar{L} acres of land only has the option of renting all \bar{L} acres or none at all. Given that it takes time to relocate oil drilling equipment, you cannot adjust to this change in the short run. Will you change how much oil you produce?
 - In the long run (when you can move equipment off land), what happens to average and marginal costs for you company? Will you change your output level?
 - Suppose the government had employed a different policy that charges a per-acre rent of q but allowed companies to rent any number of acres between 0 and \bar{L} . What do long-run average and marginal cost curves look like in that case? Would it ever be the case that a firm will rent fewer than \bar{L} acres? (*Hint:* These curves should have a flat as well as an upward-sloping portion.)
 - How much will you produce now compared to the case analyzed in (d)?
 - Suppose that under this alternative policy the government raises the rental price to q' . Will your company change its output level in the short run?
 - How do long-run average and marginal cost curves change? If you continue to produce oil under the higher land rental price, will you increase or decrease your output level, or will you leave it unchanged?
 - True or False:* The land rental rate q set by the government has no impact on oil production levels so long as oil companies do not exit the industry. (*Hint:* This is true.)

¹⁵ It may be helpful to know that for Cobb–Douglas functions that take the form $f(\ell, k) = A\ell^\alpha k^\beta$, the input demand functions are

$$\ell(w, r, p) = \left(\frac{pA\alpha^{(1-\beta)}\beta^\beta}{w^{(1-\beta)\beta}} \right)^{1/(1-\alpha-\beta)} \quad \text{and} \quad k(w, r, p) = \left(\frac{pA\alpha^\alpha\beta^{(1-\alpha)\alpha}}{w^\alpha r^{(1-\alpha)\alpha}} \right)^{1/(1-\alpha-\beta)} \quad (13.47)$$

- B.** Suppose that your production technology for oil drilling is characterized by the production function $x = f(\ell, k, L) = A\ell^\alpha k^\beta L^\gamma$ where $\alpha + \beta + \gamma = 1$ (and all exponents are positive).
- Demonstrate that this production function has constant returns to scale.
 - Suppose again that the government assigns \bar{L} acres of land to your company for oil drilling, and that there is no rental fee for the land but you cannot use the land for any other purpose. Given the fixed level of land available, what is your production function now? Demonstrate that it has decreasing returns to scale.
 - In exercise 13.2, you were asked to derive the (long-run) cost function for a two-input Cobb–Douglas production function. Can you use your result, which is also given in equation (13.43) of exercise 13.5, to derive the cost function for your oil company? What is the marginal cost function associated with this?
 - Next, consider the scenario under which the government charges a per-acre rental fee of q but only gives you the option of renting all \bar{L} acres or none at all. Write down your new (long-run) cost function and derive the marginal and average cost functions. Can you infer the shape of the marginal and average cost curves?
 - Does the (long-run) marginal cost function change when the government begins to charge for use of the land in this way?
 - Now suppose that the government no longer requires your company to rent all \bar{L} acres but instead agrees to rent you up to \bar{L} acres at the land rental rate q . What would your conditional input demands and your (total) cost function be in the absence of the cap on how much land you can rent?
 - From now on, suppose that $A = 100$, $\alpha = \beta = 0.25$, $\gamma = 0.5$, $\bar{L} = 10,000$. Suppose further that the weekly wage rate is $w = 1,000$, the weekly capital rental rate is $r = 1,000$, and the weekly land rent rate is $q = 1,000$. At what level of output \bar{x} will your production process no longer exhibit constant returns to scale (given the land limit of \bar{L})? What is the marginal and average cost of oil drilling prior to reaching \bar{x} (as a function of x)?
 - After reaching this \bar{x} , what is the marginal and average long-run cost of oil drilling (as a function of x)? Compare the marginal cost at \bar{x} to your marginal cost answer in (g) and explain how this translates into a graph of the marginal cost curve for the firm in this scenario.
 - What happens to \bar{x} as q increases? How does that change the graph of marginal and average cost curves?
 - If the price per barrel of oil is $p = 100$, what is your profit-maximizing oil production level?
 - Suppose the government now raises q from 1,000 to 10,000. What happens to your production of oil? What if the government raises q to 15,000?

13.10 Policy and Business Application: Minimum Wage Labor Subsidy: Suppose you run your business by using a homothetic, decreasing returns to scale production process that requires minimum wage labor ℓ and capital k where the minimum wage is w and the rental rate on capital is r .

- A.** The government, concerned over the lack of minimum wage jobs, agrees to subsidize your employment of minimum wage workers, effectively reducing the wage you have to pay to $(1 - s)w$ (where $0 < s < 1$). Suppose your long-run profit-maximizing production plan before the subsidy was (ℓ^*, k^*, x^*) .
- Begin with an isoquant graph that contains the isoquant corresponding to x^* and indicate on it the cost-minimizing input bundle as A . What region in the graph encompasses all possible production plans that could potentially be long run profit-maximizing when the effective wage falls to $(1 - s)w$?
 - On your graph, illustrate the slice of the production frontier to which you are constrained in the short run when capital is fixed. Choose a plausible point on that slice as your new short-run profit-maximizing production plan B . What has to be true at this point?
 - Can you conclude anything about how the marginal product of capital changes as you switch to its new short-run profit-maximizing production plan?
 - Will you hire more workers in the long run than in the short run?
 - Will you hire more capital in the long run than in the short run?
 - Once you have located B in part (b), can you now use this to narrow down the region (that you initially indicated in part (a)) where the long-run profit-maximizing production plan must lie?

- B.** Suppose, as in previous exercises, that your production function is $f(\ell, k) = 30\ell^{0.2}k^{0.6}$.
- Suppose that $w = 10 = r$ and $p = 5$. What is your profit-maximizing production plan before the labor subsidy?
 - What is the short-run profit-maximizing plan after a subsidy of $s = 0.5$ is implemented.
 - What is the new long-run profit-maximizing plan once capital can be adjusted?
 - For any Cobb–Douglas function $f(\ell, k) = A\ell^{\beta\alpha}k^{\beta(1-\alpha)}$, the CES production function $g(\ell, k) = A(\alpha\ell^{-\rho} + (1-\alpha)k^{-\rho})^{-\beta/\rho}$ converges to f as ρ approaches 0. What values for A , α , and β will do this for the production function $x = 30\ell^{0.2}k^{0.6}$?
 - ** Using a spreadsheet to program the output supply and input demand equations for a CES production function given in equation (13.38) in a footnote in the text, verify that your long-run production plans mirror those you calculated for the Cobb–Douglas function when ρ approaches 0 and α and β are set appropriately.
 - ** Finally, derive the first order condition for the short-run profit maximization problem with fixed capital using the CES production function. Then, using your spreadsheet, check to see whether those first order conditions hold when you plug in the short-run profit-maximizing quantity of labor that you calculated in (b).

13.11[†] Policy and Business Application: Business Taxes: In this exercise, suppose that your hamburger business “McWendy’s” has a homothetic decreasing returns to scale production function that uses labor ℓ and capital k to produce hamburgers x . You can hire labor at wage w and capital at rental rate r but also have to pay a fixed annual franchise fee F to the McWendy parent company in order to operate as a McWendy’s restaurant. You can sell your McWendy’s hamburgers at price p .

- A.** Suppose that your restaurant, by operating at its long-run profit-maximizing production plan (ℓ^*, k^*, x^*) , is currently making zero long-run profit. In each of the policy proposals in parts (b) through (h), suppose that prices w , r , and p remain unchanged.¹⁶ In each part, beginning with (b), indicate what happens to your optimal production plan in the short and long run.
- Illustrate the short-run AC and MC curves as well as the long-run AC curve. Where in your graph can you locate your short-run profit, and what is it composed of?
 - Suppose the government determined that profits in your industry were unusually high last year and imposes a one-time “windfall profits tax” of 50% on your business’s profits from last year.
 - The government imposes a 50% tax on short-run profits from now on.
 - The government instead imposes a 50% tax on long-run profits from now on.
 - The government instead taxes franchise fees causing the blood-sucking McWendy’s parent company to raise its fee to $G > F$.
 - The government instead imposes a tax t on capital used by your restaurant, causing you to have to pay not only r but also tr to use one unit of capital.
 - Instead of taxing capital, the government taxes labor in the same way as it taxed capital in part(f).
 - Finally, instead of any of these possibilities, the government imposes a “health tax” t on hamburgers, charging you $\$t$ for every hamburger you sell.
- B.** In previous exercises, we gave the input demand functions for a firm facing prices (w, r, p) and technology $f(\ell, k) = A\ell^{\alpha}k^{\beta}$ (with $\alpha, \beta > 0$ and $\alpha + \beta < 1$) in equation (13.47) and the long-run output supply function in equation (13.45). They were both given in footnotes to earlier end-of-chapter exercises in this chapter.
- When you add a recurring fixed cost F , how are these functions affected? (*Hint:* You will have to restrict the set of prices for which the functions are valid, and you can use the profit function given in exercise (13.7) to do this strictly in terms of A , α , β , and the prices (w, r, p) .) What are the short-run labor demand and output supply functions for a given \bar{k} ?
 - For each of (b) through (h) in part A of the exercise, indicate whether (and how) the functions you derived in part (a) are affected.

¹⁶This is only an assumption for now, which will in fact often not hold, as we will see in Chapter 14.

Competitive Markets and the “Invisible Hand”

Chapter 14 Competitive Market Equilibrium

Chapter 15 The “Invisible Hand” and the First Welfare Theorem

Chapter 16 General Equilibrium

Chapter 17 Choice and Markets in the Presence of Risk

In Part 1, we derived demand curves (and functions) for goods as well as supply curves (and functions) for labor and capital, all from an underlying model of individual choice aimed at maximizing happiness. In Part 2, we similarly derived supply curves (and functions) for goods, as well as demand curves (and functions) for labor and capital, all from an underlying model of firm choice aimed at maximizing profit. We thus have built both demand and supply relationships in both output and input markets and are now ready to combine them to analyze an entire market. This will allow us to talk about the concept of *equilibrium* for the first time, and it will enable us to analyze *how prices form* rather than taking prices as given (as we have thus far). And it will allow us to illustrate more fully some insights we have only been able to hint at: namely that, under certain conditions, competitive markets lead to a *spontaneous order* in which millions of individual choices combine to form prices that guide behavior in such a way as to allocate resources efficiently. We will refer to this result as the *first welfare theorem*.

Chapter 14 begins by combining supply and demand curves in a single industry. Again, we will distinguish between the *short run* and the *long run*, but this distinction arises for reasons somewhat different from (but related to) those in Chapter 13. In *competitive industries that are characterized by the presence of many small firms*, the short run is the period over which it is not easily possible for firms to *enter or exit* the industry, while the long run arises when firms can freely enter and exit. Thus, while short-run supply in an industry is determined by the individual supply curves of the firms that already exist in this industry, long-run supply is determined by the entry and exit decisions of firms. In both the short and long run, we will see the process by which a “spontaneous order” emerges from the interaction of many individuals in the market.

Chapter 15 then proceeds to an evaluation of the order that emerges in a competitive industry through prices that guide individual decision making. We will see how voluntary trade, guided by individual incentives, can result in winners on all sides of the market, and how the prices that form in markets provide all the information necessary for individuals to make decisions that produce the maximum surplus. In particular, we will be able to show how an omniscient and benevolent social planner who is seeking to maximize overall surplus would often use scarce resources in an industry in exactly the way that an unplanned or decentralized market does. For this reason, economists sometimes talk of markets as guided by *an invisible hand*, as if a social planner were moving the pieces underneath, but this invisible hand is simply the sum of all individuals in the market responding to the incentives that arise from prices.

However, we immediately point out in Chapter 15 that this result is predicated on several implicit assumptions that, when violated, would cause a divergence between what markets do on their own and what our mythical social planner would want to do. First, the theorem assumes that *prices are allowed to form without interference*; second, that there are *no externalities* or effects from individual choices that directly impact others who are not participating in the market; third, that there are *no informational asymmetries* that put one side of the market in the position of taking advantage of the other; and fourth, that everyone is “small” and thus *no one has market power*. Parts 4 and 5 of the text will examine closely how markets on their own will “fail” when these assumptions are violated, and how nonmarket institutions can reign in markets by aligning individual incentives with some notions of the “common good.”

Put differently, an understanding of the first welfare theorem and its underlying assumptions provides a framework for us to think about the role of nonmarket institutions in society. When the assumptions are satisfied, there is in fact no “efficiency” role for nonmarket institutions because markets already allocate resources in a way that maximized the social pie. Even then, however, we may be dissatisfied with the outcome of markets because *saying that something is efficient is not the same as saying that it is “good.”* It may, for instance, be the case that sometimes we believe that resources should be allocated more equally than what markets accomplish even though markets create the biggest possible overall level of social surplus. Thus, even if all the assumptions underlying the first welfare theorem are satisfied, there may be a *distributional role* for nonmarket institutions to aim at greater “fairness.”

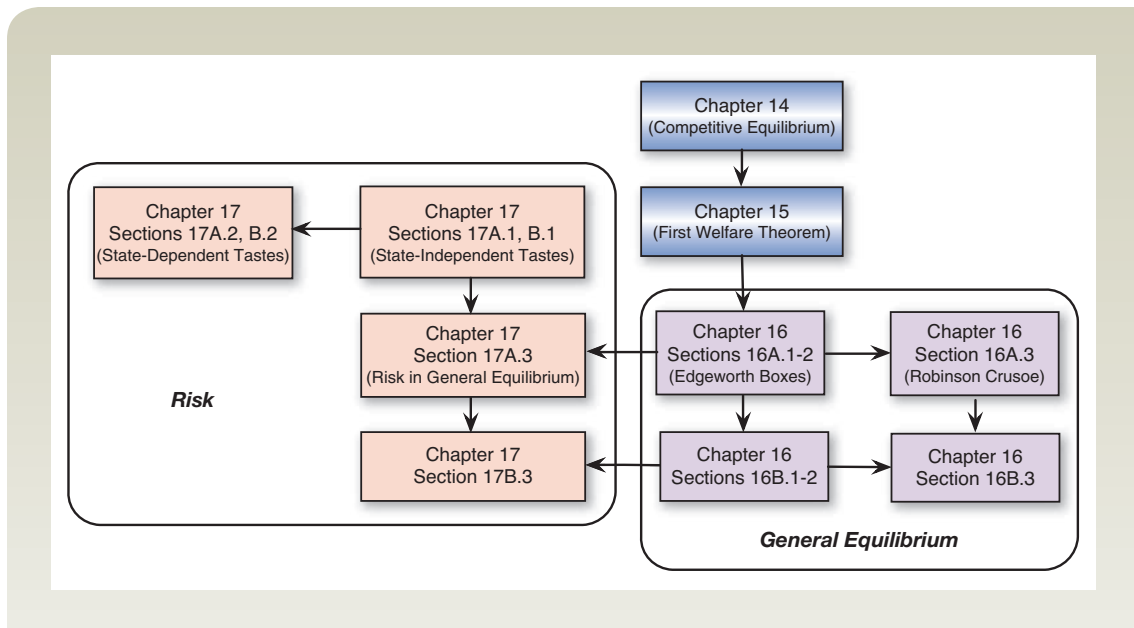

The bulk of the remaining parts of the text is therefore devoted to an analysis of what goes wrong in markets when the assumptions underlying the first welfare theorem are violated, and

what role this creates for nonmarket institutions that we will refer to as civil society and government. Before proceeding to these parts, however, we revisit the first welfare theorem in two additional (and optional, as far as most of the remainder of the text is concerned) settings.

In Chapter 16, we will present the basics of a more general model than the one used in Chapters 14 and 15 where we looked simply at a single industry in isolation. We will distinguish the single industry model as a *partial equilibrium* model that does not consider interactions across markets. Put differently, in our analysis of Chapters 14 and 15, we did not view the economy as a closed system but rather looked at one segment of the economy. Under certain circumstances, this is perfectly appropriate, but in other cases there are important spillovers from what happens in one industry to what happens in other industries. A full treatment of this is not possible in this text, but Chapter 16 attempts to give you a sense of how *general equilibrium* models that look at interactions across markets arrive at some results similar to what we illustrated in the partial equilibrium model of Chapter 15. While our examples in Chapter 16 will look quite restrictive, we will point out that the same results hold in much more general settings. We will also be able to demonstrate the *second welfare theorem* that tells us, so long as nonmarket institutions (like governments) can redistribute resources without cost, markets can be fine-tuned to give more “equitable” but still “efficient” outcomes. At the same time, we will note that governments rarely have costless ways of redistributing, which then implies that a fundamental trade-off between efficiency and certain notions of equity will emerge.

Finally, we conclude this part of the text with a demonstration of how markets deal with *risk*, a prevalent feature of life that we have until this point not introduced into our models. I waited until this point to introduce risk into our model because it is at this point that we can show how modeling risk can build directly on our models of individual choice and general equilibrium. Chapter 17 thus develops a model of risky choice and introduces markets (such as insurance markets) that can serve to distribute risk efficiently in ways analogous to the efficient allocation of resources in markets in the absence of risk.

Chapters 14 and 15 are core chapters that are best read as preparation for future chapters. Chapter 16 (on General Equilibrium) and Chapter 17 (on Risk) are optional extensions and not required for most of the remainder of the text. Furthermore, Chapter 16 is required only for the last section in each part of Chapter 17, with the first two sections requiring only basic consumer theory through Chapter 6. The connections between the chapters in this part of the text are illustrated in the following flow chart.

CHAPTER

14

Competitive Market Equilibrium

We have spent the bulk of our time up to now developing relationships between economic variables and the behavior of actors such as consumers, workers, and producers.¹ To be more precise, we began by developing “models,” simplified versions of reality, in which we then assumed that economic actors “do the best they can given their economic circumstances.” This process of “optimizing” results in the relationships between prices and behavior, such as demand curves, supply curves, and cross-price demand and supply curves. And it is these relationships we can now use to take the economic analysis to its final step: describing how the economic environment (that actors take as given) arises within the model as many individuals optimize. This economic environment is called a *competitive equilibrium*.

In this and the next chapter, we will focus on a “market” or an “industry,” terms we will use interchangeably. Firms are considered to operate in the same market (or industry) if they produce the same goods, and the market (or industry) is considered “competitive” if all firms are sufficiently small such that they cannot individually manipulate the economic environment. We will discover the important role played by equilibrium market prices in such competitive industries. Perhaps the most fascinating aspect of such prices is that they emerge “spontaneously” without anyone planning the process. Thus, the equilibrium we are about to analyze is a “decentralized market equilibrium” in the sense that it comes into being without central planning and only from the decentralized decisions of individuals who have no control over, or even awareness of, the process. In fact, production, *guided by self-interest and the emergence of market prices*, occurs in many cases without most of the participants in the process even knowing the nature of the final product they are producing. And we will see in Chapter 15 that the “spontaneous order” that is generated by this combination of self-interest and prices can create enormous benefits for society.

The insights emerging from the analysis in Chapters 14 and 15 are perhaps the most significant to come out of the discipline of economics. They derive from an internally consistent model in which the counterintuitive happens: *order emerges without planning, and self-interest does not (necessarily) conflict with the “social good.”* The same model, as we will see in upcoming chapters, also illustrates that real-world frictions may create circumstances in which the order that emerges entails conflict between private self-interest and the social good. We will thus *begin*

A market, or “industry,” is perfectly competitive if all firms are sufficiently small so as not to be able to impact prices.

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

¹ This chapter requires a good understanding of consumer theory as expounded in Chapters 2, 4 through 6, and Sections 9A.1 and 9B.1 of Chapter 9 while making only a brief reference to consumer theory as it pertains to labor and capital markets. It also relies on a good understanding of cost curves as covered in Sections 13A.1 and 13B.1 of Chapter 13.

the process of defining a role for nonmarket institutions in society. Put differently, the insights that we will discuss in this and the next chapter have come to define most aspects of the discipline of economics as it searches for nonmarket institutions that harness self-interest for the social good when market forces by themselves do not adequately do so.

14A

EQUILIBRIUM: COMBINING DEMAND AND SUPPLY CURVES

We will begin by illustrating the concept of a competitive equilibrium in the context of one industry that is composed of many small producers who compete with one another for the business of many consumers. We therefore continue to assume that each economic actor is “small” relative to the industry and the economy and that, as a result, no economic actor has sufficient power to, by him- or herself, alter the equilibrium. Rather, it is rational for each economic actor to simply take the world as given and do the best he or she can within that world, even though it is from the combination of all the individual optimizing decisions that the equilibrium and thus the economic environment springs. In later chapters, we will investigate how our understanding of an equilibrium changes when some economic actors are “large” in the sense that their behavior influences the economic environment in a significant way. While there is no need for “small” economic actors to think strategically about the impact of their behavior on the economic environment, such strategic thinking will become central to understanding the behavior of “large” actors.

Economic actors in a competitive world take all prices as given and don't think strategically.

14A.1 Equilibrium in the Short Run

As we will see shortly, an equilibrium in an industry will be defined by the intersection of market (or industry) demand and supply curves. Deriving these curves for a particular industry *in the short run* is easy in that it simply involves adding up the individual demand and supply curves that are generated from individual optimization problems. For instance, in panel (a) of Graph 14.1, we plot two individual demand curves D^1 and D^2 and a third *market demand curve* D^M that would result if these were the only two consumers in the market. At a price above \$90, individual 2 demands none of the output x_1 , which implies that individual 1 is the only consumer in the market, and this individual's demand curve therefore represents the market demand curve (for $p > 90$). For prices below \$90, however, both consumers demand some of the output. For instance, at a price of \$80, consumer 1 demands 20 units of x_1 while consumer 2 demands 10 units, for an overall market demand of 30 units. A similar process for adding up individual supply curves to get a *short-run market supply curve* S^M is illustrated in Graph 14.1b, with only firm 2 supplying output for prices below \$40 and both firms supplying output for prices above \$40. The process of adding up more than two demand or supply curves is a straightforward extension of this.

Short-run industry supply and demand curves are the sum of all individual such curves.

We will see a little later in this chapter that market supply is derived somewhat differently in the long run, and that “adding up supply curves” is the correct way of finding market supply curves only in the short run. For now, however, we will stick with the short-run curves and investigate the resulting short-run equilibrium. We will also see in Chapter 15 that we have to be careful about what precise interpretations we give to market demand curves.

14A.1.1 Short-Run Equilibrium in the Goods Market Market (or industry) demand and supply curves are powerful tools that help us predict the terms under which consumers and producers will interact in a competitive world, and how these terms will change as underlying institutional and technological constraints change. Put differently, these curves help us predict the economic environment that governs individual behavior. If you have ever taken an economics course before, you have almost certainly been exposed to this as demand and supply curves were used in your course to describe equilibrium price and quantity in a market. Our work leading up

GRAPH 14.1 Adding Up Demand and Supply Curves

to this chapter has informed us about what is behind this type of analysis, and this work will help us determine what we can and cannot say from economic analysis that relies on market demand and supply curves.

Consider, for instance, the sequence of graphs in Graph 14.2. In panel (a), we begin with the basic building blocks of the consumer model: indifference curves (representing tastes) and budgets (representing different economic environments as the price for good x_1 changes). From the budgets and indifference curves in (a), we can then derive the consumer's demand curve D^i for x_1 in panel (d) as we did in Chapter 9. If we were to conduct the same analysis for all consumers in the market, we would then be deriving many different demand curves, which we could add up to arrive at the market demand curve D^M in panel (e) (with $\sum D^i$ in the graph simply read as “the sum of all individual D^i demand curves”).

On the producer side, we are similarly starting with the fundamentals of the producer model in panel (b): the technological constraint represented by the short-run producer choice set. Panel (c) then derives the total cost curve (assuming a particular input price) from the short-run production frontier as we did in Chapter 11, allowing us to derive the average and marginal cost curves for a single firm in panel (f). The portion of the marginal cost curve above AC is then a profit-maximizing firm's supply short-run curve S^j . We could then repeat this analysis for each of the firms in the industry that produces output x_1 , thus arriving at many individual supply curves that we can simply add up to derive the market supply curve S^M in panel (e).

Focusing then on panel (e), we have a simple demand and supply picture of the market for good x_1 , with the intersection of the two curves representing the market equilibrium that results in equilibrium price p^* and equilibrium output quantity X_1^* . If price were to rise above this equilibrium, more of x_1 would be supplied than demanded, which would cause producers who are seeing their inventories build up to lower prices to sell their goods and make themselves better off. Thus, price would drop. Similarly, if price were ever below p^* , consumers would demand more than producers are willing to supply, giving an incentive to each producer to raise price and have fewer people lining up in front of the stores to buy goods the producers don't have. Thus, price would rise. *What makes p^* an equilibrium price is the fact that, if price is anything other than p^* , there*

Only at the equilibrium price does no firm have an incentive to charge a different price.

GRAPH 14.2 Equilibrium, and What's Behind It

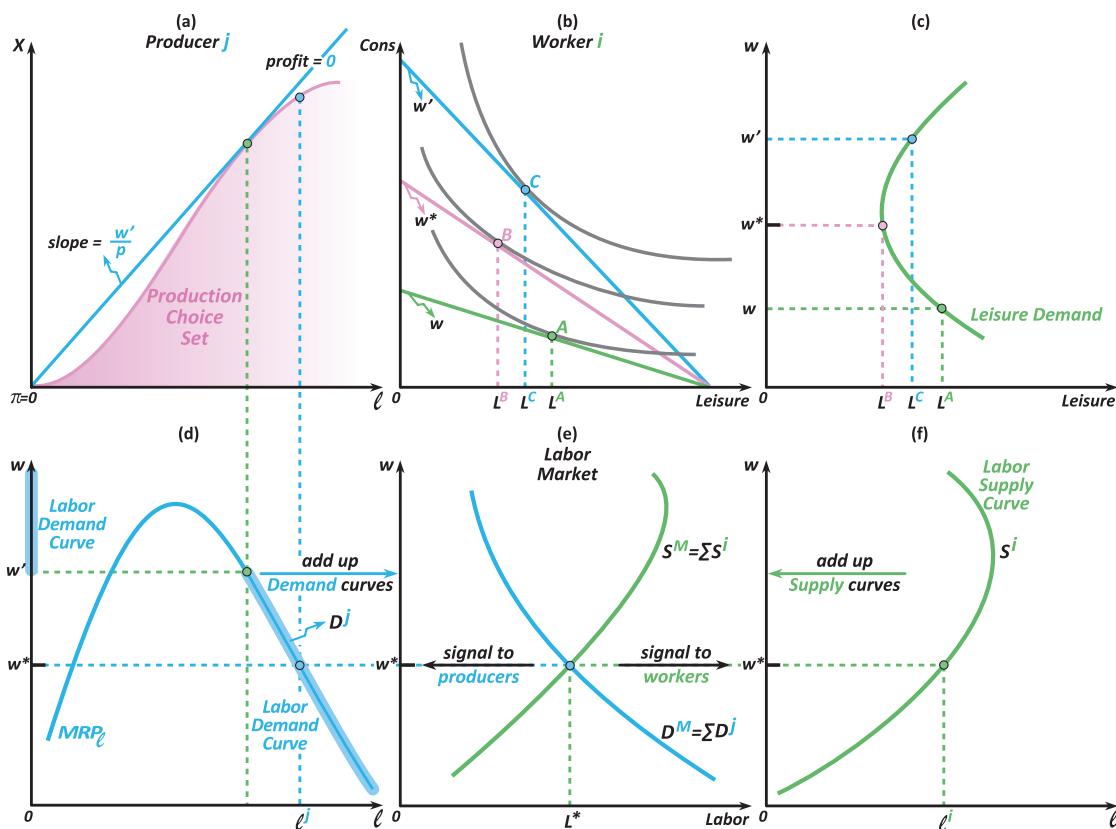

is a natural tendency of individual producers to adjust price toward p^* . Put differently, only when all firms charge p^* does no producer have an incentive to change his or her price.

Without any particular individual intentionally directing the formation of p^* , the natural tendency is in place for p^* to emerge as individual consumers and producers simply try to do the best for themselves. Once p^* is formed, it then directs individual actions, telling each consumer how much to consume and each producer how much to produce. Thus, the market signals consumers and producers through the equilibrium price, coordinating their actions in a decentralized way that, as we will see in Chapter 15, is “efficient” under some circumstances. In the case graphed here, the signal p^* tells the consumer we modeled to consume x_1^* and the producer we modeled to produce x_1^* , with the market as a whole producing X_1^* .

Equilibrium prices coordinate the actions of producers and consumers.

14A.1.2 Short-Run Equilibrium in Input Markets In an analogous way, a decentralized market equilibrium also emerges in the labor market when different producers in many different industries compete for workers. Graph 14.3 illustrates this, with producers facing short-run producer choice sets in panel (a) that result in marginal revenue product curves in panel (d), and with a portion of this marginal revenue product curve composing the short-run labor demand curve for each producer (as we first derived in Chapter 11). Workers, on the other hand, begin with preferences over leisure and consumption in panel (b), with different wages resulting in different optimal leisure choices. Panel (c) then illustrates a typical “leisure demand” curve, with panel (f) representing the implied labor supply curve for this consumer (as first derived in

GRAPH 14.3 Labor Market Equilibrium

Chapter 9).² Adding up the individual labor demand curves of firms and labor supply curves of workers, we arrive at a market demand and supply curve for the particular type of labor modeled here, with the intersection of the two resulting in an *equilibrium wage rate* w^* that sends a signal back to workers and producers. This signal causes the producer we modeled to hire ℓ^j worker hours and the worker we modeled to sell ℓ^i labor hours, with the market as a whole trading L^* labor hours across the many industries that hire the types of workers modeled in the series of graphs.

Note that while the demand curve in output markets comes from all those *consumers* who consume the output we are modeling, the demand curve in labor markets comes from all those *producers* who hire the kind of labor we are modeling. Thus, in our labor market graph, we are adding up labor demand curves from firms that could potentially be producing very different outputs but are all demanding the same kind of labor input. On the supply side, we considered in our output market only those firms that produce the particular output we are modeling, just as in the labor market we only consider those workers who supply the type of labor we are modeling.

² The shape of the labor supply depicted in panel (f), commonly known as the “backward bending” labor supply, is often found to hold in empirical studies. We illustrated in end-of-chapter exercise 9.5 how this can emerge from changing wealth and substitution effects as wage increases.

Can you explain why there is always a natural tendency for wage to move toward the equilibrium wage if all individuals try to do the best they can?

EXERCISE 14A.1

In the capital market, we could similarly derive a demand curve for capital by producers except that it would be a more long-run demand curve if capital for firms is fixed in the short run. The supply curve would emerge from consumers making trade-offs between consuming now or consuming in the future—and thus saving for future consumption—and the equilibrium price that emerges in the market is the equilibrium interest rate.

14A.2 A Market (or Industry) in Long-Run Equilibrium

As we glance at Graphs 14.2 and 14.3, we might at first think that not all that much changes in the graphs when we think of the long run rather than the short run. After all, in our exploration of the difference between short- and long-run producer behavior in Chapter 13 we simply concluded that output supply and input demand curves will tend to be shallower in the long run than in the short run (with higher “exit” prices than short-run “shut down” prices), and it might therefore seem that we just have to draw our producer pictures a little bit differently to turn our previous two graphs into long-run equilibrium pictures. This is, however, not the case because, in addition to changing their input mix more in the long run than in the short run, firms have the opportunity to *enter or exit industries in the long run*. This implies that while the number of firms in an industry is fixed in the short run (even if some of them perhaps shut down), that number is *variable* in the long run as more or fewer firms might exist in response to changing market conditions.

Formally, we thus define the “long run” for a firm as the time it takes for a firm to adjust the input levels that are fixed in the short run, and we define the “long run” for an industry as the time it takes for firms to be able to enter or exit the industry. Notice, however, that the fundamentals that underlie these two definitions of “long run” derive from a similar source. A firm may have a fixed level of capital (such as a fixed factory size) in the short run, and this keeps it from adjusting its capital as conditions change in the short run. That same firm also cannot exit an industry, or enter a new industry, in the short run for exactly the same reason: It is currently locked into a fixed level of capital that can only be changed in the long run. Thus, when we think of the “long run” for an industry as the time it takes for firms to enter or exit, we are usually thinking of the time it takes to adjust capital, to dispose of the factory if a firm exits or acquire one if a firm enters. In this sense, there is usually a nice symmetry between what we think of as the “long run” for a firm and for an industry. The only difference is that some firms might be locked into their current capital for shorter periods than others, and the “long run” for an industry does not truly emerge until sufficient numbers of firms have had the opportunity to enter or exit.

14A.2.1 Revisiting the Entry/Exit Decision Consider, as we did in Chapter 13, the case in which one of my inputs is fixed in the short run and there is a fixed cost associated with an annual license to operate my business. Graph 14.4 then illustrates the resulting AC^{SR} curve representing all my economic costs in the short run when the fixed input or license expense is sunk, and the AC^{LR} curve that represents my long-run economic costs that take into account the cost of all inputs and of renewing my annual license. In the short run, I will operate my business so long as price is not below p' , the lowest point of the short-run AC curve, while in the long run I will exit if price falls below p , the lowest point of my long-run AC curve. In between these prices, there exists a range of prices that allow me to cover my short-run costs but not my fixed expenses, sufficient to keep me open in the short run but not sufficient to keep me from exiting in the long run. If price is above p , on the other hand, I can make (long-run) positive profits, which implies that I will produce and will enter the industry if I am not already in it.

Firms can enter and exit an industry in the long run, and so we cannot simply add up firm supply curves to get the long-run industry supply curve.

Firms exit if price falls below long-run AC and enter if price rises above the lowest point of long-run AC .

GRAPH 14.4 Shutting Down versus Exiting an Industry

Go to MindTap to interact with this graph.

EXERCISE 14A.2 Suppose your firm only used labor inputs (and not capital) and that labor is always a variable input. If your firm had to renew an annual license fee, would the AC^{SR} and the long-run AC curves ever cross in this case?

EXERCISE 14A.3* Why might the AC^{SR} and the long-run AC curves cross when the difference emerges because of an input (like capital) that is fixed in the short run? (*Hint*: Review Graphs 13.2 and 13.3.)

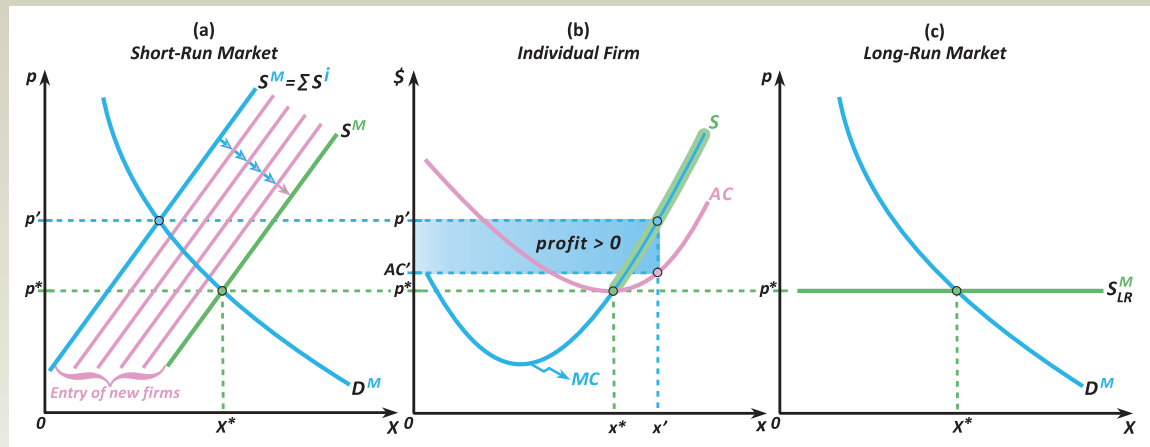

EXERCISE 14A.4 Explain why the MC curve in Graph 14.4 would be the same in the long and short run in the scenario of exercise 14A.2 but not in the scenario of exercise 14A.3.

Entry and exit of firms will shift the short-run market supply curve.

14A.2.2 Long-Run Equilibrium Price when All Producers Are Identical Now suppose there are many producers of “hero cards” like me. Each one of us wants to make as much profit as possible, and so we constantly look around for the best opportunities. In the short run, we are stuck in the particular industries in which we are currently producing, but in the long run we can switch if new opportunities open up. Put differently, we can keep track of the AC curves in many different industries, and when we notice that AC is below output price in some industry, we know there is profit to be made, and we enter. Some of us might be a little faster at doing this than others, or some of us might notice opportunities a bit sooner than others. But whatever determines the sequence of which one of us pounces on new opportunities first, the fact that we all eventually will pounce on these opportunities means that together we will shift the market supply curve as we enter, and we will keep shifting it as long as there are profits to be made.

Consider, for instance, Graph 14.5. Suppose that the market for good x finds itself in the short-run equilibrium represented by the intersection of the blue market demand and supply curves with equilibrium price p' in panel (a). This price signal tells each producer to produce x' of output along her (green) supply curve in panel (b), which generates a long-run profit equal to the shaded

GRAPH 14.5 Moving from Short-Run to Long-Run Equilibrium

blue area in panel (b) for each firm (assuming we have included all the costs relevant for the long run in the AC curve). Remember from our discussion of economic profit in Chapter 11 that positive profit, no matter how small, means that a producer is doing better here than she could do anywhere else. Thus, since we are assuming for now that all producers are identical, there are producers who currently operate in a different industry and see that they could make positive profits in the industry that produces x , which logically implies that they are making negative profit in their current industry.

Given the current price p' , there is thus an incentive in place for additional firms to enter the industry, with each entry shifting the short-run market supply curve just a little bit in panel (a). The incentive for firms to enter remains as long as (long-run) profits in the industry are positive and thus as long as price remains above p^* . Thus, the shift in short-run market supply curves in panel (a) of the graph will not stop until we arrive at the green short-run market supply curve when the price has reached the lowest point of each individual producer's long-run AC curve. Once we have reached this new short-run equilibrium, each producer in the industry makes zero (long-run) profit, eliminating any incentive for any new producers to enter and stopping short of giving an incentive to current producers to exit.

We could have drawn a similar sequence of shifts in short-run supply curves but in the opposite direction if we had drawn the original intersection of the blue supply and demand curves in panel (a) at an equilibrium price below p^* . In that case, the shift in short-run supply curves would have resulted from the exiting of firms from the industry in which firms were experiencing negative profits; that is, where firms could be doing better elsewhere. Thus, *whenever producers face identical costs and the short-run equilibrium output price lies anywhere other than the lowest point of (long-run) AC, entry and exit of firms will drive the long-run price of output to that lowest point.* In panel (c) of the graph, the long-run market supply curve is then horizontal and lies at the lowest point of AC. Put differently, the market will, in the long run when firms can enter and exit, supply any quantity that is demanded at the price p^* that falls at the lowest point for AC. This implies that the long-run market (or industry) supply curve arises not from adding up individual supply curves but rather from the entry and exit decision of firms that will drive price to the point where long-run profit is equal to zero; that is, where price settles at the lowest point of the long-run AC curve for individual firms.

Entry and exit insure that the long run equilibrium price lies at the lowest point of the marginal firm's long-run AC.

EXERCISE 14A.5 Can you draw the analogous sequence of graphs for the case when the short-run equilibrium price falls below p^* ?

EXERCISE 14A.6 How does the full picture of equilibrium in Graph 14.2 look different in the long run?

14A.2.3 Long-Run Equilibrium in Labor Markets While entry and exit of firms shape the difference between long- and short-run equilibrium in the output market for a particular industry’s good, the same is generally not true of labor market equilibria, at least not when a particular industry is small relative to the whole economy. This is because the “labor market” in Graph 14.3 is composed of firms from many different industries, and conditions that affect one particular industry will tend not to have an impact on the economy-wide labor market when an industry is small relative to the economy as a whole. Thus, whether some firms are entering or exiting a particular industry will not be perceptible as causing a shift in labor demand.

Entry and exit may play a role on the labor supply curve if an increase or decrease of wages for a particular type of labor alters perceptions sufficiently to cause workers to retrain or new workers to choose training differently from in the past. For instance, over the past 20 years, there has been a substantial increase in salaries paid to young PhD economists. While it is not easy to simply “retrain” from being a noneconomist to being an economist, one would expect that, in the long run, more college seniors might choose to get a PhD in economics when salaries for young economists have risen, thus increasing the supply of economists and driving down wages in the long run. Long-run wages in each labor market thus have to have a relationship with the relevant opportunity costs of workers, a topic you can (if it interests you) study in much more detail in a labor economics course.

EXERCISE 14A.7 How would you think the time-lag between short- and long-run changes in labor markets is related to the “barriers to entry” that workers face, where the barrier to entry into the PhD economist market, for instance, lies in the cost of obtaining a PhD?

14A.2.4 Long-Run Market Supply when Producers Differ In deriving the flat long-run industry supply curve in Graph 14.5c, we explicitly assumed that all producers had access to the same technology, and thus faced the same AC and MC curves. For the argument (that the long-run market supply curve is horizontal) to hold, it is actually only necessary to assume that all firms have technologies that give rise to long-run AC curves that reach their minimum at the same dollar value, regardless of what the remainder of the curves look like.

EXERCISE 14A.8 Can you explain why the previous sentence is true?

Now suppose that different producers have access to very different technologies. It might then be true that, at a given output price, some producers are able to make a profit while others are not. This in turn has implications for who will enter and who will exit an industry as market conditions change, and it has implications for the shape of the long-run market supply curve.

Consider, for instance, the short-run market equilibrium pictured in panel (a) of Graph 14.6 as the intersection of the blue demand and supply curves at point A (with p^* as the equilibrium

GRAPH 14.6 Long-Run Market Supply when Firms Differ

price). Suppose further that there are many potential firms for this industry, and to keep the graph manageable, suppose that each of these firms has a (long-run) AC curve that reaches its minimum at output level x^* , but some AC curves are lower everywhere than others. Six such AC curves are pictured in panel (b) of the graph, and we can imagine that there are many firms whose similarly shaped AC curves fall in between these. At the price p^* , firms 1, 2, and 3 all make at least zero profit, while firms 4, 5, and 6 would make negative long-run profit if they produced. Thus, those firms with lower average cost curves—those that are “better” at producing x —will choose to be in the industry while those with higher cost curves will not.

Next, suppose that there is a shift in market demand (from D^M to $D^{M'}$) that causes the (short-run) equilibrium price in panel (a) to rise above p^* to p' . Producer 4 would then notice that he or she is now able to make a positive profit in this industry, and would therefore have an incentive to enter the industry, as would other firms that previously would have made negative profit. This entry of new firms then shifts the short-run supply curve in panel (a) as new firms enter the market, but the process will stop *before* the price falls back to the original p^* because the firms that are entering have higher costs than the firms that originally composed the industry. In our graph, producer 5 is the last one to enter, with all producers whose costs fall below p'' also entering but no producer whose costs are higher than those of producer 5 entering. The shift in market demand from D^M to $D^{M'}$ thus causes a short-run shift in the equilibrium from A to B and a long-run shift to C in panel (a) of the graph, with a short-run increase in the price from p^* to p' and a long-run change to p'' . Panel (c) then simply graphs the long-run market supply relationship from A to C, indicating an upward-sloping long-run market supply curve when producers have different cost curves. Once again, the long-run market supply curve is not determined by the shape of individual firm supply curves, only by the distribution of the lowest point of the AC curves for firms. Industries like this, with upward-sloping (long-run) industry supply curves, are called *increasing cost industries*.

The shape of long-run market supply curves arises from entry and exit of firms.

Suppose market demand shifts inward instead of outward. Can you illustrate what would happen in graphs similar to those of Graph 14.6?

EXERCISE 14A.9

True or False: The entry and exit of firms in the long run ensures that the long-run market supply curve is always shallower than the short-run market supply curve.

EXERCISE 14A.10

It is in principle also possible for long-run market supply curves to slope down in industries where firm costs fall as the industry expands. This may occur if, for instance, the expansion of an industry leads to greater competition in one of the input markets unique to that industry, and thus to a decline in costs for all firms. Such industries are called *decreasing cost industries*. Since this is relatively rare for industries that are appropriately modeled as perfectly competitive, we will not focus on this case here and only mention it for the sake of completeness.³

EXERCISE 14A.11* *True or False:* While long-run industry supply curves slope up (in increasing cost industries) because firms have different cost curves, long-run industry supply curves in decreasing cost industries slope down even if firms have identical cost curves.

The marginal producer in a competitive industry always makes zero profit in the long run.

14A.2.5 Zero Profit for Marginal Firms in the Long Run Finally, notice that entry and exit of firms into markets always continues until the *marginal producer makes zero (long-run) profit*. By “marginal producer,” I mean the producer who has the highest costs within an industry. In the case where all producers have the same costs (as in Graph 14.5), all producers are marginal, and thus all producers make zero (long-run) profit. In the case where producers have access to different technologies and thus face different cost curves (as in Graph 14.6), on the other hand, all producers other than the marginal producer make positive (long-run) profit. Similarly, if all potential producers have the same costs as all those within the industry, then all producers who are not in the industry are also marginal and would make zero (long-run) profit if they entered. When producers face different costs, however, those who are outside the industry in long-run equilibrium would make negative profits if they entered because their costs are greater than the costs of the marginal producer in the industry (who is making zero profit).

EXERCISE 14A.12 *True or False:* In the presence of fixed costs (or fixed expenditures), short-run profit is always greater than zero in long-run equilibrium.

14A.3 Changing Conditions and Changing Equilibria

In the real world, conditions facing particular industries change constantly as new competing products enter the larger market, labor and capital input prices change, and government tax and regulatory policies are altered. The concepts of short- and long-run equilibria are useful, however, not only for those industries that find themselves in relatively stable economic environments for long periods but also for those industries that experience constantly changing conditions. Whether we remain in any particular equilibrium for very long or whether we even reach a static equilibrium before conditions change once again, knowing what the ultimate equilibrium in an economy is lets us know which way an economy is headed, and that is useful even if conditions change once again before the economy reaches the new equilibrium. It is a bit like predicting the weather: It is never quite in equilibrium, but the forces of nature are constantly aiming to get toward an equilibrium. Thus, if we know that a new high pressure system is moving into our area, we can predict what will happen to the weather because we understand how the weather will adjust in an “attempt” to head toward a new equilibrium. So it is with an economy: When

³ In Chapter 21, where we develop the concept of externalities, we provide in end-of-chapter exercise 21.9 another example of a decreasing cost industry that arises from positive production externalities. We similarly illustrate in this example that we can get upward-sloping industry supply curves from negative production externalities even when all firms have identical production technologies.

a new force is introduced, we can predict which way things are headed by knowing the equilibrium the economy is aiming for.

In our model of a competitive industry, a “change in conditions” translates in some way into a change in demand or supply curves, and thus a change in short-run and/or long-run equilibrium. In the remainder of this chapter, we will run through some of the types of changes that might have short- and long-run impacts on a particular industry. On the producer side, changing conditions might result from (1) a change in variable costs (like those associated with labor), (2) a change in fixed expenditures associated with an input that is fixed in the short run, or (3) a change in a fixed cost that is avoidable only by exiting the industry. On the consumer side, changes in consumer tastes or the appearance of new products on the market may cause shifts in market demand. For each of these cases, we will begin our analysis with the assumption that the market was in long-run equilibrium prior to the change in underlying conditions faced by the industry.

14A.3.1 Short-Run Equilibrium within a Long-Run Equilibrium Suppose that our industry is currently in long-run equilibrium, which implies that the marginal producer is making zero (long-run) profits and thus producing at a price that falls at the lowest point of the producer’s (long-run) AC curve. This is illustrated in Graph 14.7 where the market demand and market supply curves, both consisting simply of individual demand and short-run supply curves added up, cross in panel (a) at price p^* , which falls at the lowest point of the (long-run) AC curve of the marginal firm in panel (b). Since panel (b) illustrates the “marginal firm” in the industry, we know that all firms outside the industry have costs that are at least as high as this firm’s. Thus, all firms outside the industry would make zero (long-run) profit or less if they entered the industry. Similarly, we know that the firms inside the industry have costs that are no higher than the marginal firm’s. Thus, all the firms inside the industry make at least zero (long-run) profit. The industry finds itself in long-run equilibrium because no firm has an incentive to enter or exit this industry unless conditions change. Put differently, entry and exit have led to just the right number of firms such that demand and (short-run) supply intersect at the long run equilibrium price.

In long-run equilibrium, entry and exit have led to just the right number of firms such that demand and short-run market supply intersect at the long run equilibrium price.

GRAPH 14.7 An Industry in Both Short- and Long-Run Equilibrium

Go to MindTap to interact with this graph.

At the same time, note that each firm in the industry makes positive short-run profits. This is because short-run economic costs are fully contained in the short-run average cost curve whose lowest point lies below the lowest point of the long-run AC curve. It is for this reason that the green (short-run) supply curve in panel (b) of the graph extends below the lowest point of the (long-run) AC curve as we illustrated before in Graph 14.4.

EXERCISE 14A.13 Can you illustrate graphically the short- and long-run profits of the marginal firm in long-run equilibrium? (*Hint:* You can do this by inserting into the graph the AC^{SR} curve as previously pictured in Graph 14.4.)

This will then be the starting point for our analysis of the impact of changing conditions on short- and long-run equilibrium. In each case, we will need to ask ourselves which curves in our graph are affected by the change, and this will permit us to come to a conclusion about how changing firm behavior results in changes in the equilibrium. For purposes of illustration, we will also assume for the remainder of this chapter that all firms face the same cost curves, and all firms are therefore marginal firms. I will leave it to you as an end-of-chapter exercise to think about how the graphs would differ if firms had different cost curves. Before proceeding, notice that we have stripped the firm side of our pictures to only those curves that actually matter for our analysis: the short-run supply curve and the long-run AC curve, with the short-run supply curve extending below AC . We should keep in mind throughout, however, that the short-run supply curve is really a portion of the short-run MC curve and is thus moved by changes in (short-run) marginal costs.

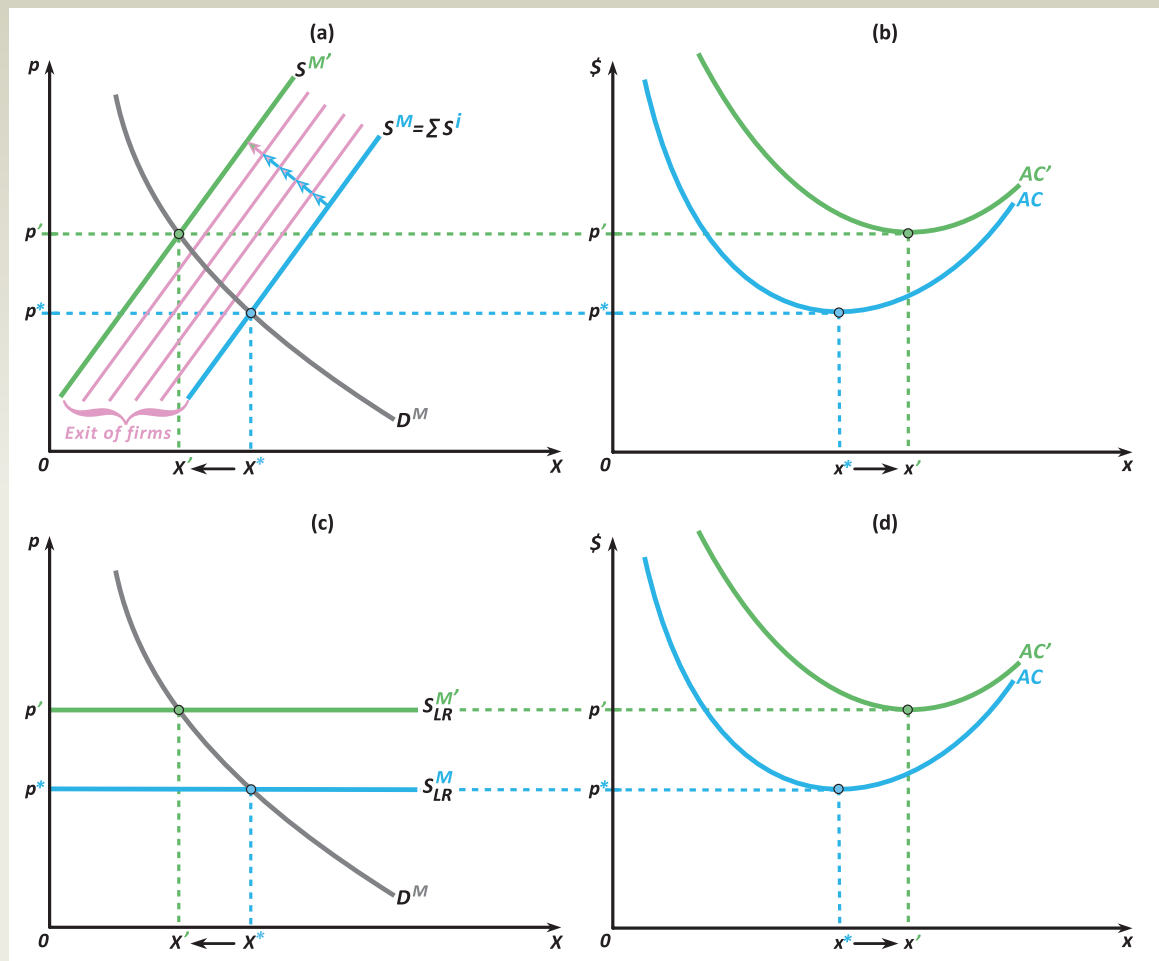

14A.3.2 A Change in a Recurring Fixed Cost Suppose first that producers in an industry incur some annual fixed cost that is not associated with an input. An annual license fee charged by the government is one example of this type of cost. Another example might involve annual insurance premiums, premiums that might insure the firm against damage to its property or liability suits from its consumers or workers. Once paid, such fees are sunk costs in the short run and thus do not enter the short-run cost curves. In the long run, however, such fees are a real economic cost of staying in the industry and thus become part of the long-run cost curve AC .

Now suppose that this fee goes up, a scenario considered in Graph 14.8. Since it is not a part of the short-run average or marginal curves, it is not part of any of the cost curves that are relevant for the firm’s short-run decisions. Thus the firm’s short-run supply curve (which is not pictured in panel (b)) remains unchanged. Since the (blue) short-run market supply curve S^M is simply composed of the sum of all firm supply curves, this also implies that the market supply curve does not change in the short run. This further implies that the equilibrium price in the market remains at p^* in the short run. As a result, the increase in the fee causes no changes in the industry in the short run.

The increased fee does, however, cause the (long-run) AC curve to move up as depicted in the green curve in Graph 14.8b. While short-run profit for the firms is unchanged, long-run profit therefore falls and, since it was zero in the initial equilibrium, it now becomes negative. This causes some firms to exit the market in the long run, which in turn causes the (short-run) market supply curve S^M to shift inward. More specifically, as individual firms exit, the magenta market supply curves in panel (a) drive up the market price, and firms will continue to exit so long as the market price remains below the new lowest point of the green AC' curve in panel (b). Only when the market price has increased all the way to p' will the firms that remain in the industry make zero profits again, eliminating any further incentive for firms to exit (or enter). The short-run market supply curve then stops shifting (as firms stop exiting) when it has reached the green S^M curve in panel (a). The firms that remain in the industry then produce x' , which is more than they produced initially (x^*), but the industry as a whole produces less (X' rather than X^* in panel (a)).

An increase in recurring fixed costs has no immediate impact on short-run equilibrium.

GRAPH 14.8 An Increase in a Long-Run Fixed Cost

Why does the increase in the fee result in a new (green) AC' curve that converges to the original (blue) AC curve?

EXERCISE 14A.14

If you add the firm's long-run supply curve into panel (b) of the graph, where would it intersect the two average cost curves? Would the same be true for the firm's initial short-run supply curve? (*Hint:* For the second question, keep in mind that the firm will change its level of capital as its output increases.)

EXERCISE 14A.15

We could similarly illustrate the long-run change in the equilibrium by simply focusing on what happens in graphs using only curves relevant in the long run. This is done in panels (c) and (d), where the long-run market supply curve in (c) is drawn flat because we are assuming that all firms in the industry are identical. As the lowest point of the individual firms' AC curves shifts up, we know that the price in the long run has to shift up by the same amount in order for the industry to reach a new long-run equilibrium in which all firms in the industry make zero profits

Changes in recurring fixed costs impact the long-run equilibrium price through entry and exit of firms.

as they produce at the lowest points on their AC curves. Thus, the horizontal long-run supply curve (which is always located at the price corresponding to the lowest point on individual AC curves) shifts up, causing an increase in price to p' , a reduction in industry output to X' (in panel (c)) and an increase in output by those firms that stay in the industry to x' (in panel (d)). This is, of course, the same result we got in panels (a) and (b), but in panel (a) we are illustrating how the industry transitions from the initial long-run equilibrium to the new one, while in panel (c) we simply illustrate the starting and ending points. You can infer from the fact that each firm produces more while the industry produces less that firms must have exited.

14A.3.3 Change in the Price of an Input that Is Fixed in the Short Run Next, consider an increase in the price of capital, the input we have assumed fixed in the short run and variable in the long run. This increase might happen, for instance, if conditions in the capital market have changed, thus increasing the equilibrium price of capital. Or it might happen if the government imposes a tax on capital, thus raising the rental rate demanded in the capital market.

Since we are assuming that capital is fixed in the short run, this is again a change in a long-run cost and thus does not affect any of the cost curves relevant for short-run decision making. Unlike the increase in a fixed fee, a long-run (recurring) fixed cost, this is an increase in a long-run *variable cost*, not a long-run fixed cost. As a result, the shift in the (long-run) AC curve for each firm will look a little different than it did in the previous section where the new (green) AC' curve converged to the original (blue) AC curve. More specifically, while the average cost curve will definitely shift up, its lowest point might lie either to the right or left of where it was previously depending on the underlying technology. As we did in Chapter 13, we will graph the shift here (in Graph 14.9) as one that keeps the lowest point of the AC curve at the same output level, but this is simply a special case of what might happen more generally.

EXERCISE 14A.16 Could the AC curve shift similarly in the case where the increase in cost was that of a long-run fixed cost?

GRAPH 14.9 An Increase in the Rental Rate of Capital

This can get a little confusing at first because it seems to involve a logical contradiction: How can it be that the lowest point of the long-run AC curve can remain at the same output quantity when we know that the short-run MC curve has to cross the (long-run) AC curve at its lowest point in the new long-run equilibrium? After all, doesn't the short-run MC curve include only the cost of labor and not the cost of capital that has just increased? The apparent contradiction is resolved, however, if we recognize that the firm will shift away from capital and toward labor when r increases. This implies that, from a short-run perspective (in the new long-run equilibrium), costs will be higher since more labor will be involved in producing each unit of output. It is for this reason that the short-run MC curve shifts as a result of moving to the new long-run equilibrium, but that shift only happens in the long run when firms substitute away from capital and toward labor. This is illustrated in panel (b) of Graph 14.9 where the blue curves represent the original (long-run) AC and (short-run) MC curves and the green curves represent the new (long-run) AC and (short-run) MC .

The rest of the story of how the equilibrium changes is then similar to what we discussed in the previous section for an increase in a fixed fee. Nothing changes in the short run (since none of the short-run curves are affected *in the short run* by an increase in the cost of an input that is fixed in the short run). However, each firm in the industry now makes negative profits, which means that the industry is no longer in long-run equilibrium. The new long-run industry supply curve must shift up to the lowest point of the new long-run AC , the price at which all firms will once again be making zero profit. Industry output falls to X' in panel (a) of Graph 14.9, with each firm in the industry continuing to produce the same as it did before. The fact that individual firms do not change how much they produce but the industry produces less at the higher long-run price necessarily implies that, in this case, firms must have exited.

How would you illustrate the transition from the short run to the long run using graphs similar to those in panels (a) and (b) in Graph 14.8?

EXERCISE 14A.17

However, the case (in Graph 14.9) where an increase in the cost of capital causes the lowest point of long-run AC to shift up but remain at the same output level is a special case. It is logically possible that the underlying production technology for firms is such that an increase in the cost of capital causes the lowest point of long-run AC to instead shift to the right (as it did for an increase in recurring fixed costs). This would imply that more firms will exit as there is room for fewer firms to produce the new market quantity X' when each firm (that remains in the industry) produces more than it did originally. It is also, however, logically possible for the underlying production technology to give rise to a leftward shift of the lowest point of long-run AC when the cost of capital increases. In such a case, fewer firms would exit as relatively more firms would be needed to produce the new long-run market quantity X' when each firm produces less. If the leftward shift in the lowest point of long-run AC is sufficiently large, it is even possible for the number of firms to increase as a result of an increase in the cost of capital, particularly if the decline in the market quantity is small.

Whether the number of firms increases or decreases when the cost of capital increases depends on which way the lowest point of AC shifts and how much the market quantity demanded falls as price rises.

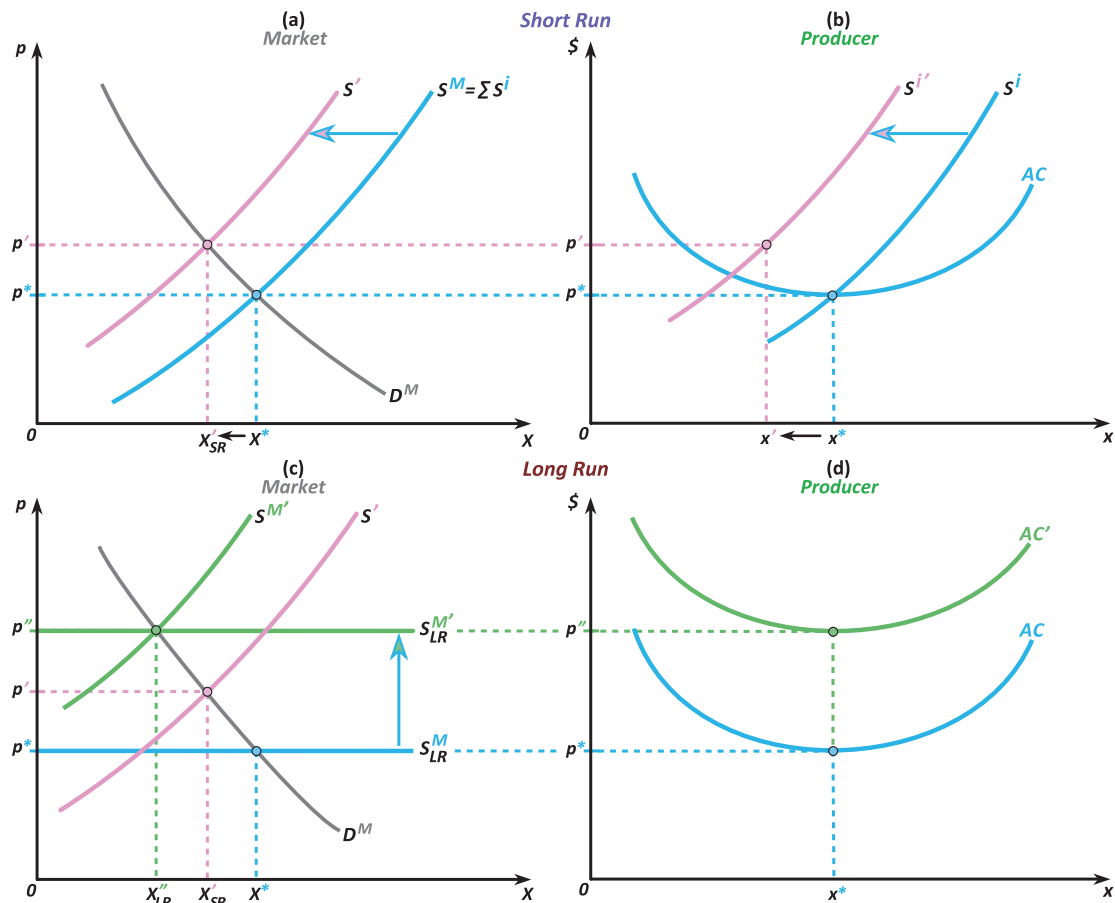

Consider two scenarios: In both scenarios, the cost of capital increases, causing the long-run AC curve to shift up, with the lowest point of the AC curve shifting up by the same amount in each scenario. But in Scenario 1, the lowest point of the AC curve shifts to the right while in Scenario 2 it shifts to the left. Will the long-run equilibrium price be different in the two scenarios? What about the long-run equilibrium number of firms in the industry?

EXERCISE 14A.18

14A.3.4 A Change in (Short- and Long-Run) Variable Costs Now suppose that something causes variable costs for producers in an industry to rise immediately. Perhaps labor costs go up because of changes in the national labor market, or a per-unit tax is imposed on output, or wage taxes have increased. Let's begin with the simplest of these cases: A per-unit tax on the output produced in all firms. This will cause an immediate increase in short-run MC for all firms, which in turn implies an upward (or, equivalently, leftward) shift in each firm's short-run supply curve in panel (b) of Graph 14.10. Since this is happening to all firms in the industry, the same shift will happen to the short run market supply curve in panel (a)—leading to an immediate increase in output price from p to p' .

In the short run, the industry as a whole will therefore produce less, X'_{SR} instead of X^* , with the number of firms staying the same (as no firms can enter or exit in the short run). Since all firms are assumed to be identical, each firm will continue to produce in the short run, which implies each firm produces less (x' rather than x^* in panel (b)). Thus, price in the short run rises sufficiently (to p') to ensure that short-run profit remains above zero. (If we assumed instead

GRAPH 14.10 An Increase in Short-Run Variable Cost

that some firms had lower cost curves than others, some higher cost firms might shut down in the short run if they can no longer make non-negative short-run profits.)

In the long run however, price has to adjust to the new lowest point of (long-run) AC' , which implies that the long-run market supply curve in panel (c) rises from the initial blue horizontal line to the new green line at price p'' . Since the per-unit tax applies the same to all units that are produced, we know in this case that the long-run AC shifts up exactly as shown in the graph, with each point shifting up by the amount of the tax. Thus, the lowest point of the average cost curve remains at the same output quantity x^* in panel (d). In the long run, each firm that remains in the industry will therefore produce as much as it did before costs increased (panel (d)), but since the overall market output falls at higher prices, some firms must have exited as we transition from the short run to the long run. It is for this reason that we can place the magenta short-run shift in the market supply curve (that resulted from an increase in short-run MC for all firms) in panel (c) intersecting the demand curve at a price below the long run price p'' , with the shift from this magenta curve to the new (green) final short-run supply curve resulting from the exit of firms that experienced negative long-run profits at the price p' . Thus, even though each firm that remains in the industry will end up producing as much as it did before costs increased, the market produces less (X''_{LR}) as the industry has shrunk.

A per-unit tax on output would be passed to consumers in the long run, with fewer firms producing in the industry as a result.

The previous side quote makes the statement that a per-unit tax on output will be fully passed on to consumers in the long run. Can you explain what that means in the context of Graph 14.10? Does it also hold in the short run?

EXERCISE 14A.19

Next, suppose instead that the increased variable cost came from a higher cost of labor—either because the market wage went up or because the government imposed a tax on wages (rather than output). It is then possible that the exact same analysis we did for the per-unit output tax holds, but only if the lowest point of the long-run AC curve shifts up without shifting to the left or right. While in the case of the per-unit output tax we knew this to be the case, with an increase in labor costs this lowest point of AC might shift to the left or right instead, depending on the exact nature of the underlying production technology. If it shifted to the right, we could similarly conclude that the number of firms in the industry has fallen as a result of the increase in the wage (just as when the lowest point of AC shifts vertically up). This is because we know the industry produces less (at the higher price) and *each firm* produces more when the lowest point of the long-run AC curve shifts to the right. In fact, the farther right this lowest point shifts, the more exit of firms we must observe. But if that lowest point shifts to the left instead, then it is no longer as clear whether the number of firms in the industry will increase or decrease. While the total industry output would fall just as before (because consumers demand less when prices are higher), it may still take more firms to produce that lower industry output if each firm produces sufficiently less than before (and the market quantity at the new price does not fall too much.). In this case, p'' and p' in panel (c) of Graph 14.10 would be reversed, with the short-run increase in price being sufficiently high to attract new firms into the industry. Put differently, the short-run (magenta) shift in market supply would be larger than the long run (green) shift, thus causing the short-run price to “overshoot” the long-run price—leading to entry of new firms.

An increase in labor costs might result in more or fewer firms in an industry—depending on which way the long-run AC curve shifts and how the quantity demanded is affected by higher prices.

If an increase in the wage causes an increase in the number of firms in an industry, does this give you enough information to know whether the lowest point of long-run AC for firms shifted to the left or right? What if instead an increase in the wage causes a decrease in the number of firms in the industry?

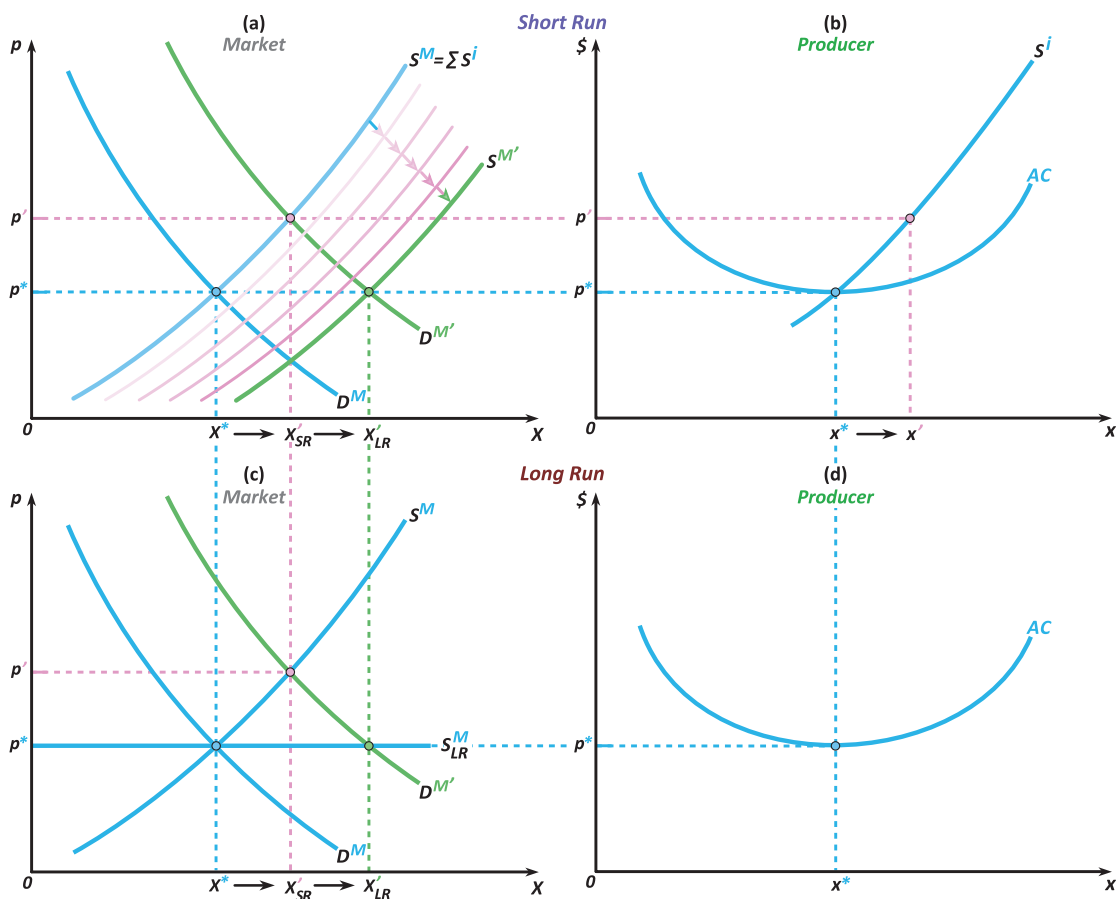

EXERCISE 14A.20

Shifts in market demand may result from changing consumer tastes, from new products in a related market, or from new consumers entering the market.

14A.3.5 A Change in Demand As we already demonstrated in Graph 14.6 when we considered the shape of long-run market supply when firm costs differ, an industry may be impacted not only by changing costs but also by changing market demand. The market for standard portable music players, for instance, may be affected when the demand curve for such players shifts in as new MP3 players gain in popularity. The market demand for MP3 players, on the other hand, might be affected as it becomes easier to purchase music via the Internet by the song rather than in standard tape or CD formats. Such shifts in market demand may result from changing tastes (that change individual demand curves that compose the market demand curve), from the introduction of new products in a related market, or from new consumers entering a market. Such shifts in demand have no impact on the cost curves of firms, which implies that we will not need to change any of the firm cost curves.

Consider, for instance, the increase in demand for the good x graphed in panel (a) of Graph 14.11, and let's stick with the assumption that all firms are identical in terms of their cost structure. We begin at the initial industry equilibrium, with the industry producing X^* at the equilibrium price p^* . When demand shifts from the blue demand curve to the green, there is an immediate

GRAPH 14.11 An Increase in Market Demand

increase in price to p' as the existing firms in the industry meet the new demand along the existing individual supply curves that sum to the market supply curve. But, since firms were initially making zero long-run profits, the increase in price now allows them to earn positive long-run profits. This provides new firms an incentive to enter the industry, and the (short-run) market supply curve therefore shifts out with each new entrant. This in turn puts downward pressure on price, with that pressure continuing so long as firms in the industry are making positive long-run profits. Thus, entry into the industry will stop (assuming all firms have identical costs) only when price falls back to the original p^* where all firms once again make zero long-run profits. The final short-run market supply curve therefore settles at the green curve S^M .

While panel (a) of the graph illustrates the transition from the initial change in the short-run equilibrium to the final long-run equilibrium by showing the shifting (magenta) supply curves as new firms enter, panel (c) illustrates the change from the initial long-run equilibrium to the final long-run equilibrium by focusing on the long-run supply curve S^M_{LR} that does not shift (because the lowest point of the long-run AC curve for firms does not shift). In both panels (a) and (c), we see that industry output rises to X'_{SR} in the short run and ultimately settles at the larger industry output X'_{LR} . In panel (b), we furthermore see that each firm in the industry initially increases its production, but panel (d) illustrates that each firm will ultimately end up producing the same as it did before the increase in demand. The larger industry output therefore arises solely from the fact that the industry as a whole has expanded through the entry of new firms.

14A.3.6 Changes Affecting a Single Firm versus Changes Affecting the Industry In everything we have done thus far in this section, we have assumed that the change we are analyzing affects every firm in the industry. Sometimes, however, only a single firm in the industry might experience a change. The analysis of what happens for such firm-specific changes is then considerably simpler because each firm in a competitive industry is sufficiently small so that any change in behavior by that firm will not affect the short- or long-run market equilibrium.

Suppose, for instance, that I am one of many producers who produces trading cards with heroes (economists, in my case) pictured on them. I am only one of many producers of “hero cards,” and so what I do has no impact on the market. Now suppose the government gets upset at me because economists are critical of government policy and, in the view of the government, therefore do not represent legitimate heroes for children. As a result, the government raises my annual license fee for operating in the hero card market, but it does not raise the fees for anyone else. In that case, I’ll continue to produce in the short run as if nothing happened until my license fee for next year comes due. Since I (as every other firm in the industry) was initially making zero profits, I would now make negative long-run profits if I paid the license fee again and continued to produce. So, I will exit the industry, leaving the market equilibrium unchanged (since I am one of many producers and therefore can’t by myself shift the market supply curve).

Sometimes, the change in costs that affect a single firm are less obvious than the simple example of the government imposing a fee or tax on just me. Suppose, for instance, that I discovered that the economist card factory I owned sits on land that contains substantial oil reserves underneath. This new information would imply that the value of the land under my factory is considerably higher than I initially thought, and thus the opportunity cost of using this land for my factory has gone up. Thus, my long-run AC shifts up, implying that I will now make negative profits if I continue to produce economist cards. I will therefore exit the industry and either go into the oil business or sell the land to an oil company. The increase in my costs has thus driven me out of the hero card business, even though I am better off since I get to make more money in the oil business (or make more money by selling the land). If, on the other hand, I had rented the land rather than owned it, the rent for the land would have increased, thus again raising my long-run AC and driving me out of business, but now the owner of the land would have benefited rather than me. In either case, though, the increase in opportunity costs for me as a hero card producer increased and drove me out of the industry.

Due to entry and exit of firms, shifts in demand do not impact long-run equilibrium prices as long as all firms are identical.

Changes that impact only a single firm have no impact on short- or long-run price.

EXERCISE 14A.21 *True or False:* Regardless of what cost it is, if it increases for only one firm in a competitive industry, that firm will exit in the long run but it might not shut down in the short run.

14A.4 An Overview of Changes Affecting Firms and Industries

In this chapter, we have—for the first time—aggregated both the consumer and producer sides of a competitive market. By understanding what moves the supply side of the goods market, we have then been able to trace the short- and long-run impacts of changes in several types of market conditions on prices and output levels within affected industries. Table 14.1 summarizes our main conclusions.

The table gives an example for four general market conditions we have covered: (1) changes in recurring fixed costs (e.g., license fees); (2) changes in costs associated with inputs that are fixed in the short run but variable in the long run (e.g., the price r of capital); (3) changes in costs associated with inputs that are immediately variable (e.g., the price w of labor); and (4) changes in consumer demand for the product produced in the industry. For each of these, the table first indicates which of the key cost curves are affected in firms in both the short and long run. It then indicates short- and long-run movements in equilibrium prices, industry output levels, and individual firm output levels. Single arrows (such as \uparrow) indicate a smaller change than a double arrow (such as $\uparrow\uparrow$) when variables are expected to move in the same direction in both the short and long run; a horizontal line ($-$) indicates no change from the initial equilibrium; and a question mark (?) indicates that the theory, absent additional assumptions, allows for changes in either direction. Finally, the last column indicates whether the change causes the overall number of firms in the industry to increase or decrease in the long run, indicating whether firms are expected to enter or exit the industry as a result of the change.⁴

EXERCISE 14A.22* What would a fifth row for an increase in per-unit taxes on output look like? Can you then also replicate Table 14.1 for the cases where the demand and the various cost examples decrease rather than increase.

TABLE 14.1 The Impact of Changing Conditions of Firms and Industries (Assuming Identical Firms)

Example	Affected Costs		Market Price	Industry Output	Firm Output	LR # of Firms
	SR	LR				
\uparrow License Fee	None	AC	$-SR \uparrow LR$	$-SR \downarrow LR$	$-SR \uparrow LR$	\downarrow
$\uparrow r$	None	AC, MC	$-SR \uparrow LR$	$-SR \downarrow LR$	$-SR ? LR$?
$\uparrow w$	AC, MC	AC, MC	$\uparrow SR \uparrow LR$	$\downarrow SR \downarrow LR$	$\downarrow SR ? LR$?
\uparrow Demand	None	None	$\uparrow SR _ LR$	$\uparrow SR \uparrow LR$	$\uparrow SR _ LR$	\uparrow

⁴ See Graphs 14.8, 14.9, 14.10, and 14.11 and surrounding discussion for details on each of the rows in Table 14.1.

14B

THE MATHEMATICS OF INDUSTRY (OR MARKET) EQUILIBRIUM

Given that we have derived demand and supply for various scenarios quite carefully, there is little in terms of new mathematics that has to be added at this point to further our understanding of the intuitive concepts related to industry or market equilibrium in Section A. I will therefore use Section B in this chapter to simply run through an example illustrating how we use all we have learned to calculate an industry equilibrium from knowing some basics about an economy. This is obviously going to be a stylized example, not one meant in any way to approximate any real-world industry. Nevertheless, it is often the case that understanding the full implications of what one learns is more than understanding the sum of all the parts. It is for this reason that I think we benefit from fully developing an industry equilibrium from the ground up.

We will begin with consumers who all have tastes over the good x and “all other goods” y that can be represented by the quasilinear utility function

$$u(x, y) = 50x^{1/2} + y. \quad (14.1)$$

You can check for yourself that such consumers have the demand function

$$x^d(p) = \left(\frac{25}{p}\right)^2 = \frac{625}{p^2}, \quad (14.2)$$

where we assume a price of 1 for the composite good y and let p denote the price of good x .

Why is the demand function not a function of income?

EXERCISE
14B.1

Suppose further that producers operate in competitive input markets in which labor costs $w = 20$ and capital costs $r = 10$, and that all producers (and potential producers) for the good x face the same technology that can be captured by the production function

$$f(\ell, k) = 20\ell^{2/5}k^{2/5}. \quad (14.3)$$

Note that this is the same decreasing returns to scale technology for which we calculated the various functions in the duality picture in Chapter 12. Suppose that in addition to the inputs ℓ and k , however, the firm must purchase a recurring operating license that costs \$1,280 from the government. As you should have concluded if you did end-of-chapter exercise 12.4, an addition of a recurring fixed cost such as this to a decreasing returns to scale production process results in a U-shaped long-run average cost curve for the producer.

We can demonstrate this here by combining results we already derived (for the most part) elsewhere. In Chapter 12 (equation (12.46)), we derived the cost function for the production function (14.3) as $C(w, r, x) = 2(wr)^{1/2}(x/20)^{5/4}$. With the additional recurring fixed cost of 1,280, this implies a long-run cost function for the production process in equation (14.3) of

$$C(w, r, x) = 2(wr)^{1/2}\left(\frac{x}{20}\right)^{5/4} + 1,280 \quad (14.4)$$

or, when $w = 20$ and $r = 10$,

$$C(x) = 0.66874x^{5/4} + 1,280. \quad (14.5)$$

This further implies an AC function (when $w = 20$ and $r = 10$) of

$$AC(x) = 0.66874x^{1/4} + \frac{1,280}{x}, \quad (14.6)$$

which is U-shaped and attains its minimum at $x = 1,280$ at an average cost of \$5 per unit.

EXERCISE 14B.2 Demonstrate that the average cost of production is U-shaped and reaches its lowest point at $x = 1,280$ where $AC = 5$. (*Hint:* You can illustrate the U-shape by showing that the derivative of AC is zero at 1,280, negative for output less than 1,280, and positive for output greater than 1,280.)

14B.1 Industry Equilibrium in the Short Run

Short-run industry equilibrium is then determined solely by the intersection of market demand and supply curves, where demand and supply curves are represented by the sum of all individual demand curves from consumers and supply curves from producers who are currently operating in the industry. Adding up demand curves in our example is particularly easy because the demand functions (equation (14.2)) of *all* consumers are exactly identical (since they share the same quasilinear tastes and thus their income does not matter for demand). “Adding up” demand curves for all consumers therefore simply means “multiplying” equation (14.2) by the number of consumers in the market for good x . For instance, suppose the total number of consumers in the market is 64,000. Then the market demand function $D^M(p)$ is

$$D^M(p) = 64,000x^d(p) = 64,000\left(\frac{625}{p^2}\right) = \frac{40,000,000}{p^2}. \quad (14.7)$$

14B.1.1 Short-Run Industry Supply To calculate the short-run market supply curve, we need to first know the individual short-run supply function for each producer and then similarly “add up” these functions. In equation (11.33) of Chapter 11, we concluded that the supply function for a producer with technology $f(\ell) = A\ell^\alpha$ is

$$x(p, w) = A\left(\frac{w}{\alpha Ap}\right)^{\alpha/(\alpha-1)}. \quad (14.8)$$

If capital is fixed at k^A in the short run, then our production function from equation (14.3) is simply

$$f(\ell) = A\ell^\alpha \text{ where } A = 20(k^A)^{2/5} \text{ and } \alpha = 2/5. \quad (14.9)$$

Suppose, for instance, that $k^A = 256$, which we will show shortly in Section 14B.2 is the case in long-run equilibrium. Then, using the values for A and α specified in equation (14.9) and plugging them into equation (14.8), we get a short-run supply function

$$x(p, w) = 3,225.398\left(\frac{p}{w}\right)^{2/3} \text{ or } x^s(p) = 437.754p^{2/3} \text{ when } w = 20. \quad (14.10)$$

Since we are assuming all producers are identical, “adding up” these supply functions to get short-run market supply is again equivalent to “multiplying” them by the number of firms *that are currently operating in the industry*. Suppose that number is 1,250 (which we will shortly show is the correct number of firms in long-run equilibrium). Then the short-run industry supply function $S^M(p)$ is

$$S^M(p) = 1,250x^s(p) = 1,250(437.754)p^{2/3} = 547,192p^{2/3}. \quad (14.11)$$

14B.1.2 Short-Run Industry Equilibrium With market demand and market supply given by equations (14.7) and (14.11) respectively, we can now calculate the short-run equilibrium by setting the two equations equal to one another and solving for the equilibrium price; that is, solve

$$S^M(p) = 547,192p^{2/3} = \frac{40,000,000}{p^2} = D^M(p), \quad (14.12)$$

which gives $p = 5$. Thus, with 64,000 consumers and 1,250 producers, with tastes and technologies described by equations (14.1) and (14.3), with short-run capital k^A fixed at 256 units and with the wage rate given by $w = 20$, market demand and supply intersect at an equilibrium price $p^* = 5$. Plugging this back into the individual consumer and producer equations, this implies that each consumer in the market consumes 25 units of x , and each producer produces 1,280 units of output by hiring 128 labor hours.

Verify these individual production and consumption quantities.

**EXERCISE
14B.3**

To make sure that each firm is in fact making non-negative short-run profits, we can compare total revenues to total short-run economic costs. Total revenues are simply given by the output quantity (1,280) times price (\$5), for a total of \$6,400. Short-run economic costs in this case include only labor costs: 128 labor hours at a wage of \$20, or \$2,560. Thus, short-run profit for each producer is \$3,840. At the same time, the producer also incurs fixed short-run *expenses* of \$10 for each of the 256 units of capital that are fixed in the short run *and* the recurring fixed license fee of \$1,280, for a total of \$3,840 in total expenditures that are not costs in the short run.

We have already indicated that $k = 256$ is in fact the optimal long-run quantity of capital when $(p, w, r) = (5, 20, 10)$. Can you then conclude that the industry is in long-run equilibrium from the information in the previous paragraph? (*Hint*: This can only be true if no firm has an incentive to enter or exit the industry.)

**EXERCISE
14B.4**

14B.2 An Industry in Long-Run Equilibrium

We already concluded after equation (14.6) that the long-run *AC* curve for each of the firms (assuming $w = 20$ and $r = 10$) is U-shaped and attains its lowest point of \$5 at output quantity 1,280. We also know that *in the long run, the number of firms in the market will adjust to keep the equilibrium price at this lowest point of the long-run AC curve*; that is, in the long run, equilibrium price is \$5. With market demand given by equation (14.7), this implies that the industry will produce a total of 1,600,000 units of x , which is the quantity demanded by the market when price is \$5. And, since each firm will produce at the lowest point of its *AC* curve in long-run equilibrium, we know that each individual firm will produce 1,280 units of x , implying that there will be exactly 1,250 producers in the industry.

The short-run equilibrium we calculated in the previous section is therefore also the long-run equilibrium, with the short-run fixed quantity of capital (256 units per firm) exactly equal to how much capital each firm desires to utilize given the current prices. The industry equilibrium is pictured in Graph 14.12, with panel (b) illustrating the short-run industry demand curves whose intersection signals prices to the typical consumer in panel (a) and the typical producer in panel (c). Note that the supply and demand curves are once again actually plotted as inverse supply and demand functions given that they are functions of prices but prices appear on the vertical axes.

GRAPH 14.12 A Graphical Representation of the Industry Equilibrium

The graph looks similar to those we are used to seeing from Section A except for the fact that short-run firm supply curves begin at the origin in panel (b) whereas we drew them as beginning at the lowest point of short-run average cost AC^{SR} in our graphs in Section A. When you think about the underlying assumptions in Graph 14.12, however, the reasons for this difference should become apparent. The short-run production function (given in equation (14.9)) has decreasing returns to scale throughout, implying increasing MC throughout. In our graphs of Section A, on the other hand, we implicitly assumed a sigmoid shaped short-run production function of the type we introduced in Chapter 11, with an initial portion that has increasing marginal product of labor before eventually exhibiting diminishing marginal product of labor. This assumption then led to a U-shaped AC^{SR} , with the portion of the MC above AC^{SR} forming the short-run firm supply curve. In the case of our short-run production function that has diminishing marginal product of labor throughout, however, the AC^{SR} is not U-shaped and has its lowest point at the origin.

EXERCISE 14B.5

Can you graph the AC^{SR} into panel (c) of Graph 14.12?

14B.3 Changing Conditions and Changing Equilibrium

At this point in Section A, we proceeded to demonstrate how the short- and long-run equilibrium changes as different parts of the economic environment change. We began by noting that our starting point will always be an industry in long-run equilibrium, and we can think of a short-run equilibrium lying embedded in this long-run equilibrium. This is what we in fact have just calculated and graphed in Graph 14.12: The industry is in long-run equilibrium because each firm is producing at the lowest point of (long-run) AC , and this lowest point lies on the short-run supply curve that is formed from assuming that each firm currently has the long-run optimal quantity of capital given its current production of 1,280 units of output. The total number of firms in the industry is then exactly sufficient to cause the short-run industry demand curve to intersect the market demand curve at \$5, which keeps the industry in long-run equilibrium with no incentive for any firm to enter or exit.

We can then illustrate, beginning at this equilibrium, the impact of changes in long-run fixed costs (represented in our example by the recurring license fee), changes in cost associated with inputs that are fixed in the short run but variable in the long run (represented in our example by the cost of capital), changes in costs associated with variable inputs (represented in our example by the cost of labor) and, finally, changes in demand for the industry's output. As in Section A, we will consider positive changes in each of these and will leave it to you to investigate what happens when these changes are in the opposite direction.

14B.3.1 An Increase in a Long-Run Fixed Cost Suppose, then, that the government seeks to cover a deficit by raising all license fees by 75%, implying an increase in the recurring license fee for our firms from \$1,280 to \$2,240. Since the license fee does not appear in the short-run firm supply functions in equation (14.10), the short-run market supply does not shift and nothing changes in the short run. In the long run, however, firms would experience a negative profit of \$960 each period, giving an incentive for some of them to exit the industry. This will cause an upward shift in the market supply curve until profits are once again zero in the industry.

Why does the long-run profit become negative \$960 if nothing changes?

EXERCISE 14B.6

To see at what output price profits will be zero, we simply have to see where the new lowest point of each producer's long-run AC curve lies. Instead of the AC in equation (14.6), the increase in the license fee causes the new long-run AC' curve to be

$$AC'(x) = 0.66874x^{1/4} + \frac{2,240}{x}, \quad (14.13)$$

which is once again U-shaped but now has its lowest point at approximately $x = 2,000$ where average cost is approximately \$5.59 per unit. We therefore know that the new long-run equilibrium will have an output price of approximately \$5.59 (up from the previous price of \$5.00 per unit), with each firm that remains in the industry producing approximately 2,000 units of output each period (up from the previous 1,280 units produced by each firm in the industry). Plugging this new price into the market demand function in equation (14.7), we find that consumers will demand approximately 1,280,000 units of output each period at this new long-run equilibrium price. With each firm in the industry producing approximately 2,000 units, this implies that the new long-run equilibrium will have approximately 640 firms, down from 1,250 before the increase in the license fee. Finally, we can insert the new price into the individual demand functions in equation (14.2) to conclude that each consumer will lower his or her consumption from 25 to approximately 20 units of x each period.

**EXERCISE
14B.7**

Verify these calculations.

**EXERCISE
14B.8**

Compare the changes set off by an increase in the license fee to those predicted in Graph 14.8.

14B.3.2 An Increase in the Cost of Capital Next, suppose that, instead of an increase in the license fee, the cost of capital r increases from \$10 per unit to \$15 per unit. Since capital is a fixed input in the short run, this change once again does not alter the short-run supply curve of firms (equation (14.10)) and thus has no impact on the short-run market equilibrium. However, as capital becomes a variable input in the long run, it becomes an economic cost, and profit for each firm becomes negative unless output price rises.

How high the price rises again depends on how far up the lowest point of the producers' (long-run) AC curve has shifted. Plugging in the wage $w = 20$ and the new rental rate $r' = 15$ into the general cost function in equation (14.5), we get cost as a function of output given by

$$C(x) = 0.819036x^{5/4} + 1,280, \quad (14.14)$$

with accompanying average cost given by

$$AC'(x) = 0.819036x^{1/4} + \frac{1,280}{x}. \quad (14.15)$$

This new AC' curve reaches its lowest point at approximately $x = 1,088$ where average cost is approximately \$5.88 per unit, up from \$5.00 per unit before the increase in r . Thus, the new long-run equilibrium price has to be approximately \$5.88, with each firm that remains in the industry producing 1,088 units of x each period. At this price, the market demand function tells us that consumers will demand approximately 1,156,925 units of x , which implies that the new long-run equilibrium will have approximately 1,063 producers, down from the initial 1,250.

**EXERCISE
14B.9**

Verify these calculations.

**EXERCISE
14B.10**

Are these results consistent with Graph 14.9?

**EXERCISE
14B.11**How much capital and labor are hired in the industry before and after the increase in r ?

Notice that in this example, the lowest point of the long-run AC curve has shifted to the left (from 1,280 to 1,088). Thus, each firm is producing less in the new long-run equilibrium, but, because industry demand fell sufficiently much due to the long-run increase in price (from \$5 to \$5.88), this still required some firms to exit. Were the industry demand curve steeper and thus less responsive to the price increase, this result could have gone in the opposite direction, with more rather than fewer firms in the new long-run equilibrium.

14B.3.3 An Increase in the Cost of Labor The most complicated cost change we analyzed in Section A was that of an increase in the wage rate w because labor can be adjusted in both the short and long run. Suppose, for instance, that the wage rate increases from \$20 to \$30 (with the

cost of capital remaining at \$10 and the license fee remaining at \$1,280). From equation (14.10), we know that the short-run supply function for each producer is $x(p, w) = 3,225.398(p/w)^{2/3}$, which implies that the supply function shifts from $x^s(p) = 437.754p^{2/3}$ when $w = 20$ to

$$x^s(p) = 334.069p^{2/3}. \quad (14.16)$$

With 1,250 producers in the industry, this implies that short-run industry supply shifts from $S^M(p) = 547,192p^{2/3}$ to

$$S^M(p) = 417,586p^{2/3}. \quad (14.17)$$

When set equal to the (unchanged) market demand $D^M(p) = 40,000,000/p^2$, we get a short-run equilibrium price of approximately \$5.53 (up from the initial equilibrium price of \$5.00 before the wage increase). At this price, each firm produces approximately 1,045 units of output (down from 1,280), earning revenue of approximately \$5,782 each period.

Verify these calculations.

**EXERCISE
14B.12**

In the short run, expenses associated with capital and license fees are not economic costs, and labor costs are the only short-run economic costs. With each firm's capital fixed at 256 units, approximately 77 units of labor are hired by each firm to produce the 1,045 units of output, implying that short-run economic costs are approximately \$2,310. Given \$5,782 in revenue, this leaves a short-run economic profit of \$3,472.

How much does the industry production change in the short run?

**EXERCISE
14B.13**

In the long run, however, license costs and costs associated with capital become economic costs. Were each firm to continue to produce as it does in short-run equilibrium, total costs would therefore include \$2,560 for capital inputs and \$1,280 for the license to operate, implying that each firm would earn a long-run economic profit of $-\$367$ each period. Thus, firms have an incentive to exit until long-run profit is once again zero for all firms that remain in the industry. This will occur when price reaches the lowest point of the new (long-run) AC' curve, which happens when long-run output price settles at approximately \$5.88 (up from \$5.53 in the short run). At this long-run equilibrium price, each producer that remains in the market will produce approximately 1,088 units of output (up from 1,045 in the short run) while the market demand for output falls to approximately 1,156,925 (from 1,306,395 in the short run). This leaves room for approximately 1,063 producers in the industry (down from 1,250).

Verify these calculations and compare the results with our graphical analysis of an increase in the wage rate in Graph 14.10.

**EXERCISE
14B.14**

As in the case of an increase in the rental rate in the previous section, note again that the lowest point of the long-run AC curve has shifted to the left (from 1,280 to 1,088). Thus, each firm is again producing less in the new long-run equilibrium, but, because industry demand fell sufficiently much due to the long-run increase in price (from \$5 to \$5.53), this still required

some firms to exit. Were the industry demand curve steeper and thus less responsive to the price increase, this could again result in more rather than fewer firms in the new long-run equilibrium. Were that the case, the short-run increase in price would have over-shot the long-run zero-profit price.

14B.3.4 An Increase in Market Demand Finally, we concluded Section A with a brief analysis of how the industry changes in the short and long run when there is an increase in market demand. Suppose, for instance, that some unexpected news coverage of the health benefits of consuming our mythical x good increases the number of consumers in our market from 64,000 to 100,000. Market demand, initially equal to $D^M(p) = 64,000x^d(p) = 40,000,000/p^2$ then shifts to the new $D^M(p)$ given by

$$D^M(p) = 100,000x^d(p) = 100,000\left(\frac{625}{p^2}\right) = \frac{62,500,000}{p^2}. \quad (14.18)$$

The short-run market supply function $S^M(p) = 547,192p^{2/3}$ remains unchanged (since each firm’s cost curves remain unchanged). Setting this equal to the new demand function, we then get a new short-run equilibrium price of approximately \$5.91 (up from \$5.00). At this price, each of the 1,250 existing firms produce (given their short-run supply curves from equation (14.10)) approximately 1,431 units of output (up from 1,280), with industry supply rising to approximately 1,789,234 (from 1,600,000).

EXERCISE 14B.15 How much does individual consumption by consumers who were originally in the market change in the short run?

At the new short-run equilibrium price, each firm earns positive economic profits, thus providing an incentive for new firms to enter the industry until price is driven back to \$5.00 when all firms in the industry make zero profits. At \$5, the new market demand curve tells us that consumers demand 2,500,000 units of x . With each firm once again producing at the lowest point of its long-run average cost curve (where $x = 1,280$), this implies that there will be approximately 1,953 producers in the new long-run equilibrium (up from 1,250).

EXERCISE 14B.16 Verify these calculations and compare the results with Graph 14.11, where we graphically illustrated the impact of an increase in market demand.

CONCLUSION

In this chapter, we have combined for the first time the results from consumer and producer models to illustrate how competitive or decentralized market equilibria arise. These equilibria are based on the assumption that individuals—producers and consumers—are “small” relative to the economy and thus cannot individually influence the economic environment in which they operate. Put differently, competitive equilibrium arises when individuals are price-takers with no incentive to think strategically about how their own actions influence prices. Later on, we will see how the notion of an equilibrium changes when some individuals in an economy are not “small.”

While the difference between the short and long run for firms is defined by the time it takes for all inputs to become variable, the difference between the short and long run for the industry is defined by the time it takes for new firms to enter or old ones to exit. Firms can exit once they can release the inputs that are fixed in the short run, which implies that the time horizon for the short run to turn into the long run is

the same from the firm's and the industry's perspective (if the fixed input is fixed for the same time period for all firms). Firms can enter once they can release their fixed inputs in other industries and convert them to inputs in the industry they wish to enter, and it is convenient as well as plausible to assume that this, too, is similar to the period during which inputs are fixed in the industry we are analyzing. The most important insight to emerge from all this is that the short-run equilibrium emerges from the intersection of demand and supply of *existing firms* in the industry, while the long-run equilibrium is entirely derived from the entry/exit decisions that drive long-run profits (of marginal firms) to zero.

The competitive equilibrium that we have described is, as we noted at the beginning of the chapter, remarkable in that it describes a “spontaneous order.” By “order” we mean that a mechanism is put in place to signal, through market prices, to millions of individual actors in the market how they should cooperate with others in that market. By “spontaneous” we mean that the order arises without anyone planning it; each individual simply considers his or her own economic circumstances and makes the best decision he or she can. We will now turn to another remarkable result: Under certain conditions, this spontaneous order turns out to maximize the overall gains to society from the scarce resources that are available to the society.

END-OF-CHAPTER EXERCISES

- 14.1†** In Table 14.1, the last column indicates the predicted change in the number of firms within an industry when economic conditions change.
- A.** In two cases, the table makes a definitive prediction, whereas in two other cases it does not.
- Explain first why we can say definitively that the number of firms falls as a recurring fixed cost (that is, license fee) increases. Relate your answer to what we know about firm output and price in the long run.
 - Repeat (a) for the case of an increase in demand.
 - Now consider an increase in the wage rate and suppose first that this causes the long-run AC curve to shift up without changing the output level at which the curve reaches its lowest point. In this case, can you predict whether the number of firms increases or decreases?
 - Repeat (c) but assume that the lowest point of the AC curve shifts up and to the right.
 - Repeat (c) again but this time assume that the lowest point of the AC curve shifts up and to the left.
 - Is the analysis regarding the new equilibrium number of firms any different for a change in r ?
 - Which way would the lowest point of the AC curve have to shift in order for us not to be sure whether the number of firms increases or decreases when w falls?
- B.** Consider the case of a firm that operates with a Cobb–Douglas production function $f(\ell, k) = A\ell^\alpha k^\beta$ where $\alpha, \beta > 0$ and $\alpha + \beta < 1$.
- The cost function for such a production process, assuming no fixed costs, was given in equation (13.43) of exercise 13.5. Assuming an additional recurring fixed cost F , what is the average cost function for this firm?
 - ** Derive the equation for the output level x^* at which the long-run AC curve reaches its lowest point.
 - How does x^* change with F , w , and r ?
 - True or False:* For industries in which firms face Cobb–Douglas production processes with recurring fixed costs, we can predict that the number of firms in the industry increases with F but we cannot predict whether the number of firms will increase or decrease with w or r .
- 14.2** Table 14.1 was constructed under the assumption that all firms in the industry are identical.
- A.** Suppose that all firms in an industry have U-shaped long-run average cost curves.
- Leaving aside the column labeled “Firm Output,” what would change in the table if firms have different cost structures; that is, some firms have lower marginal and average costs than others?

*conceptually challenging

**computationally challenging

†solutions in Study Guide

- b. Industries such as those described in (a) are sometimes called *increasing cost industries* compared with *constant cost industries* where all firms are identical. Can you derive a rationale for these terms?
- c. It has been argued that, in some industries, the average and marginal costs of *all* firms decline as more firms enter the market. For instance, such industries might make use of an unusual labor market skill that becomes more plentiful in the market as more workers train for this skill when many firms demand it. How would the long-run industry supply curve differ in this case from that discussed in the text as well as that described in (a)?
- d. Industries such as those described in (c) are sometimes referred to as *decreasing cost industries*. Can you explain why?

14.3[†] Everyday and Business Application: *Fast Food Restaurants and Grease (cont'd)*: In exercise 12.8, you investigated the impact of hybrid vehicles that can run partially on grease from hamburger production on the number of hamburgers produced by a fast food restaurant. You did so, however, in the absence of considering the equilibrium impact on prices and assumed instead that prices for hamburgers are unaffected by the change in demand for grease.

- A. Suppose again that you use a decreasing returns to scale production process for producing hamburgers using only labor and that you produce 1 ounce of grease for every hamburger. In addition, suppose that you are part of a competitive industry and that each firm also incurs a recurring fixed cost F every week.
 - a. Suppose that the cost of hauling away grease is $q > 0$ per ounce. Illustrate the shape of your marginal and average cost curve (given that you also face a recurring fixed cost).
 - b. Assuming all restaurants are identical, illustrate the number of hamburgers you produce in long-run equilibrium.
 - c. Now suppose that, as a result of the increased use of hybrid vehicles, the company you previously hired to haul away your grease is now willing to pay for the grease it hauls away. How do your cost curves change?
 - d. Describe the impact this will have on the equilibrium price of hamburgers and the number of hamburgers you produce in the short run.
 - e. How does your answer change in the long run?
 - f. Would your answers change if you instead assumed that restaurants used both labor and capital in the production of hamburgers?
 - g. In exercise 12.8, you concluded that the cholesterol level in hamburgers will increase as a result of these hybrid vehicles if restaurants can choose more or less fatty meat. Does your conclusion still hold?
- B. Suppose, as in exercise 12.8, that your production function is given by $f(\ell) = A\ell^\alpha$ (with $0 < \alpha < 1$) and that the cost of hauling away grease is q . In addition, suppose now that each restaurant incurs a recurring fixed cost of F .
 - a. Derive the cost function for your restaurant.
 - b. Derive the marginal and average cost functions.
 - c. How many hamburgers will you produce in the long run?
 - d.** What is the long-run equilibrium price of hamburgers?
 - e. From your results, determine how the long-run equilibrium price and output level of each restaurant changes as q changes.

14.4 Business Application: *Brand Names and Franchise Fees*: Suppose you are currently operating a hamburger restaurant that is part of a competitive industry in your city.

- A. Your restaurant is identical to others in its homothetic production technology, which employs labor ℓ and capital k and has decreasing returns to scale.
 - a. In addition to paying for labor and capital each week, each restaurant also has to pay recurring weekly fees F to operate. Illustrate the average weekly long-run cost curve for your restaurant.

EVERYDAY
APPLICATION

BUSINESS
APPLICATION

BUSINESS
APPLICATION

- b. On a separate graph, illustrate the weekly demand curve for hamburgers in your city as well as the short-run industry supply curve assuming that the industry is in long-run equilibrium. How many hamburgers do you sell each week?
- c. As you are happily producing burgers in this long-run equilibrium, a representative from the national MacWendy's chain comes to your restaurant and asks you to convert your restaurant to a MacWendy's. It turns out, this would require no effort on your part; you would simply have to allow the MacWendy's company to install a MacWendy's sign, change some of the furniture, and provide your employees with new uniforms, all of which the MacWendy's parent company is happy to pay for. MacWendy's would, however, charge you a weekly franchise fee of G for the privilege of being the only MacWendy's restaurant in town. When you wonder why you would agree to this, the MacWendy's representative pulls out his marketing research that convincingly documents that consumers are willing to pay $\$y$ more per hamburger when it carries the MacWendy's brand name. If you accept this deal, will the market price for hamburgers in your city change?
- d. On your average cost curve graph, illustrate how many hamburgers you would produce if you accepted the MacWendy's deal.
- e. Next, for a given y , illustrate the largest that G could be in order for you to accept the MacWendy's deal.
- f. If you accept the deal, will you end up hiring more or fewer workers? Will you hire more or less capital?
- g. Does your decision on how many workers and capital to hire under the MacWendy's deal depend on the size of the franchise fee G ?
- h.* Suppose that you accepted the MacWendy's deal and, because of the increased sales of hamburgers at your restaurant, one hamburger restaurant in the city closes down. Assuming that the total number of hamburgers consumed remains the same, can you speculate whether total employment (of labor) in the hamburger industry went up or down in the city? (*Hint*: Think about the fact that all restaurants operate under the same decreasing returns to scale technology.)
- B.** Suppose all restaurants in the industry use the same technology that has a long-run cost function $C(w, r, x) = 0.028486(w^{0.5}r^{0.5}x^{1.25})$, which, as a function of wage w and rental rate r , gives the weekly cost of producing x hamburgers.⁵
- a. Suppose that each hamburger restaurant has to pay a recurring weekly fee of \$4,320 to operate in the city in which you are located and that $w = 15$ and $r = 20$. If the restaurant industry is in long-run equilibrium in your city, how many hamburgers does each restaurant sell each week?
- b. At what price do hamburgers sell in your city?
- c. Suppose that the weekly demand for hamburgers in your city is $x(p) = 100,040 - 1,000p$. How many hamburger restaurants are there in the city?
- d. Now consider the MacWendy's offer described in A(c) of this exercise. In particular, suppose that the franchise fee required by MacWendy's is $G = 5,000$ and that consumers are willing to pay 94 cents more per hamburger when it carries the MacWendy's brand name. How many hamburgers would you end up producing if you accept MacWendy's deal?
- e. Will you accept the MacWendy's deal?
- f. Assuming that the total number of hamburgers sold in your city will remain roughly the same, would the number of hamburger restaurants in the city change as a result of you accepting the deal?
- g. What is the most that the MacWendy's representative could have charged you for you to have been willing to accept the deal?
- h. Suppose the average employee works for 36 hours per week. Can you use Shephard's Lemma to determine how many employees you hire if you accept the deal? Does this depend on how high a franchise fee you are paying?

⁵For those who find unending amusement in proving such things, you can check that this cost function arises from the Cobb–Douglas production function $f(\ell, k) = 30\ell^{0.4}k^{0.4}$.

- i. How does this compare with the number of employees hired by the competing non-MacWendy’s hamburger restaurants? In light of your answer to (f), will overall employment in the hamburger industry increase or decrease in your city as a result of you becoming a MacWendy’s restaurant?

14.5[†] Business Application: “*Economic Rent*” and *Profiting from Entrepreneurial Skill*: Suppose, as in exercise 14.4, that you are operating a hamburger restaurant that is part of a competitive industry. Now you are also the owner, and suppose throughout that the owner of a restaurant is also one of the workers in the restaurant and collects the same wage as other workers for the time he/she puts into the business each week. (In addition, of course, the owner keeps any weekly profits.)

- A. Again, assume that all the restaurants are using the same homothetic decreasing returns to scale technology, but now the inputs include the level of entrepreneurial capital c in addition to weekly labor ℓ and capital k . As in exercise 14.4, assume also that all restaurants are required to pay a recurring weekly fixed cost F .
 - a. First, assume that all restaurant owners possess the same level of entrepreneurial skill c . Draw the long-run AC curve (for weekly hamburger production) for a restaurant and indicate how many weekly hamburgers the restaurant will sell and at what price assuming that the industry is in long-run equilibrium.
 - b. Suppose next that you are special and possess more entrepreneurial and management skill than all those other restaurant owners. As a result of your higher level of c , the marginal product of labor and capital is 20% greater for any bundle of ℓ and k than it is for any of your competitors. Will the long-run equilibrium price be any different as a result?
 - c. If your entrepreneurial skill causes the marginal product of capital and labor to be 20% greater for any combination of ℓ and k than for your competitors, how does your isoquant map differ from theirs? For a given wage and rental rate, will you employ the same labor to capital ratio as your competitors?
 - d. Will you produce more or less than your competitors? Illustrate this on your graph by determining where the long-run MC and AC curves for your restaurant will lie relative to the AC curve of your competitors.
 - e. Illustrate in your graph how much weekly profit you will earn from your unusually high entrepreneurial skill.
 - f. Suppose the owner of MacroSoft, a new computer firm, is interested in hiring you as the manager of one of its branches. How high a weekly salary would it have to offer you in order for you to quit the restaurant business assuming you would work for 36 hours per week in either case and assuming the wage rate in the restaurant business is \$15 per hour?
 - g. The benefit that an entrepreneur receives from his or her skill is sometimes referred to as the *economic rent* of that skill because the entrepreneur could be renting that skill out (to someone like MacroSoft) instead of using it in his or her own business. If the economic rent of entrepreneurial skill is included as a cost to the restaurant business you run, how much profit are you making in the restaurant business?
 - h. Would counting this economic rent on your skill as a cost in the restaurant business affect how many hamburgers you produce? How would it change the AC curve in your graph?
- B. Suppose that all restaurants are employing the production function $f(\ell, k, c) = 30\ell^{0.4}k^{0.4}c$ where ℓ stands for weekly labor hours, k stands for weekly hours of rented capital and c stands for the entrepreneurial skill of the owner. Note that, with the exception of the c term, this is the same production technology used in exercise 14.4. The weekly demand for hamburgers in your city is, again as in exercise 14.4, $x(p) = 100,040 - 1,000p$.
 - a. First, suppose that $c = 1$ for all restaurant owners, that $w = 15$ and $r = 20$, that there is a fixed weekly cost \$4,320 of operating a restaurant, and the industry is in long-run equilibrium. Determine the weekly number of hamburgers sold in each restaurant, the price at which hamburgers sell, and the number of restaurants that are operating. (If you have done exercise 14.4, you should be able to use your results from there.)
 - b. Next, suppose that you are the only restaurant owner who is different from all the others in that you are a better manager and entrepreneur and that this is reflected in $c = 1.24573$ for you. Determine your long-run AC and MC functions. (Be careful not to use the cost function given

in exercise 14.4 since c is no longer equal to 1. You can instead rely on the cost function derived for Cobb–Douglas technologies given in equation (13.43) in exercise 13.5 (and remember to add the fixed cost.)

- How many hamburgers will you produce in long-run equilibrium?
- How many restaurants will there be in long-run equilibrium given your higher level of c ?
- How many workers (including yourself) and units of capital are you hiring in your business compared with those hired by your competitors? (Recall that the average worker is assumed to work 36 hours per week.)
- How does your restaurant's weekly long-run profit differ from that of the other restaurants?
- Suppose MacroSoft is interested in hiring you as described in part A(f). How high a weekly salary would MacroSoft have to offer you in order for you to quit the restaurant business and accept the MacroSoft offer?
- If you decide to accept the MacroSoft offer and you exit the restaurant business, will total employment in the restaurant business go up or down?

14.6 Business and Policy Application: Capital Gains Taxes: Taxes on capital gains are applied to income earned on investments that return a profit or “capital gain” and not on income derived from labor. To the extent that such capital gains taxes are taxes on the return on capital, they will impact the rental rate of capital in ways we will explore more fully in a later chapter. For now, we will simply investigate the impact of a capital-gains-tax-induced increase in the rental price of capital on firms within an industry.

- Suppose you are running a gas station in a competitive market where all firms are identical. You employ weekly labor ℓ and capital k using a homothetic decreasing returns to scale production function, and you incur a weekly fixed cost of F .
 - Begin with your firm's long-run weekly average cost curve and relate it to the weekly demand curve for gasoline in your city as well as the short-run weekly aggregate supply curve assuming the industry is in long-run equilibrium. Indicate by x^* how much weekly gasoline you sell, by p^* the price at which you sell it, and by X^* the total number of gallons of gasoline sold in the city per week.
 - Now suppose that an increase in the capital gains tax raises the rental rate on capital k (which is fixed for each gas station in the short run). Does anything change in the short run?
 - What happens to x^* , p^* and X^* in the long run? Explain how this emerges from your graph.
 - Is it possible for you to tell whether you will hire more or fewer workers as a result of the capital gains tax-induced increase in the rental rate? To the extent that it is not possible, what information could help clarify this?
 - Is it possible for you to be able to tell whether the number of gasoline stations in the city increases or decreases as a result of the increase in the rental rate? What factors might your answer depend on?
 - Can you tell whether employment of labor in gasoline stations increases or decreases? What about employment of capital?
- Suppose that your production function is given by $f(\ell, k) = 30\ell^{0.4}k^{0.4}$, $F = 1,080$ and the weekly city-wide demand for gallons of gasoline is $x(p) = 100,040 - 1,000p$. Furthermore, suppose that the wage is $w = 15$ and the current rental rate is 32.1568. Gasoline prices are typically in terms of tenths of cents, so express your answer accordingly.
 - Suppose the industry is in long-run equilibrium in the absence of capital gains taxes. Assuming that you can hire fractions of hours of capital and produce fractions of gallons of gasoline, how much gasoline will you produce and at what price do you sell your gasoline? (Use the cost function derived for Cobb–Douglas technologies given in equation (13.43) in exercise 13.5 (and remember to add the fixed cost).)
 - How many gasoline stations are there in your city?
 - Now suppose the government's capital gains tax increases the rental rate of capital by 24.39% to \$40. How will your sales of gasoline be affected in the new long-run equilibrium?
 - What is the new price of gasoline?
 - Will you change the number of workers you hire? How about the hours of capital you rent?

- f. Will there be more or fewer gasoline stations in the city? How is your answer consistent with the change in the total sales of gasoline in the city?
- g. What happens to total employment at gasoline stations as a result of the capital gains tax? Explain intuitively how this can happen.
- h.* Which of your conclusions do you think is qualitatively independent of the production function used (so long as it is decreasing returns to scale), and which do you think is not?
- i.* Which of your conclusions do you think is qualitatively independent of the demand function, and which do you think is not?

14.7[†] Business and Policy Application: *Using License Fees to Make Positive Profit:* Suppose you own one of many identical pharmaceutical companies producing a particular drug x .

- A. Your production process has decreasing returns to scale but you incur an annually recurring fixed cost F for operating your business.
 - a. Begin by illustrating your firm’s average long-run cost curve and identify your output level assuming that the output price is such that you make zero long-run profit.
 - b. Next to your graph, illustrate the market demand and short-run market supply curves that justify the zero-profit price as an equilibrium price.
 - c. Next, suppose that the government introduces an annually recurring license fee G for any firm that produces this drug. Assume that your firm remains in the industry. What changes in your firm and in the market in both the short and long run as a result of the introduction of G and assuming that long-run profits will again be zero in the new long-run equilibrium?
 - d. Now suppose that G is such that the number of firms required to sustain the zero-profit price in the new long-run equilibrium is not an integer. In particular, suppose that we would require 6.5 firms to sustain this price as an equilibrium in the market. Given that fractions of firms cannot exist, how many firms will actually exist in the long run?
 - e. How does this affect the long-run equilibrium price, the long-run production level in your firm (assuming yours is one of the firms that remains in the market), and the long-run profits for your firm?
 - f. *True or False:* Sufficiently large fixed costs may in fact allow identical firms in a competitive industry to make positive long-run profits.
 - g. *True or False:* Sufficiently large license fees can cause a competitive industry to become more *concentrated*, by which we mean fewer firms are competing for each customer.
- B. Suppose that each firm in the industry uses the production function $f(\ell, k) = 10\ell^{0.4}k^{0.4}$ and each incurs a recurring annual fixed cost of \$175,646.
 - a. Determine how much each firm produces in the long-run equilibrium if $w = r = 20$. (You can use the cost function derived for Cobb–Douglas technologies given in equation (13.43) in exercise 13.5 (and remember to add the fixed cost).)
 - b. What price are consumers paying for the drugs produced in this industry?
 - c. Suppose consumer demand is given by the aggregate demand function $x(p) = 1,000,000 - 10,000p$. How many firms are in this industry?
 - d. Suppose the government introduces a requirement that each company has to purchase an annual operating license costing \$824,354. How do your answers to (a), (b), and (c) change in the short and long run?
 - e. Are any of the firms that remain active in the industry better or worse off in the new long-run equilibrium?
 - f. Suppose instead that the government’s annual fee were set at \$558,258. Calculate the price at which long-run profits are equal to zero.
 - g. How many firms would this imply will survive in the long run assuming fractions of firms can operate?
 - h. Since fractions of firms cannot operate, how many firms will actually exist in the long run? Verify that this should imply an equilibrium price of approximately \$48.2. (*Hint:* Use the supply function given for a Cobb–Douglas production process in equation (13.45) found in the footnote to exercise 13.7.)
 - i. What does this imply for how much profit each of the remaining firms can actually make?

14.8 Policy and Business Application: Business Taxes (cont'd): In exercise 13.11, we introduced a number of possible business taxes and asked what a firm's response would be *assuming that prices w , r , and p remained unchanged*. Now that we have introduced the notion of equilibrium price formation, we can revisit the exercise.

- A.** Suppose the restaurant industry is in long-run equilibrium, all restaurants use the same homothetic decreasing returns to scale technology, and all have to pay a fixed annual franchise fee F .
- Illustrate the average cost curve for a restaurant and the related (short-run) supply and demand graph for the industry.
 - Revisit parts A(b) through A(h) of exercise 13.11 and explain whether the assumption that prices remained unchanged was warranted and, if not, why not.
- B.** Consider the same technology as the one used in exercise 13.11 as well as the recurring fixed cost F .
- ** Determine the long-run equilibrium price p^* and output level x^* as a function of A , α , β , w , and r . (You can use the cost function given in equation (13.43) in exercise 13.5 as well as the profit function given equation (13.46) in exercise 13.7.)
 - In exercise 13.11, we focused on the impact of policies from A(b) through A(h) on output supply and input demand functions. Now use your result from (a) to determine the impact of each of these policies on the long-run equilibrium price and firm output level.

14.9⁺ Policy and Business Application: Minimum Wage Labor Subsidy (cont'd): In exercise 13.10, we investigated the firm's decisions in the presence of a government subsidy for hiring minimum wage workers. Implicitly, we assumed that the policy has no impact on the prices faced by the firm in question.

- A.** Suppose again that you operate a business that uses minimum wage workers ℓ and capital k . The minimum wage is w , the rental rate for capital is r , and you are one of many identical businesses in the industry, each using a homothetic, decreasing returns to scale production process and each facing a recurring fixed cost F .
- Begin by drawing the average cost curve of one firm and relating it to the (short-run) supply and demand in the industry assuming we are in long-run equilibrium.
 - Now the government introduces a wage subsidy s that lowers the effective cost of hiring minimum wage workers from w to $(1 - s)w$. What happens in the firm and in the industry in the short run?
 - What happens to price and output (in the firm and the market) in the long run compared with the original quantities?
 - Is it possible to tell whether there will be more or fewer firms in the new long-run equilibrium?
 - Is it possible to tell whether the long-run price will be higher or lower than the short-run price? How does this relate to your answer to part (d)?
- B.** Suppose that the firms in the industry use the production technology $x = f(\ell, k) = 100\ell^{0.25}k^{0.25}$ and pay a recurring fixed cost of $F = 2,210$. Suppose further that the minimum wage is \$10 and the rental rate of capital is $r = 20$.
- What is the initial long-run equilibrium price and firm output level?
 - Suppose that $s = 0.5$, implying that the cost of hiring minimum wage labor falls to \$5. How does your answer to (a) change?
 - How much more or less of each input does the firm buy in the new long-run equilibrium compared with the original one? (The input demand functions for a Cobb–Douglas production process were previously derived and given in equation (13.47) of exercise 13.8.)
 - If price does not affect the quantity of x demanded very much, will the number of firms increase or decrease in the long run?
 - Suppose that demand is given by $x(p) = 200,048 - 2,000p$. How many firms are there in the initial long-run equilibrium?
 - Derive the short-run market supply function and illustrate that it results in the initial long-run equilibrium price.
 - Verify that the short-run equilibrium price falls to approximately \$2.69 when the wage is subsidized.
 - How much does each firm's output change in the short run?
 - Determine the change in the long-run equilibrium number of firms when the wage is subsidized and make sense of this in light of the short-run equilibrium results.

14.10 Policy Application: School Vouchers and the Private School Market: In the United States, private schools charge tuition and compete against public schools that do not. One policy proposal that is often discussed involves increasing demand for private schools through *school vouchers*. A school voucher is simply a piece of paper with a dollar amount V that is given to parents who can pay for some portion of private school tuition with the voucher if they send their child to a private school. (Private schools can then redeem the vouchers for a payment of V from the government.) Assume throughout that private schools strive to maximize profit.

- A.** Suppose private schools have U-shaped average (long-run) cost curves, and the private school market in a metropolitan area is currently in long-run equilibrium (in the absence of private school vouchers).
- Begin by drawing a school’s average long-run cost curve (with the number of private school seats on the horizontal axis). Then, in a separate graph next to this, illustrate the city-wide demand curve for seats in private schools as a function of the tuition price p . Finally, include the short-run aggregate supply curve that intersects with demand at a price that causes the private school market to be in long-run equilibrium.
 - Illustrate what happens to the demand curve as a result of the government making available vouchers in the amount of V to all families that live in the city. What happens to the number of seats made available in each existing private school, and what happens to the tuition level p in the short run?
 - Next, consider the long run when additional private schools can enter the market. How does the tuition level p , the number of seats in each school, and the overall number of children attending private schools change?
 - Opponents of private school vouchers sometimes express concern that the implementation of vouchers will simply cause private schools to increase their tuition level and thus cause no real change in who attends private school. Evaluate this concern from both a short- and long-run perspective.
 - Proponents of private school vouchers often argue that the increased availability of private schools will cause public schools to offer higher quality education. If this is true, how would your answers to (b) and (c) change as a result?
 - If private school vouchers are made available to anyone who lives within the city boundaries (but not to those who live in suburbs), some families who previously chose to live in suburbs to send their children to suburban public schools might choose instead to live in the city and send their children to private schools. How would this affect your answers to (b) and (c)?
- B.** In the following, all dollar values are expressed in thousands of dollars. Suppose that the total city-wide demand function for private school seats x is given by $x(p) = 24,710 - 2,500p$ and each private school’s average long-run cost function is given by $AC(x) = 0.655x^{1/3} + (900/x)$.
- Verify that $AC(x)$ arises from a Cobb–Douglas production function $x = f(\ell, k) = 35\ell^{0.5}k^{0.25}$ when $w = 50$ and $r = 25$ and when private schools face a fixed cost of 900. One unit of x is interpreted as one seat (or one child) in the school, and ℓ is interpreted here as a teacher. Since dollar values are expressed in thousands, $w = 50$ represents a teacher’s salary of \$50,000 and the fixed cost of 900 represents a recurring annual cost of \$900,000.
 - In order for the private school market to be in long-run equilibrium, how many children are served in each private school? What is the tuition (per seat in the school) charged in each private school?
 - Given that you know the underlying production function, can you determine the class size in each private school? (*Hint:* You already determined the total number of children in part (a) and now need to determine the number of teachers in each private school.⁶)
 - How many private schools are operating?
 - Now suppose that the government makes private school vouchers in the amount of 5.35 (that is, \$5,350) per child available to parents. How will this change the demand function for seats in private schools? (*Hint:* Be careful to add the voucher in the correct way; that is, to make the demand *curve* shift up.)

⁶ It may be helpful to check equation (13.47) in exercise 13.8.

- f.* Given this change in demand, what will happen to tuition and the number of children served in existing private schools in the short run assuming the number of schools is fixed and no new schools can enter in the short run? (*Hint:* You will need to know the current level of capital, derive the short-run supply function for private schools, then aggregate them across the existing private schools.)
- g. What happens to private school class size in the short run?
- h. How do your answers change in the long run when new schools can enter?

14.11† Policy Application: *Public School Teacher Salaries, Class Size, and Private School Markets:* In exercise 14.10, we noted that private schools that charge tuition operate alongside public schools in U.S. cities. There is much discussion in policy circles regarding the appropriate level of public school teacher salaries (which are set by the local or state government) as well as the appropriate number of public school teachers (that determines class size in public schools).

- A. Suppose again that private schools face U-shaped long-run AC curves for providing seats to children and that the private school market is currently in long-run equilibrium.
 - a. Begin by drawing two graphs, one with the long-run AC curve for a representative private school and a second with the demand and (short-run) aggregate supply curves (for private school seats) that are consistent with the private school market being in long-run equilibrium (with private school tuition p on the vertical axis).
 - b. Now suppose the government initiates a major investment in public education by raising public school teacher salaries. In the market for private school teachers (with private school teacher salaries on the vertical and private school teachers on the horizontal), what would you expect to happen as a result of this public school investment?
 - c. How will this impact private school tuition levels, the number of seats in private schools and the overall number of children attending private schools in the short run?
 - d. How does your answer change in the long run as private schools can enter and exit the industry?
 - e. Suppose that instead of this teacher salary initiative, the city government decides to channel its public school investment initiative into hiring more public school teachers (as the city government is simply recruiting additional teachers from other states) and thus reducing class size. Assuming that this has no impact on the equilibrium salaries for teachers but does cause parents to feel more positively about public schools, how will the private school market be impacted in the short and long run?
 - f. How will your long-run answer to (e) be affected if the government push for more public school teachers also causes equilibrium teacher salaries to increase?
- B. As in exercise 14.10, assume a total city-wide demand function $x(p) = 24,710 - 2,500p$ for private school seats and let each private school's average long-run cost function be given by $AC(x) = 0.655x^{1/3} + (900/x)$. Again, interpret all dollar values in thousands of dollars.
 - a. If you have not already done so, calculate the initial long-run equilibrium size of each school, what tuition price each charges, and how many private schools there are in the market.
 - b. If you did B(a) in exercise 14.10, you have already shown that this $AC(x)$ curve arises from the Cobb–Douglas production function $x = f(\ell, k) = 35\ell^{0.5}k^{0.25}$ when $w = 50$ and $r = 25$ and when private schools face a fixed cost of 900. If you have not already done so, use this information to determine how many teachers and how much capital each school hires.
 - c. Suppose that the increased pay for public school teachers drives up the equilibrium wage for private school teachers from 50 to 60 (that is, from \$50,000 to \$60,000 per year). What happens to the equilibrium tuition price in the short run?
 - d. What happens to school size and class size?
 - e. How will your answers on school size, tuition level, and class size change in the long run? (*Hint:* You can use the cost function given in equation (13.43) of exercise 13.5 to derive the AC function; just make sure you keep track of the fixed cost of 900!)
 - f. How many private schools will remain in the market in the long run?

14.12 Policy Application: Pollution Taxes on Output: Suppose you are one of many firms that refine crude oil into gasoline. Not surprisingly, this process creates pollution. The government therefore announces a new tax of $\$t$ on each gallon of gasoline that leaves a refinery (to be paid by the refinery).

- A.** For purposes of this exercise, assume that the refinement process of crude oil into gasoline has decreasing returns to scale but entails a recurring fixed cost.
- Begin by illustrating the industry in pre-tax equilibrium, showing one firm's average cost curve as well as the (short-run) market supply and demand that supports an industry in long-run equilibrium.
 - What changes for each firm and in the industry in the short run when the tax is introduced?
 - What changes in the long run?
 - True or False:* While refineries bear some of the burden of this tax in the short run, they will pass all of the tax on to consumers in the long run.
 - I recently heard the following comment on one of the TV news shows (regarding a tax similar to the one we are analyzing here): “Regulators are particularly concerned about reports that companies in the industry managed to pass the pollution tax fully onto consumers and view this as a sign that the industry is not competitive but is rather engaged in strategic manipulation of gasoline prices.” What do you make of this TV wisdom?
 - Will refineries change the mix of labor and capital in the long run (assuming they continue operating)?
 - Here is another quote from a recent TV analysis: “In talking to this refinery's owner, it seems that there are no plans in place to lay off any workers in response to the pollution tax on refined gasoline. Jobs in the industry therefore appear to be safe for now.” Do you agree?
- B.** Once again, suppose that the production function used by firms in the gasoline refinery industry is $f(\ell, k) = A\ell^\alpha k^\beta$ with $\alpha, \beta > 0$ and $\alpha + \beta < 1$, and suppose that each refinery pays a recurring fixed cost F .
- If you did not already do so in exercise 14.1, derive the expression for the output level x^* at which the long-run AC curve reaches its lowest point. (This should be a function of A , α , β , w , and r .)
 - How does x^* change under the per-gallon tax on gasoline leaving the refinery?
 - Can you use your answer to determine whether the number of gasoline refineries will increase or decrease as a result of the tax?
 - If you have not already done so in exercise 14.1, determine the long-run equilibrium price p^* before the tax (a function of A , α , β , w , and r). How does this change under the tax?
 - Can you use your answer to determine who actually pays the tax?
 - Will the tax result in less pollution? If so, why?

The “Invisible Hand” and the First Welfare Theorem

In Chapter 14, we combined all of the pieces of the consumer and producer models to arrive at a definition of market or industry equilibrium.¹ We saw how tastes and budget constraints result in individual output demand and input supply curves that, when added up, give us output market demand and input market supply curves. On the producer side, we similarly saw how production frontiers combine with prices to form individual firm supply and input demand curves that, when added up, result in short-run market supply curves and input market demand curves. Furthermore, we saw how the entry and exit of firms results in long-run market supply curves that differ from short-run curves in goods markets.

The individual demand and supply relationships were derived by considering how changing economic environments—changing input and output prices—would cause consumers, workers, and firms to change their behavior. The economic environment itself, however, arises in equilibrium from the many individual decisions that are made in the economy, giving rise to equilibrium prices that consumers and producers in a competitive world take as given when they decide how to behave. The prices that arise in equilibrium therefore serve the purpose of coordinating the many individuals in the market, signaling to consumers how much they should consume, to workers how much they should work, and to producers how much they should produce. No one plans this; it happens “spontaneously” as everyone in the economy simply tries to do the best he or she can. The resulting equilibrium is therefore sometimes referred to as a “spontaneous order” created by market forces.

This insight that order can emerge without anyone planning it is quite remarkable in and of itself. What is even more remarkable, however, is that, under certain conditions, the spontaneous order generated in a decentralized market precisely mimics what a central planner might wish to implement if he or she knew everything there was to know about the individuals in the market. Put differently, not only do the incentives in a decentralized market generate a predictable equilibrium but also, under certain conditions, there is no way that the resulting situation could be altered to make some people better off without making anyone worse off. In the language we developed earlier in this book, the spontaneous order of the decentralized market is, under certain conditions, fully efficient. This chapter, and much of the remainder of the book, is devoted to demonstrating this important result. We will demonstrate the conditions necessary for the result to hold as well as the real-world conditions that might cause the result to break down, making room for civil society or government institutions to improve on the spontaneous order of the market.

An equilibrium is efficient if there is no possible change we could implement such that some people become better off without anyone becoming worse off.

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

¹ This chapter builds on Chapter 14 and uses the concepts of marginal willingness to pay and consumer surplus introduced in Chapter 10.

WELFARE ANALYSIS IN EQUILIBRIUM

Consumer/worker surplus measures welfare in the consumer/worker model, whereas profit (also called “producer surplus”) measures welfare on the firm side.

In order to demonstrate the welfare properties of markets, we will need to measure the benefit each economic actor derives from being able to participate in markets. In output markets, this requires us to measure the benefit to consumers and producers, whereas in input markets we need to measure the benefit to workers, to firms, and to those supplying capital. The suppliers of capital are often individuals who are lending financial capital by saving, and the demanders of capital are often firms that invest in order to produce goods and services.

Fortunately, we have already defined the basic building blocks for conducting this analysis. For consumers, we developed in Chapter 10 the notion of “consumer surplus,” which we defined as the benefit consumers derive from being able to participate in a market. We can straightforwardly extend this concept to workers, with “worker surplus” defined as the benefit workers derive from being able to sell their labor in labor markets, and we can similarly define the surplus that is derived from being able to plan for the future by those who provide capital to the market. On the producer side, defining a measure for how much better off producers are for being able to operate in markets is more straightforward: Since producers care about profit, we will simply use profit, which we can also call “producer surplus,” as the relevant measure for producers. We will discuss each of these in turn before illustrating how markets, under certain conditions, maximize the sum of producer and consumer surplus—which is another way of saying that the equilibrium is efficient.

15A.1 Consumer and Worker Surplus

In Chapter 10, we illustrated that individual consumer surplus can be measured as the area underneath the compensated demand (or marginal willingness to pay) curve and above the price at which a consumer consumes. However, unless consumer tastes for the good that we are analyzing are borderline between normal and inferior (and tastes are thus quasilinear in the good of interest), the compensated demand curves for individual consumers are different from their regular demand curves that we added up in Chapter 14 to derive market demand. This tells us immediately that we cannot, in general, illustrate the total consumer surplus for all the consumers in a market along the market demand curve that we use to derive the equilibrium. While the market demand curve therefore allows us to predict behavior, it is not typically the right curve on which to measure consumer surplus.

To simplify our thinking about market demand curves, we are often tempted to think of them as if they had emerged from a single choice problem (the way individual demand curves do). When we think this way, we are implicitly assuming that we can treat the demand side in the goods market as if it emerged from a single “representative consumer,” and if we then assume a certain indifference map for that representative consumer, we can derive not only the observable market demand curve but also the compensated market demand curve (on which we measure consumer surplus), just as we did in Chapter 10. This sounds strange at first since we have made a big point of the fact that the equilibrium that arises in a competitive market results from the decentralized actions of many individuals that simply take the economic environment as given. Nevertheless, we will see that there exist circumstances under which we can in fact simply think of all these individuals as a single individual who also takes the economic environment as given. Macroeconomists do this all the time in their models, but even microeconomists often find themselves doing this when they lump individuals into groups (such as “households”) and treat their aggregate demand curves as if they emerged from one individual’s decision.

15A.1.1 “Representative Consumers” What, then, has to be true about individuals in a group that would allow us to treat the group as if it was a single individual with well-defined tastes? To develop some intuition, suppose first that the group is composed of only me and my wife, with the market demand curve simply being our “household demand curve” that results from summing our individual demand curves. To be even more specific, suppose that my wife,

the true master of our household, has exogenous disposable income $I^1 = 800$ and she has generously permitted me to have exogenous disposable income $I^2 = 400$ as we go to Walmart to buy clothes (denoted x_1) and “other goods” (denoted x_2). Within Walmart we face the same prices (p_1 and p_2) and end up at two different checkout counters with two different baskets of goods (A^1 and A^2) that emerged from both of us doing the best we can, given our individual circumstances at Walmart. The composition of these individual baskets thus depends on our individual tastes, our individual incomes, and the common prices we face.

If we truly meant what we said at our wedding, that the two of us henceforth are a single unit, we might think that our “household demand” really is as if it had arisen from a single consumer doing the best she can, given our total household budget. Put differently, if our household jointly behaves like a single individual, it should not matter how our household’s exogenous income is divided between me and my wife. Thus, if a streak of righteous indignation at the inequity of our exogenous incomes led you to take \$200 out of my wife’s purse and put it into my wallet so that each of us now has \$600 as we walk into Walmart, we would jointly come out of Walmart with the same number of clothes and other goods as if we had gone in with our original budgets. Our individual baskets at the checkout counters would be different (with more stuff in mine and less in hers), but when we put it in the trunk of our car, we would end up having exactly the same items as if you had never interfered. Only if this is true do we really behave as if we were the single mystical unit we forged on that fateful wedding day.

This does not, however, have to imply that my wife and I have exactly the same tastes. Suppose, for instance, that my wife and I initially faced the blue and magenta budget lines in Graph 15.1. She arrives at the checkout counter with bundle A^1 as her optimal basket, and I arrive with bundle A^2 in my basket. Then, let’s imagine that instead you had pulled off your righteous transfer of \$200 from her purse into my wallet before we entered Walmart, causing both of us to face the green budget rather than the initial blue and magenta. In order for us to end up putting the same overall basket into our family car’s trunk, it must be that the change in my wife’s optimal basket from her initial blue to her new green budget is exactly offset by the

A group can be treated as if it was a single optimizing individual if redistributions of income within the group do not alter the overall consumption basket chosen by the group.

GRAPH 15.1 Two Consumers Behaving as One Unit

change in my optimal basket as I move from my initial magenta to my new green budget. Put differently, the blue arrow linking my wife’s original optimum A^1 to her new optimum B^1 must be exactly parallel to the magenta arrow from my original optimum A^2 to my new optimum B^2 . Our individual tastes may therefore be quite different, but the change in our individual behavior as income is redistributed between us keeps our overall consumption bundle constant. As long as this holds over the relevant range of economic environments that is of interest to us, our mystical union is complete and we behave as a single “representative actor.” This implies that we behave in the aggregate as if we were a single individual with rational tastes, tastes that give rise to demand and compensated demand curves that have exactly the interpretation we developed in Part 1 of the text for a single consumer.

EXERCISE 15A.1 Suppose that my tastes and my wife’s tastes are exactly identical. If our tastes are also homothetic, does our household behave like a single representative actor? What if our tastes are quasilinear and neither individual is at a corner solution?

EXERCISE 15A.2 Can you illustrate a case where our tastes are identical but we do not behave as a representative actor?

EXERCISE 15A.3 Suppose both my wife and I have homothetic tastes but they are not identical. Does this still imply that we behave like a single representative actor?

15A.1.2 Consumer Surplus and the Special Case of Quasilinear Tastes In Section B of this chapter, we formalize the intuition we have just developed and specify exactly what range of individual tastes can permit us to assume that a group of consumers can be treated as a single consumer. For our purposes here, however, it is enough for us to focus on one special case: The case when both my tastes and my wife’s tastes are quasilinear in the good x_1 .

Consider exactly the same budget lines for me and my wife as we did in Graph 15.1 with the same initially optimal baskets for my wife (A^1) and me (A^2) when our incomes are \$800 and \$400. Then suppose that you succeed in redistributing \$200 of my wife’s income to me and both of us therefore now face the green budget. If our tastes are indeed quasilinear in x_1 , then we know that my wife’s *MRS* is the same as it is at basket A^1 all along the (blue) dashed vertical line going through A^1 , and similarly my *MRS* is the same as at basket A^2 all along the (magenta) dashed vertical line going through A^2 . Since the slope of our individual budgets has not changed as you transferred income from my wife to me, this implies that my wife’s new optimal basket will be B^1 directly below A^1 on the green budget, and my new optimal basket will be B^2 directly above A^2 on the green budget. As a result, we each arrive at the checkout counter with exactly the same quantity of x_1 in each of our baskets (and thus the same overall quantity), and the reduction of x_2 in my wife’s basket is exactly offset by the increase of x_2 in my basket. This is because the blue arrow indicating the change in my wife’s behavior is exactly parallel to the magenta arrow indicating the change in my behavior (as shown in Graph 15.2).

The assumption of quasilinearity of our tastes is thus sufficient to cause us to jointly behave *as if* we were a single consumer, with our overall consumption bundle depending solely on our household income and not on the way in which income is distributed between us.² More specifically, *if our individual tastes are quasilinear, we behave as if our household was a single individual who also has quasilinear tastes* since our consumption of x_1 remains the same no

If everyone in the group has tastes that are quasilinear, then the group can be modeled as a single individual with quasilinear tastes.

² A slight caveat to this is that the conclusion holds only so long as neither of us has reached a corner solution, but for the ranges of economic environments that we are typically interested in analyzing, the assumption that none of the relevant economic actors is at a corner solution is often fine.

GRAPH 15.2 Aggregating Consumers with Quasilinear Tastes

matter how large our household income gets (so long as the prices we face remain the same). This should make intuitive sense: The whole challenge in aggregating consumers and treating them as if they were a single consumer arises from the fact that individual consumers change their consumption bundles when we redistribute income within a group. Put differently, the challenge arises from the presence of *income effects* that cause people to change their consumption. When income effects are assumed away, as they are when we assume quasilinearity of tastes, then the problem of aggregating consumers goes away.

The uncompensated market demand curve for a good can be treated as a compensated demand curve (along which we measure consumer surplus) when tastes of all individuals in the market are quasilinear in that good.

True or False: As long as everyone has quasilinear tastes, the group will behave like a representative actor even if all the individuals do not share the same tastes (assuming no one is at a corner solution). The same is also true if everyone has homothetic tastes.

EXERCISE 15A.4

Suppose, then, that we move beyond the simple example of my household and we consider all the consumers in a particular output market. If we can assume that all consumers have tastes that are quasilinear in the output, then we can, by the same logic we just used for my household, treat the market demand curve (that sums all the individual demand curves) as if it had arisen from a single representative consumer who also has quasilinear tastes. Since the only difference between compensated and regular demand curves arises from income effects, and since quasilinear tastes do not give rise to income effects, we can furthermore assume that the regular demand curve is also the compensated demand curve, and that this demand curve therefore also represents the marginal willingness to pay curve along which we can measure consumer surplus. We have therefore identified the conditions that individual tastes have to satisfy in order for us to use the (uncompensated) market demand curve for measuring aggregate consumer surplus.

Suppose that my wife and I share identical homothetic tastes (that are not over perfect substitutes). Will our household demand curve be identical to our marginal willingness to pay curve?

EXERCISE 15A.5

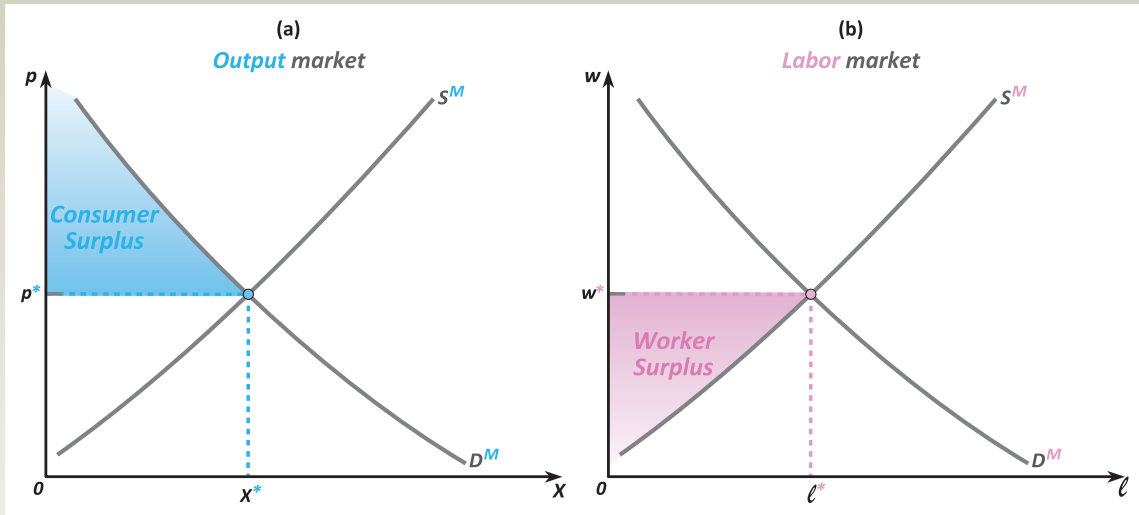

When worker tastes are quasilinear in leisure, we can measure worker surplus along the market labor supply curve.

15A.1.3 Worker and Saver Surplus Measuring the surplus that workers attain in labor markets is exactly analogous to measuring consumer surplus in output markets because worker behavior arises from the same underlying “consumer model” in which we simply replace goods x_1 and x_2 with “Leisure” L and “Consumption” c . The important difference is that the two-good consumer model produces output *demand* curves when x_1 and x_2 are the goods that are modeled, but it results in labor *supply* curves when L and c are the “goods” we model (with the difference between leisure endowment and leisure consumption resulting in labor supply). We will explore this in more detail in Chapter 19 where we will show that worker surplus can be measured as an area above the *compensated* labor supply curve just as consumer surplus can be measured as an area below the *compensated* output demand curve. Once again, however, compensated and regular curves overlap when tastes are quasilinear. Thus, when tastes for leisure are quasilinear for all workers, then each worker’s labor supply curve is equal to his or her *compensated* labor supply curve, and the market labor supply curve can be treated as if it had arisen from a single worker’s choices, with that worker’s tastes themselves also being quasilinear in leisure.

Graph 15.3 then depicts consumer and worker surplus in two graphs of output and labor markets that are in equilibrium. These are graphs that you may well have seen in previous economics courses, but our analysis of the underlying consumer model now lets us know that the surplus areas in these graphs are correct only for the special case where consumers and workers can be modeled as representative actors who have quasilinear tastes (in x_1 in panel (a) and in leisure in panel (b)). To be more precise, while the description of the equilibrium prices and quantities is correct regardless of underlying assumptions about tastes, the depiction of consumer and producer surplus areas is correct only in the special case of quasilinear tastes.

Finally, we could draw an analogous graph representing the surplus attained by those who save financial capital (and therefore lend it to others at the market interest rate). Note that it becomes particularly problematic, however, to assume that the underlying tastes that result in capital supply curves are quasilinear. Recall that these curves arise from choices in the consumer model where consumption this period is put on the horizontal axis and consumption in some future period is put on the vertical. It seems relatively implausible that tastes are indeed quasilinear in consumption in either period, with consumption in that period being neither a normal nor an inferior good

GRAPH 15.3 Aggregate Consumer and Worker Surplus When Tastes Are Quasilinear

but consumption in the other period being normal. Consumption, one would think, is likely to be a normal good regardless of when it takes place. We will therefore need to be particularly cautious with welfare analysis involving those who plan for the future by saving in financial markets.

15A.2 “Producer Surplus” or Profit

While it was not immediately obvious at first how we would arrive at a dollar value for the benefit a consumer derives from being able to participate in a market, it is much easier to arrive at such a dollar value for producers. After all, producers are in business to make profit, and if a producer is able to earn positive economic profit, the producer has by definition been made better off by the amount of that profit by being able to participate in this market (rather than pursue his or her next best alternative). Economic profit is then our measure of the “surplus” producers derive from being able to participate in markets. We will therefore use the terms *producer surplus* and *economic profit* interchangeably.³

15A.2.1 Measuring Producer Surplus on the Supply Curve In our development of producer theory, we ran into two ways of illustrating profit (in the absence of fixed costs) graphically, using either the *MC* curve or the *AC* curve. As it turns out, we can now combine these methods of illustrating profit to demonstrate that profit can also be measured as an area above the producer’s supply curve.

Consider first the *AC* curve pictured in panel (a) of Graph 15.4. Suppose that the equilibrium price was p^* and that you initially think about producing quantity x^A corresponding to the lowest point of the *AC* curve. In that case, your total revenues would be p^* times x^A while your total costs would be AC_{\min} times x^A , and the difference between those two areas in the graph would be equal to the shaded blue area.

Of course, we know from our previous work that a profit-maximizing producer would produce more than x^A if facing the conditions in panel (a) of Graph 15.4. In particular, the producer

GRAPH 15.4 Three Ways of Illustrating Short-Run Profit or Short-Run Producer Surplus

Go to MindTap to interact with this graph.

³ Some textbooks make a distinction between the term “producer surplus” and “economic profit,” using the former to refer to what we have called short-run economic profit and the latter to what we called long-run economic profit.

would produce until price is equal to MC . In panel (b) we therefore graph the MC curve, with the portion of the MC that lies above AC (and thus above point A from panel (a)) highlighted. We already know that we can measure the profit a producer makes by producing x^A units of output as the blue area in panel (a), and so we are now interested in how much *additional* profit the producer will make by producing x^* rather than x^A . This *additional* profit is simply equal to the difference between the *additional* revenue and the *additional* cost the producer incurs. The additional revenue is represented by the area formed by the vertical distance p^* times the horizontal distance $(x^* - x^A)$, while the additional cost is represented as the area below the MC curve in the interval between x^A and x^* . The difference between these areas, representing the additional profit from producing x^* rather than x^A , is then the shaded magenta area in panel (b).

Since the blue area in panel (a) is the profit the producer makes when producing x^A and the magenta area in panel (b) is the *additional* profit the producer makes when producing x^* rather than just x^A , the two areas summed together are equal to total profit from producing x^* at price p^* . This is depicted as the green area in panel (c) of the graph, and you can see that this green area is simply the area to the left (or “above”) the firm’s supply curve up to the equilibrium price.

The argument that *profit can be measured as the area above the producer’s supply curve* then applies to both short-run and long-run profit. In the case of short-run profit, the blue area in panel (a) is measured along the short-run AC curve, while in the case of long-run profit it is measured along the long-run AC curve. Similarly, the magenta area in panel (b) is measured along the short-run MC curve for short-run profit and along the long-run MC curve for long-run profit. In panel (c), profit is measured either along the short-run or the long-run firm supply curve depending on whether we want to measure short-run or long-run profit.

Profit can be measured as the area above the firm’s supply curve up to the equilibrium price.

EXERCISE 15A.6 Does this measure of long-run profit apply also when the firm encounters long-run (recurring) fixed costs?

15A.2.2 Treating Producers in an Industry as a Single “Representative Producer”

In our discussion of “representative consumers,” we noted the difficulty of treating market demand *as if* it had arisen from a single representative consumer. This difficulty arose from the fact that in order for a group of consumers to be treated as a single consumer, it was necessary to know that individual tastes are such that any redistribution in income among the individuals in the group does not result in a change in the overall demand for the good of interest from that group. Put differently, the difficulty in treating groups of consumers as if they were a single consumer resulted from the presence of income effects.

In the case of producers, there are no analogous income effects to cause any difficulty in aggregating producers and treating them as a single representative producer. Therefore, when we add individual producer supply curves into market supply curves, the area above the market supply curve is simply the sum of the areas above individual supply curves, and *producer surplus as measured on the market supply curve is simply the sum of the individual producer surpluses of the firms in the industry*. In other words, we can simply treat the market supply curve as if it was the supply curve of a single representative producer.

15A.2.3 Producer Surplus in Labor Markets We can make a similar argument about the area *under* a firm’s demand curve for labor. Recall that short-run demand for labor arises from the downward-sloping part of the marginal revenue product of labor curve pictured in Graph 15.5a. More precisely, there exists a “break-even” wage w^A at which the producer will make exactly zero profit by hiring ℓ^A labor hours. At that wage, the loss incurred for hiring the first ℓ' workers is exactly offset by the gain from hiring the remaining workers. (You should be able to find the areas on the graph corresponding to this gain and loss.) If the equilibrium wage falls below this break-even wage, the firm will then hire along the blue portion of the MRP_ℓ curve in panel (a) of Graph 15.5, which corresponds to the firm’s short-run labor demand curve D^i .

Aggregate producer surplus (or profit) can always be measured as the area above market supply up to the equilibrium price.

GRAPH 15.5 Producer Surplus in Labor Markets

Suppose, for instance, that the market wage is w^* and that the firm stopped hiring at ℓ^A . We can then ask how much additional profit the firm makes from what it would have made had the wage been the break-even wage w^A where profit was zero. Since the firm has to pay $(w^A - w^*)$ less per worker hour, this becomes surplus (or profit) for the firm for each of the ℓ^A worker hours. Summing over all ℓ^A worker hours, the total surplus from being able to hire ℓ^A worker hours at the market wage w^* is therefore equal to the shaded blue area in panel (a) of Graph 15.5.

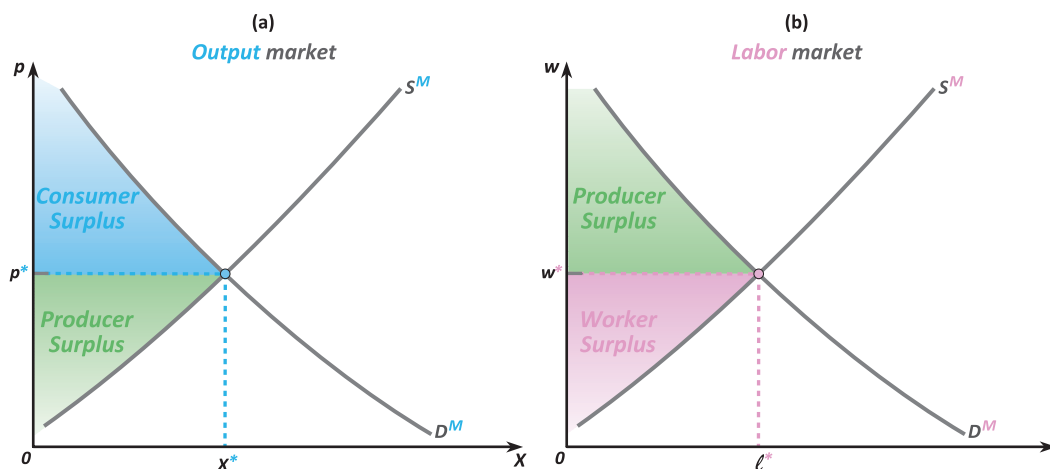

Of course, the producer would not stop hiring at ℓ^A if the market wage was w^* but would hire ℓ^* worker hours instead. For each additional worker hour the firm hires beyond ℓ^A , the additional surplus would be the difference between the MRP_ℓ for that worker hour and the wage w^* . Thus, the additional profit made on the worker hours hired beyond ℓ^A is equal to the shaded magenta area in panel (a) of the graph, and the total surplus for the producer is the sum of the blue and magenta areas.

In panel (b) of the graph, we then simply graph the entire short-run labor demand curve for the producer, which includes the bold segment from the MRP_ℓ curve in panel (a) and the vertical blue line segment at $\ell = 0$ for wages above the break-even wage w^A . The green area in panel (b) is then exactly equal to the sum of the blue and magenta areas in panel (a) and represents short-run producer surplus. Note that this *producer surplus is equal to the area below the firm's labor demand curve down to the market wage*. The treatment of long-run labor demand curves and firm surpluses is somewhat more complicated and we will therefore not get into it here.

15A.2.4 Putting All Surpluses Together Graph 15.6 completes what we started in Graph 15.3. Panel (a) depicts the output market in equilibrium, with the industry producing X^* output and selling it at price p^* . Under the assumption of quasilinear tastes on the part of consumers, we previously concluded that the blue area represents aggregate consumer surplus. And from our work in this section, we have concluded that we can measure producer surplus (or profit) as the area above the industry supply curve up to the equilibrium price. Thus, the green area represents producer surplus, and the two areas together represent the total surplus gained by producers and consumers from the existence of the market for good X .

How would the picture be different if we were depicting an industry in long-run equilibrium with all firms facing the same costs? What would long-run producer surplus be in that case?

EXERCISE
15A.7

GRAPH 15.6 Surpluses in Output and Labor Markets When Tastes Are Quasilinear

In panel (b) of the graph, on the other hand, we previously concluded that the magenta area above the market supply curve for labor up to the equilibrium wage is the aggregate worker surplus under the assumption that tastes are quasilinear in leisure. From what we have done in this section, we can now furthermore conclude that the area below the market demand curve for labor down to the equilibrium wage is equal to the producer surplus. Note that the blue area in panel (a) and the magenta area in panel (b) are derived from the consumer model while the green areas are derived from the producer model. Thus, the blue and magenta areas require our assumption of quasilinearity in tastes because this assumption is required for us to be able to treat the market curves as if they depicted an economic relationship derived from a single “representative actor” doing the best he or she can in the absence of income effects. The green areas, on the other hand, do not require any particular assumptions since they are derived from the producer model that is not subject to the income effects that make aggregating individual economic relationships and interpreting welfare measures along them problematic.

EXERCISE 15A.8

Suppose we were not concerned about identifying producer and worker surplus but instead wanted to only predict the equilibrium wage and the number of workers employed. Would we then also have to assume that leisure is quasilinear for workers?

15A.3 The Invisible Hand and the First Welfare Theorem

We are now ready to consider seriously the question of how well decentralized market forces do in maximizing the total surplus for society. To do this, we have to come up with some ideal benchmark of what could be accomplished for society and compare to this benchmark how the market measures up. Economists establish this ideal by imagining that, instead of market forces determining how much is produced in each industry, a fictional all-knowing and benevolent “social planner” was in charge and dictated how much of each good is produced in the economy, which firms produce what, and how much each consumer gets to consume.

15A.3.1 “Barney” as the Benevolent Social Planner Although my children are teenagers now, I still recall having to endure hours of “Barney,” the purple PBS dinosaur who get young children to annoyingly sing “I love you, you love me, we’re a happy family” until one can

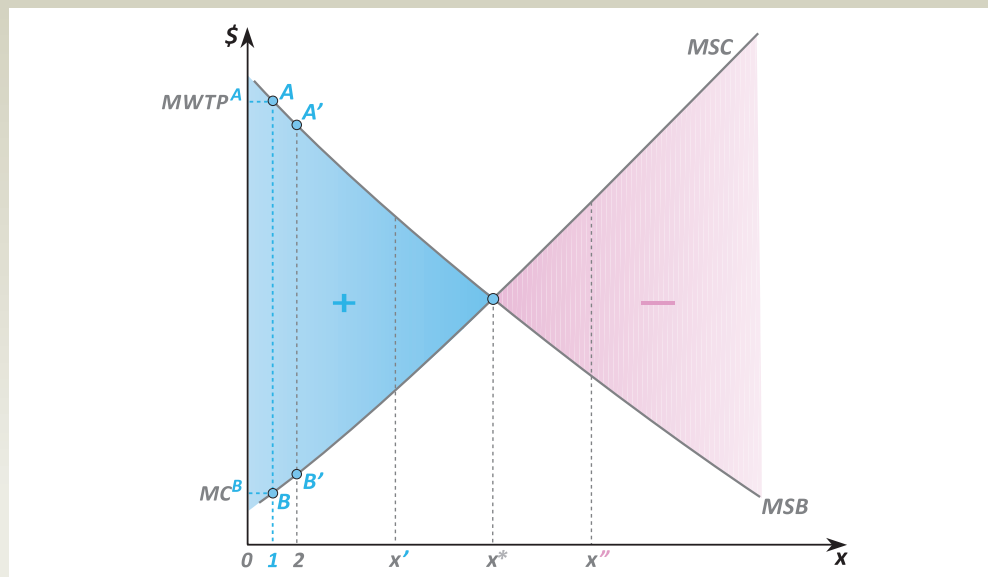

no longer stand it and must resort to using earphones to listen to the soothing sounds of ABBA on one’s iPod. I imagine the fictional “social planner” employed by economists as an omniscient version of “Barney,” a dinosaur that knows all our desires and dreams, knows all the different production technologies of all the possible firms in the world, and desires to create the greatest possible surplus for the world. What would this benevolent and omniscient Barney do?

Let’s begin with the simplest possible world in which Barney wants to maximize overall surplus and knows that all our tastes for good x are quasilinear (and thus Barney does not have to consider income effects). Barney would then try to calculate how much of x should be produced by finding those firms that can produce x at the lowest possible cost and try to match what these firms produce with those consumers who value x the most. In particular, Barney would try to begin by finding the consumer who values the first good x more than anyone else, and is thus willing to pay more than anyone else for it. Similarly, he would try to find the producer who can produce that first good at the lowest possible cost. Suppose that this first consumer has a marginal willingness to pay $MWTP^A$ and this first producer has a marginal cost MC^B for that first unit of x . These quantities are graphed for the first x in Graph 15.7. Then, after getting this first unit produced and channeling it to the right consumer, Barney would move to the next unit, finding the consumer who has the highest marginal willingness to pay for the next unit and matching the consumer with the producer who can produce this unit at the lowest marginal cost. By continuing to do this for each additional unit of output, Barney would slowly plot the *marginal social benefit* (MSB) and the *marginal social cost* (MSC) for all levels of output as depicted in Graph 15.7.

For the first unit of x , the total surplus for society would be the difference between how much society has benefited from this unit of x and how much it has cost society. So long as the only beneficiary of a unit of x is the person who consumes that unit, $MWTP^A$ is a measure of the marginal social benefit, and so long as the only costs society incurs are those incurred by the producer of x , MC^B is a measure of the marginal social cost (since the value of the resources employed in production could have been used elsewhere in society). Thus, the dashed blue line connecting A to B is society’s surplus from the first unit of output. The same is then true for each additional unit of output, with society’s surplus for each *additional* output represented by the

Economists often employ the fictional construct of a benevolent and omniscient “social planner” as a benchmark against which to compare market outcomes.

GRAPH 15.7 A Social Planner Finding the “Optimal” Output x^*

Go to MindTap to interact with this graph.

vertical difference between the *MSB* and the *MSC* curves. As long as that difference is positive, Barney would decide it is worth it to continue producing. And this difference remains positive so long as Barney produces less than x^* , the output level at which *MSB* and *MSC* intersect, but the difference becomes negative for any output level beyond x^* .

The *total surplus for society is therefore maximized at the output level x^** , with the blue area representing this maximum level of surplus. For instance, were Barney to stop producing at x' before x^* is reached, society would be left with only the portion of the blue area to the left of x' and would therefore give up the blue area to the right of x' . Similarly, were Barney to produce x'' above x^* , society would get all of the blue area but would *lose* the magenta area to the left of x'' .

15A.3.2 The Market versus Barney By now you have surely guessed where all this is headed. As long as consumers gain all the benefits of consuming the output, the *MSB* curve in Graph 15.7 is the aggregate *MWTP* curve for all the consumers in the market, and if all the consumers have tastes that are quasilinear in x , the aggregate *MWTP* curve is the market demand curve. Similarly, as long as producers bear all of the costs of producing, the *MSC* curve in Graph 15.7 is the industry supply curve. The decentralized market (in which consumers and producers just selfishly try to do the best they can given their circumstances) therefore produces where market demand and supply intersect, which is, under the assumptions we have made, exactly the same intersection as that of the *MSB* and *MSC* curves in Graph 15.7. *The decentralized market therefore produces exactly the quantity the social planner would have chosen to produce if the planner’s objective was to maximize the total surplus for society!*

This result, known in its most general form as the First Welfare Theorem, is probably the most important result ever derived by economists, and it is a result that is considerably more general than might be apparent at this point. It states that, *under certain conditions, decentralized markets maximize total surplus for society, leaving no possible way for anyone, even an omniscient social planner, to change the situation and make someone better off without making anyone else worse off*. Put differently, the first welfare theorem states that, *under certain conditions, markets are efficient*. Of course, the social planner could decide to distribute the overall surplus differently than the market does, giving more to consumers or more to producers than the market does, but omniscient Barney *cannot increase the total pie*.

The First Welfare Theorem states that, under certain conditions, a competitive market results in an efficient allocation of resources and thus maximizes social surplus.

EXERCISE 15A.9 Imagine that you are Barney and that you would like consumers to get a bigger share of the total “pie” than they would get in a decentralized market. How might you accomplish this? (*Hint: Given your omnipotence, you are not restricted to charging the same price to everyone.*)

EXERCISE 15A.10 Suppose the social marginal cost curve is perfectly flat, as it would be in the case of identical producers in the long run. Would you, as Barney, be able to give producers a share of the surplus?

To appreciate this result, imagine for a minute how much information Barney would have to have and process in order to achieve what the decentralized market achieves by itself. He would have to know everyone’s tastes and every potential producer’s costs in every market for every good in the world. He would then have to calculate everyone’s demand and supply curves and aggregate these. And, as conditions in the world change, he would constantly have to recalculate. It is a task that is absurdly infeasible; no one in the world can ever come close to obtaining the necessary information required for Barney’s task, and no supercomputer could ever be fast enough to continually process this information as it continually changes.

Consider even the simplest task, one we mentioned already in Chapter 1: ensuring that consumers who value pencils sufficiently much have access to No. 2 pencils when they need them. Pencils, as it turns out, are not that easy to make from scratch. The right trees have to be grown and harvested for wood; the wood has to be cut just right and treated with chemicals; the lead has to be mined and refined, then cut into just the right shape; the eraser has to be manufactured from

various raw materials; the metal holding the eraser on the pencil has to be produced and shaped; the yellow paint, and the black lettering on the paint indicating what kind of pencil it is, has to be produced and applied, then coated with a finish to make it stick. Literally hundreds of thousands of steps are involved, with each step requiring different expertise, and raw materials from literally all corners of the world have to come together in just the right way. It is not an exaggeration to say that no one in the world actually knows how to make a No. 2 pencil. Rather, thousands of individuals are somehow coordinated in just the right way, motivated at each turn by their own desire to do the best they can given their circumstances, and somehow, almost *as if guided by an invisible hand*,⁴ their actions result in cheap pencils available in abundance in our stores. Most of these individuals have no idea that they are participating in a sequence of events that leads to the availability of pencils, and yet it happens. And because of the complexity of the process involved in getting it to happen, the world has seen in centrally planned economies that when a single individual is put in charge of planning the process, it almost always results in a vast shortage of pencils.

15A.3.3 The Crucial Role of Information Contained in Prices How on earth can a decentralized and unplanned market then do what no planner in the world could ever accomplish? The answer lies in the information contained in market prices. Prices, whether in input or output markets, signal to consumers and producers what they need to do in order to “do the best they can.” If milk in New York City is running low, prices will rise, signaling to suppliers of milk that they can make a profit by shipping milk to New York. Lead for pencils is running short thus driving up the price of lead, signaling to mining companies across the world that profit can be made by increasing production. Miners themselves may be needed to get to more lead, causing wages for miners to go up as mining companies compete with other firms for labor, which signals to workers that they might want to switch to mining lead. Prices everywhere therefore capture the information Barney so desperately needs and thus coordinate the actions of millions across thousands of different markets around the world.

It is because of the information implicitly contained in prices that individuals do not need to know anything beyond their individual circumstances to determine what their next step should be as they try to do the best they can. It is not necessary for any individual actor in the market to know how his or her actions fit into the bigger picture because prices ensure that our actions fit together. This is one of the great advantages of decentralized markets: Markets do not require anyone to have information that is not easily available at their fingertips. Relying on central planning, on the other hand, requires us to rely on the central planner, our mythical Barney, to gather and process vast amounts of information. The success of decentralized market economies in their competition with centrally planned economies in the 20th century has much to do with this insight.⁵

When the conditions of the first welfare theorem hold, market prices contain all relevant information necessary for coordinating individuals to maximize social surplus.

15A.3.4 The Crucial Role of Self Interest A second advantage in decentralized markets is that the emergence of efficient market equilibria does not presume any benevolence on anyone’s part as the implementation of Barney’s social planning does. Rather, markets explicitly rely on individuals, consumers, workers, and producers alike, to be guided purely by their own perceptions of what is in their self-interest.

Adam Smith (1723–1790), who was one of the earliest economists to focus sharply on the spontaneous order generated by decentralized market forces, gives the example of a consumer purchasing bread from a baker. He asks rhetorically: Do we appeal to the baker’s benevolence when we come to get his bread? Do we present our “need” for bread and ask him to consider this carefully in deciding whether to give us bread? Or do we instead rely on his self-interest,

⁴ The reference to the market process operating “as if guided by an invisible hand” is from Adam Smith (1723–1790) who coined the phrase in *The Wealth of Nations*.

⁵ The case for the informational content in prices was made eloquently by F. A. Hayek (1889–1992) (who would go on to win the Nobel Prize in Economics in the 1970s) during the great debate about planned versus decentralized economies in the 1940s. It is summarized in the following (quite readable) article: F. A. Hayek, “The Use of Knowledge in Society,” *American Economic Review* 35(4), (1945) 519–30. It is well worth reading for anyone interested in the role of markets in the world.

Successful market processes rely on self-interested behavior whereas central planning typically presumes benevolence on the part of the planner.

proposing to pay him an amount that is larger than the value he places on the bread? Does he in turn ask for our benevolence when he appeals to us to pay him? Does he give us a list of all the reasons why he needs or deserves some money so that he can buy clothing and shelter for his family? Or does he simply appeal to our self-interest as he agrees to accept payment that is lower than the value we place on the bread (but higher than the value he places on it)? The answer, of course, is that we interact in markets with a clear understanding that each of us is trying to do the best we can for ourselves, and it is from this self-interested behavior that market demand and supply curves emerge and generate the equilibrium that maximizes the social surplus.

Decentralized markets therefore generate outcomes that maximize social surplus not only because they process information efficiently but also because they rely on the aspect of human nature that governs most of our actions. Centralized planning runs into difficulty not only because it faces enormous hurdles in gathering and processing the required information but also because it relies on powerful central planners to be benevolent in ways that appear not to happen when such planners are put in place. While there are many real-world limits (which we will discuss shortly) to this result, it remains, as we have said, central to an understanding of much that the economist does.

15A.3.5 Extending the First Welfare Theorem to Include All Rational Tastes

Before we move on to the limitations of the first welfare theorem, however, we need to note that while the assumption of quasilinear tastes will make policy analysis significantly easier in some of the upcoming chapters, it is *not* a necessary condition for the result that competitive markets result in efficient output levels. Suppose, for instance, that the good x is normal. In this case, we would find the market equilibrium exactly as we did before: by adding up all the individual (regular) demand curves and finding where the market demand curve intersects with the market supply curve. In panel (b) of Graph 15.8, this results in the intersection of the market supply curve S^M with the blue market demand curve D^M at price p^A . The market demand curve is composed of individual demand curves such as the blue curve D^i in panel (a).

If tastes for good x are normal, then we know that there exists a *MWTP* curve for each consumer that intersects the individual’s regular demand curve at the equilibrium price p^A from above; that is a *MWTP* curve that is steeper than the demand curve. This is the *MWTP* curve that is formed from the indifference curve that the individual finds himself or herself on in equilibrium, and it is plotted as the magenta curve in panel (a) of the graph. These curves, just like the individual demand curves, can then be added up and placed in the market picture in panel (b), and consumer surplus is now appropriately measured on this “aggregate *MWTP*” curve as the

GRAPH 15.8 The First Welfare Theorem with More General Tastes

shaded blue area. Without assuming that individual income effects exactly offset each other, we cannot treat the market demand and aggregate *MWTP* curves as if they came from a single representative consumer. But notice that, just as in the case where the demand and *MWTP* curves were the same under quasilinear tastes, it is still the case that each good that is produced has lower social marginal cost (as represented by the supply curve) than social marginal benefit (as measured by the magenta *MWTP* curve), and if any additional goods were produced, the marginal social value would fall below the marginal social cost. Thus, once again the market produces where the total surplus in the x market is maximized, and the validity of the first welfare theorem is not contingent on any particular assumption about individual consumer tastes. In the absence of quasilinearity, we simply have to be careful if we want to determine the precise size of the consumer surplus, but the efficiency result remains.

How would Graph 15.8 look if good x were an inferior good for all consumers?

EXERCISE
15A.11

True or False: If goods are normal, we will underestimate the consumer surplus if we measure it along the market demand curve, and if goods are inferior we will overestimate it.

EXERCISE
15A.12

There is, however, an important wrinkle that is added by introducing income effects through tastes in ways that do not permit the market demand to be modeled by a representative consumer. In the absence of income effects, Barney’s choice of the overall output level of x remains the same regardless of how Barney decides to distribute income across individuals. But in the presence of income effects, the overall level of x production chosen by Barney will depend on how other resources in the economy are distributed. Put differently, if Barney’s ideal income distribution across individuals is different than the actual income distribution, Barney may choose a different output level for x than the market will choose if tastes are not quasilinear in x . He will do so not because the market’s output level is inefficient; rather, he will do so because he prefers a *different* efficient output level that satisfies his desire for a different distribution of overall resources in the economy. Markets still give rise to efficiency and the first welfare theorem still holds in the presence of income effects, but the market outcome may violate some notions of “equity.” This is explored further in end-of-chapter exercises 15.5 and 15.6. The possible existence of different efficient allocations of resources, with some striking us as more equitable than others, will also be further discussed in Chapter 16 as well as Chapter 29. In fact, we will be able to show that Barney could achieve his preferred outcome by simply redistributing income first and then letting the market find the efficient level of x .

When there are income effects, redistribution of income in pursuit of equity goals changes the efficient output level in markets.

As we will see in some upcoming chapters, the first welfare theorem is indeed quite general, extending well beyond the model we have illustrated thus far. For now, however, we will conclude by stating some of the limits of this theorem, and in the process we will set the stage for many of the remaining chapters in this book.

15A.4 Conditions Underlying the First Welfare Theorem

At this point, some of you are getting a little worried and are asking yourself if all this isn’t getting a bit too ideological. It appears so far that we are saying that if we just leave everything to markets, we can enter the wonderful world of Barney and leave our worries behind. The benefit of using rigorous models to investigate the role of decentralized markets in dealing with self-interested individuals, however, is that it takes ideology out of it and allows us to investigate the issue through the logical lens of the models. Yes, so far our models appear to point to an important role played by competitive markets in organizing economies to allocate resources to their most efficient uses. But within these models are also the built-in assumptions, some explicit and some implicit, that are crucial for markets to have the wonderful properties we have just discussed. By knowing what these assumptions are, we will understand better both the benefits *and*

The First Welfare Theorem assumes that all prices are undistorted by government policy; that there are no externalities and all property rights are well established; that there is no relevant information asymmetry between buyers and sellers; and that no one has market power.

Chapters 18–20 deal with price distortions.

Chapters 21 and 27 deal with externalities and property rights.

the costs of decentralized markets. Put differently, by understanding the conditions that generate the first welfare theorem in our models, we can judge when these conditions are violated in the real world, and when there might be government or civil society institutions that can improve on a purely decentralized market outcome.

Much of the remainder of the book is therefore devoted to an exploration of the real-world conditions that undermine the first welfare theorem. After all, we see many problems in the real world that appear to not be adequately addressed by decentralized market forces: excessive pollution, too much poverty and human suffering, exploitation of certain natural resources, corporate abuses, and so on. Our model so far does not give any particular explanation for such phenomena because it excludes some of the real-world frictions that chip away at the first welfare theorem. It is these frictions that occupy many economists whose research is aimed at discovering the real-world institutions that might act as a lubricant to permit decentralized markets to work with less friction, and produce better results. We will mention these only briefly here and point to the upcoming chapters that deal with these issues more comprehensively.

15A.4.1 Policy Distortions of Prices The first implicit assumption we have made is that market prices actually operate as modeled, that they are permitted to form in such a way as to send an undistorted signal to the various actors in the market. A primary cause for this signal to become distorted lies in deliberate government policies such as taxes, price regulation, wage controls, subsidy programs, or, in some instances, the explicit prohibition of a market. Saying that such policies can distort market prices and therefore move the market away from the situation where it maximizes social surplus is, however, *not necessarily* the same as saying that we should not have these policies. As I will try to suggest throughout, there may be circumstances when policy makers are perfectly aware of the fact that price-distorting policies will shrink the total social surplus as we have measured it thus far but nevertheless believe that some other sufficiently useful purpose is served by the policy. Other times, the loss in social surplus seems so stark—and the distortionary policy so contrary to its stated purpose once we consider the impact on markets—that it becomes difficult to believe policy makers truly thought that a sufficiently useful *social* purpose was served by the policy to justify its social cost.⁶ We will consider a number of common price-distorting policies in Chapters 18 through 20.

15A.4.2 Externalities, Social Costs, and Property Rights In arguing that the *MSB* and *MSC* curves in Graph 15.7 are the same as the market demand and supply curves, we made a very crucial assumption: The only individuals whose welfare is affected by the production of a particular unit of x are the producer and the consumer of that unit. This is not, however, always the case. Consider, for instance, the greenhouse gases that are produced by firms in certain industries; literally everyone in the world might be affected by this pollution through global warming. The *MSC* is therefore higher than the producers' costs that result in the market supply curve. Similarly, my consumption of certain goods, traveling in my polluting car, for instance, may affect others in ways that are not captured in demand (or even *MWTP*) curves for cars. Whenever this is the case, we will say that there exists an *externality*, and whenever an externality exists, the intersection of *MSC* and *MSB* will be different from the intersection of market demand and supply. Thus, in the presence of externalities, the decentralized market does *not* produce the efficient quantity, and the market price signals sent to consumers and producers coordinate their behavior in ways that do not maximize social surplus. We will discuss these issues in more detail in Chapters 21 and 27. In Chapter 21, we will also uncover explicitly the most important efficiency-enhancing role of governments: to ensure that property rights are well established and enforced so as to minimize the inefficiencies from externalities that arise when property is “commonly” owned.

⁶In such cases, economists tend to search for explanations that treat policy makers themselves as self-interested individuals who are (at least in part) attempting to make policy with their individual welfare in mind. We will have more on this to say in Chapter 28.

15A.4.3 Asymmetric Information In addition to an absence of externalities, we have implicitly assumed that all economic actors have the same information about the relevant aspects of the market. Consumers and producers can look at good x and both fully know its uses and quality; employers can fully discern the qualification of workers and those selling used cars know just as much about the cars as the potential buyers. But this is, of course, not always so, and when it isn't, new issues enter the analysis as more informed parties can use their information to take advantage of less informed parties. We will consider this in more detail in Chapter 22.

15A.4.4 Market Power Throughout this text so far, we have always assumed that economic actors—consumers, workers, financial planners, and producers—are “small” relative to the market. Thus, we have assumed that each economic actor takes his or her economic environment as exogenously given, with no one able to control prices in the economy. Put differently, we have assumed that no one in the economy has *market power*, which is the power to influence the economic environment itself. But when an industry is composed of a single or only a few firms, each firm may well be large enough to impact the economic environment in the industry. (The same is true when one or only a few consumers make up all the demand for a particular good.) What we have concluded in this chapter in the form of the first welfare theorem thus does not necessarily hold when the assumption of competitive behavior is relaxed. We have also not paid much attention to the surplus created by innovative activities that create new goods and new markets, and the role of the profit motive in generating new surplus rather than simply producing surplus within existing markets. We will deal with instances of this in more detail in Chapters 23 through 26.

15A.4.5 Efficiency versus Alternative Social Objectives Finally, we have made an implicit assumption that attaining efficient outcomes is the most desirable objective for society. In some sense, this has some intuitive appeal: If we find a way of organizing society so that the total “pie” is as large as possible, then there is more pie to go around, so why not get it to be as large as possible? But of course most of us care not only about the size of the pie but also about its distribution. If the pie is huge but only one person gets to eat it while everyone else starves, few of us would think we have reached a “good society.” And the market not only maximizes the total pie (under certain conditions) but it also divides this pie between producers and consumers, firms and workers in ways that may not be as appealing to us as we might like. We will mention this concern at various times and return to an explicit treatment of considerations other than efficiency in Chapter 29.

Chapter 22 deals with information asymmetries.

Chapters 23 through 26 deal with market power.

A potential efficiency role for non-market institutions emerges when assumptions of the first welfare theorem do not hold; and a potential equity role for such institutions emerges when initial income distributions violate some notion about fairness.

15B

EQUILIBRIUM WELFARE ANALYSIS: PRELIMINARIES AND AN EXAMPLE

The fully generalized version of the first welfare theorem is quite general, and quite mathematically involved. Chapter 16 will contain some indications of how this theorem was actually developed and how it relates to other important results. For now, I will simply illustrate some of the intuitions of the current model in more mathematical detail.

15B.1 Consumer Surplus

We already developed in Section A the point that market demand functions cannot automatically be treated as if they had the same properties as individual demand functions; that is, as if they fit nicely into a duality picture derived from a single set of rational tastes. For the special case of quasilinear tastes, however, we illustrated that we *can* treat market demand as if it had arisen from the optimization of rational (and quasilinear) tastes by a single “representative consumer.” And we developed the intuition in Graph 15.1 that market demand has the properties of individual demand curves more generally so long as individual tastes are such that income can

be redistributed among individual consumers with no overall change in demand; that is, with changes in individual demand resulting from such redistributions exactly offsetting one another. We can now treat these topics a little more formally and demonstrate more precisely how the intuitions of Section A translate into the mathematics of the consumer model.

15B.1.1 “Representative Consumers” Consider again the example of the aggregated household demand for me and my wife, and whether this household demand can be treated as if it had arisen from rational “household tastes.” Intuitively, we argued in Graph 15.1 that my household’s demand can indeed be treated as if it was an individual demand function if and only if my household’s demand for each good is independent of who controls the money in my family. Put differently (and in terms easily seen in Graph 15.1), the change in my demand for good x_i when my income changes must be exactly the same as the change in the demand when my wife’s income changes *regardless of how income is initially divided*. Letting me be denoted by the superscript n and my wife by the superscript m , this implies that

$$\frac{\partial x_i^n}{\partial I^m} = \frac{\partial x_i^m}{\partial I^n} \text{ and } \frac{\partial^2 x_i^n}{\partial (I^m)^2} = \frac{\partial^2 x_i^m}{\partial (I^n)^2} = 0. \quad (15.1)$$

The first derivative of our demands with respect to income must be the same in order for the changes in demand from income redistribution to offset one another, and the second derivative must be zero in order for changes to always offset one another regardless of where we start. In order for the second derivative of a demand function with respect to income to be zero, income cannot enter the function in any way other than linearly (so that it drops out when we take the first derivative). With a little work (that you are asked to do in the upcoming within-chapter exercises), we can then see that the demand functions must take the form

$$\begin{aligned} x_i^m(p_1, p_2, I^m) &= a_i^m(p_1, p_2) + I^m b_i(p_1, p_2), \\ x_i^n(p_1, p_2, I^n) &= a_i^n(p_1, p_2) + I^n b_i(p_1, p_2), \end{aligned} \quad (15.2)$$

where a_i^m denotes a function specific to good i and individual m while b_i denotes a function specific to good i but the same for all individuals.

Groups can be treated as if they were a single individual if and only if income enters individual demand functions linearly.

EXERCISE 15B.1

Demonstrate that the conditions in equation (15.1) are satisfied for the demand functions in (15.2).

EXERCISE 15B.2

Can you see why equation (15.2) represents the most general way of writing demands that satisfy the conditions in equation (15.1)?

Demand functions of this type are known in microeconomics as satisfying the *Gorman Form*, and it is whenever individual demand functions are of the Gorman Form that aggregate demand functions can be treated as if they arose from the utility maximization of a representative consumer.⁷

15B.1.2 The Special Case of Quasilinear Tastes In Section A, we focused on the special case of quasilinear tastes, demonstrating in Graph 15.2 that changes in individual demand (for both x_1 and x_2) exactly offset one another as income is redistributed. Suppose, for instance, that we know both my wife and I have tastes that are quasilinear in x_1 , with her tastes represented by

⁷ This condition is often expressed in terms of conditions on the indirect utility function, with tastes (for individual m) that satisfy the Gorman Form leading to indirect utility functions of the form $V^m(p_1, p_2, I^m) = \alpha^m(p_1, p_2) + \beta(p_1, p_2)I^m$, where α and β are functions.

the utility function $u^n(x_1, x_2) = v^n(x_1) + x_2$ and mine represented by $u^m(x_1, x_2) = v^m(x_1) + x_2$. From our work in earlier chapters, we then know that both of our demand functions for x_1 are *not* a function of income while our demand for x_2 is simply determined by the income left over after we purchase the amount of x_1 (that does not depend on our income); that is,

$$\begin{aligned}x_1^m &= x_1^m(p_1, p_2) \quad \text{and} \quad x_2^m = \frac{I^m}{p_2} - \frac{p_1 x_1^m(p_1, p_2)}{p_2} \\x_1^n &= x_1^n(p_1, p_2) \quad \text{and} \quad x_2^n = \frac{I^n}{p_2} - \frac{p_1 x_1^n(p_1, p_2)}{p_2}\end{aligned}\tag{15.3}$$

You can check for yourself that these demand functions satisfy the Gorman Form, and thus the first and second derivative conditions in equation (15.1). It is furthermore the case that the aggregate (household) demand then takes the form it would take if it had been derived from a single quasilinear utility function.

What are my household demand functions (for x_1 and x_2) if my wife’s and my individual demands are those in equation (15.3)? Do the household demand functions also satisfy the Gorman Form?

**EXERCISE
15B.3**

15B.1.3 Aggregate Consumer Surplus We already know from our work in Chapter 10 that individual consumer surplus in the market for the good x can be measured as the area below the *MWTP* (or Hicksian or compensated demand) curve down to the price (where the relevant *MWTP* curve is derived from the indifference curve that contains the consumption bundle the individual has chosen). This can be expressed mathematically using an integral as

$$\text{Consumer Surplus in } x_1 \text{ Market} = \int_{p_1}^{\infty} h_1(p_1, p_2, u) dp, \tag{15.4}$$

where $h_1(p_1, p_2, u)$ is the compensated (or Hicksian) demand function. If you have not yet taken integral calculus, $\int_{p_1}^{\infty}$ is the “integral” of the function above p_1 , which simply means “the area underneath the function above the price p_1 .” In many cases, we might approximate this function with a strictly linear function, in which case Consumer Surplus can be calculated simply as the area of the triangle that is equivalent to this integral. And when all individual tastes are quasilinear, we can replace the compensated demand function $h_1(p_1, p_2, u)$ with the uncompensated demand function $x_1(p_1, p_2, I)$ in equation (15.4).

Finally, when individual demands satisfy the Gorman Form, we know we can treat aggregate market demand as if it had arisen from a single representative consumer. Thus, since quasilinear demand functions satisfy the Gorman Form, we can avoid having to calculate aggregate consumer surplus by going to all individual demand functions and adding up individual consumer surpluses. Instead, we can treat the *aggregate* demand function as if it had arisen from the optimization problem of a representative consumer whose tastes are quasilinear. Thus, applying the formula in equation (15.4) with $h_1(p_1, p_2, u)$ replaced by the (uncompensated) aggregate demand function will give consumer surplus for the fictional representative consumer, which in turn is the same number we would get if we added up individual consumer surpluses.

In our example of the equilibrium we calculated in Chapter 14 and depicted graphically in Graph 14.12, for instance, the underlying individual tastes are assumed to be quasilinear, implying that individual demand curves are equivalent to *MWTP* curves and that aggregate demand curves can be interpreted as if they had arisen from a single representative consumer with quasilinear tastes. In Graph 15.9a, we replicate panel (b) from Graph 14.12—the picture of market equilibrium with the numerical example we have been using. To this picture, we have added the labels (a), (b), and (c) to indicate areas, and our work in Part A of this chapter suggests that the blue area (a) is equal to consumer surplus and the magenta area (b) is equal to producer surplus (or profit).

GRAPH 15.9 $S^M(p) = 547,192/p^{2/3}$ and $D^M(p) = 40,000,000/p^2$ from Graph 14.12

As noted in Chapter 14, however, this picture graphs the *inverse* of the relevant slices of the underlying demand and supply functions. Panel (b) of Graph 15.9 then inverts panel (a) to get a picture of the actual (slices of the) demand and supply functions we have calculated mathematically. Area (a) now clearly shows up as the area *underneath* the demand function beginning at the equilibrium price $p = 5$, or the integral identified in equation (15.4). For the numerical example we used in Chapter 14, the market demand function was $D^M(p) = 40,000,000/p^2$. Thus, if you are comfortable with the concept of computing an integral, consumer surplus can be calculated as

$$\text{Consumer Surplus} = \int_5^{\infty} \frac{40,000,000}{p^2} dp = 8,000,000. \quad (15.5)$$

15B.2 Producer Surplus

We have demonstrated in Graph 15.4 that profit (or producer surplus) can be measured as an area on individual (as well as aggregate) supply curves. In Graph 15.9, this is equivalent to area (b) in the two panels of the graph. Using the supply function in panel (b) (as opposed to the inverse supply function in panel (a)), we can then see that this is equivalent to the area *underneath* the supply function up to the market price measured either on the short-run supply function (for short-run producer surplus) or the long-run supply function (for long-run producer surplus). Put into equations for a single firm,

$$\begin{aligned} \text{Short-Run Producer Surplus} &= \int_0^p x_{k^A}(w, p) dp \quad \text{and} \\ \text{Long-Run Producer Surplus} &= \int_0^p x(w, r, p) dp, \end{aligned} \quad (15.6)$$

where $x_{k^A}(\ell, p)$ and $x(\ell, r, p)$ are the short-run and long-run supply functions (with capital assumed to be fixed at k^A in the short run). Since cost functions (which make up supply functions) can be aggregated (into market supply functions), and since the market supply function can then be interpreted as if it had arisen from a single representative firm, aggregate producer surplus

can also be measured using the same formulas as those in equation (15.6), with individual supply functions replaced by aggregate market supply functions.

In the short-run equilibrium depicted graphically in Graph 15.9, for instance, we assumed an underlying production function of $f(\ell, k) = 20\ell^{2/5}k^{2/5}$ for each firm in the market, with each firm also incurring a recurring fixed license fee of \$1,280 and a short-run fixed level of capital $k_A = 256$. Using equations in (13.31) and (13.33) from Chapter 13, we derived the following short- and long-run input demand and output supply functions for each of the firms:

$$\begin{aligned} \text{Short Run: } x_{k^A=256}(p, w) &= 3,225\left(\frac{p}{w}\right)^{2/3} \quad \text{and} \quad \ell_{k^A=256}(p, w) = 1,290\left(\frac{p}{w}\right)^{5/3} \\ \text{Long Run: } x(p, w, r) &= 81,920\frac{p^4}{(wr^2)}, \quad \ell(p, w, r) = \frac{(8p^5)}{w^3r^2} \quad \text{and} \quad k(p, w, r) = \frac{(8p^5)}{w^2r^3}. \end{aligned} \quad (15.7)$$

Given that the firms encounter a recurring fixed cost of \$1,280, which of the previous functions should actually be qualified to take account of this fixed cost?

EXERCISE 15B.4

When prices are $(p, w, r) = (5, 20, 10)$, we furthermore concluded in Chapter 14 that there are 1,250 firms. At these prices, each firm produces 1,280 units for an overall output level of 1,600,000 and industry revenue (at $p = 5$) of $1,250(1,280)(5) = \$8,000,000$. In equation (14.11) of Chapter 14, we used this information to calculate the short-run market supply function at $w = 20$ as $S^M(p) = 547,192p^{2/3}$. The long-run market supply curve, on the other hand, is horizontal at the lowest point of the firm AC curves, which happens at \$5 in our example. Using again the notion of an integral to calculate the area below a function, we can then calculate short- and long-run producer surplus as

$$\begin{aligned} \text{Short-Run Producer Surplus} &= \int_0^5 547,192p^{2/3} dp = 4,800,000 \quad \text{and} \\ \text{Long-Run Producer Surplus} &= 0, \end{aligned} \quad (15.8)$$

with zero long-run surplus simply arising from the fact that the long-run supply curve is horizontal at $p = 5$.

We can check to see that this is correct by calculating the short-run and long-run profits of each firm in equilibrium more directly—simply subtracting the appropriate economic costs from revenue—and then adding these up across the number of firms that exist in equilibrium. Plugging prices $(p, w, r) = (5, 20, 10)$ into equations in (15.7), we get that each firm uses 128 units of labor and 256 units of capital to produce 1,280 units of output. In the short run, the firm then incurs a cost for labor equal to \$2,560 while earning revenue of \$6,400. Since the fixed license fee and the cost of capital are not economic costs in the short run, each firm therefore earns producer surplus equal to \$3,840, and since there are 1,250 firms in equilibrium, the aggregate (short-run) producer surplus is \$4,800,000 just as we calculated by taking the integral in equation (15.8). In the long run, each firm incurs an additional license fee of \$1,280 and a cost for capital of \$2,560, which results in a long-run profit of \$0 for each firm.

15B.3 The First Welfare Theorem

We will postpone more formal treatments of the first welfare theorem to the next chapter but can for now demonstrate its applicability to the example we have used in Graph 15.9. To do this, we can consider once again the optimization problem faced by the fictional benevolent social planner, the benevolent “Barney” from Section A.

In essence, we could view Barney as both the representative consumer and producer who is simply attempting to maximize his own well-being. He knows the long-run cost of producing x ,

which we have assumed in our example to be \$5 per unit. This allows him to draw a social *production possibilities frontier*, which is a society-wide budget constraint that illustrates the trade-offs faced as we produce more x in terms of a composite good y . Since the composite good y is denominated in dollars, 1 unit of x costs society 5 units of y , and the most y we could produce is simply equal to the total income I of all the consumers in the society.

If we now know a utility function $U(x, y)$ that can represent the “representative consumer’s” tastes, we could write Barney’s problem of attempting to maximize social surplus in the world as

$$\max_{x, y} U(x, y) \text{ subject to } I = 5x + y. \quad (15.9)$$

EXERCISE 15B.5 Draw the production possibility frontier previously described. How would it look differently if the long-run market supply curve slopes up? (*Hint:* With an upward-sloping supply curve, society is facing an increasing cost of producing x , implying that the trade-off in the society-wide production possibility frontier must reflect that increasing cost.)

As it turns out, it is possible to recover a utility function that would indeed give rise to the demand function $D^M(p) = 40,000,000/p^2$ from our example in Chapter 14. For instance, you can check for yourself that the utility function $U(x, y) = 12,649.11x^{1/2} + y$ accomplishes this. Solving the problem in equation (15.9) using this utility function for Barney gives the solution that Barney should produce 1,600,000 units of x , which is precisely the equilibrium quantity produced in the market.

EXERCISE 15B.6 Verify that this is indeed the case.

EXERCISE 15B.7 One way to verify that the representative consumer’s utility function is truly “representative” is to calculate the implied demand curve and see whether it is equal to the aggregate demand curve $D^M(p) = 40,000,000/p^2$ that we are trying to represent. Illustrate that this is the case for the utility function $U(x, y) = 12,649.11x^{1/2} + y$.

CONCLUSION

In this chapter, we have moved from *predicting* (a competitive equilibrium) to *evaluating* (it), from what we called “positive” economics to something that has a much more “normative” flavor. We have done so by imagining how the outcome of decentralized market competition would differ if the economy instead were managed by an omniscient and benevolent “social planner,” a social planner whose goal it was to achieve the highest possible overall “surplus” for society. And we have concluded that, under the stark conditions assumed so far, the social planner would in fact choose centrally what the market produces through the decentralized choices made by individuals who simply know their own circumstances and whose self-interested actions are guided by the signals they receive through market prices. Put differently, the “spontaneous order” of the market is, at least under certain conditions, “efficient,” which is not to say that it is necessarily “good,” a judgment that requires a deeper grounding in philosophy than what a simple economist can offer (at least for now). Still, it is a remarkable result—one that we have already suggested has its limits, but remarkable nonetheless.

Along the way, we have stumbled into a few issues that will appear throughout the remainder of this book. First, we saw that it is not trivial to simply think about groups as if they were individuals, that tastes do not “aggregate” easily and that we cannot treat the choices made by groups as if they were made by an individual unless we restrict the kinds of tastes that members of the group have. This is a theme we will see reappear in a somewhat different form in Chapter 28 when we think about political decisions made by groups. Second, we reintroduced the importance of income effects in evaluating welfare changes for individuals, the fact that, in the presence of income effects, we cannot simply measure consumer (or worker or investor) surplus along the usual demand (or supply) curves. This point will reappear in a number of applications throughout the text as we think through policies where making the mistake of forgetting about income

effects can lead to the wrong conclusions. Third, we ended Part A of the chapter by listing the implicit underlying conditions of the “first welfare theorem” and pointed out that much of the remainder of the text is organized around the fact that these conditions are often violated in the real world. Finally, we have already mentioned that “efficient” is not the same as “good,” but that the “good” is something that most economists are not particularly great at talking about. We will return to this issue at the end of the text in Chapter 29.

We will begin our analysis of what happens when the underlying conditions of the first welfare theorem are violated in the real world in Part 4 of the text with Chapter 18. But before getting to this, we now turn to a somewhat different way of thinking about the first welfare theorem and related results (Chapter 16) and a discussion of how economists think about the inclusion of risk in our models (Chapter 17).

END-OF-CHAPTER EXERCISES

15.1[†] Everyday Application: Labor-Saving Technologies: Consider inventions such as washing machines or self-propelled vacuum cleaners. Such inventions reduce the amount of time individuals have to spend on basic household chores, and thus in essence increase their leisure endowments.

- A.** Suppose that we wanted to determine the aggregate impact such labor-saving technologies will have on a particular labor market in which the wage is w .
- Draw a graph with leisure on the horizontal axis and consumption on the vertical and assume an initially low level of leisure endowment for worker A. For the prevailing wage w , indicate this worker’s budget constraint and his or her optimal choice.
 - On the same graph, illustrate the optimal choice for a second worker B who has the same leisure endowment and the same wage w but chooses to work more.
 - Now suppose that a household labor-saving technology (such as an automatic vacuum cleaner) is invented and both workers experience the same increase in their leisure endowment. If leisure is quasilinear for both workers, will there be any impact on the labor market?
 - Suppose instead that tastes for both workers are homothetic. Can you tell whether one of the workers will increase his or her labor supply by more than the other?
 - How does your answer suggest that workers in an economy cannot generally be modeled as a single “representative worker” even if they all face the same wage?
- B.*** Consider the problem of aggregating actors in an economy where we assume individuals have an exogenous income.
- In a footnote in this chapter, we stated that when the indirect utility for individual m can be written as $V^m(p_1, p_2, I^m) = \alpha^m(p_1, p_2) + \beta(p_1, p_2)I^m$, then demands can be written as in equation (15.2). Can you demonstrate that this is correct by using Roy’s Identity?
 - Now consider the case of workers who choose between consumption (priced at 1) and leisure. Suppose they face the same wage w but different workers have different leisure endowments. Letting the two workers be superscripted by n and m , can you derive the form that the leisure demand equations $l^m(w, L^m)$ and $l^n(w, L^n)$ would have to take in order for redistributions of leisure endowments to not impact the overall amount of labor supplied by these workers (together) in the labor market?
 - Can you rewrite these in terms of labor supply equations $\ell^m(w, L^m)$ and $\ell^n(w, L^n)$?
 - Can you verify that these labor supply equations have the property that redistributions of leisure between the two workers do not affect overall labor supply?

15.2 Business Application: Disneyland Pricing Revisited: In end-of-chapter exercise 10.10, we investigated different ways that you can price the use of amusement park rides in a place like Disneyland. We now return to this example. Assume throughout that consumers are never at a corner solution.

- A.** Suppose again that you own an amusement park and assume that you have the only such amusement park in the area; that is, suppose that you face no competition. You have calculated your cost curves for operating the park, and it turns out that your marginal cost curve is upward sloping throughout. You have also estimated the downward-sloping (uncompensated) demand curve for your amusement

*conceptually challenging

**computationally challenging

†solutions in Study Guide

park rides, and you have concluded that consumer tastes appear to be identical for all consumers and quasilinear in amusement park rides.

- a. Illustrate the price you would charge per ride if your aim was to maximize the overall surplus that your park provides to society.
 - b.* Now imagine that you were not concerned about social surplus and only about your own profit. Illustrate in your graph a price that is slightly higher than the one you indicated in part (a). Would your profit at that higher price be greater or less than it was in part (a)?
 - c. *True or False:* In the absence of competition, you do not have an incentive to price amusement park rides in a way that maximizes social surplus.
 - d. Next, suppose that you decide to charge the per-ride price you determined in part (a) but, in addition, you want to charge an entrance fee into the park. Thus, your customers will now pay that fee to get into the park, and then they will pay the per-ride price for every ride they take. What is the most that you could collect in entrance fees without affecting the number of rides consumed?
 - e. Will the customers who come to your park change their decision on how many rides they take? In what sense is the concept of “sunk cost” relevant here?
 - f. Suppose you collect the amount in entrance fees that you derived in part (d). Indicate in your graph the size of consumer surplus and profit assuming you face no fixed costs for running the park.
 - g. If you do face a recurring fixed cost (FC) how does your answer change?
 - h. *True or False:* The ability to charge an entrance fee in addition to per-ride prices restores efficiency that would be lost if you could only charge a per-ride price.
 - i. In the presence of fixed costs, might it be possible that you would shut down your park if you could not charge an entrance fee but you keep it open if you can?
- B.** Suppose, as in exercise 10.10, tastes for your consumers can be modeled by the utility function $u(x_1, x_2) = 10x_1^{0.5} + x_2$, where $x_1 = x$ represents amusement park rides and x_2 represents dollars of other consumption. Suppose further that your marginal cost function is given by $MC(x) = x/(250,000)$.
- a. Suppose that you have 10,000 consumers on any given day. Calculate the (aggregate) demand function for amusement park rides.
 - b. What price would you charge if your goal was to maximize total surplus? How many rides would be consumed?
 - c. In the absence of fixed costs, what would your profit be at that price?
 - d. Suppose you charged a price that was 25% higher. What would happen to your profit?
 - e. Derive the expenditure function for your consumers.
 - f.* Use this expenditure function to calculate how much consumers would be willing to pay to keep you from raising the price from what you calculated in (b) to 25% more. Can you use this to argue that raising the price by 25% is inefficient even though it raises your profit?
 - g.* Next, determine the amount of an entrance fee that you could charge while continuing to charge the per-ride price you determined in (b) without changing how many rides are demanded.
 - h. How much is your profit now? What happens to consumer surplus? Is this efficient?
 - i. Suppose the recurring fixed cost of operating the park is \$200,000. Would you operate it if you had to charge the efficient per-ride price but could not charge an entrance fee? What if you could charge an entrance fee?

15.3[†] Business and Policy Application: License Fees and Surplus without Income Effects: In previous chapters, we explored the impact of recurring license fees on an industry’s output and price. We now consider their impact on consumer and producer surplus.

- A.** Suppose that all firms in the fast food restaurant business face U-shaped average cost curves prior to the introduction of a recurring license fee. The only output they produce is hamburgers. Suppose throughout that hamburgers are a quasilinear good for all consumers.
 - a. First, assume that all firms are identical. Illustrate the long-run market equilibrium and indicate how large consumer and long-run producer surplus (that is, profit) are in this industry.

- b. Illustrate the change in the long-run market equilibrium that results from the introduction of a license fee.
 - c. Suppose that the license fee has not yet been introduced. In considering whether to impose the license fee, the government attempts to ascertain the cost to consumers by asking a consumer advocacy group how much consumers would have to be compensated (in cash) in order to be made no worse off. Illustrate this amount as an area in your graph.
 - d. Suppose instead that the government asked the consumer group how much consumers would be willing to pay to avoid the license fee. Would the answer change?
 - e. Finally, suppose the government simply calculated consumer surplus before and after the license fee is imposed and subtracted the latter from the former. Would the government’s conclusion of how much the license fee costs consumers change?
 - f. What in your answers changes if, instead of all firms being identical, some firms had higher costs than others (but all have U-shaped average cost curves)?
- B.** Suppose that each firm’s cost function is given by $C(w, r, x) = 0.047287w^{0.5}r^{0.5}x^{1.25} + F$ where F is a recurring fixed cost.⁸
- a. What is the long-run equilibrium price for hamburgers x (as a function of F) assuming wage $w = 20$ and rental rate $r = 10$?
 - b. Suppose that prior to the imposition of a license fee, the firm’s recurring fixed cost F was \$1,280. What is the pre-license fee equilibrium price?
 - c. What happens to the long-run equilibrium price for hamburgers when a \$1,340 recurring license fee is introduced?
 - d. Suppose that tastes for hamburgers x and a composite good y can be characterized by the utility function $u(x, y) = 20x^{0.5} + y$ for all 100,000 consumers in the market, and assume that all consumers have budgeted \$100 for x and other goods y . How many hamburgers are sold before and after the imposition of the license fee?
 - e. Derive the expenditure function for a consumer with these tastes.
 - f.* Use this expenditure function to answer the question in A(c).
 - g.* Use the expenditure function to answer the question in A(d).
 - h.** Take the integral of the demand function that gives you the consumer surplus before the license fee and repeat this to get the integral of the consumer surplus after the license fee is imposed.
 - i. How large is the change in consumer surplus from the price increase? Compare your answer with what you calculated in parts (f) and (g).

15.4 Business and Policy Application: License Fees and Surplus with Income Effects: In this exercise, assume the same set-up as in exercise 15.3 except that this time we will assume that hamburgers are a normal good for all consumers.

- A.** As in exercise 15.3, we’ll consider the long-run impact of a license fee for fast food restaurants on consumer surplus. In (a) and (b) of exercise 15.3, you should have concluded that the long-run price increases as a result of the license fee.
- a. Consider your graph from part (c) of exercise 15.3. Does the area you indicated over- or underestimate the amount consumers would have to be compensated (in cash) in order to accept the license fee?
 - b. Does the area over- or underestimate the amount consumers are willing to pay to avoid the license fee?
 - c. How would your answers to (a) and (b) differ if hamburgers were instead an inferior good for all consumers?
 - d. Do any of your conclusions depend on the assumption (made explicitly in exercise 15.3) that all firms are identical?

⁸You can check for yourself that this is the cost function that arises from the production function $f(\ell, k) = 20\ell^{0.4}k^{0.4}$.

- B.** Suppose that tastes by consumers are characterized by the utility function $u(x, y) = x^{0.25}y^{0.75}$ and that each consumer had \$100 budgeted for hamburgers x and other goods y .
- Calculate how many hamburgers each consumer consumes—and how much utility (as measured by this utility function) each consumer obtains—when the price of hamburgers is \$5 (and the price of “other goods” is \$1).
 - Derive the expenditure function for a consumer with such tastes.
 - Suppose that the license fee causes the price to increase to \$5.77 (as in exercise 15.3). How does your answer to (a) change?
 - * Using the expenditure function, calculate the amount the government would need to compensate each consumer in order for them to agree to the imposition of the license fee.
 - * Calculate the amount that consumers would be willing to pay to avoid the license fee.
 - ** Suppose you used the demand curve to estimate the change in consumer surplus from the introduction of the license fee. How would your estimate compare to your answers in (d) and (e)?
 - ** Can you use integrals of compensated demand curves to arrive at your answers from (d) and (e)?

15.5⁺ Policy Application: Redistribution of Income without Income Effects: Consider the problem a society faces if it wants to maximize efficiency while also ensuring that the overall distribution of “happiness” in the society satisfies some notion of “equity.”

- A.** Suppose that everyone in the economy has tastes over x and a composite good y , with all tastes quasi-linear in x .
- Does the market demand curve (for x) in such an economy depend on how income is distributed among individuals (assuming no one ends up at a corner solution)?
 - Suppose you are asked for advice by a government that has the dual objective of maximizing efficiency as well as ensuring some notion of “equity.” In particular, the government considers two possible proposals: Under proposal A, the government redistributes income from wealthier individuals to poorer individuals before allowing the market for x to operate. Under proposal B, on the other hand, the government allows the market for x to operate immediately and then redistributes money from wealthy to poorer individuals after equilibrium has been reached in the market. Which would you recommend?
 - Suppose next that the government has been replaced by an omniscient social planner who does not rely on market processes but who shares the previous government’s dual objective. Would this planner choose a different output level for x than is chosen under proposal A or proposal B in part (b)?
 - True or False:* As long as money can be easily transferred between individuals, there is no tension in this economy between achieving many different notions of “equity” and achieving efficiency in the market for x .
 - To add some additional realism to the exercise, suppose that the government has to use distortionary taxes in order to redistribute income between individuals. Is it still the case that there is no trade-off between efficiency and different notions of equity?
- B.** Suppose there are two types of consumers: Consumer type 1 has utility function $u^1(x, y) = 50x^{1/2} + y$, and consumer type 2 has utility function $u^2(x, y) = 10x^{3/4} + y$. Suppose further that consumer type 1 has income of 800 and consumer type 2 has income of 1,200.
- Calculate the demand functions for x for each consumer type.
 - Calculate the aggregate demand function when there are 32,000 of each consumer type.
 - Suppose that the market for x is a perfectly competitive market with identical firms that attain zero long-run profit when $p = 2.5$. Determine the long-run equilibrium output level in this industry.
 - How much x does each consumer type consume?
 - Suppose the government decides to redistribute income in such a way that, after the redistribution, all consumers have equal income; that is, all consumers now have income of 1,000. Will the equilibrium in the x market change? Will the consumption of x by any consumer change?
 - Suppose instead of a competitive market, a social planner determined how much x and how much y every consumer consumes. Assume that the social planner is concerned about both the absolute welfare of each consumer as well as the distribution of welfare across consumers,

with more equal distribution more desirable. Will the planner produce the same amount of x as the competitive market?

- g. *True or False:* The social planner can achieve his or her desired outcome by allowing a competitive market in x to operate and then simply transferring y across individuals to achieve the desired distribution of happiness in society.
- h. Would anything in your analysis change if the market supply function were upward sloping?
- i. Economists sometimes refer to economies in which all individuals have quasilinear tastes as “transferable utility economies,” which means that in economies like this, the government can transfer happiness from one person to another. Can you see why this is the case if we were using the utility functions as accurate measurements of happiness?

15.6 Policy Application: Redistributing Income with Income Effects: Consider again, as in exercise 15.5, the problem faced by a society that wants to both maximize efficiency and achieve some notion of “equity.”

- A. Suppose again that everyone has tastes over x and a composite good y , but now suppose that tastes are homothetic.
 - a. Does the market demand curve (for x) depend on how income is distributed among individuals?
 - b. Would your answer to (a) be different if you thought that everyone had identical (homothetic) tastes?
 - c. Suppose you are again asked for the same advice as in exercise 15.5A(b). What is your answer now?
 - d. Repeat part A(c) from exercise 15.5 for this economy.
 - e. Recall that we defined a situation as “efficient” if there is no way to change the situation and make someone better off without making someone else worse off. In general (that is, not just within the context of the example in this exercise), is it possible to have two efficient outcomes where some individuals prefer the first outcome while others prefer the second?
 - f. *True or False:* If the government redistributes income between individuals prior to the market for x operating, the outcome is efficient so long as income can be redistributed without cost.
 - g. *True or False:* In the quasilinear example of exercise 15.5, all efficient outcomes (excluding those that involve corner solutions) will involve the same level of production of x , but in the example of the current exercise this is no longer the case.
 - h. *True or False:* Assuming redistribution takes place before the market opens, a trade-off between efficiency and equity only emerges in this economy if redistributing money between individuals involves the use of distortionary taxes.
 - i. Does your conclusion in (h) hold more generally for nonhomothetic tastes as well?
- B. Suppose again, as in exercise 15.5, that there are two types of individuals in the economy. Type 1 has utility function $u^1(x, y) = x^\alpha y^{(1-\alpha)}$ and type 2 has utility function $u^2(x, y) = x^\beta y^{(1-\beta)}$ (with both α and β falling between 0 and 1). Suppose further that type 1 individuals have income I and type 2 individuals have income I' .
 - a. What is each type’s demand function for x assuming price p for x and a price of 1 for y ?
 - b. What is the market demand function for x if there is an equal number N of each type in the economy?
 - c. Suppose $\alpha = \beta$ and money can be transferred across individuals without cost. Will the equilibrium output level in the x market be affected by income redistribution policies? Will individual consumption levels of x be affected by such policies?
 - d. Next, suppose $\alpha \neq \beta$. Will the equilibrium output level in the x market be affected by income redistribution policies?
 - e. Suppose again that you are asked for your advice on the two alternative policies described in exercise 15.5A(b) (assuming again that the government has the dual objective of maximizing efficiency and achieving some notion of “equity”). What is your advice now assuming that individuals cannot trade goods with one another after they have purchased x ?
 - f. Assume again that the government is replaced with an omniscient social planner who shares the previous government’s dual objective. Will the social planner’s decision on how much x to produce mirror the outcome of either of the two policies you considered in part (e)?

15.7⁺ Policy Application: *Deadweight Loss from Subsidy of Mortgage Interest:* The U.S. tax code subsidizes housing through a deduction of mortgage interest. For new homeowners, mortgage interest makes up the bulk of their housing payments, which tend to make up about 25% of a household’s income. Assume throughout that housing is a normal good.

- A.** For purposes of this problem, we will assume that all housing payments made by a household represent mortgage interest payments. If a household is in a 25% tax bracket, allowing the household to deduct mortgage interest on its taxes then is equivalent to reducing the price of \$1 worth of housing consumption to \$0.75.
- Illustrate a demand curve for a consumer, indicating both the with- and without-deductibility housing price.
 - On the same graph, illustrate the compensated (or *MWTP*) curve for this consumer assuming that housing costs are deductible.
 - On your graph, indicate where you would locate the amount that a consumer would be willing to accept in cash instead of having the subsidy of housing through the tax code.
 - On your graph, indicate the area of the deadweight loss.
 - If you used the regular demand curve to estimate the deadweight loss, by how much would you over- or underestimate it?
- B.** Suppose that a household earning \$60,000 (after taxes) has utility function $u(x, y) = x^{0.25}y^{0.75}$, where x represents dollars worth of housing and y represents dollars worth of other consumption. (Thus, we are implicitly setting the price of x and y to \$1.)
- How much housing does the household consume in the absence of tax deductibility?
 - If the household’s marginal tax rate is 25% (and if all housing payments are deductible), how much housing will the household consume?
 - How much does the implicit housing subsidy cost the government for this consumer?
 - Derive the expenditure function for this household (holding the price of other consumption at \$1 but representing the price of housing as p).
 - Suppose the government contemplates eliminating the tax deductibility of housing expenditures. How much would it have to compensate this household for the household to agree to this?
 - ** Can you derive the same amount as an integral on a compensated demand function?
 - * Suppose you only knew this household’s (uncompensated) demand curve and used it to estimate the change in consumer surplus from eliminating the tax deductibility of housing expenditures. How much would you estimate this to be?
 - Are you over- or underestimating the deadweight loss from the subsidy if you use the (uncompensated) demand curve?
 - Suppose that all 50,000,000 homeowners in the United States are identical to the one you have just analyzed. What is the annual deadweight loss from the deductibility of housing expenses? By how much would you over- or underestimate this amount if you used the aggregate demand curve for housing in this case?

15.8 Policy Application: *Markets, Social Planners, and Pollution:* One of the conditions we identified as important to the first welfare theorem is that there are no *externalities*. One of the most important externalities in the real world is pollution from production (which we will explore in detail in Chapter 21).

- A.** Suppose that we consider the production of some good x and assume that consumers have tastes over x and a composite good y where x is quasilinear.
- Illustrate the market equilibrium in a graph with x on the horizontal and the price p of x on the vertical axis. Assume that the supply curve is upward sloping, either because you are considering the short run in the industry or because the industry is composed of firms that differ in their cost curves.
 - On your graph, indicate the consumer surplus and producer profit (or producer surplus).
 - In the absence of externalities, why is the market equilibrium output level the same as the output level chosen by a social planner who wants to maximize social surplus?
 - Now suppose that for every unit of x that is produced, an amount of pollution that causes social damage of δ is emitted. If you wanted to illustrate not just the marginal cost of

production (as captured in supply curves) but also the additional marginal cost of pollution (that is not felt by producers), where would that “social marginal cost” curve lie in your graph?

- e. In the absence of any nonmarket intervention, do firms have an incentive to think about the marginal cost of pollution? Will the market equilibrium change as a result of the fact that pollution is emitted in the production process?
 - f. Would the social planner who wishes to maximize social surplus take the marginal social cost of pollution into account? Illustrate in your graph the output quantity that this social planner would choose and compare it to the quantity the market would produce.
 - g. Redraw your graph with the following two curves: the demand curve and the marginal social cost curve (that includes both the marginal costs of producers and the cost imposed on society by the pollution that is generated). Also, indicate on your graph the quantity x^* that the social planner wishes to produce as well as the quantity x^M that the market would produce. Can you identify in your graph an area that is equal to the deadweight loss that is produced by relying solely on the competitive market?
 - h. Explain how pollution-producing production processes can result in inefficient outcomes under perfect competition. How does your conclusion change if the government forces producers to pay δ in a per-unit tax?
- B.** In exercise 15.2, you should have derived the aggregate demand function $X^D(p) = 250,000/p^2$ from the presence of 10,000 consumers with tastes that can be represented by the utility function $u(x, y) = 10x^{0.5} + y$. Suppose that this accurately characterizes the demand side of the market in the current problem. Suppose further that the market supply curve is given by the equation $X^S(p) = 250,000p$.
- a. Derive the competitive equilibrium price and quantity produced in the market.
 - b.** Derive the size of consumer surplus and profit (or producer surplus).
 - c. Consider a social planner who wants to maximize the social surplus. How would this planner arrive at the same output quantity as the market?
 - d. Now suppose that each unit of x that is produced results in a pollution cost to society of \$0.61. What would be the market outcome in the absence of any nonmarket intervention?
 - e. Verify that, when each unit of x results in \$0.61 pollution cost, the social planner would choose $x = 160,000$ as the optimal output quantity.
 - f. Calculate the total social cost of pollution under the competitive market outcome. How much is social surplus reduced from what it would be in the absence of pollution?
 - g.** Calculate the overall social surplus (including the cost of pollution) under the social planner’s preferred outcome.
 - h. What deadweight loss is produced as a result of the market’s overproduction?

15.9⁺ Policy Application: Anti-Price-Gauging Laws: As we will discuss in more detail in Chapter 18, governments sometimes interfere in markets by placing restrictions on the price that firms can charge. One common example of this is so-called “anti-price-gauging laws” that restrict profits for firms when sudden supply shocks hit particular markets.

- A.** A recent hurricane disrupted the supply of gasoline to gas stations on the East Coast of the United States. Some states in this region enforce laws that prosecute gasoline stations for raising prices as a result of natural disaster–induced drops in the supply of gasoline.
- a. On a graph with weekly gallons of gasoline on the horizontal and price per gallon on the vertical, illustrate the result of a sudden leftward shift in the supply curve (in the absence of any laws governing prices).
 - b. Suppose that gasoline is a quasilinear good for consumers. Draw a graph similar to the one in part (a) but include only the post-hurricane supply curve (as well as the unchanged demand curve). Illustrate consumer surplus and producer profit if price is allowed to settle to its equilibrium level.
 - c. Now consider a state that prohibits price adjustments as a result of natural disaster–induced supply shocks. How much gasoline will be supplied in this state? How much will be demanded?
 - d. Suppose that the limited amount of gasoline is allocated at the pre-crisis price to those who are willing to pay the most for it. Illustrate the consumer surplus and producer profit.

- e. On a separate graph, illustrate the total surplus achieved by a social planner who ensures that gasoline is given to those who value it the most and sets the quantity of gasoline at the same level as that traded in part (c). Is the social surplus different than what arises under the scenario in (d)?
 - f. Suppose that instead the social planner allocates the socially optimal amount of gasoline. How much greater is social surplus?
 - g. How does the total social surplus in (f) compare to what you concluded in (b) that the market would attain in the absence of anti-price-gauging laws?
 - h. *True or False:* By interfering with the price signal that communicates information about where gasoline is most needed, anti-price-gauging laws have the effect of restricting the inflow of gasoline to areas that most need gasoline during times of supply disruptions.
- B.**** Suppose again that the aggregate demand function $X^D(p) = 250,000/p^2$ arises from 10,000 local consumers of gasoline with quasilinear tastes (as in exercise 15.8).
- a. Suppose that the industry is in long-run equilibrium and that the short-run industry supply function in this long-run equilibrium is $X^S(p) = 3,906.25p$. Calculate the equilibrium level of (weekly) local gasoline consumption and the price per dollar.
 - b. What is the size of the consumer surplus and (short-run) profit?
 - c. Next suppose that the hurricane-induced shift in supply moves the short-run supply function to $\bar{X}^S = 2,000p$. Calculate the new (short-run) equilibrium price and output level.
 - d. What is the sum of consumer surplus and (short-run) profit if the market is allowed to adjust to the new short-run equilibrium?
 - e. Now suppose the state government does not permit the price of gasoline to rise above what you calculated in part (a). How much gasoline will be supplied?
 - f. Assuming that the limited supply of gasoline is bought by those who value it the most, calculate overall surplus (that is, consumer surplus and (short-run) profit) under this policy.
 - g. How much surplus is lost as a result of the government policy to not permit price increases in times of disaster-induced supply shocks?

General Equilibrium

Our analysis of competitive markets has thus far focused on a single market. It has not treated the entire economy as an interrelated system in which there are equilibrium forces that cross markets, and for this reason the model is often called a *partial equilibrium model*.¹ With the assumption of quasilinear tastes, the model not only gives a convenient way of illustrating equilibrium in a single market but it also allows us to measure welfare along market demand and supply curves in a manner consistent with how the material is typically presented in introductory economics texts. The simplicity of the model makes it a powerful tool for economists to develop insights about markets, and, as we have suggested in the last chapter, it provides a convenient benchmark for us to think about economic forces that may “distort” markets.

At the same time, the partial equilibrium model is restrictive in a number of ways. We have already illustrated that a deviation from quasilinearity in tastes creates complications for the simple “introductory economics” approach because of the emergence of income or wealth effects. In addition, we have to assume that the single market that is being analyzed is “small” relative to other markets, thus not impacting prices in those other markets. But often markets are fundamentally interrelated, with changes in one market spilling over into others through changes in input prices, through substitution effects as consumers switch between products and through the creation of wealth effects (due to nonquasilinear tastes). *General equilibrium models* therefore view the economy as a closed system of related markets, explicitly taking into account the effects that are assumed away in partial equilibrium analysis. Such models can be particularly important in policy analysis because policies represent institutional changes that affect many markets and create feedback effects that are ignored if we consider only a single market at a time.

Over the past 50 years, economists have therefore developed a large number of increasingly sophisticated models of this “general equilibrium” kind, with different models making different simplifying assumptions depending on the particular application for which they are designed.² These models now show up in different forms in virtually all subfields in economics. It is beyond the scope of this text to provide a thorough review of these approaches, and you will encounter them in different forms in a variety of future classes. For now, we will simply illustrate some very simple examples, and show how the first welfare theorem remains fully intact as we move

Partial equilibrium models treat a single market in isolation whereas general equilibrium models treat the economy as a closed system of related markets.

Almost all graphs in the text can be viewed as narrated video animations within MindTap.

¹ This chapter is built on the foundations of consumer theory as illustrated in Chapter 6 as well as a basic understanding of producer theory as illustrated in Chapter 11.

² The pioneers in this area were Ken Arrow (1921–), Gerard Debreu (1921–2004), and Lionel McKenzie (1919–2010). In 1972, Arrow was awarded the Nobel Prize in economics, followed by a 1983 Nobel award to Debreu.

away from the assumptions of the partial equilibrium model. Within these simple general equilibrium models, we can further illustrate some other important general equilibrium concepts: the “second welfare theorem,” a notion of stability of resource allocations known as the “core,” and the result that this “core” in fact converges to what emerges through decentralized market forces. At the end of the chapter, we will then discuss some more general examples of the importance of general equilibrium effects, examples that go beyond the analytic tools we can illustrate here.

16A

A GRAPHICAL EXPOSITION OF GENERAL EQUILIBRIUM

There are three basic economic activities that occur in a market economy: production, exchange, and the consumption that results from these. Rich general equilibrium models in which large numbers of firms and consumers engage in economic activity have been developed mathematically with the basic tools we have introduced in this text, but some of the underlying concepts and ideas that emerge from these models can be illustrated in small examples that lend themselves to a graphical approach, with the same insights generalizing to a much richer setting.

We will introduce these ideas in two steps: In 16A.1, we begin by introducing what we will call a pure exchange economy in which no production occurs and two consumers simply engage in trade of two types of goods that they already own. We can then demonstrate some of the fundamental general equilibrium ideas and results that also hold in settings with many consumers and many goods (in Section 16A.2). In Section 16A.3, we will move on to consider production in an economy in which a single actor acts as both a producer and a consumer.

16A.1 A Pure Exchange Economy

We begin with a treatment of what is known as a *pure exchange economy* defined as *an economy in which there is no production and in which consumers are endowed with different bundles of goods*. Obviously, a model of an economy without production is not one that aims to be a fully realistic model. Rather, it offers us the simplest possible setting in which to illustrate the basic insights and methods of general equilibrium theory.

The simplest possible version of an exchange economy is one with two consumers and two goods. Suppose, for instance, we consider my wife and me on a weekend getaway in a secluded cottage on a remote island in the Bahamas. In the rush to catch our flight, we grabbed a few fruits to sustain us over the weekend. Suppose she grabbed a basket with 10 oranges and 4 bananas, and I took a basket with 3 oranges and 6 bananas. As we consider our situation over the weekend, we therefore have a total of 13 oranges and 10 bananas to sustain us, and each of us is interested in exploring a trade that would make us both better off.

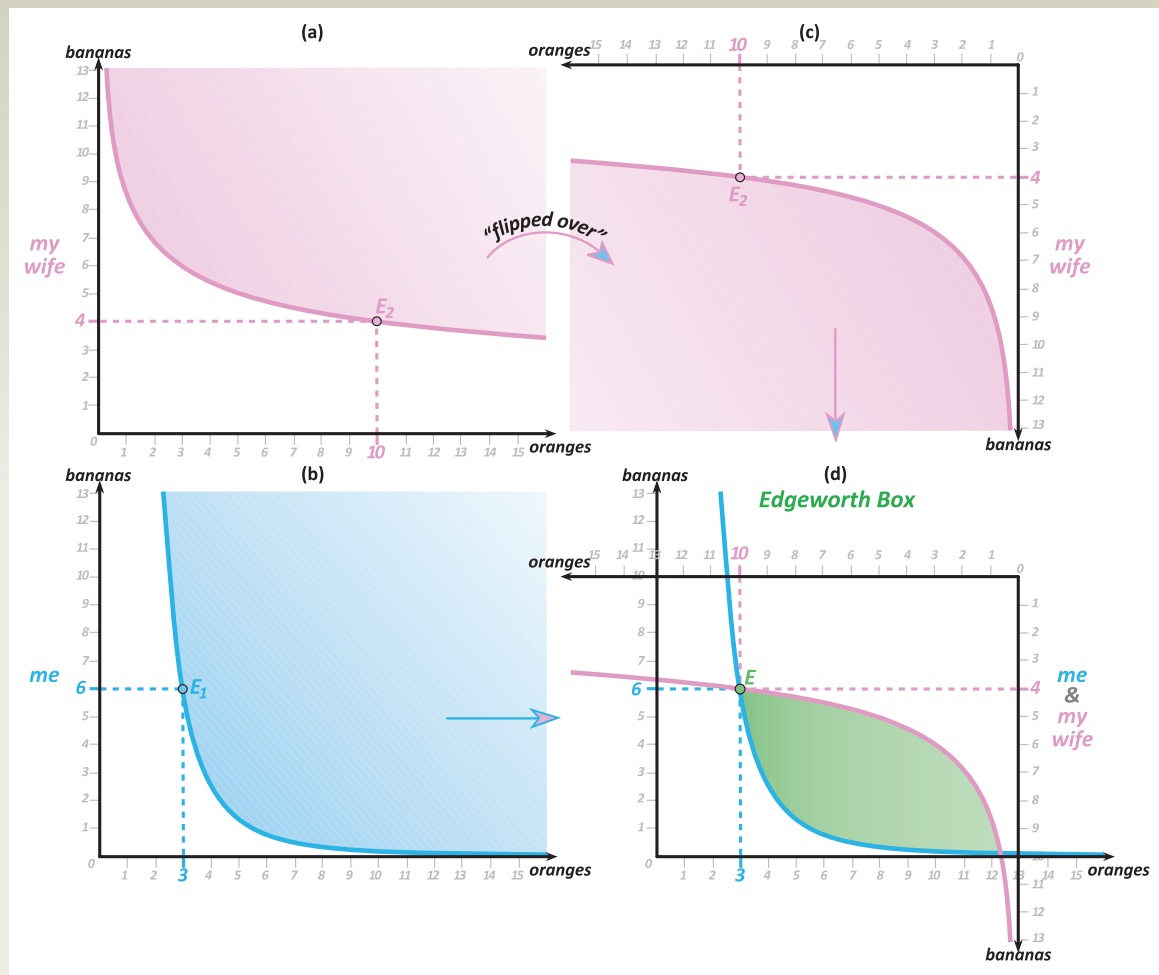

More formally, our little economy is defined simply by (1) the individuals in the economy (me and my wife), (2) our tastes over goods, and (3) the endowments of goods that we own in the economy (our baskets of oranges and bananas). If all we do is consume our individual endowments, we can each get to a certain indifference curve on our indifference map. These indifference curves are illustrated in panels (a) and (b) of Graph 16.1, with the bundle E_2 denoting my wife’s endowment bundle in panel (a) and the bundle E_1 denoting my endowment bundle in panel (b). My wife and I are now interested in exploring whether there are other feasible distributions of our joint endowment that could make both of us better off and thus lead to a mutually beneficial trade.

It is not easy to see whether such trades are possible when my wife’s and my situation are depicted separately as they are in panels (a) and (b). Economists, beginning with the 19th-century economist Francis Edgeworth (1845–1926), have therefore developed a graphical technique that allows us to see the fundamentals of this exchange economy within a single picture.³ In panel (c),

An exchange economy is a model in which there is no production and people simply trade what they own.

³ It is generally believed that Edgeworth was also the first person to draw an indifference curve in his 1881 book titled *Mathematical Psychics*, where he also developed the idea of the “core” as well as the idea of “core convergence,” both introduced later in this chapter and developed further in the appendix.

GRAPH 16.1 Deriving a Graphical Depiction of a Two-Person, Two-Good Exchange Economy

we simply take the picture from panel (a) by the origin and “flip it over” so that the origin now lies on the northeast (i.e., upper right) rather than the southwest (i.e., lower left) corner. Then, we replicate panel (b) in panel (d) and move the “flipped” graph in panel (c) on top of this graph in such a way that point E_2 lies exactly on top of point E_1 . Although points E_1 and E_2 now appear to be the same point, they remain distinct points with the relevant levels of oranges and bananas read off the axis with the origin at the lower left corner for me and off the axis with the origin on the upper right corner for my wife.

The box in panel (d) of the graph is known as the *Edgeworth Box*. Notice that by moving point E_2 on top of point E_1 , we have caused the width of the box to be equal to 13 oranges and the height of the box to be 10 bananas, with 13 oranges and 10 bananas representing the total endowment that my wife and I jointly have. All the points inside the box therefore represent different ways of dividing the total endowment in our little economy between me and my wife. The endowment point $E = E_1 = E_2$ thus represents one possible way of dividing the total endowment in the economy: 3 oranges and 6 bananas for me and 10 oranges and 4 bananas for my wife.

The points in an Edgeworth Box represent all possible ways a two-good economy's endowment can be divided between two individuals.

EXERCISE 16A.1 What would the Edgeworth Box for this example look like if oranges appeared on the vertical and bananas on the horizontal axis?

EXERCISE 16A.2 What would the Edgeworth Box for this example look like if my wife’s axes had the origin in the lower left corner and my axes had the origin in the upper right corner?

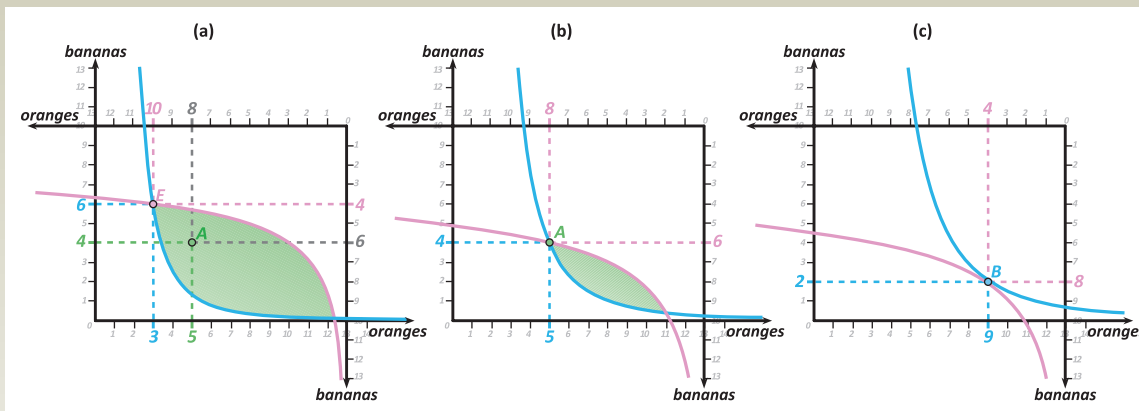

The potential for mutually beneficial trades can be seen in the Edgeworth Box as a lens-shaped area between indifference curves that pass through the endowment bundle.

16A.1.1 Mutually Beneficial Trades in the Edgeworth Box Since “more is better” for me, any bundle *above* the blue indifference curve is better for me. Similarly, any bundle above the magenta indifference curve in panel (a) of Graph 16.1 or *below* the magenta indifference curve in panel (c) is better for my wife. These areas are indicated by the shaded areas in panels (a) and (c) for my wife and panel (b) for me. In the Edgeworth Box, this then implies that all the divisions of the economy’s endowment that fall in the green lens-shaped area in panel (d) are better for me *and* my wife. It is this lens-shaped area that therefore contains bundles that we could reach in trades that are mutually beneficial to us; that is, in trades that both my wife and I would find attractive relative to not trading and consuming our individual endowments.

Suppose, then, that I approach my wife with the following romantic proposal: “I will trade you 2 bananas if you give me 2 oranges in exchange.” This would result in us moving from *E* to a new point *A* that gives me 5 oranges and 4 bananas and my wife 8 oranges and 6 bananas. Point *A* lies inside the lens we have concluded is mutually beneficial to both of us and is depicted in panel (a) of Graph 16.2. We are both more blissful at *A* than at *E*, which is what makes the trade I proposed so romantic.

In panel (b) of the graph, we assume that my wife has agreed to the trade I proposed and that we now have a new endowment bundle *A*. By graphing my (blue) indifference curve as well as my wife’s (magenta) indifference curve through this point, we can now ask whether there are additional gains from trading further. Since there is once again a shaded (green) area between our indifference curves, we can conclude that, while we are both better off at *A* than we were at our original endowment *E*, there are indeed additional gains from trade because whenever there are feasible bundles that lie *above* my indifference curve and *below* my wife’s, we can both do better by trading more. There is still room for more romantic trading!

GRAPH 16.2 Exhausting Gains from Trade in the Edgeworth Box

True or False: Starting at point *A*, any mutually beneficial trade will involve me trading bananas for oranges, and any trade of bananas for oranges will be mutually beneficial. (*Hint:* Part of the statement is true and part is false.)

EXERCISE
16A.3

It is therefore reasonable to assume that my wife and I will continue to trade until we reach a point in the Edgeworth Box that does *not* give rise to a lens-shaped area between our indifference curves through that point. Panel (c) of the graph illustrates such a point: point *B* that contains 9 oranges and 2 bananas for me and 4 oranges and 8 bananas for my wife. If we trade to the point *B* (where I have given up 4 bananas in exchange for 6 oranges from the original endowment *E*), we will find that any further trade that is proposed will make either me or my wife worse off. Put differently, if we reach point *B* in the Edgeworth Box, we will have exhausted all gains from trade and have thus reached an efficient division of our economy's endowment. With no further gains from trade, we will now have to find other ways of expressing our romantic inclinations toward one another.

In Chapter 6, we argued that consumers leave Walmart with the same tastes "at the margin," that is, with the same marginal rates of substitution between goods that they have purchased, and that this fact implies that all gains from trade have been exhausted. How is this similar to the condition for an efficient distribution of an economy's endowment in the exchange economy?

EXERCISE
16A.4

16A.1.2 The Contract Curve: Pareto Efficient Points in the Edgeworth Box Recall that a situation is *efficient*, or what is often referred to as *Pareto efficient*, if there is no way to make someone better off without making anyone else worse off. The division of our little economy's endowment at point *B* in Graph 16.2c is an example of such a situation: No matter what direction we move within the Edgeworth Box from point *B*, someone will be worse off. Points *E* and *A*, on the other hand, are not efficient because we found ways to move within the box such that both my wife and I became better off.

Point *B* is by no means, however, the only Pareto efficient distribution of the economy's endowment. Think of it this way: Suppose my wife gets all of the endowment, all 13 oranges and all 10 bananas, and, as a result, I get nothing. In the Edgeworth Box, this point lies at the lower left corner of the box, or the origin of the axes that refer to me. This point is also Pareto efficient because any movement away from this point, while making me better off, will make my wife worse off. Of course, despite my infatuation with my wife, I would never agree to move to this point if I start out with the endowment *E*, but that does not mean that, were we somehow to reach that point, it would not be Pareto efficient.

Starting at the point where my wife gets the entire endowment of the economy, are there points in the Edgeworth Box that make my wife worse off without making me better off (assuming that bananas and oranges are both essential goods for me)?

EXERCISE
16A.5

Is the point on the upper right-hand corner of the Edgeworth Box Pareto efficient?

EXERCISE
16A.6

If bananas and oranges are essential goods for both me and my wife, can any points on the axes (other than those at the upper right and lower left corners of the Edgeworth Box) be Pareto efficient?

EXERCISE
16A.7*

Now suppose that we consider an arbitrary blue indifference curve for me, such as that depicted in panel (a) of Graph 16.3. We can then start at a relatively low indifference curve

GRAPH 16.3 The Contract Curve: Pareto Efficient Allocations in the Edgeworth Box

(such as the grey curve) for my wife and ask if we can make her better off without pushing me below the blue indifference curve we have picked. As long as there is a lens-shaped area between the blue curve and the grey curve, the answer is yes, we can move to higher and higher indifference curves for my wife. This process stops when we reach the magenta indifference curve in the graph, a curve that is just tangent to the blue curve at point C . Once we reach C , any higher indifference curve for my wife implies that I will end up below the blue indifference curve.

Point C then represents another Pareto efficient point, an allocation of the economy's endowment where it is not possible to make one of us better off without making the other worse off. But of course we could have picked any other arbitrary indifference curve for me and gone through exactly the same process to find a tangency with an indifference curve for my wife, thus again arriving at a Pareto efficient allocation. Panel (b) of the graph then illustrates that there is a whole range of Pareto efficient points, beginning at the lower left corner of the Edgeworth Box and extending to the upper right corner. Points B (in Graph 16.2c) and C (in Graph 16.3a) are simply two examples of such points. Because it is reasonable to assume that, regardless of where the initial endowment in the economy falls, individuals will find trades (or "contracts") that lead to efficient allocations of the economy's endowment, *the entire set of Pareto efficient allocations of the economy's endowment is called the contract curve.*

Efficient allocations in the Edgeworth Box are those points where indifference curves of the two individuals are tangent; the set of all such efficient allocations is called the contract curve.

EXERCISE 16A.8* What would the contract curve look like if bananas and oranges were perfect complements for both me and my wife? (*Hint:* It is an area rather than a "curve.") What if they were perfect complements for me and perfect substitutes for my wife?

EXERCISE 16A.9* What does the contract curve look like if bananas and oranges are perfect substitutes (one for one) for both me and my wife? (*Hint:* You should get a large area within the Edgeworth Box as a result.)

16A.1.3 Mutually Beneficial Efficient Trades and the “Core” We have already noted that the mere fact that a particular allocation of bananas and oranges is Pareto efficient does not imply that we would expect that allocation to emerge from mutually agreed upon trades by me and my wife. After all, I already know that I can be guaranteed a minimum level of utility by simply consuming my endowment E_1 , and similarly my wife knows she can be guaranteed a minimum level of utility by consuming her endowment E_2 . No matter how good or bad we are at negotiating with one another, there is no reason to expect that either one of us will agree to trades that make us worse off than we were before we started trading. At the same time, we also saw that we both have an incentive to trade with one another so long as the allocation of bananas and oranges is not Pareto efficient.

As a result, it would be reasonable to predict that we will (1) trade until we have reached an efficient allocation that lies on the contract curve and (2) that neither one of us will be worse off than we were at our respective endowment points (E). In Graph 16.4, we therefore draw the indifference curves that my wife and I would attain were we to simply consume our endowment, the shaded (green) lens-shaped area that indicates the set of allocations that make both of us better off, and the (grey) line representing efficient allocations where our indifference curves are tangent to one another. Predicting that we will (1) exhaust all gains from trade and (2) agree only to trades that improve our well-being then implies that the set of possible allocations we might agree on will lie on the green portion of the contract curve.

Without knowing more about our relative bargaining skills, it is difficult to say much beyond that. My wife is clearly the better negotiator in our marriage, which would lead me to predict that we would probably end up on the lower portion of the green segment where my wife ends up enjoying more of the gains from trade than I do. If I am completely incompetent at bargaining, my wife might even end up convincing me to trade to the very lowest point on this green segment where I end up just as well off as I was at point E and she becomes much better off. But even my meager negotiating skills are sufficient to keep me from agreeing to anything less than that.

GRAPH 16.4 The Core: Predicting the Outcome from Negotiated Trades in the Edgeworth Box

In a two-person exchange economy, the “core” is equal to the part of the contract curve on which both individuals are better off than they are at their endowment.

This green segment on the contract curve is then often referred to as the *core* of the two-person exchange economy. *An allocation lies in the core if and only if no subset of individuals in the economy can make themselves better off by trading among one another.* In our example of an exchange economy with only two individuals, this implies that, for an allocation of the endowment to lie in the core, there is no way the two individuals can figure out a means for both to become better off. In the two-person case, the core is then equivalent to the set of Pareto efficient allocations that lies within the lens-shaped mutually beneficial region. As we will discuss shortly, however, when the economy is composed of more than two individuals, the core will typically be a subset of this (green) portion of the contract curve.

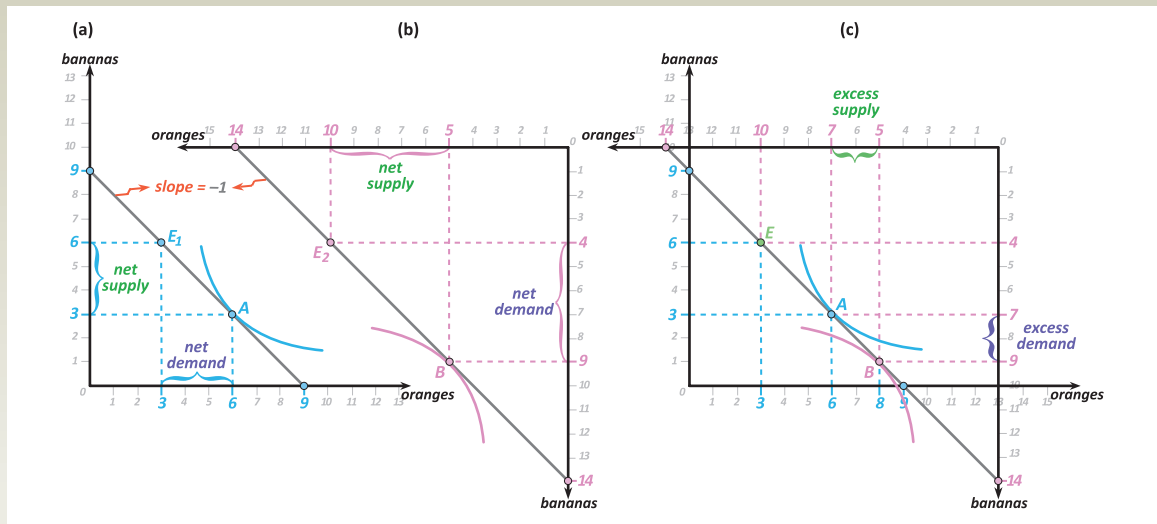

16A.1.4 Competitive Equilibrium in the Edgeworth Box Now suppose that you find yourself on the same secluded island and you agree to spare my wife and me the pain of negotiating with one another. To minimize marital conflict (and maximize marital bliss), you propose the following: You will try to find a set of prices for oranges and bananas such that I will agree to sell you some of my bananas and my wife will sell you some of her oranges, and you in turn will sell me some of the oranges you bought from my wife (and sell her some of the bananas you bought from me) at those same prices. My wife and I in turn promise to take the prices you quote as given and trade based on those prices; that is, we agree to be “price-takers.” Your problem, however, is that, since you have no bananas or oranges of your own, you have to find prices such that what I am selling you is what my wife will agree to buy and what I am buying from you is what my wife will agree to sell. Put differently, you will try to find prices such that demand for both goods is equal to supply.

First, remember from our development of budget constraints in Chapters 2 and 3 how such constraints arise when income is based solely on endowments (and not on some exogenous money income). Since it is always possible, regardless of what prices are quoted, for me to consume my endowment E_1 and not trade anything at those prices, E_1 will always lie on my budget constraint. The prices you quote will then determine the slope at which my budget line passes through point E_1 . More precisely, the ratio $-p_1/p_2$, or the price of good 1 (oranges) *relative* to the price of good 2 (bananas), determines the slope of my budget through my endowment E_1 . Since the *ratio* of prices is what matters when income is defined by an endowment, we can then simply let one of the prices be equal to 1 and focus on the other price. We can therefore start by setting the price of the good on the horizontal axis (oranges) to 1 and focus on the price of the good on the vertical axis (bananas). (The good whose price is set to 1 is often referred to as the *numeraire* in general equilibrium models.)

Suppose that you start by setting the price of bananas also equal to 1, thus making the ratio of prices 1. In essence, you have set prices such that 1 orange can be traded for 1 banana. Panel (a) of Graph 16.5 illustrates the resulting budget constraint for me, while panel (b) illustrates the budget constraint for my wife with her graph “flipped over” as it will appear in the Edgeworth Box. As a result, you notice that I choose A as my optimal consumption bundle on this budget, supplying 3 bananas to your store and demanding 3 oranges. My wife, on the other hand, chooses B as her optimal point, thus supplying 5 oranges and demanding 5 bananas. You should quickly notice that you have a problem: My wife is supplying more oranges than I am demanding from you, and I am supplying fewer bananas than she is demanding from you. The prices you have chosen therefore do not equilibrate supply and demand but rather cause an excess supply of oranges and an excess demand for bananas. This can be seen in the Edgeworth Box in panel (c) where my wife and I choose different allocations of bananas and oranges at the prices you have set. Put differently, at the current prices, my wife and I want to end up at different points in the Edgeworth Box, and there is no way for you to make both of our wishes come true. Under the prices as specified, we are in disequilibrium.

The only way that supply will equal demand is if, at the prices you quote, my wife is willing to give up exactly as many oranges as I want to buy and I am willing to give up exactly as many bananas as she is willing to buy. Since setting the price of bananas equal to the price of

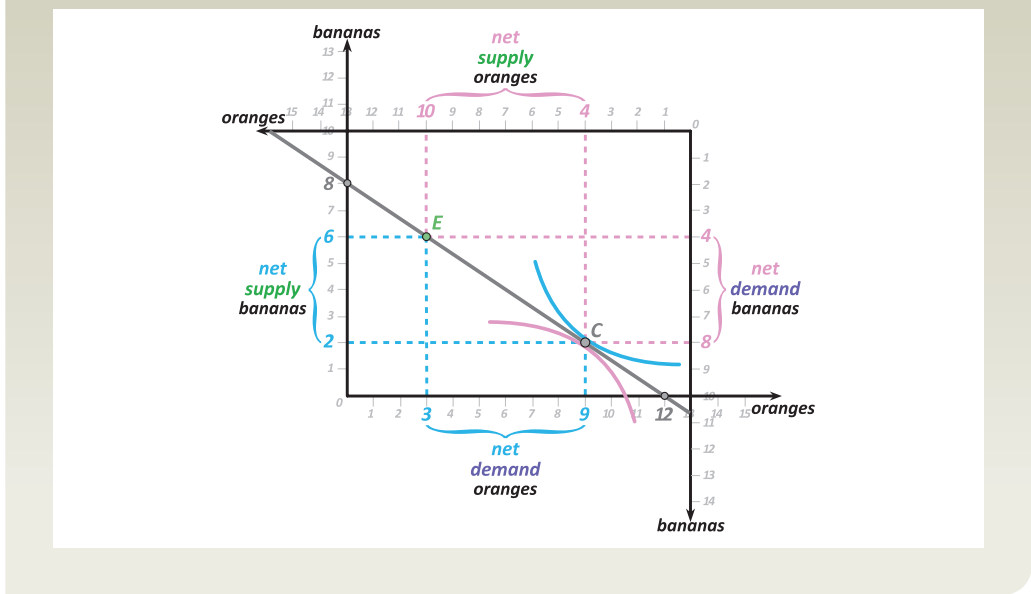

GRAPH 16.5 A Disequilibrium Price: Supply Is Not Equal to Demand

Go to MindTap to interact with this graph.

oranges (as we did in Graph 16.5) resulted in an excess supply of oranges and an excess demand for bananas, it would seem reasonable that you have set the price of bananas too low relative to the price of oranges. So suppose you next try to raise the price of bananas to 1.5 (leaving the price of oranges at 1). The resulting price ratio is then 2/3, forming the budget constraint in the Edgeworth Box of Graph 16.6.

GRAPH 16.6 Competitive Equilibrium Prices: Supply Equals Demand

**EXERCISE
16A.10**

What are the intercepts of this budget on my wife’s axes for oranges and bananas?

Equilibrium prices in the Edgeworth Box cause both individuals to choose the same point.

Since oranges have become relatively cheaper and bananas relatively more expensive, I end up choosing to demand more oranges while my wife decides to demand fewer bananas. If you have raised the price of bananas by just the right amount, this will result in the quantities demanded and supplied by my wife and me to exactly equal one another, which in turn results in both of us choosing the same point in the Edgeworth Box as our optimal point. Of course, this does not mean that we will consume identical bundles since my wife’s consumption bundle is read off of a different axis than mine. In Graph 16.6, my wife sells 6 oranges (earning \$6) and buys 4 bananas (for \$6) while I sell 4 bananas (earning \$6) and buy 6 oranges (for \$6). Demand equals supply and we end up choosing the allocation *C*. You have therefore successfully found a set of prices that result in both me and my wife individually optimizing in such a way that we end up at *C*. Since these prices then result in demand equaling supply when my wife and I act as price-takers, they are *competitive equilibrium prices* for our economy.

**EXERCISE
16A.11**

Suppose both oranges and bananas are normal goods for both me and my wife. Draw separate graphs for me and my wife, with the initial budget constraint when the prices were both equal to 1 and the new budget constraint when the price of bananas is raised to 1.5. Illustrate, using substitution and wealth effects, why my demand for oranges will unambiguously increase and my wife’s demand for bananas will unambiguously decrease. Can you say unambiguously what will happen to my demand for bananas and my wife’s demand for oranges?

**EXERCISE
16A.12**

Suppose you had decided to leave the price of bananas at 1 and to rather change the price of oranges. What price (for oranges) would you have to set in order to achieve the same equilibrium outcome?

**EXERCISE
16A.13**

Suppose you set the price of oranges equal to 2 instead of 1. What price for bananas will result in the same equilibrium outcome?

Of course, there is something artificial in this exercise: Why would individuals in a two-person economy ever be price-takers? In such a setting, it is much more reasonable to assume that the two individuals find their way to an efficient outcome through bargaining rather than assuming some fixed price. But the only reason we have restricted ourselves to a two-person exchange economy here is that it allows us to graph some basic intuitions and derive some fundamental results. This same intuition, it turns out, then works for much larger economies in which there are many individuals who could reasonably be assumed to take prices as given since each is small relative to the economy.

One final note before we move on: We have implicitly assumed thus far that there exists only one competitive equilibrium in an exchange economy like the one composed of me and my wife. For most of the mathematical examples that we would usually work with, this is in fact the case. But one can imagine instances where indifference maps for me and my wife are such that more than one equilibrium is possible. We will explore scenarios of this type in some end-of-chapter exercises (such as exercise 16.7).

16A.2 The Fundamental Welfare Theorems and Other Results

Three basic results lie at the heart of general equilibrium theory, and an understanding of these in turn lies at the heart of appreciating the role markets play, the limits they encounter, and the degree to which nonmarket institutions can improve on market outcomes. The first is one we have already

encountered in our partial equilibrium model of competitive markets. It is the *first welfare theorem* that provides conditions under which market outcomes are efficient. The second, known as the *second welfare theorem*, is in some sense the inverse of the first: It states that, as long as the government can redistribute endowments in a lump sum way, any efficient allocation can in fact be a market equilibrium. Thus, if initial endowments result in an equilibrium that gives rise to unacceptable levels of inequality (for instance), then, in the presence of lump sum redistribution, the government can rely on markets to produce more equitable outcomes once it redistributes some endowments. Finally, it has been shown that, as economies become large, the core of an economy shrinks down to just the set of market equilibrium outcomes, a result we will refer to as *core convergence*. This is perhaps the most abstract of the results, but it provides some real reason as to why we think the concept of a competitive market equilibrium is such a powerful one for predicting outcomes. Since it is reasonable to expect that individuals, using their bargaining skills, will trade with one another until they reach an allocation in the core, the result suggests that when individual bargaining power is diluted as many consumers enter an economy, the competitive equilibrium outcome is in fact the only one we should expect to arise. We will discuss each of these results in sequence.

16A.2.1 The First Welfare Theorem In the previous chapter’s “partial equilibrium” model where we investigated a single market at a time, we derived our first version of what we called the “First Welfare Theorem.” This theorem states simply that, under certain conditions, the competitive equilibrium in a market is efficient. We can now see in the “general equilibrium” model of an exchange economy (where we are analyzing equilibrium across several markets such as the market for oranges and for bananas) that the same theorem holds (again under the conditions outlined at the end of the previous chapter).

In the two-person, two-good exchange economy of the Edgeworth Box, the insight is almost instantly obvious in Graph 16.6: Since an equilibrium price results in the two consumers optimizing along their budgets at the same point in the Edgeworth Box, and since their indifference curves are tangent to identically sloped budget constraints, the indifference curves are tangent to one another. As we saw earlier, when an allocation in the Edgeworth Box is such that the indifference curves through that allocation are tangent to one another and therefore do not give rise to a lens-shaped area in between the indifference curves, the allocation is Pareto efficient. This insight holds for exchange economies with many individuals and many goods as well, with the intuition virtually identical to what emerges from the simple Edgeworth Box.

The First Welfare Theorem states that, under certain conditions, the allocation achieved through competitive equilibrium prices is efficient.

True or False: When the First Welfare Theorem holds, competitive equilibria in an exchange economy result in allocations that lie on the contract curve but not necessarily in the core.

EXERCISE
16A.14

16A.2.2 The Second Welfare Theorem While, as we discussed in some detail in Chapter 15, the First Welfare Theorem contains remarkable insights, it does not imply that we necessarily have to believe that the allocation of goods that results from competitive market prices is “good.” Rather, the theorem simply tells us that, under the conditions outlined in Chapter 15, the market allocation of goods will be efficient. As we have seen in our derivation of the contract curve, however, there are many different “efficient” allocations, and most of us would probably judge some of these to be more desirable than others. For instance, under many notions of “equity” or “fairness,” we might be disturbed if the allocation in the economy is such that one person gets almost everything while everyone else gets little to nothing, even if that allocation is Pareto efficient.

Thinking along these lines leads us to a second general equilibrium insight known as the *Second Welfare Theorem*. This theorem is in some sense a mirror image of the first. It states that *any Pareto efficient allocation can result from a competitive equilibrium so long as the initial endowments are redistributed appropriately*. Thus, while the First Welfare Theorem says that competitive equilibria are efficient, the Second Welfare Theorem says that any efficient

The Second Welfare Theorem states that, under certain conditions, any efficient allocation can be supported through competitive equilibrium prices once appropriate (lump-sum) redistribution of endowments has been undertaken.

allocation can be a competitive equilibrium allocation *so long as the government can redistribute endowments without shrinking the economy in the process.*

Again, the intuition for this is easily seen in the Edgeworth Box for two-person, two-good exchange economies. Suppose, as before, that E in Graph 16.7 is the initial endowment point for this economy but that, for some reason, we wanted to get the efficient allocation D to be the competitive equilibrium allocation. It should be clear that no set of prices for bananas and oranges could possibly result in my wife and me trading from E to D ; after all, the magenta indifference curve that contains D lies *below* E , which implies that my wife would prefer to consume her initial endowment rather than agree to trade to D .

If D were to become an equilibrium allocation, it would have to be the case that we could draw a budget constraint into the Edgeworth Box such that this constraint passes through D and has exactly the slope of the blue and magenta indifference curves at point D . The green line in Graph 16.7 satisfies these conditions and would therefore have to be the equilibrium budget constraint for me and my wife in order for D to be an equilibrium allocation. But, since budget lines always pass through endowment points, the only way this line can be a budget constraint for us is if our endowment point lies on that line. For instance, were our initial endowment at E' rather than E , then D would be an equilibrium allocation.

The Second Welfare Theorem as stated at the beginning of this section says that any efficient allocation can be an equilibrium allocation so long as the initial endowments are redistributed appropriately. In our example in Graph 16.7, one “appropriate” redistribution from the initial endowment E would be to redistribute 5 oranges and 2 bananas from my wife to me, which would make the new endowment point E' .

EXERCISE 16A.15

Can you think of other redistributions of oranges and bananas that would be “appropriate” for ensuring that D is the competitive equilibrium outcome?

GRAPH 16.7 The Second Welfare Theorem

Go to MindTap to interact with this graph.

At first glance, this Second Welfare Theorem seems very powerful because it appears to suggest that, if we find the competitive market outcome inequitable, we can redistribute the endowments of individuals in the economy in a more “equitable” manner and then allow the market to find a new equilibrium that will once again be efficient. Thus, the theorem appears to suggest that there is no trade-off between equity and efficiency, that we can achieve more equitable market outcomes through redistribution of endowments and then rest assured that the market will preserve efficiency.

Given what we have learned in earlier chapters, however, we need to be very cautious in not reading too much into this “first glance” impression of what the Second Welfare Theorem states. The hidden assumption in the theorem is that we can undertake redistribution without cost, that we can redistribute without shrinking the size of the economy. Put differently, the Second Welfare Theorem assumes that “lump sum redistribution”—redistribution through the use of lump sum taxes and subsidies—is possible. However, as we have argued in previous chapters, lump sum taxes and subsidies are exceedingly rare in the real world, and almost all real-world taxes and subsidies give rise to deadweight losses. Put differently, redistribution achieved through real-world (distortionary) taxes and subsidies shrinks the economy (or the Edgeworth Box). Thus, it isn’t really possible to “redistribute appropriately” as the Second Welfare Theorem envisions because real-world redistributions will result in inefficiencies. As a result, if endowments in an economy are inequitably distributed, leading to an efficient but inequitable market outcome, a trade-off between equity and efficiency emerges, with redistribution leading to inefficiency but potentially more equity (depending on how one defines what is equitable). We will return to this issue more explicitly in Chapter 29.

In the real world, an efficiency-equity trade-off emerges because lump sum redistribution is generally not possible.

16A.2.3 Equilibrium and the Core We began our discussion of the simple Edgeworth Box exchange economy by asking where trade by two individuals (like my wife and me) might take them. Our conclusion was that it would be reasonable to assume that individuals would continue to trade until no further mutually beneficial trades were possible and that this implies that they will end up with some allocation of the economy’s endowment that lies in the core (i.e., on the contract curve and between the indifference curves through the original endowment). Where exactly they would end up in the core depended on assumptions about the individuals’ relative bargaining skills, but nothing outside the core was likely to last since individuals would still have an incentive to find mutually beneficial trades.

We then defined a much stricter (and seemingly unrelated) tool for predicting where individuals in Edgeworth Box exchange economies would end up: competitive prices. We acknowledged at the outset that, with only two individuals in the economy, the assumption of competitive, or “price-taking,” behavior is silly, but we foreshadowed that terms of trade arising from competitive prices (rather than relative bargaining skills) would be more realistic and important in general equilibrium economies with many individuals.

As it turns out, however, the core and the set of competitive equilibrium allocations in an exchange economy are quite related. You should be able to easily convince yourself from what we have done that the competitive equilibrium allocation *must* lie in the set of core allocations but that the latter is typically a much larger set than the former. What is not obvious from what we have done so far is that, as an exchange economy gets “larger,” the set of core allocations shrinks; and as the size of the economy becomes really large, the core shrinks to just the set of competitive equilibrium allocations. Thus, were we to predict who gets what in a large exchange economy by simply finding allocations that lie in the “core” of the economy, it would be exactly the same exercise as finding the set of allocations that can be supported by competitive market prices. Put differently, in large economies, only stable allocations in which no subgroup can find a way to make itself better off can arise as a competitive equilibrium, and no allocation that cannot arise as a competitive equilibrium has that stability property.

If this sounds interesting to you, you can explore the intuition behind this result in much more detail in the appendix to this chapter. But the basic intuition behind the result goes as

As an exchange economy becomes large, the bargaining power of each individual becomes small and thus the core converges to the set of competitive equilibrium allocations.

follows: We know that when it is only me and my wife in the economy, I have bargaining power because the only way my wife is ever going to be able to make a trade is to make it with me. But as we envision larger economies with other consumers who are a lot like me, my wife suddenly has options: If I don’t trade with her, she can find someone else who is pretty similar to me to trade with. Thus, the increasing competition from others like me reduces my bargaining power. Similarly, as the economy gets large there are others like my wife, and her bargaining power is decreasing for the same reason as mine. What is remarkable is that the competition between me and consumers like me as we all try to make bargains without any reference to any prices leads to the exact same outcome as if we were in a competitive equilibrium in which market prices (rather than competition with others in bargaining) governed everyone’s behavior.

Think of it this way: Suppose you compare two countries that are identical in all ways except that in one there are shopping malls in which stores post their prices (with “no haggling” allowed or tolerated) and in the other the stores post no prices but each merchant tries to get you to bargain about the price. In the first country, we would predict that who gets what is determined by a competitive market process in which individual behavior is guided by the posted prices. In the second country, on the other hand, we would predict that who gets what depends on bargaining skills of individuals as everyone tries to haggle toward the best possible deal. But if there are many similar shops along the street, our results suggest that the competition between similar merchants will lead to exactly the same outcome as the price mechanism produces in the first country.

16A.3 A Simple “Robinson Crusoe” Production Economy

Suppose that on the way to the island in the Bahamas, my wife and I encountered unexpected turbulence and I was accidentally ejected from the airplane as I panicked and pressed the “eject” button. Fortunately, I always travel with a parachute strapped to my back, and so I was able to land safely on one of the many islands in the Bahamas. But the love of my life, who has a pilot’s license and does not panic as easily, ended up landing the plane safely on another island, leaving me to fend for myself on my island without any of the provisions of oranges and bananas we had packed.

If I am going to survive, I will therefore have to expend some effort to find food. Suppose I find that the only food that grows on this island is bananas. You could then think of me as a producer and a consumer: I am a producer who uses labor to produce bananas, and I am a consumer who gives up leisure in order to be able to eat. I am just like the fictional character Robinson Crusoe, which is why the “economy” I find myself in is often referred to by economists as a *Robinson Crusoe economy*.⁴ It is the simplest possible economy that contains both a producer and a consumer.

If you thought an exchange economy with me and my wife trading oranges and bananas was silly, you will surely find the Robinson Crusoe economy in which I act as both a producer and consumer of bananas silly. And, taken at face value, both these types of economies are silly. But, as we have now said repeatedly, they illustrate, within a simple setting in which we can use graphs, the very insights that continue to hold up in much more complicated economies. So, if the idea of a single consumer and a single producer behaving competitively really bothers you, just remember that the analysis holds equivalently for a large number of identical consumers and producers. And the broader results further apply to economies with many different types of consumers and producers.

16A.3.1 Robinson Crusoe Doing the Best He Can We can imagine my search for bananas as being characterized by a set of feasible production plans inside a simple production frontier such as the one depicted in Graph 16.8a. Here, the only input into production is labor

⁴Daniel Defoe published the novel *Robinson Crusoe* in 1719. The novel explores the fictional life of an English castaway (named Robinson Crusoe) stranded on a remote tropical island. While Robinson Crusoe initially finds himself alone, he eventually encounters natives, most notably a man he names “Friday,” and escapes our “Robinson Crusoe production economy.”

A Robinson Crusoe economy is the simplest possible model that contains both a producer and a consumer.

GRAPH 16.8 Robinson Crusoe Choosing His Optimal Bundle

hours per week ℓ on the horizontal axis, and the only output is the number of bananas harvested per week x on the vertical axis. We assume that the producer choice set ends at $\ell = 60$ and thus assume that I have a total leisure endowment of 60 hours per week.

Does this production frontier exhibit increasing, decreasing, or constant returns to scale? Is the marginal product of labor increasing, constant, or decreasing?

EXERCISE
16A.16

In panel (b) of the graph, we illustrate a set of indifference curves for me on a graph that again has labor hours on the horizontal and bananas on the vertical axis. Since we are illustrating these indifference curves with *labor* rather than *leisure* on the horizontal axis, I become better off as my consumption bundle shifts to the northwest of the graph, with less labor (i.e., more leisure) and more consumption.

As drawn, which of our usual assumptions about tastes—rationality, convexity, monotonicity, continuity—are violated?

EXERCISE
16A.17

Panel (c) of the graph then combines the first two panels to illustrate the optimal decision for me on this island. Once I reach the bundle that has me working 30 hours per week and consuming 72 bananas, I have reached the highest possible indifference curve that still contains at least 1 bundle that lies within my producer choice set.

16A.3.2 Robinson Crusoe with a Split Personality So far, there isn't much of a market here; I am simply choosing my optimal bundle from my choice set, with no one trading anything at any particular prices. But now let's imagine that I have a split personality, with part of me

acting only as a profit-maximizing producer and part of me acting only as a utility-maximizing consumer. Let’s assume further that both parts of me behave as price-takers, taking as given the price of labor w and the price of bananas p .

In panel (a) of Graph 16.9, we then simply graph the producer’s profit maximization problem, with isoprofit lines representing the indifference curves for me as a producer. This is identical to the single-input production analysis of Chapter 11 where each isoprofit line corresponds to all production plans that yield a given level of profit. As we derived in Chapter 11, the intercept of an isoprofit is equal to the profit π along that set of production plans divided by p , and the slope of each isoprofit is w/p . The profit-maximizing production plan A is one that hires 11 labor hours and produces 43 bananas per week.

In panel (b) of the graph, we then view the problem entirely from the perspective of me as a consumer who faces the price p for bananas and the wage w per labor hour. In addition, to whatever extent the firm is producing profits π , we will assume that I, as the owner of the firm, take that profit as part of the income I derive and can use for purchasing bananas, and we’ll assume as we have done in previous chapters that I have a total endowment of 60 leisure hours per week that I can potentially devote to earning income (by selling leisure at the wage w).

Even if I do not work at all, I will have the profits of the firm available for spending on bananas. For instance, if my profits from the firm are \$60 and the price of a banana is $p = 10$, I can purchase 6 bananas without expending any labor effort. Thus, my budget constraint starts at the intercept π/p . As I sell labor, I will earn a wage w with which I can buy additional bananas. I will earn w for the first hour I sell, which will permit me to buy w bananas if the price of a banana is \$1 or w/p bananas if the price is given by p . Thus, the slope of my budget, starting at the intercept π/p , is w/p , and my budget constraint ends when I have sold all my 60 available leisure hours.

We can then add the indifference curves from Graph 16.8b to panel (b) of Graph 16.9 to find the optimal consumption bundle B given this budget constraint: 36 hours of labor and 94 bananas per week.

GRAPH 16.9 Robinson Crusoe as Price-Taking Producer and Consumer

16A.3.3 Disequilibrium and Equilibrium in the Robinson Crusoe Economy It should be immediately obvious from the two panels of Graph 16.9 that the wage and price that are being taken as given by me as a producer and me as a consumer are *not* equilibrium prices. As a producer, I want to hire 11 hours of labor to produce 43 bananas per week, but as a consumer I want to sell 36 hours of labor to consume 94 bananas per week. There is thus an *excess supply of labor* and an *excess demand for bananas* under this wage and price.

At competitive equilibrium prices, Robinson Crusoe will choose the same point in his role as a producer as he does in his role as a consumer.

We can illustrate this disequilibrium in a single graph once we notice that the budget constraint in panel (b) of Graph 16.9 is exactly identical to the optimal isoprofit line in panel (a). Moving the two panels on top of each another, we get panel (a) of Graph 16.10, with the producer choosing bundle *A* that is feasible and the consumer choosing bundle *B* that is not feasible in this economy. In order for this economy to be in equilibrium, *p* and *w* have to change such that the optimal production plan for the producer coincides with the optimal consumption plan for the consumer.

Panel (b) then illustrates a combination of *w** and *p** that results in such an equilibrium. Here, both the producer and the consumer, taking *w** and *p** as given, choose optimal plans (point *C*) that result in demand equaling supply in both the labor and output markets.

16A.3.4 First and Second Welfare Theorems Recall that a first welfare theorem is a theorem that specifies the conditions under which a competitive equilibrium is (Pareto) efficient. In an economy with a single individual, Pareto efficiency simply means that the single individual, our Robinson Crusoe, is doing the best he can given his circumstances. In Section 16A.3.1, we illustrated how I would choose the best possible bundle available to me on this deserted island: I simply found the highest indifference curve that still contained a consumption bundle that was feasible (in Graph 16.8). In panel (b) of Graph 16.10, on the other hand, we illustrated a competitive market equilibrium in which I maximize profits as a producer and maximize utility as a consumer, subject to market prices *p** and *w**. If you simply remove the isoprofit line (which doubles as the consumer budget constraint) in Graph 16.10b, you are left with exactly Graph 16.8c that

illustrated how I “do the best I can given my circumstances.” Thus, *the competitive equilibrium in the Robinson Crusoe economy is Pareto efficient* and the first welfare theorem holds. Similarly, we can quickly see that the second welfare theorem holds in the Robinson Crusoe economy. Recall that the second welfare theorem says that any Pareto optimum in an economy can be supported as an equilibrium. A Pareto optimum simply looks like Graph 16.8c with an indifference curve tangent to the production frontier. But this means that we can fit a line that is tangent to both the production frontier and the optimal indifference curve, a line that defines a ratio w/p , which results in this optimum being an equilibrium so long as the producer and consumer both take w and p as given. In end-of-chapter exercise 16.5, we will illustrate a caveat to this conclusion: The second welfare theorem is guaranteed to hold only if the producer choice set and tastes are arc convex. (The same caveat applies to the second welfare theorem for exchange economies.)

16A.4 General Equilibrium Analysis and Policy

Public policy is often all about making large institutional changes in an economy, changes that alter the budget constraints faced by consumers, the production constraints faced by producers, and/or the prices faced by both. The first welfare theorem suggests that such policy changes will generate inefficiencies unless there are already distortionary forces at work and the policy is designed to combat the impact of these forces. Much of the remainder of the book is devoted to carefully analyzing the types of distortionary forces that invalidate the conclusions of the first welfare theorem and thus give rise to the possibility of nonmarket institutions improving efficiency.

But there is also a more general lesson that emerges from taking a general equilibrium view of policy analysis. As we will see in upcoming chapters, for instance, taxes and subsidies change the prices in particular markets. Sometimes, these changes happen in such a way that we can isolate a market and analyze it fruitfully without considering the general equilibrium in an economy, but often, even if a policy explicitly alters only a single price, individual decisions that follow then “spill over” in important ways into other markets. This complicates policy analysis considerably, but economists have shown that the general equilibrium effects (or the *unintended* consequences) that follow from a policy change are frequently more important than the initial partial equilibrium effects (or the *intended* consequences) that a policy maker might have at the forefront of his or her mind. Although the tools we have developed will not always allow us to demonstrate this to the extent to which more complex models can, we will see hints of this basic theme repeatedly in upcoming chapters. For now, however, I want to just offer an example of a case that has been important in some of my own research.

Suppose we want to analyze the way in which schools are financed. In the United States, public schools are financed by a combination of local and state taxes, and children are admitted to public schools based on where their parents live. This has resulted in a particular equilibrium in which the quality of local public schools shows up in housing prices, with houses in good public school districts often significantly more expensive than houses in bad public school districts. As a result, while public schools are nominally “free,” parents effectively pay tuition by paying a higher housing price in good districts than in bad districts. This pricing of public school access through housing markets in turn supports an equilibrium in which public schools differ dramatically in quality, with poorer parents relegated to worse public school districts because they cannot afford housing in good school districts.

Now suppose the government considers a new policy: private school vouchers. Such vouchers are simply pieces of paper that have a dollar figure printed on them, and the holder of such a voucher can take this piece of paper and use it toward tuition in a private school (which the private school can then present to the government for reimbursement). If we simply think of this policy in “partial equilibrium” terms, we would then analyze how budget constraints of households change as a result of receiving a voucher and conclude from that who will take the voucher

and switch to a private school. (This was done in end-of-chapter exercise 14.10.) But it turns out that such a partial equilibrium analysis will miss what are likely the most important effects resulting from the introduction of government-funded private school vouchers.

Think of it this way: Consider the “marginal” family that is stretching its budget to buy a relatively small house in a good school district in order to send the children to good public schools. Now this family receives a voucher that makes private schooling a real option. If the family chooses to use the voucher, why would it continue to pay the high premium on housing in the good public school district? The answer is that it would not, and that this family can likely find real housing bargains in a bad public school district now that it no longer cares about the public school in that district. Using the voucher for this family therefore implies a move to a larger house in another district, which in turn drives up demand for such housing and therefore causes an increase in housing prices in bad school districts (and a corresponding decrease in prices for houses in good school districts). This in turn implies that those who own houses in bad school districts will see an increase in their wealth (because their houses are worth more) while those who own houses in good school districts will see a decline in their wealth (as their housing prices fall). The introduction of private school vouchers, aimed at altering individual decisions about schooling, therefore causes general equilibrium price effects in housing markets, which in turn cause wealth effects that alter decisions individuals make. Research on this suggests that most families will be impacted more by these general equilibrium changes in housing markets than by the change in school markets, which implies that an analysis of school vouchers that ignores general equilibrium effects will lead to incorrect predictions about who benefits and who is hurt by this policy.⁵

In votes on referenda on school vouchers, researchers have found that renters vote differently than homeowners. Consider a renter and homeowner in a bad public school district. Who do you think will be more likely to favor the introduction of school vouchers and who do you think will be more likely to be opposed?

**EXERCISE
16A.18**

How do you think the elderly (who do not have children in school but who typically do own a home) will vote differently on school vouchers depending on whether they currently live in a good or bad public school district?

**EXERCISE
16A.19**

If you were considering opening up a private school following the introduction of private school vouchers, would you be more likely to open your school in poor or in rich districts?

**EXERCISE
16A.20**

Suppose two different voucher proposals were on the table: The first proposal limits eligibility for vouchers only to families below the poverty line, while the second limits eligibility to those families who live in bad public school districts. Which policy is more likely to lead to general equilibrium effects in housing markets?

**EXERCISE
16A.21**

This is just one example of how policy analysis that focuses too narrowly on partial equilibrium effects can be misleading. At this point, a general lesson from our example is simply that, after thinking through the partial equilibrium effects of a policy, we should ask carefully: Are there other markets that are likely to be impacted in significant ways by this policy? If so, how are these effects likely to change our predictions?

⁵ See, for instance, T. Nechyba, “Mobility, Targeting and Private School Vouchers,” *American Economic Review* 90, no. 1 (2000), 130–46.

16B

THE MATHEMATICS OF COMPETITIVE GENERAL EQUILIBRIUM

General equilibrium theory is one of the more mathematical branches of modern economics, and we will here only scratch the surface of a rich literature that evolved over the latter half of the 20th century. At its heart lie the basic insights developed intuitively in part A of this chapter—the nature of competitive equilibrium prices, the first and second welfare theorems and the idea that the “core” of an economy converges to the set of competitive equilibria if the economy gets large. We will show in this section how the basic model of an exchange economy can be formalized for many individuals and many goods, and we will prove somewhat more formally the first welfare theorem. But our main focus will be on demonstrating how we can use the basic tools we learned so far to calculate an equilibrium in both an exchange economy and a Robinson Crusoe economy.

16B.1 A Pure Exchange Economy

An exchange economy is fully defined by the set of endowments and preferences of individuals in the economy.

When we introduced the concept of an exchange economy in Section 16A.1, we defined it as *an economy in which there is no production and in which consumers are endowed with different bundles of goods*. More formally, we can define an exchange economy as a collection of consumers with preferences and endowments. Suppose, for instance, that the economy contains N consumers (denoted by $n = 1, 2, \dots, N$) who choose among M goods (denoted by $m = 1, 2, \dots, M$). An exchange economy is then fully defined by

$$\{(e_1^n, e_2^n, \dots, e_m^n)\}_{n=1}^N, \{u^n: \mathbb{R}^M \rightarrow \mathbb{R}^1\}_{n=1}^N, \quad (16.1)$$

where $(e_1^n, e_2^n, \dots, e_m^n)$ gives the endowment of each of the M goods for individual n and $u^n: \mathbb{R}^M \rightarrow \mathbb{R}^1$ is individual n 's utility function over the M goods. The notation $\{\}_{n=1}^N$ then simply indicates that whatever appears in the curly brackets is listed for each of the N different consumers in the economy.⁶ It will be our convention in this chapter to let individuals appear as superscripts and goods as subscripts; thus e_m^n is read as “individual n 's endowment of good m .”

Suppose we returned to the example (from Section 16A.1) of me and my wife on a weekend getaway with oranges and bananas on a deserted island. In this case, $N = 2$ (since there are only two consumers) and $M = 2$ (since the only goods are oranges and bananas). In this example, I am endowed with 3 oranges and 6 bananas while my wife is endowed with 10 oranges and 4 bananas. Letting oranges be denoted by x_1 and bananas by x_2 , and letting me be denoted by the superscript 1 and my wife by the superscript 2, we can then denote our endowments as $(e_1^1, e_2^1) = (3, 6)$ and $(e_1^2, e_2^2) = (10, 4)$. Furthermore, our tastes are represented by a utility function $u^1: \mathbb{R}^2 \rightarrow \mathbb{R}^1$ for me and $u^2: \mathbb{R}^2 \rightarrow \mathbb{R}^1$ for my wife, and in many of the graphs in Section A we have implicitly assumed that $u^1(x_1, x_2) = x_1^{3/4}x_2^{1/4}$ and $u^2(x_1, x_2) = x_1^{1/4}x_2^{3/4}$.

The endowment point in such an economy is, as we have seen in the Edgeworth Box, only one possible way of dividing the economy's endowment among the individuals in the economy. Any other allocation of goods between the individuals in the economy is *feasible* so long as we are not allocating more of each good than what is available overall. For any good m , we can define the economy's overall endowment E_m by simply adding up all the individual endowments; that is,

$$E_m = e_m^1 + e_m^2 + \dots + e_m^N. \quad (16.2)$$

We can then define the *set of feasible allocations* FA in an exchange economy as

$$FA = \{(x_1^n, x_2^n, \dots, x_M^n)\}_{n=1}^N \in \mathbb{R}_+^{NM} \mid x_m^1 + x_m^2 + \dots + x_m^N = E_m \text{ for all } m = 1, 2, \dots, M\}. \quad (16.3)$$

An allocation is a division of the economy's endowment across the individuals in the economy. The set of endowments is one such allocation.

⁶ An even “purer” form of defining an exchange economy would simply specify a preference ordering rather than a utility function representing that preference ordering for each consumer.

The statement to the left of the “|” sign simply states that the allocation has to specify how much of each of the M goods each individual is allocated. Since there are M goods and N individuals, this implies that we have to specify NM quantities, and thus a point in \mathbb{R}_+^{NM} . The statement following the “|” sign indicates that the sum of what is given out for each of the M goods must be equal to the overall endowment (of that good) that is available in the economy. We can then read the full statement in equation (16.3) as “the set of feasible allocations of goods to individuals is such that the total amount of each good that is allocated between the individuals is equal to the economy’s endowment of that good.” When $M = N = 2$ in our example, this set is equivalent to what we have drawn as the allocations in the Edgeworth Box and can be written formally as

$$FA = \{(x_1^1, x_2^1, x_1^2, x_2^2) \in \mathbb{R}_+^4 \mid x_1^1 + x_1^2 = 13 \text{ and } x_2^1 + x_2^2 = 10\}. \quad (16.4)$$

The set of feasible allocations in an exchange economy is equal to the Edgeworth Box when there are two goods and two individuals.

Can you see how the Edgeworth Box we drew in Section A contains all the allocations in this set?

EXERCISE
16B.1

True or False: The Edgeworth Box represents a graphical technique that allows us to graph in a two-dimensional picture points that lie in four dimensions.

EXERCISE
16B.2

16B.1.1 Mutually Beneficial Trades Before we engage in any trade, my wife and I can already achieve some level of “utility” by simply consuming our endowments. We can refer to the level of utility that we can attain on our own as our *reservation utility*. In order for trade to be mutually beneficial, it must be that the division of the economy’s endowment that emerges from trade gives each one of us at least our reservation utility. Letting individual n ’s reservation utility be denoted by U^n , we can calculate the appropriate reservation utility value by simply evaluating utility at the endowment; that is,

$$U^n = u^n(e_1^n, e_2^n, \dots, e_M^n). \quad (16.5)$$

What are the reservation utilities for me and my wife in our example (given the utility functions previously specified)?

EXERCISE
16B.3

The set of allocations (of the economy’s endowment) that is mutually beneficial for everyone in the economy (denoted MB) is then simply the set of feasible allocations that give each consumer at least his or her reservation utility; that is,

$$MB = \{(x_1^n, x_2^n, \dots, x_M^n)_{n=1}^N \in FA \mid u^n(x_1^n, x_2^n, \dots, x_M^n) \geq U^n \text{ for all } n = 1, 2, \dots, N\}. \quad (16.6)$$

The statement to the left of the “|” sign simply states that the allocation has to be a feasible allocation, while the statement after the “|” sign states that, given what each of the N individuals is given, it must be the case that everyone achieves at least his or her reservation utility. We can then read the full statement in equation (16.6) as “the set of mutually beneficial allocations is equal to the set of feasible allocations of goods to individuals such that each individual attains at least his or her reservation utility.” This is equivalent to the set of allocations in the lens-shaped area between the indifference curves that pass through the endowment point in an Edgeworth Box.

The mutually beneficial allocations are those that make some people better off without making anyone worse off relative to the endowment allocation.

For the example of me and my wife, write the set of mutually beneficial allocations in the form of equation (16.6). Can you see that the lens-shaped area identified in the Edgeworth Box in Graph 16.2 is equivalent to this set?

EXERCISE
16B.4

The set of Pareto efficient allocations is composed of those allocations from which any deviation will make at least someone worse off.

16B.1.2 The Contract Curve As we saw in our development of the Edgeworth Box in Section A, not all mutually beneficial trades necessarily lead to a Pareto efficient allocation nor is it the case that all efficient allocations lie in the lens-shaped region of mutually beneficial trades. In Graph 16.2, for instance, my wife and I initially trade from our endowment E to the new point A , but our indifference curves through point A still formed a lens-shaped area in which both of us could be made better off. Viewed from our initial endowment, point A was therefore mutually beneficial, but it was not efficient because we could still think of ways of making both of us better off. The allocation where my wife is given the entire endowment of the economy, on the other hand, is efficient because there is no way to make one of us better off without making the other worse off. At the same time, such an allocation is not mutually beneficial when viewed from our initial endowment.

To calculate the set of Pareto efficient allocations, or what we called the *contract curve*, we therefore had to find allocations in the Edgeworth Box where indifference curves are tangent to one another and thus no lens-shaped area of mutually beneficial trades is possible. We can define this set PE (for the more general setting of N individuals and M goods) as

$$PE = \{ \{(x_1^n, x_2^n, \dots, x_M^n)\}_{n=1}^N \in FA \mid \text{there does not exist } \{(y_1^n, y_2^n, \dots, y_M^n)\}_{n=1}^N \in FA \\ \text{where } u^n(y_1^n, y_2^n, \dots, y_M^n) \geq u^n(x_1^n, x_2^n, \dots, x_M^n) \text{ for all } n = 1, 2, \dots, N \quad (16.7) \\ \text{and } u^n(y_1^n, y_2^n, \dots, y_M^n) > u^n(x_1^n, x_2^n, \dots, x_M^n) \text{ for some } n \}.$$

Again, the statement to the left of the “ \mid ” sign simply states that the allocation has to be a feasible allocation. The statement following the left of the “ \mid ” sign then states that there does not exist another feasible allocation that makes everyone at least as well off and at least one person better off.

EXERCISE 16B.5 Can you see that no allocation in the set PE of an Edgeworth Box could have indifference curves pass through it in a way that creates a lens-shaped area between them?

Returning to the example of me and my wife with oranges and bananas, suppose again that our tastes can be represented by the utility functions $u^1(x_1, x_2) = x_1^{3/4}x_2^{1/4}$ and $u^2(x_1, x_2) = x_1^{1/4}x_2^{3/4}$ and our endowments by $(e_1^1, e_2^1) = (3, 6)$ and $(e_1^2, e_2^2) = (10, 4)$. Within the Edgeworth Box, if a consumption bundle (x_1^1, x_2^1) is given to me, it means that my wife received the remaining available goods; that is, $(x_1^2, x_2^2) = (13 - x_1^1, 10 - x_2^1)$ (since the economy as a whole is endowed with 13 of the x_1 good and 10 of the x_2 good). A Pareto efficient allocation then occurs wherever our indifference curves are tangent to one another in the Edgeworth Box; that is, wherever my marginal rate of substitution $MRS^1(x_1^1, x_2^1)$ is equal to my wife’s $MRS^2(13 - x_1^1, 10 - x_2^1)$. For the utility functions specified for me and my wife, this tangency of our indifference curves then implies that

$$MRS^1(x_1^1, x_2^1) = \frac{3x_2^1}{x_1^1} = \frac{(10 - x_2^1)}{3(13 - x_1^1)} = MRS^2(13 - x_1^1, 10 - x_2^1). \quad (16.8)$$

Solving the middle part of expression (16.8) for x_2^1 , we get

$$x_2^1 = \frac{10x_1^1}{(117 - 8x_1^1)}. \quad (16.9)$$

This equation represents all my consumption bundles for oranges and bananas where my indifference curve is exactly tangent to my wife’s in the Edgeworth Box. In other words, equation (16.9) is the contract curve identified in Graph 16.3. More formally, we can use this equation to define the set PE for this exchange economy as

$$PE = \left\{ (x_1^1, x_2^1, x_1^2, x_2^2) \in \mathbb{R}_+^4 \mid x_2^1 = \frac{10x_1^1}{(117 - 8x_1^1)}, x_1^2 = 13 - x_1^1 \text{ and } x_2^2 = 10 - x_2^1 \right\}. \quad (16.10)$$

Verify that the contract curve we derived goes from one corner of the Edgeworth Box to the other.

**EXERCISE
16B.6**

A different way to find the contract curve would be to maximize my utility subject to the constraint that my wife's utility is held constant at utility level u^* and that her consumption bundle is whatever is left over after I have been given my consumption bundle. Put mathematically, this problem can be written as

**EXERCISE
16B.7***

$$\max_{x_1, x_2} x_1^{3/4} x_2^{1/4} \text{ subject to } u^* = (13 - x_1)^{1/4} (10 - x_2)^{3/4}$$

(where we drop the superscripts given that all variables refer to my consumption). Demonstrate that this leads to the same solution as that derived in equation (16.9).

16B.1.3 The Core The *core* of a two-person exchange economy was then defined in Section A as the set of Pareto efficient allocations that is also mutually beneficial given the endowments that individuals in the economy have. Put differently, the core in the two-person case is then simply the intersection of the set *MB* and *PE*; that is,

$$\text{Core} = MB \cap PE. \quad (16.11)$$

For the example of me and my wife, we can then define the core as the subset of the contract curve *PE* that contains allocations yielding utility above our reservation utilities. Our reservation utilities are simply found by plugging our endowments (3, 6) and (10, 4) into our utility functions, which gives reservation utilities of $U^1 = 3^{3/4} 6^{1/4} = 3.57$ and $U^2 = 10^{1/4} 4^{3/4} = 5.03$. The core can then be written as

$$\text{Core} = \{(x_1^1, x_2^1, x_1^2, x_2^2) \in PE \mid (x_1^1)^{3/4} (x_2^1)^{1/4} \geq 3.57 \text{ and } (x_1^2)^{1/4} (x_2^2)^{3/4} \geq 5.03\}. \quad (16.12)$$

This corresponds to the core allocations we derived graphically in Graph 16.4. Note, however, that this definition of the core as the intersection of *MB* and *PE* holds only for the case of two-person exchange economies. More generally, the core is defined as the set of allocations under which no “coalition” of individuals can do better on their own. With only two individuals, this is equivalent to saying that an allocation lies in the core when the two individuals cannot reallocate goods such that both are better off, leaving us with the intersection of *MB* and *PE*. In the appendix, we will treat the more general case of how the core of an exchange economy evolves when there are more than two individuals in the economy.

16B.1.4 Competitive Equilibrium In our development of consumer theory, we drew a distinction between models in which income was *exogenously* given and models where income arose *endogenously* as the consumer sold some endowment. When income is exogenously given, the (uncompensated) demand function for some good m took the form $x_m(p_1, p_2, \dots, p_M, I)$ where p_m represents the price of good m and I represents the exogenous income. When income is derived endogenously from endowments, the I term is replaced by the market value of the consumer's endowment, or $p_1 e_1 + p_2 e_2 + \dots + p_M e_M$. In a two-good exchange economy in which trade is governed by prices, for instance, the demand for good m by individual n can then be expressed as $x_m^n(p_1, p_2, (p_1 e_1^n + p_2 e_2^n))$. To cut down on notation, we will assume a two-good, two-person exchange economy for the rest of this section, but you should be able to see that everything we are doing can be written more generally with additional notation.

In equilibrium, the market prices for goods have to then be such that supply is equal to demand. A consumer n becomes a *net supplier* of a good m if his or her demand at the market prices is less than his or her endowment (i.e., $x_m^n(p_1, p_2, (p_1 e_1^n + p_2 e_2^n)) - e_m^n < 0$), and the consumer becomes a *net demander* if his or her demand is greater than his or her endowment (i.e., $x_m^n(p_1, p_2, (p_1 e_1^n + p_2 e_2^n)) - e_m^n > 0$). Supply is then equal to demand whenever the amount

The core of an exchange economy is the set of allocations from which no sub-group in the economy could deviate (with their endowments) and make everyone in the sub-group better off. In the two-person case, this reduces to the intersection of the mutually beneficial set and the Pareto efficient set of allocations.

A competitive equilibrium in an exchange economy is defined by a set of prices and an allocation that results from everyone optimizing (given those prices), with supply equal to demand in all markets.

supplied by net suppliers is cancelled out exactly by the amount demanded by net demanders. A set of equilibrium prices for a two-person, two-good exchange economy can therefore be defined as a set of prices (p_1, p_2) such that

$$\begin{aligned} (x_1^1(p_1, p_2, (p_1e_1^1 + p_2e_2^1)) - e_1^1) + (x_1^2(p_1, p_2, (p_1e_1^2 + p_2e_2^2)) - e_1^2) &= 0 \\ (x_2^1(p_1, p_2, (p_1e_1^1 + p_2e_2^1)) - e_2^1) + (x_2^2(p_1, p_2, (p_1e_1^2 + p_2e_2^2)) - e_2^2) &= 0. \end{aligned} \quad (16.13)$$

Alternatively, we can rewrite this same condition for equilibrium prices by adding the endowment terms to both sides to get

$$\begin{aligned} x_1^1(p_1, p_2, (p_1e_1^1 + p_2e_2^1)) + x_1^2(p_1, p_2, (p_1e_1^2 + p_2e_2^2)) &= e_1^1 + e_1^2 \\ x_2^1(p_1, p_2, (p_1e_1^1 + p_2e_2^1)) + x_2^2(p_1, p_2, (p_1e_1^2 + p_2e_2^2)) &= e_2^1 + e_2^2; \end{aligned} \quad (16.14)$$

that is, aggregate demand for each good (on the left-hand side of the equations) is equal to the aggregate endowment of that good (on the right-hand side).

Suppose, for instance, that we return to the example of me and my wife, with my endowment $(e_1^1, e_2^1) = (3, 6)$, my wife's endowment $(e_1^2, e_2^2) = (10, 4)$, and with our tastes represented by the utility functions $u^1(x_1, x_2) = x_1^{3/4}x_2^{1/4}$ and $u^2(x_1, x_2) = x_1^{1/4}x_2^{3/4}$. Solving our optimization problems (using the value of our endowments as our “income”), we get demands

$$\begin{aligned} x_1^1(p_1, p_2) &= \frac{3(3p_1 + 6p_2)}{4p_1} \quad \text{and} \quad x_2^1(p_1, p_2) = \frac{3p_1 + 6p_2}{4p_2} \\ x_1^2(p_1, p_2) &= \frac{10p_1 + 4p_2}{4p_1} \quad \text{and} \quad x_2^2(p_1, p_2) = \frac{3(10p_1 + 4p_2)}{4p_2}. \end{aligned} \quad (16.15)$$

EXERCISE 16B.8

Verify that these are the correct demands for this problem.

We concluded in our discussion of the Edgeworth Box that a set of equilibrium prices in this exchange economy cannot be determined unless we normalize one of the prices because the budget constraints of each individual always go through the endowment point with slope $-p_1/p_2$. Put differently, if we find one set of equilibrium prices that give rise to the “right” slope to get both individuals to optimize at the same point in the Edgeworth Box, any other set of prices that give rise to the same ratio of prices will also work. Thus, all we can do is determine the *relative prices* that can create an equilibrium.

Consider the first of the two equations in expression (16.14): demand equal to supply for good 1. Plugging in the relevant expressions from (16.15), we get that

$$\frac{3(3p_1 + 6p_2)}{4p_1} + \frac{(10p_1 + 4p_2)}{4p_1} = 3 + 10, \quad (16.16)$$

which reduces to

$$p_2 = \frac{3}{2}p_1. \quad (16.17)$$

This implies that, in order for the good 1 market to be in equilibrium, the price of good 2 has to be 1.5 times the price of good 1. Normalizing p_1 to be equal to 1, p_2 then has to be equal to $3/2$ in equilibrium.

EXERCISE 16B.9

Write down the equilibrium condition in the x_2 market (from the second equation in expression (16.14)) using the appropriate expressions from (16.15) and solve for the equilibrium price ratio. You should get the same answer.

To determine what my wife and I will consume in equilibrium, we can then simply plug in the equilibrium prices $p_1 = 1$ and $p_2 = 3/2$ into the demand functions in expression (16.15) to get

$$(x_1^1, x_2^1) = (9, 2) \quad \text{and} \quad (x_1^2, x_2^2) = (4, 8); \quad (16.18)$$

that is, I end up consuming 9 oranges and 2 bananas while my wife ends up consuming 4 oranges and 8 bananas in equilibrium, precisely the equilibrium we depicted graphically in Graph 16.6.

The reason we can find only a price ratio (and not precise prices) without normalizing one of the prices first can be seen intuitively in our graphs of budget constraints with endowments in which the price ratio determines the slope of the budget and the endowment point determines its location in each consumer's optimization problem. Mathematically, this arises from the fact that *demand functions are homogeneous of degree 0 in prices*. So long as all prices rise by the same proportion, the consumer is just as well off because, while goods are more expensive, endowments are worth more. Thus, for any individual n and good m , $x_m^n(p_1, p_2, (p_1 e_1^n + p_2 e_2^n)) = x_m^n(tp_1, tp_2, (tp_1 e_1^n + tp_2 e_2^n))$ for any $t > 0$.

Demonstrate that the same equilibrium allocation of goods will arise if $p_1 = 2$ and p_2 is 1.5 times p_1 ; that is, $p_2 = 3$.

EXERCISE
16B.10

A *competitive equilibrium* for an exchange economy is then defined as a set of prices and a set of allocations such that, at those prices, each individual in the economy will choose the equilibrium allocation and supply is equal to demand.⁷

Can you demonstrate that the equilibrium allocation we derived for me and my wife lies in the core that we defined in equation (16.12)?

EXERCISE
16B.11

16B.1.5 Walras's Law In our calculation of the competitive equilibrium for the two-person, two-good economy, you might have wondered why it is that we do not need to solve the system of the two equations in expression (16.14) to solve for the equilibrium price ratio. Rather, each of the two equilibrium equations individually yielded the same result. The reason for this is that we implicitly have a third equation that is a natural consequence of individuals optimizing.

To be more precise, we know that the budget constraint for each individual *binds* at the optimum; that is, that at the optimum a consumer's indifference curve is tangent to the budget constraint. Mathematically, this can be stated for consumer n simply as $p_1 x_1^n + p_2 x_2^n = p_1 e_1^n + p_2 e_2^n$; that is, spending (on the left-hand side) for consumer n is equal to income (on the right-hand side). But if this holds for each individual consumer, it also holds for the economy as a whole: *the aggregate budget constraint for the economy binds*. In the two-person, two-good economy, this aggregate budget constraint for the economy simply becomes

$$p_1(x_1^1 + x_1^2) + p_2(x_2^1 + x_2^2) = p_1(e_1^1 + e_1^2) + p_2(e_2^1 + e_2^2). \quad (16.19)$$

⁷ Several technical issues related to competitive equilibria in exchange economies are not discussed here. One issue relates to the *existence* of such equilibria. A formal proof of the conditions under which competitive equilibria in fact exist can be found in graduate texts such as Mas-Colel, Whinston, and Green (1996). The main condition that is required is that tastes are convex, and one of the end-of-chapter exercises will demonstrate that such equilibria might not exist when tastes are non-convex. A second issue relates to *uniqueness* of equilibria. Under what condition is there only a single competitive equilibrium allocation? Again, you can find formal treatments of this in graduate texts, but in general there might be more than a single such equilibrium allocation. However, with the functional forms for utility that we use in this text, there will generally be a single equilibrium in our examples. Finally, economists have worried about conditions under which equilibria are *stable*, and again you will find treatments of the conditions under which stability arises in graduate texts. For examples in this text, the equilibrium is always stable.

Walras’s Law says that equilibrium in all but one market implies equilibrium in the remaining market.

The condition is known as *Walras’s Law*.⁸ Since it follows directly from individual optimizing behavior, it is implicit that when we write down the first equation in expression (16.14), the second equation will hold; that is, demand equals supply in the good 1 market necessarily implies that demand equals supply in the good 2 market. It is for this reason that we can simply solve one of the two equations in expression (16.14) to solve for the equilibrium price ratio.

More generally, if we are dealing with an N -person, M -good exchange economy, we can write down M different “demand equals supply” equations such as those in expression (16.14), but because of Walras’s Law, we only need to solve $(M - 1)$ equations to find the relative prices for the M goods because if “demand equals supply” holds in $(M - 1)$ markets, it necessarily holds in the last market.

16B.2 The Fundamental Welfare Theorems and Other Results

As in Section A of this chapter, we will now turn to some of the main results of general equilibrium theory, results that establish a benchmark for when we can think of market economies as efficient. These results include the first welfare theorem, the second welfare theorem, and the core convergence theorem.

16B.2.1 The First Welfare Theorem The first welfare theorem simply states that (under certain conditions) the competitive equilibrium is efficient. We saw the result intuitively for a two-person, two-good exchange economy within the context of the Edgeworth Box. We will now prove it a bit more formally using the notation we have developed thus far and will again confine ourselves to the case of a two-person, two-good exchange economy to keep the notation to a minimum. The exact same logic, however, can be used to demonstrate the first welfare theorem for an N -person, M -good exchange economy, although the notation gets a little more involved.

Suppose, then, that $\{p_1, p_2, x_1^1, x_2^1, x_1^2, x_2^2\}$ is a competitive equilibrium for an exchange economy defined by $\{e_1^1, e_2^1, e_1^2, e_2^2, u^1, u^2\}$, where u^1 and u^2 are utility functions that represent the two individuals’ tastes. We will use what is known as a *proof by contradiction* (also known in Latin as *reductio ad absurdum*) to illustrate that the equilibrium allocation $(x_1^1, x_2^1, x_1^2, x_2^2)$ must be Pareto efficient. A “proof by contradiction” is a logical method of proving a statement to be true by assuming that it is not true and showing how that assumption leads to a logical contradiction. If we can show that assuming the statement to be untrue leads to a logical contradiction, we have then shown that the statement must be true.

So, suppose the equilibrium allocation $(x_1^1, x_2^1, x_1^2, x_2^2)$ is *not* efficient. This would imply that there must exist another feasible allocation of the economy’s goods that makes no one worse off and at least one person better off. Let’s call that allocation $(y_1^1, y_2^1, y_1^2, y_2^2)$. Suppose that in fact both individuals are better off under this allocation (as opposed to the equilibrium allocation). Since each individual did the best he or she could at the equilibrium prices (p_1, p_2) to get to the equilibrium allocation, it must be that (y_1^1, y_2^1) is not affordable for individual 1 at the equilibrium prices and (y_1^2, y_2^2) is not affordable for individual 2 under those prices. Thus

$$p_1 y_1^1 + p_2 y_2^1 > p_1 x_1^1 + p_2 x_2^1 \quad \text{and} \quad p_1 y_1^2 + p_2 y_2^2 > p_1 x_1^2 + p_2 x_2^2. \quad (16.20)$$

Adding each side of these inequalities together then implies

$$p_1(y_1^1 + y_1^2) + p_2(y_2^1 + y_2^2) > p_1(x_1^1 + x_1^2) + p_2(x_2^1 + x_2^2). \quad (16.21)$$

The right-hand side of this equation is the same as the left-hand side of equation (16.19), which is Walras’s Law. Thus, equations (16.19) and (16.21) imply

⁸ Walras’s Law is named after Leon Walras (1934–1910), one of the earliest mathematical economists who built the initial foundations of general equilibrium theory and is considered by many the “father of general equilibrium theory.” He is also the dude that graphed demand functions with p on the horizontal and x on the vertical axis the mathematically correct way, but the profession ignored him in that regard and continued graphing inverse demand functions as demand curves.

A “proof by contradiction” proceeds by assuming that a proposition does not hold, and then illustrates that this assumption leads to a logical contradiction. The First Welfare Theorem can be proved in this way.

$$p_1(y_1^1 + y_1^2) + p_2(y_2^1 + y_2^2) > p_1(e_1^1 + e_1^2) + p_2(e_2^1 + e_2^2), \quad (16.22)$$

which can be rewritten as

$$p_1(y_1^1 + y_1^2 - e_1^1 - e_1^2) + p_2(y_2^1 + y_2^2 - e_2^1 - e_2^2) > 0. \quad (16.23)$$

Since prices are positive, this then implies that $(y_1^1 + y_1^2 - e_1^1 - e_1^2)$ or $(y_2^1 + y_2^2 - e_2^1 - e_2^2)$ or both are greater than zero, which in turn implies that $(y_1^1 + y_1^2) > (e_1^1 + e_1^2)$ and/or $(y_2^1 + y_2^2) > (e_2^1 + e_2^2)$. But that implies that the allocation $(y_1^1, y_2^1, y_1^2, y_2^2)$ is not feasible because it allocates more than the economy has of at least one of the goods. So, assuming that there exists a feasible allocation $(y_1^1, y_2^1, y_1^2, y_2^2)$ that is preferred by everyone to the equilibrium allocation $(x_1^1, x_2^1, x_1^2, x_2^2)$ leads to a logical contradiction, which implies that there cannot be such a universally more preferred allocation. Thus, the equilibrium allocation $(x_1^1, x_2^1, x_1^2, x_2^2)$ must in fact be efficient.

In our proof, we began by assuming that there exists an allocation $(y_1^1, y_2^1, y_1^2, y_2^2)$ that is strictly preferred by everyone to $(x_1^1, x_2^1, x_1^2, x_2^2)$ and showed that there cannot be such an allocation within this economy. Can you see how the same logic also goes through if we assume that there exists an allocation $(z_1^1, z_2^1, z_1^2, z_2^2)$ that is strictly preferred by one of the individuals while leaving the other indifferent to $(x_1^1, x_2^1, x_1^2, x_2^2)$?

EXERCISE
16B.12*

For the more complicated setting of N individuals and M goods, the same steps we just went through will lead to the conclusion that any allocation that is at least as good as the equilibrium for everyone and better for at least one person will similarly lead to the conclusion that this alternative allocation will not be feasible given the economy's endowment.

Can you demonstrate that this is in fact the case for an N -person, M -good economy?

EXERCISE
16B.13*

16B.2.2 The Second Welfare Theorem The formal proof of the second welfare theorem, which states that there always exists a redistribution of the economy's endowment such that any point on the contract curve can be supported as a competitive equilibrium after the redistribution, is somewhat more difficult. It furthermore assumes that tastes are convex (which the first welfare theorem does not require).⁹ We will forego a formal demonstration of this here,¹⁰ but the intuition is relatively straightforward. For instance, one could redistribute the endowment so that it coincides with the Pareto efficient allocation on the contract curve and then demonstrate that there exists a set of prices such that each individual would in fact choose to remain at this new endowment point. (Of course any other endowment allocation on the budget line formed in this way would also work.)

The first welfare theorem is powerful in that it tells us that there are conditions under which a competitive equilibrium is efficient. The second welfare theorem, as we discussed in Section A, is somewhat less powerful because it assumes that we can redistribute endowments without cost; that is, that there exist what we have previously called "lump sum taxes" that do not give rise to substitution effects. It furthermore assumes that we have enough information about the individuals in the economy to be able to redistribute in just the right way to get our preferred point on the contract curve to emerge as an equilibrium. Nevertheless, the second welfare theorem suggests that, so long as redistribution of endowments is possible, competitive markets can
