In addition to the strong genetic links to the spondyloarthropathies, important associations exist between specific bacterial agents and disease pathogenesis. Genitourinary infection with *C. trachomatis* or diarrheal illness with *Shigella*, *Salmonella*, *Campylobacter*, and *Yersinia* species, as well as *Klebsiella pneumoniae* infection, can induce reactive arthritis. These infections appear to trigger an inflammatory response, possibly as a result of persistence of bacterial antigens. However, no one theory of pathogenesis of spondyloarthropathies explains the clinical spectrum of these disorders, and more research is clearly needed to solidify an understanding of their origin. The complex role of the

immune system in the spondyloarthropathies is highlighted by the observation that patients infected with HIV appear more likely to have severe disease, especially psoriatic arthritis. It is interesting to note that when HIV infection is treated with antiviral agents, the incidence of spondyloarthropathy declines.

Although there has been a dramatic increase in our understanding of the cellular and molecular mechanisms in inflammatory joint disease, the pathophysiology of spondyloarthropathies remains incompletely understood. Inflammation of the sacroiliac joints, spine, and entheses is a unique feature of these disorders. Pathophysiologic studies show that the inflammation originates at the interface of bone and cartilage in the sacroiliac joint, and bone and fibrocartilage in the enthesis. Macrophages and CD4⁺ and CD8⁺ T cells are present, and the proinflammatory cytokine *tumor necrosis factor- α* (TNF- α) is abundant. Synovial tissue becomes inflamed and osteoclasts are activated, leading to bone resorption, reminiscent of rheumatoid arthritis (RA) joint inflammation. Unlike in RA, this early bone resorption is followed by a secondary phase during which osteoblast activity predominates, leading to new bone formation in periarticular bone (hyperostosis) and around joints (osteophytosis) or vertebral bodies (syndesmophytes). Ultimately, bony fusion of joints (ankylosis) occurs. The relationship between these paradoxical phases of bone resorption and proliferation is an area of active investigation.

Clinical Features

COMMON CLINICAL FEATURES AMONG THE SPONDYLOARTHROPATHIES

The spondyloarthropathies have considerable clinical overlap with one another and are most easily considered as a group of related disorders. Table 80-1 outlines the clinical features of these disorders. The cardinal clinical features

common to all of these disorders are inflammatory spine pain or an asymmetrical predominantly lower extremity oligoarthritis. Inflammatory spine pain should be suspected in young patients (younger than age 40) who have an insidious onset of chronic low back pain or buttock pain associated with prolonged morning stiffness and relieved by exercise. The characteristic peripheral joint disease typically involves one to four joints, usually in the lower extremities, and may be associated with tendon insertion inflammation (enthesitis) or sausage digits (dactylitis). Symmetrical polyarthropathy involving the upper extremities and clinically similar to RA is seen in some forms of psoriatic and inflammatory bowel disease–related arthritis. The presence of anterior uveitis, enthesitis, dactylitis, psoriatic skin or nail changes, inflammatory bowel disease, a family history of spondyloarthropathy, or a history of a preceding gastrointestinal or genitourinary infection is suggestive of spondyloarthropathy. Subcutaneous nodules, rheumatoid factor, and anti-nuclear antibodies are usually absent. In a given patient the clinical features of these disorders may accumulate over a prolonged period of time. Some patients will not initially demonstrate the typical findings of a specific disorder. These patients are considered to have *undifferentiated spondyloarthropathy*; many will later manifest clinical findings consistent with one of the specific subtypes of spondyloarthropathy.

Inflammatory spine pain is caused by *sacroiliitis* and *spondylitis*. Sacroiliitis may develop in a subtle fashion with low back or gluteal area pain, but it can also cause severe pain. Patients generally have significant morning stiffness, sometimes of many hours' duration, and pain after periods of inactivity. Spondylitis may occur at any area of the spine, but it often begins in the lumbar spine and subsequently progresses to the cervical and thoracic regions. The sacroiliac joints and spine become painful and stiff with increasingly reduced range of motion as bony fusion of the vertebral column and facet joints occurs over time. Involvement of

Table 80-1 Comparison of the Spondyloarthropathies

	Ankylosing Spondylitis	Posturethral Reactive Arthritis	Postdysenteric Reactive Arthritis	Enteropathic Arthritis	Psoriatic Arthritis

Data from Cush JJ, Lipsky PE: The spondyloarthropathies. In Goldman L, Bennett JC (eds): Cecil Textbook of Medicine, 21st ed. Philadelphia, WB Saunders, 2000, pp 1499-1507.

the thoracic spine and costovertebral joints may result in a restrictive lung physiologic condition. Fusion of the spine increases the risk of vertebral fractures in patients with spondyloarthropathies and, depending on the angle of fusion, may cause significant kyphosis and reduced line of sight. When bony fusion is complete, the pain may be significantly reduced.

Enthesitis may occur in many different anatomic locations. These include spinous processes, costosternal junctions, ischial tuberosities, plantar aponeuroses, and Achilles tendons.

The *peripheral arthritis* of the spondyloarthropathies, when it occurs, begins as an episodic, asymmetrical, oligoarticular process often involving the lower extremities. The arthritis can progress and may become chronic and disabling. A unique feature of spondyloarthropathies is the appearance of fusiform swelling of an entire finger or toe, referred to as *dactylitis* or *sausage digits*.

Uveitis, or inflammatory disease of the anterior chamber of the eye, is a common extra-articular manifestation of the spondyloarthropathies, especially among patients who are HLA-B27 positive. Bouts of uveitis are usually monocular, acute at onset, painful, and accompanied by eye redness and blurred vision. Recurrent attacks are common. Uveitis may be serious and lead to blindness. Anterior uveitis may be the presenting symptom of spondyloarthropathy; thus all patients with anterior uveitis should be screened for signs and symptoms of these disorders.

Spondyloarthropathies may occasionally involve other organ systems and may cause significant morbidity and mortality. *Aortitis*, especially occurring in the ascending segment, can result in aortic insufficiency from aortic root dilation, aortic dissection, and cardiac conduction system abnormalities. Pulmonary fibrosis of the apical regions can occur, often in an insidious fashion. Spinal cord compression can result from atlantoaxial joint subluxation, cauda equina syndrome, or vertebral fractures. In rare cases, longstanding spondyloarthropathy is associated with secondary amyloidosis.

SPECIFIC CLINICAL FEATURES OF THE SPONDYLOARTHROPATHIES

Ankylosing Spondylitis

The cardinal clinical feature of ankylosing spondylitis is inflammatory spine pain. Over time, spine involvement ascends from the sacroiliac joints to involve all levels of the spine. There is progressive loss of motion owing to ankylosis of the vertebral column and apophyseal joints. Costovertebral involvement leads to decreased chest expansion and restrictive lung physiology. There is a high risk of traumatic spine fracture because of loss of mobility and secondary osteoporosis of the vertebral bodies. Axial involvement of the shoulders and hips is common and associated with a worse prognosis. Peripheral oligoarthritis, enthesitis, and dactylitis are more common in females. Diagnosis requires demonstration of radiographic sacroiliitis (sacroiliac joint erosions, sclerosis, and/or ankylosis). Anterior uveitis is common. Aortitis, upper lobe pulmonary fibrosis, cauda equina syndrome, and amyloidosis are less common and seen in late disease.

Reactive Arthritis

Among the unique clinical features of reactive arthritis (Reiter syndrome) are *urethritis*, *conjunctivitis*, and certain dermatologic problems. The urethritis may be secondary to the chlamydial infection that triggers the disease, or it may be a sterile inflammatory discharge also seen in diarrhea-associated disease. Conjunctivitis may be mild in reactive arthritis and is distinct from uveitis. *Keratoderma blennorrhagicum* is a distinct papulosquamous rash usually found on the palms or soles. *Circinate balanitis* is a rash that may appear on the penile glans or shaft of men with reactive arthritis. Nonpitting *nail thickening* and *oral ulcers* may also occur in patients with reactive arthritis. These lesions can be confused with similar findings in patients with psoriasis and inflammatory bowel disease, respectively.

Reactive arthritis usually manifests with oligoarthritis, *without* the classic triad of Reiter syndrome. Therefore this term is no longer preferred. Most cases will be self-limited. Chronic or relapsing arthritis and chronic spondylitis is associated with HLA-B27 and *Chlamydia* infection.

Psoriatic Arthritis

Five identifiable clinical patterns of psoriatic arthritis are recognized: (1) *distal interphalangeal joint involvement with nail pitting*; (2) *asymmetrical oligoarthritis* of both large and small joints; (3) *arthritis mutilans*, a severe, destructive arthritis; (4) *symmetrical polyarthritis*, identical to RA; and (5) *spondyloarthropathy*. These patterns are not exclusive, and clinical overlap is significant. Spondylitis or sacroiliitis may occur along with any of the other four patterns. The prevalence of HLA-B27 is increased among the patients with spondylitis or sacroiliitis but not among patients with the other patterns. Psoriatic skin or nail disease predates arthritis in most cases, but both may occur concomitantly or joint disease may precede skin involvement. Rarely, joint disease indistinguishable from psoriatic arthritis is present in patients with a family history but no personal history of psoriatic skin disease.

Enteropathic Arthritis (Inflammatory Bowel Disease)

Crohn disease and ulcerative colitis (see also Chapter 38) are frequently associated with both spondyloarthropathy and peripheral arthritis. The peripheral arthritis is typically nonerosive, oligoarticular, and episodic, and degree of joint involvement fluctuates with gut activity. In addition, a more chronic, symmetrical polyarthritis may occur in Crohn disease.

Radiographic Features

The radiographic features of the spondyloarthropathies are highly specific and, in the correct clinical setting, virtually diagnostic of these diseases. Sacroiliitis is usually the earliest radiographic sign of spine disease and results in sclerosis and erosions of the sacroiliac joints with eventual bony fusion (Fig. 80-1A). Many different radiographic changes occur secondary to chronic spondylitis, including ossification of the annulus fibrosus, calcification of spinal ligaments, bony sclerosis and *squaring* of vertebral bodies, and ankylosis of apophyseal joints. These changes can lead to vertebral fusion and a bamboo spine appearance (Fig. 80-1B). Radiographic findings progress over many

Figure 80-1 A, Bilaterally symmetrical sacroiliitis in ankylosing spondylitis. B, Lumbar spondylitis in ankylosing spondylitis with symmetrical, marginal bridging syndesmophytes and calcification of the spinal ligament. (From Cush JJ, Lipsky PE: The spondyloarthropathies. In Goldman L, Bennett JC [eds]: Cecil Textbook of Medicine, 21st ed. Philadelphia, WB Saunders, 2000, pp 1499-1507.)

years of illness and may not be apparent in early disease. However, during this “preradiographic period,” magnetic resonance imaging (MRI) demonstrates bone inflammation (osteitis) and erosion at the sacroiliac joints and vertebral bodies, and computed tomography (CT) shows bony sclerosis and joint erosions.

Bone erosions, sclerosis, and new bone formation may occur at sites of enthesitis. Erosions at bone-cartilage interface (subchondral erosions), sclerosis, and bone proliferation are hallmarks of reactive and psoriatic arthritis. In severe cases such as the arthritis mutilans form of psoriatic arthritis, total or subtotal bone resorption (osteolysis) of a phalanx may occur.

Treatment

No cure has yet been found for any of the spondyloarthropathies, but effective treatment for many of the manifestations is available. *Patient education* regarding the disease is essential and allows for identification of affected family members and early presentation of urgent clinical features such as uveitis. *Physical therapy*, including a daily stretching program, postural adjustments, and strengthening, can be useful in maintaining proper bony alignment, reducing deformities, and maximizing function. Selective use of *orthopedic surgery* may be highly effective in correcting significant spinal deformities or instability.

Nonsteroidal anti-inflammatory drugs (NSAIDs) can provide significant relief of spinal pain and stiffness, and many patients take these drugs continually for years. No clear evidence indicates that systemic glucocorticoids benefit patients with spondyloarthropathies, and these agents are generally avoided. *Intra-articular glucocorticoid injection* into the sacroiliac or other involved joints may provide temporary relief. Similarly, the role and efficacy of older immuno-

suppressive agents in the treatment of the axial manifestations of the spondyloarthropathies have not been established. In contrast, the peripheral arthritis of spondyloarthropathies has been shown in clinical trials to improve with *sulfasalazine*. *Methotrexate* is also regularly used for the peripheral arthritis, but no large clinical trials have been performed with this agent in these diseases.

TNF blockers (infliximab, etanercept, and adalimumab) represent a substantial breakthrough in treatment of the spondyloarthropathies. The efficacy of these agents is now well established, and these drugs have rapidly become the treatment of choice for patients with ankylosing spondylitis who do not satisfactorily or fully respond to NSAIDs and physical therapy. TNF blockers can significantly reduce pain, improve function, and improve quality of life and may prevent or slow disease progression and structural damage. These drugs are effective in psoriatic arthritis and have been demonstrated to retard radiographic progression in the peripheral joints. Infliximab and adalimumab reduce gut inflammation in ulcerative colitis and Crohn disease, with concomitant reduction in symptoms of joint and spine inflammation.

Flares of *uveitis* require care by an ophthalmologist experienced in treating inflammatory eye diseases. Topical or intraocular glucocorticoids may suffice, but systemic therapy with glucocorticoids or immunosuppressive medications may be necessary to control the inflammation and prevent permanent visual loss. The role of TNF blockers in uveitis is under study.

Reactive arthritis is usually self-limited, and joint symptoms are managed with NSAIDs or intra-articular corticosteroid injections. When chronic arthritis or spondylitis develops, interventions are similar to those employed in ankylosing spondylitis. Evaluation and treatment for *C.*

trachomatis and associated sexually transmitted diseases in patients with reactive arthritis and their sex partners are essential. Early treatment reduces the frequency of reactive arthritis. Long term antibiotics are ineffective for treatment

of gastroenteritis-associated reactive arthritis. In reactive arthritis after *C. trachomatis*, clinical trials of long-term antibiotics have had mixed results, and this practice will require further study before it can be adopted.

Prospectus for the Future

- Increased insights into the immunogenetics of the spondyloarthropathies may lead to greater understanding of the pathophysiologic features of these diseases.
- Further research on the use of biologic agents, especially antitumor necrosis- α products, in the treatment of

spondyloarthropathies may help determine whether the structural and functional deterioration these diseases often cause can be prevented with long-term therapy.

Systemic Lupus Erythematosus

Jennifer Rae Elliott

Systemic lupus erythematosus (SLE, lupus) is the classic systemic autoimmune disease and is of unknown cause. Lupus predominantly affects young women of childbearing age but can also afflict young men and older individuals of either sex. The clinical manifestations are protean, ranging from fatigue and oral ulcerations to life-threatening renal and neurologic disease. Typically the disease fluctuates with periods of flares and clinical quiescence. In the long term this leads to damage to internal organs from inflammation and medication use. Lupus is diagnosed via a thorough history and physical examination combined with laboratory testing. Although there is no cure for SLE, patients are treated aggressively with a variety of medications, including immunosuppressants. Unique considerations must be given to patients with SLE regarding pregnancy, cardiovascular disease (CVD), malignancy, and bone health.

Epidemiology

The reported incidence and prevalence of SLE vary greatly, reflecting the heterogeneity of the disease. The incidence of SLE is estimated at 1.8 to 7.6 cases per 100,000 per year and appears to have increased over time. Prevalence rates range widely from 14.6 to 149.5 per 100,000 persons.

Lupus is a disease of women, the majority of whom are diagnosed between the ages of 15 and 45. During these childbearing years, the female to male ratio is 10 to 15:1. This discrepancy is less distinct (2:1) in young children and older patients.

Lupus also has a predilection for non-white groups. The prevalence rates of lupus in blacks (3×), Caribbean blacks (5×), Asians (2×), and Hispanics are greater than in whites. Blacks and Hispanics also have more severe disease and an overall worse prognosis than whites.

In 1955, lupus patients had a 50% 5-year survival rate. Since then, landmark advances have been made in the diagnosis (antinuclear antibody testing and classification criteria for SLE) and care (antibiotics, corticosteroids, and hemo-

dialysis) of lupus patients. Current 5- and 10-year survival rates are >90%. In addition to ethnicity (described earlier), renal and neurologic disease are poor prognostic markers for mortality.

A bimodal pattern of mortality is seen in lupus. Early (<5 years) deaths are attributed to active lupus disease and infections; later deaths (>5 years) are sequelae of chronic SLE complications and medications, as well as of CVD and infections. Recent data suggest that malignancy-associated morbidity and mortality are lifelong risks, but are greatest early in the disease.

Pathogenesis

Although the pathogenesis of SLE is not completely known, persons who develop lupus likely have a genetic predisposition, in the setting of immune system dysregulation, environmental triggers, and hormonal milieu. The genetic contribution to SLE is emphasized by the high concordance rate in monozygotic twins (>20%) as opposed to the lower concordance among other siblings (<5%). The search for potential genes in lupus is an active area of research. Genes coding for certain human leukocyte antigens, complement system components, immunoglobulin receptors, and various other specific proteins have all been considered possible candidate genes associated with SLE. Many different immune abnormalities have been noted in patients with SLE, a finding implicating dysregulation of both the humoral and cellular immune systems in the pathogenesis of the disease. This dysregulation leads to loss of tolerance and autoimmune destruction of healthy tissues, hallmarked by the production of autoantibodies and immune complexes. Various environmental triggers, including microorganisms and ultraviolet light exposure, may influence the development of lupus and lupus activity itself. In addition, the striking differences in disease prevalence between men and women, as well as the effect of pregnancy on lupus disease activity, suggest a role for hormones in the pathogenesis of SLE.

Clinical Manifestations

Virtually any organ system may be involved in SLE, often in many different ways. Table 81-1 outlines the many clinical manifestations of SLE.

CONSTITUTIONAL

Fatigue, fever, lymphadenopathy, and generalized arthralgias and myalgias are common in lupus patients. The most common symptom, fatigue (>90%), can also be the most debilitating. One should exclude other reasons for fatigue, including anemia, hypothyroidism, and fibromyalgia. Malignancy should also be suspected if lymphadenopathy persists (see later).

MUCOCUTANEOUS

Oral ulcerations may be painful or painless and are classically located on the tongue or palate. Skin manifestations of SLE are protean and include the classic malar (butterfly) rash, discoid lesions (permanent scarring and disfigurement), alopecia, and photosensitivity.

MUSCULOSKELETAL

Arthralgias and inflammatory arthritis are common manifestations in lupus (>75%). The arthritis of lupus is usually nonerosive (as opposed to rheumatoid arthritis), but a subset of patients (10%) have *Jaccoud arthropathy* with reversible hand deformities secondary to inflammation and joint laxity.

CARDIOPULMONARY

More than 60% of lupus patients have pericarditis and pleuritis during their disease course. Subsequent pericardial or pleural effusions are typically exudative, with low normal glucose levels. Valvular thickening and noninfective Libman-Sacks endocarditis are frequently observed on echocardiography and autopsy studies. Myocarditis should be suspected in patients with cardiopulmonary symptoms and fever. Pulmonary hemorrhage is a rare and potentially catastrophic manifestation of SLE that may result in fulminant hemoptysis and respiratory failure. Premature CVD in lupus is described later.

RENAL

Nephritis is a major cause of morbidity and mortality in lupus patients. It can manifest with hematuria and/or proteinuria, and the clinical spectrum of glomerulopathies is classified by the World Health Organization (Class I to VI). Class IV (diffuse, proliferative) lupus nephritis has the worst prognosis but is also the most amenable to aggressive systemic therapy.

NEUROPSYCHIATRIC

Neuropsychiatric symptoms are broad, including sensorimotor neuropathy, headache, cognitive dysfunction, anxiety,

and psychosis, as well as life-threatening cerebrovascular, vasculitis, and transverse myelopathy.

HEMATOLOGIC

Leukopenia, primarily lymphopenia, anemia, and thrombocytopenia are very common in SLE patients. Anemia is secondary to hemolysis or chronic disease. Antiphospholipid and anticardiolipin antibodies are present in one third of lupus patients and are associated with multiple thromboses, thrombocytopenia, and recurrent spontaneous miscarriages (see Chapter 78).

VASCULAR

Over 40% of all lupus patients have Raynaud phenomenon. Venous (pulmonary emboli, deep venous thrombosis) and arterial clots are typically secondary to antiphospholipid and anticardiolipin antibodies. Small vessel vasculopathy or vasculitis can occur in any organ system (neurologic, gastrointestinal) and can be life threatening.

OCULAR

Keratoconjunctivitis sicca from secondary Sjögren syndrome (see Chapter 86) is the most common ocular manifestation of SLE. Episcleritis, scleritis, and retinal vasculitis are rare.

Diagnosis

SLE is a clinical diagnosis; no single test or feature is definitively diagnostic of the disease. Many patients' clinical disease evolves over time, and only after several years (and several different visits to physicians) are patients recognized as having SLE.

Criteria for the classification of SLE were established to more accurately conduct lupus research studies (Table 81-2). Although these classification criteria are not meant to be diagnostic, practicing clinicians can use them, with a comprehensive examination, as a guide to help diagnose SLE. One must always consider other rheumatic diseases (rheumatoid arthritis, Sjögren syndrome), infections (endocarditis, hepatitis), and malignancy in the differential diagnosis of SLE.

Various autoantibodies are found in patients with SLE and are the hallmark laboratory feature of the disease (Table 81-3). These autoantibodies are often present before the onset of SLE clinical manifestations. Virtually all patients with SLE (>95%) test positive for antinuclear antibodies. Although many of the specific antigens to which these antinuclear antibodies are directed have been determined and are useful both diagnostically and clinically in SLE, some antibodies are also seen in other autoimmune diseases. Antibodies to double-stranded DNA and the Smith antigen are highly specific for lupus, whereas antibodies to SSA/Ro and SSB/La antigens are also commonly found in patients with Sjögren syndrome and rheumatoid arthritis. Certain antibodies are associated with specific clinical manifestations of disease, particularly anti-double-stranded DNA antibodies with lupus nephritis. Autoantibodies alone are not

diagnostic for any autoimmune disease but must be interpreted in the clinical context.

Clinical Subsets

Some patients with autoimmune symptoms have clinical and laboratory features of two or more specific autoimmune

diseases and are considered to have an overlap syndrome. Mixed connective tissue disease is characterized by overlaps among SLE, scleroderma, and myositis with a high titer of anti-U1 RNP antibody levels. For patients who have a few autoimmune manifestations but do not yet meet criteria of a specific autoimmune disease, the term *undifferentiated connective tissue disease* is used. These patients typically are

Table 81-2 Updated Criteria for Classification of Systemic Lupus Erythematosus*

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, is observed over the malar eminences, tending to spare the nasolabial folds.
2. Discoid rash	Erythematous raised patches develop with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions.
3. Photosensitivity	Skin rash occurs as a result of unusual reaction to sunlight by patient history or physician observation.
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, is observed by the physician.
5. Arthritis	Nonerosive arthritis involves two or more peripheral joints, characterized by tenderness, swelling, or effusion.
6. Serositis	a. Pleuritis: Convincing history of pleuritic pain exists, or rub is heard by a physician, or pleural effusion is in evidence. OR b. Pericarditis: Is documented by electrocardiogram or rub or evidence of pericardial effusion.
7. Renal disorder	a. Persistent proteinuria is >0.5 g/day or $>3+$ if quantitation is not performed. OR b. Cellular casts: May be red cell, hemoglobin, granular, tubular, or mixed.
8. Neurologic disorder	a. Seizures: Occur in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, electrolyte imbalance) OR b. Psychosis: Occurs in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, electrolyte imbalance)
9. Hematologic disorder	a. Hemolytic anemia: Develops with reticulocytosis. b. Leukopenia: $<4000/\text{mm}^3$ total is documented on two or more occasions. c. Lymphopenia: $<1500/\text{mm}^3$ is documented on two or more occasions. OR d. Thrombocytopenia: $<100,000/\text{mm}^3$ develops in the absence of offending drugs.
10. Immunologic disorder	a. Anti-DNA: Antibody to native DNA in abnormal titer. b. Anti-Sm: Presence of antibody to Sm nuclear antigen. OR c. Positive finding of antiphospholipid antibodies is based on (1) an abnormal serum level of immunoglobulin G (IgG) or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive result from a serologic test for syphilis is known to be positive for at least 6 months and is confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test.
11. Antinuclear antibody	An abnormal titer of antinuclear antibody is documented by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome.

*The classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have SLE if any four or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

early in their disease course and will eventually develop a specific autoimmune disease.

Treatment

No cure for lupus has yet been identified, and treatment is aimed at educating patients, reducing inflammation, suppressing the immune system, and closely monitoring patients to identify disease manifestations as early as possible. Treatment with glucocorticoids and immunosuppressive agents has reduced both the morbidity and the mortality of patients with SLE, although these treatments themselves are associated with extensive toxicity. Physicians caring for lupus patients must carefully weigh the benefits of therapy against the known risks of treatment.

Patient education and prophylactic measures to prevent disease flares are key in the care of patients with lupus. Sunscreens (high sun protection factor [SPF]) and ultraviolet

ray protective clothing are very effective in avoiding photosensitivity skin rashes and systemic flares. Protective or warm clothing is helpful in treating Raynaud phenomenon in SLE, and these patients may also benefit from vasodilator therapy. Low-dose aspirin is frequently prescribed for patients with positive antiphospholipid and anticardiolipin antibodies to prevent thrombotic events. Other treatments for antiphospholipid antibody syndrome are discussed in Chapter 82. Routine (non-live) immunizations, such as those for influenza and pneumococcus, are recommended for all patients. Psychological support is essential for patients with SLE because this chronic disease may lead to depression and feelings of being overwhelmed.

Nonsteroidal anti-inflammatory medications may be used for mild arthralgias, but glucocorticoids remain the main anti-inflammatory agent and one of the most effective medications for lupus. Glucocorticoids are used for almost all manifestations of lupus in doses ranging from low alternate-day doses to large intravenous (IV) doses. Given the chronic nature of the disease, glucocorticoids are often used over many years and may lead to extensive toxicity, including obesity, diabetes mellitus, accelerated atherosclerosis, osteoporosis, avascular necrosis, cataracts, and increased risk of infections. To avoid such toxicities, different immunomodulating or immunosuppressant agents (described later) are used to provide a steroid-sparing effect, as well as for greater disease control.

Antimalarial medications (hydroxychloroquine and chloroquine) are very effective agents in SLE and are considered standard of care for lupus. Antimalarials are especially beneficial for fatigue, mild arthritis, and mucocutaneous manifestations of SLE. These medications are often chronic therapies and are safe to use in pregnancy. The most serious side effect of antimalarials is retinal toxicity, although it is extremely uncommon. Risk factors for retinal toxicity are therapy >5 years, renal or hepatic disease, age >60 years, dose >6.5 mg/kg, and obesity. Patients should have baseline and annual ophthalmologic examinations with visual field testing.

Azathioprine and methotrexate are both immunosuppressive agents prescribed in patients with lupus either when glucocorticoids alone are not fully effective or to allow for a reduction in the glucocorticoid dose. Toxicities of azathioprine include cytopenias, increased infection risk, and potential association of hematologic malignant disease (controversial). Azathioprine may be used during pregnancy for severe internal organ lupus (especially nephritis). Methotrexate is particularly effective with inflammatory arthritis associated with lupus. In addition to cytopenias and infections, liver function abnormalities, alopecia, nausea, and pneumonitis are potentially seen with methotrexate. Because it is teratogenic, methotrexate should be stopped 3 to 6 months before pregnancy. Both drugs require monthly laboratory monitoring.

Mycophenolate mofetil (MMF) is increasingly used to treat patients with internal organ involvement of lupus, particularly nephritis. MMF inhibits purine synthesis of lymphocytes and has been standard treatment in the prevention of solid-organ transplant rejection. Recent clinical trials have shown that MMF is as efficacious as intravenous (IV) cyclophosphamide (described later) for inducing remission of active lupus nephritis. Toxicity of MMF includes gastroin-

testinal disturbance and leukopenia; it also has a category D rating in pregnancy.

Patients with neurologic lupus, rapidly progressive nephritis, or vasculitis of internal organ systems are often treated with cyclophosphamide, the most potent immunosuppressive agent (alkylating agent) used to treat SLE. Because it is extremely toxic, this drug is generally reserved for the most severe disease manifestations of lupus. In a series of studies, primarily conducted at the National Institutes of Health, monthly IV cyclophosphamide was effective in reducing the rate of progression of lupus nephritis to end-stage renal disease. Acute toxicities of cyclophosphamide include pancytopenia, alopecia, mucositis, and hemorrhagic cystitis. Long-term cyclophosphamide use may lead to transitional cell carcinoma, hematologic malignant disease, sterility, premature menopause, and opportunistic infections.

Many other treatments have been used in SLE, although extensive clinical trials demonstrating efficacy are lacking. Among these drugs, intravenous immunoglobulin may be effective for SLE-related thrombocytopenia and catastrophic antiphospholipid syndrome. Thrombotic thrombocytopenic purpura secondary to SLE may be treated with plasmapheresis. Immunoablation with high-dose cyclophosphamide with or without autologous stem cell transplant has been tried in a small number of patients with progressive active disease that is refractory to conventional immunosuppressive therapy; unfortunately mortality is high, and data are preliminary.

Great potential and optimism exist for “biologic” immunomodulating agents that focus on various aspects of the immune system, including B cells, interactions between B and T cells, and cytokines. The most promising current therapeutic agents are those that deplete B cells, producers of autoantibodies. Among these, rituximab has been successfully used in refractory lupus patients with hematologic and renal disease manifestations.

Special Issues in the Care of Patients with Systemic Lupus Erythematosus

PREGNANCY

Pregnant women with lupus have higher rates of both pregnancy loss (miscarriage and stillbirth) and preterm delivery (premature rupture of membranes, preeclampsia, and intrauterine growth restriction). Lupus activity preceding conception, especially nephritis, hypertension, and antiphospholipid antibody syndrome, are clear risk factors for pregnancy complications in SLE. Pregnancy itself may place women with lupus at greater risk for a flare, particularly if the disease, specifically nephritis, was active before conception.

Neonatal lupus is a rare disorder in which maternal anti-SSA/Ro-SSB/La antibodies cross the placenta and injure the fetus. Mothers with these autoantibodies have a 2% risk of having a child with congenital heart block (CHB). These mothers are screened with fetal heart tones and fetal echocardiography between weeks 16 and 34 of gestation. Treatment with a fluorinated corticosteroid (dexamethasone)

may be beneficial; however, a considerable number of children with CHB do not survive (30%) or experience morbidity, with over 60% requiring pacemakers. More common manifestations of neonatal lupus are skin rashes, cytopenias, and hepatosplenomegaly, all of which resolve within 6 to 8 months (after maternal autoantibodies are removed from the child's circulation). Mothers of children with neonatal lupus do not necessarily have SLE or Sjögren syndrome; however, some of these women eventually are diagnosed with an autoimmune disease.

With careful prenatal screening and planning, women with lupus can successfully have a healthy child. Prenatal monitoring of anti-SSA/Ro-SSB/La antibodies and antiphospholipid and anticardiolipin antibodies and a prepregnancy high-risk obstetric consultation are critical. Ideally, women with lupus should have clinical quiescence for 6 months before considering a planned pregnancy. Special consideration must also be given to medications, as the majority of immunosuppressants (methotrexate, mycophenolate mofetil, and cyclophosphamide) are teratogenic.

HORMONAL THERAPY

Hormones are thought to play a role in the development of SLE, given its female predominance. Consequently, rheumatologists have historically been hesitant to prescribe estrogen therapy for fear of inducing a flare. Recently, randomized, placebo-controlled clinical trials, described in the next paragraphs, have helped to guide hormonal therapy in women with lupus.

A multicenter randomized trial revealed that oral contraceptive therapy does not appear to increase the risk of SLE flares in women with mild or stable SLE disease activity. However, this is not generalizable to all women with SLE, in particular those whose disease is active or severe and those with prior thrombotic events or antiphospholipid and anticardiolipin antibodies. Clearly, an effective form of birth control is necessary for young sexually active women with SLE, especially those taking teratogenic medications. Physicians must carefully discuss the risks and benefits of birth control with lupus patients.

Hormone replacement therapy (HRT) is a controversial topic, regardless of lupus status. However, it is of particular interest in SLE because some women with lupus reach menopause prematurely. In a recent clinical trial of HRT in SLE patients with mild or stable disease, with no prior thrombotic events, antiphospholipid and anticardiolipin antibodies, or malignancies of women, no lupus patients had severe clinical flares, but 20% did have mild to moderate flares. These findings suggest that brief (1 year) HRT may have a role in alleviating menopausal symptoms or in treating osteoporosis in a certain subset of women with SLE.

CARDIOVASCULAR DISEASE

As survival and therapies for lupus have improved, CVD has emerged as a leading cause of morbidity and mortality. Lupus patients are 5 to 10 times more likely than healthy individuals to have a coronary event. More striking, premenopausal women aged 35 to 44 are more than 50 times as likely as healthy women to experience a myocardial infarction.

Autopsy series have revealed atherosclerotic heart disease as the underlying mechanism of CVD in SLE. The cause of this premature atherosclerosis in lupus is multifactorial and includes inflammatory mediators, lupus-related factors (premature menopause, corticosteroid therapy, disease activity), and traditional cardiovascular risk factors.

Prevention of CVD is a critical aspect of the care of lupus patients. Although no firm CV management guidelines exist for SLE patients, many argue that lupus patients should be considered and treated as coronary heart disease risk equivalents. Cardiac disease must be thought of and aggressively evaluated in SLE patients with both typical and atypical cardiac symptoms, regardless of age.

MALIGNANCY

Recently, a multicenter international cohort of nearly 10,000 lupus patients reported an increased risk of malignancy in SLE compared with the general population. Most striking was a threefold to fourfold increased risk of non-Hodgkin lymphoma. Other hematologic, lung, and hepatobiliary cancers were also described with increased frequency in SLE patients. Malignancy risk appears to be highest early in the disease course, but malignancy is clearly a risk throughout a patient's life span. Older age, tobacco use, SLE disease damage, and immunosuppressant use appear to be associated with cancers in SLE; however, the exact mechanism of malignancy in SLE is not yet fully elucidated.

Although lymph node enlargement is a common manifestation in lupus patients, physicians must have a high index of suspicion for malignancy if the lymphadenopathy does not resolve with lupus treatment, is tender or nonmobile, or occurs without other lupus symptoms.

BONE HEALTH

Lupus patients have higher rates of low bone mineral density (BMD), osteoporosis, and fractures, than do healthy age-matched subjects. The increased risk is accounted for by both traditional risk factors, such as female sex, white race, older age, and low body weight, and lupus-associated factors. Fatigue and articular symptoms secondary to SLE may limit physical activity, leading to loss of bone strength. Furthermore, therapies commonly used in lupus contribute to overall loss of bone health. Corticosteroids reduce bone mass and are an independent risk factor for fractures in women with SLE. Cyclophosphamide use can lead to premature ovarian failure, another risk factor for osteoporosis. In addition, lupus disease damage, regardless of steroid use, leads to low BMD, suggesting that SLE itself is a risk factor for low BMD. Another contributing factor may be that lupus patients are commonly asked to avoid sun exposure, which can lead to low vitamin D levels and insufficient absorption of calcium.

Given these SLE-specific risk factors for low BMD, prevention of osteoporosis is extremely important. Although osteoporosis screening guidelines for SLE patients are the same as for the general population, bone density scans should also be considered in patients with premature menopause and those who are or who will be on chronic (>3 months) corticosteroids.

Prospectus for the Future

- Advances in the understanding of the immunopathologic features of SLE, providing a logical framework for specific targeting and testing of new biologic therapies.
- Clinical trial data to evaluate the efficacy of new biologic agents for the treatment of SLE.
- Development of formal management guidelines for osteoporosis and cardiovascular care in patients with SLE.

Antiphospholipid Antibody Syndrome

Surabhi Agarwal and Amy H. Kao

Antiphospholipid antibody syndrome (APS) is a disorder characterized by recurrent vascular thrombosis and/or recurrent pregnancy loss in the presence of positive antiphospholipid (aPL) antibodies. The aPL antibodies were initially identified in patients with false-positive syphilis screening test results (positive result in the absence of syphilis). Lupus anticoagulant (LAC) was later described in patients with systemic lupus erythematosus (SLE), which was also frequently associated with a false-positive result of a screening test for syphilis and was paradoxically associated with thrombosis and recurrent pregnancy loss. LAC is a misnomer because this *in vitro* anticoagulant effect reflects the prolonged activated partial thromboplastin time (aPTT), and the presence of LAC does not indicate a diagnosis of lupus. Furthermore, both LAC and anticardiolipin (aCL) antibodies were shown to bind to phospholipid-binding plasma proteins and not directly to phospholipids.

Pathogenesis

Animal studies suggest that aPL may be directly pathogenic. The linear correlation between antibody levels and risk of thrombosis further supports their pathogenic role. aPL can cause β_2 -glycoprotein I (β_2 -GPI)-dependent endothelial activation by upregulation of expression of adhesion molecules and secretion of proinflammatory cytokines. β_2 -GPI interferes with Von Willebrand factor-dependent platelet activation; neutralization of this effect by β_2 -GPI antibodies may also potentiate the risk of thrombosis. aPL also induces platelet activation, leading to increased platelet adhesion and thromboxane synthesis. In addition, aPL may confer acquired resistance to the anticoagulant properties of protein C and annexin A5, further contributing to the increased risk of thrombosis. aPL displaces annexin A5 from the trophoblastic surface, which may contribute to pregnancy loss. Important to note, aPL-mediated thrombosis and fetal loss are complement-dependent, and heparin therapy acts via

complement inhibition rather than as an anticoagulant as previously believed.

Clinical Features

A subset of people with aPL antibodies eventually exhibit manifestations of APS. Both arterial and venous thrombosis may occur in vessels of any size. Venous thrombosis, especially of the lower extremities, is by far the most common manifestation. Up to half of affected patients develop associated pulmonary embolism. The most common site of arterial thrombosis is the central nervous system, with manifestations including seizures, stroke, dementia, and psychosis. Transverse myelitis, chorea, and Guillain-Barré syndrome have also been reported. In addition, *microthrombotic* disease is being recognized as a manifestation of APS. Renal failure may occur as a result of microthrombosis and renal artery thrombosis.

Cardiac valve thickening (Libman-Sacks endocarditis) is frequently found in patients with APS. These noninfectious vegetations may be a source of embolism. Any valve can be affected, with mitral regurgitation being the most frequent hemodynamic abnormality, followed by aortic regurgitation. This is frequently asymptomatic; and the need for surgery is uncommon. Unlike rheumatic heart disease and bacterial endocarditis, valvular thickening is diffuse and rarely causes rupture.

A major feature of APS is recurrent pregnancy loss, especially after the 10th week of gestation. Fetal distress, intrauterine growth retardation, premature births, uteroplacental insufficiency, and oligohydramnios contribute to major pregnancy morbidity. Preeclampsia and HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) are also frequent complications.

Other prominent manifestations of APS include mild thrombocytopenia, with platelet count usually above 50,000/mL; APS seldom causes hemorrhage. Hemolytic anemia is relatively uncommon and may occur simultaneously with thrombocytopenia (Evans syndrome). Livedo reticularis

may often be noted on physical examination of patients with APS. Leg ulcers, gangrene, thrombophlebitis, nailfold infarcts, cutaneous necrosis, and necrotizing purpura may be seen.

The term *catastrophic APS* (CAPS) has been coined to describe patients who exhibit multiple microthromboses, positive aPL antibodies, and often a life-threatening illness resulting in multi-organ failure that can be clinically indistinguishable from sepsis or thrombotic thrombocytopenic purpura. Although the precise cause of CAPS remains unclear, preceding infection has been reported in multiple cases and is thought to be a precipitating factor.

Diagnosis

The classification criteria of APS are shown in Table 82-1. The presence of clinical features with laboratory evidence of aPL antibodies is necessary to establish the diagnosis of APS. In addition, the patient should repeat testing for aPL antibodies at least 12 weeks apart using the same laboratory because transient elevation can be seen with

infections, malignancies, medications, and other autoimmune diseases.

APS is considered *primary* if it occurs in isolation and *secondary* if it occurs in conjunction with other autoimmune diseases such as SLE. There are no major differences in severity or clinical consequences between primary and secondary APS. Progression from primary APS to SLE is unusual. The reported prevalence of various aPL antibodies in SLE ranges from 16% to 55%. Patients with SLE who have aPL antibodies not only have an increased risk of thromboembolism and pregnancy complications but are also found to have a higher prevalence of pulmonary hypertension, Libman-Sacks endocarditis, and neurologic complications (seizures, strokes, and transverse myelitis).

As mentioned previously in this chapter, aPL antibody assays detect a heterogeneous group of antibodies that bind serum proteins such as β_2 -GPI, prothrombin, cardiolipin, annexin A5, and other negatively charged phospholipids. The assays that are useful clinically include LAC, aCL, and β_2 -GPI antibodies. Various methods, such as the Russell viper venom time, aPTT, kaolin clotting time, and hexagonal lipid neutralization test, are used to test for LAC. Anticoagulation therapy may interfere with these assays. The presence of LAC is the strongest predictor of thrombosis among aPL antibodies. The immunoglobulin (Ig) isotypes of aCL antibodies may be IgG, IgM, or IgA. The specificity of these antibodies for APS increases with higher titer and is the highest with the IgG isotype.

Table 82-1 Revised Classification Criteria of Antiphospholipid Syndrome

Antiphospholipid antibody syndrome (APS) is present if at least one clinical criterion and one laboratory criterion are met.

Clinical Criteria

1. Vascular thrombosis: One or more clinical episodes of arterial, venous, or small vessel thrombosis, in any tissue or organ. Thrombosis must be confirmed by objective validated criteria (i.e., unequivocal findings of appropriate imaging studies or histopathology). For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.
2. Pregnancy morbidity
 - (a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus *OR*
 - (b) One or more premature births of a morphologically normal neonate before the 34th week of gestation because of (i) eclampsia or severe preeclampsia; (ii) recognized features of placental insufficiency *OR*
 - (c) Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded.

Laboratory Criteria

1. Lupus anticoagulant (LAC) present in plasma on two or more occasions at least 12 weeks apart.
2. Anticardiolipin (aCL) antibody of immunoglobulin G (IgG) and/or IgM isotype in serum or plasma, present in medium or high titer (i.e., >40 GPL or greater than the 99th percentile), on two or more occasions at least 12 weeks apart, measured by a standardized enzyme-linked immunosorbent assay (ELISA).
3. Anti- β_2 -glycoprotein I antibody of IgG and/or IgM isotype in serum or plasma (in titer greater than the 99th percentile) present on two or more occasions at least 12 weeks apart, measured by a standardized ELISA.

Management

Currently, treatment for APS is tailored to the patient and the associated clinical manifestations. For patients with vascular thrombosis, indefinite anticoagulation is usually prescribed as prophylaxis against recurrence. Warfarin is the usual drug of choice for long-term therapy, with a target of international normalized ratio (INR) between 2 and 3. Higher INR level (3 to 4) is not more effective and is associated with bleeding complications. Unfractionated and low-molecular-weight heparin is also an effective anticoagulant for APS patients and is used in patients who experience recurrent events while on warfarin therapy or in patients who are or plan to become pregnant.

Treatment in patients with persistently elevated aPL antibody levels without thrombosis has not been well established and is not clearly indicated. Low-dose aspirin (75 to 100 mg) has been considered a logical option, but its efficacy has not been substantiated by prospective studies. Hydroxychloroquine, an antimalarial drug commonly used in SLE, may be protective against the development of thrombosis by reducing the binding of aPL- β_2 -GPI complexes to phospholipid bilayers. Risk factor modification, including avoidance of oral contraceptives and hormonal therapy, smoking cessation, and aggressive management of dyslipidemia, hypertension, and diabetes, should always be considered in these patients. Anticoagulation prophylaxis should be also considered in high-risk situations, such as surgery and prolonged immobilization.

Risk of recurrent pregnancy loss in APS can be reduced with combination treatment of low-dose aspirin and heparin. Intravenous immunoglobulin (IVIG) and plasmapheresis

have been used with mixed results in refractory cases. Warfarin should be switched to therapeutic doses of heparin before and during pregnancy because of the teratogenic effects of warfarin. Pregnancy in APS patients is considered high risk and requires a team approach with careful monitoring by the obstetrician and hematologist.

Corticosteroids and immunosuppression have a minimal role in management of thrombosis in APS except in CAPS.

Although there are no randomized controlled trials for treatment of CAPS, combinations of corticosteroids, anticoagulation, and/or plasmapheresis have been used. Evidence to support the use of cyclophosphamide has been documented mainly in patients with SLE with CAPS. Infections have been identified as a major precipitating factor for initiation of CAPS cascade; hence infection must be treated aggressively in these patients.

Prospectus for the Future

- Large cohort studies may provide data for better risk stratification and targeted prophylactic therapy.
- Complement inhibition may be a potential novel therapy in the treatment of recurrent pregnancy loss in patients with APS. However, further studies are warranted.

Systemic Sclerosis (Scleroderma)

Robyn T. Domsic and Thomas A. Medsger, Jr.

The hallmark of systemic sclerosis (SSc) is cutaneous and visceral fibrosis, which is reflected in the other common term for the disease, *scleroderma*, which derives from the Greek *scleros*, meaning thick, and *derma*, referring to skin. The disorder can range from a relatively benign condition to a rapidly progressive disease leading to significant morbidity or death. Although cutaneous manifestations are the most obvious, it is the visceral involvement that can be the most severe or disabling. Awareness of and monitoring for potential organ complications are essential in caring for patients with SSc, as early detection and treatment of complications minimize morbidity and mortality.

Epidemiology

The annual incidence of SSc in the United States is approximately 20 cases per million persons. As many patients with SSc live for many years, the prevalence is 240 cases per million. The incidence and prevalence varies somewhat throughout the world and is generally lower in Europe and Asia.

SSc more commonly affects women, with a 3:1 female:male ratio. It occurs in individuals of all ages, from childhood to the elderly, but is most frequent in the fourth through seventh decades. The familial pattern of inheritance is not as evident in SSc as in other rheumatic diseases, although many patients with SSc have family histories of autoimmune thyroid disease, rheumatoid arthritis, and lupus. Twin studies have demonstrated a 5% rate of concordance in both monozygotic and dizygotic twins, suggesting that both genetics and environment contribute to its occurrence.

Pathologic Considerations

The pathogenesis of SSc is complex and has not been fully elucidated. However, there are three clear components: (1)

fibrosis with overproduction of collagen and other connective tissue matrix proteins, (2) vascular injury and obliteration, and (3) immune system activation (Fig. 83-1). The involvement of all three of these systems initially became evident from autopsy examinations. Examination of the skin reveals thickening of the dermis with excessive deposition of collagen fibrils, and fibrous replacement of subcutaneous fat and secondary skin appendages such as hair follicles and sebaceous glands. Vascular changes include endothelial cell injury and subintimal thickening leading to luminal narrowing with occasional vascular occlusion. Periadventitial fibrosis is frequent. The vascular changes are seen in the skin but also may occur in the pulmonary, cardiac, and renal systems and involve arteries, arterioles, and capillaries. Cutaneous inflammatory infiltrates consist of activated mononuclear cells, T lymphocytes, and monocytes in the dermis, often in a perivascular distribution. True vasculitis is conspicuously absent.

The interplay among the vascular, connective tissue, and immunologic changes is complex. Fibroblasts are found in increased numbers in the skin and other tissues, live longer, and produce an overabundance of collagen. Although fibroblasts can be activated by the immune system in normal skin repair, cultured skin fibroblasts have a persistent SSc phenotype, suggesting an abnormality not requiring continued immune stimulation. Other potential factors may contribute to fibrosis, including hypoxia and local cytokine changes. Endothelial cell activation with resultant leukocyte migration, smooth muscle cell proliferation, and matrix deposition have been implicated in the vascular changes. In the serum, increased levels of inflammatory markers (sedimentation rate) and circulating cytokines are seen. More than 95% of patients with SSc have one of nine serum autoantibodies relatively specific to scleroderma, all of which are directed at distinct antigens. These antibodies are helpful in classifying patients, but to date, their pathogenic role has not been elucidated.

Figure 83-1 Pathogenetic processes in systemic sclerosis. Vascular injury leads to intimal proliferation of both endothelial cells (red) and smooth muscle cells (blue). Fibroblasts are activated to deposit increased amounts of interstitial matrix. IL, interleukin; PDGF, platelet-derived growth factor; TGF- β , transforming growth factor- β .

Clinical Features

SKIN CLASSIFICATION

SSc is separated into two major clinical subsets, diffuse cutaneous and limited cutaneous sclerosis, defined by the degree and extent of skin involvement. Patients with limited cutaneous involvement experience skin thickening limited to the extremities (below the elbows and knees). Patients with diffuse cutaneous SSc have similar distal changes and also involvement of the upper arms, thighs, or trunk at some time during the disease course. A small proportion of patients (<1%) have no skin thickening but have one or more typical SSc visceral manifestations. The term *SSc sine scleroderma* has been used to describe these patients whose disease behaves like that in individuals with limited skin disease. This distinction is important, as patients with diffuse disease are more likely to develop certain complications such as renal crisis, whereas those with limited disease are more predisposed to other problems such as pulmonary arterial hypertension (Table 83-1).

SEROLOGIC CLASSIFICATION

Serologic classification is also important, as autoantibodies define patients with SSc with similar clinical manifestations. For example, patients with anticentromere antibody almost always have limited skin disease and are at risk for pulmonary hypertension during follow-up. Individuals with anti-topoisomerase (also termed *anti-Scl-70*) or anti-RNA polymerase III antibody are likely to have diffuse disease. Those with anti-RNA polymerase III antibody have an increased risk of “renal crisis,” whereas those with anti-Scl-70 have a higher frequency of interstitial lung disease (ILD).

RAYNAUD PHENOMENON AND PERIPHERAL VASCULAR INVOLVEMENT

Nearly all patients with SSc experience Raynaud phenomenon, which is defined as a triphasic vascular response to cold consisting of pallor, cyanosis, and reactive hyperemia. The onset of Raynaud phenomenon can precede the development of skin changes by years in some patients. Severe involvement may result in ischemia with loss of digital tip tissue including digital pitting scars, ulcers, and, rarely, gangrene. A frequent finding in late-stage disease is visibly dilated capillaries and venules of the hands, face, and lips.

INTERSTITIAL LUNG DISEASE

ILD can be one of the most serious complications of SSc and needs to be monitored for routinely. The initial presentation is often a nonproductive cough and gradual onset of dyspnea on exertion (often over several months to years). High-resolution chest computed tomography (CT) typically shows bibasilar fibrotic changes, which can be progressive, and pulmonary function tests show reduced forced vital capacity (FVC). On pathology, the most frequently seen pattern is nonspecific interstitial pneumonitis. Patients with anti-Scl-70 are at highest risk for development of ILD.

PULMONARY ARTERIAL HYPERTENSION

Pulmonary arterial hypertension not associated with ILD is detected in 10% to 25% of patients with SSc, more commonly in those with limited disease, although it can occur in those with long-standing diffuse disease. Presentation is generally with rapidly progressive dyspnea (over several months). Pulmonary function tests reveal a reduced diffusion capacity for carbon monoxide (DLCO) out of

Table 83-1 Clinical Features of Systemic Sclerosis

	Diffuse	Limited
Skin induration	Widespread; extremities, trunk, face	Face and extremities distal to the elbow or knee
Raynaud phenomenon	80%-90%; ischemia, digital ulcers	95%-100%; ischemia, digital ulcers
Telangiectasia	Common	May be extensive
Calcinosis	Occurs, more frequent in limited	Common
Esophageal hypomotility and reflux	80% may be severe; strictures	90%; may be severe
Intestinal hypomotility or malabsorption	Common, may be severe	Less common, not usually severe
Interstitial lung disease	Common, major cause of death	Frequent
Pulmonary hypertension	Often secondary to pulmonary fibrosis; primary type less common	10%; primary type
Cardiac fibrosis, cardiomyopathy	Common	Less common
Renal disease	Renal crisis and vasculopathy	Very rarely seen
Myositis	<20%; may be severe	<20%; may be severe
Tendon friction rubs	Common with active skin disease	Rarely—indicate likely progression to diffuse disease if present
Antinuclear antibodies	98%	98%
Anti-SCL-70	30%-40%	10%-15%
Anti-RNA polymerase III	Up to 50%	
Anti-centromere	3%	40%-50%

proportion to any concomitant reduction in FVC. Screening is generally performed by echocardiogram and should be confirmed by right heart cardiac catheterization. Both left ventricular diastolic dysfunction and associated ILD should be considered as causes of pulmonary arterial hypertension in patients with SSc.

SCLERODERMA RENAL CRISIS

Renal crisis generally manifests as the abrupt onset of accelerated hypertension accompanied by a rise in serum creatinine and microscopic hematuria and proteinuria on urinalysis. Microangiopathic hemolytic anemia and thrombocytopenia are frequent. Although once the major contributor to mortality, renal crisis can now be easily managed with an angiotensin-converting enzyme (ACE) inhibitor. The typical setting for renal crisis is early diffuse disease. During this time patients should check their blood pressure once weekly, reporting a rise in systolic blood pressure of >30 mm Hg from baseline.

CARDIAC INVOLVEMENT

Patients with SSc experience three primary types of cardiac involvement. These include pericarditis, myocarditis, and myocardial fibrosis leading to congestive heart failure and arrhythmias because of fibrosis of the conduction system. These complications can be underrecognized in patients with SSc but are frequently found at autopsy.

GASTROINTESTINAL MANIFESTATIONS

At least one gastrointestinal manifestation will affect 80% or more of patients with SSc. Gastrointestinal manifestations are a significant cause of morbidity. All areas of the gastrointestinal tract may be affected. Patients experience heartburn and distal dysphagia of solid foods owing to relaxation of the esophageal sphincter and esophageal dysmotility,

respectively. Neuropathic changes and fibrosis of the muscularis of the small intestine can lead to hypomotility and symptoms of postprandial abdominal distention. The hypomotility can lead to bacterial overgrowth and ultimately to malabsorption, as the bacteria may digest pancreatic enzymes. Signs and symptoms include abdominal pain and distention, along with watery diarrhea or steatorrhea. Occasionally, when severe atony of the small intestine develops, patients will develop a functional ileus, or intestinal pseudo-obstruction. Similar to the small bowel, the colon may develop impaired motor function, resulting in constipation, and occasionally “overflow” diarrhea. Wide-mouthed diverticula can be seen. The internal anal sphincter may become fibrotic, resulting in fecal incontinence.

MUSCULOSKELETAL MANIFESTATIONS

Musculoskeletal manifestations are common. Tendons can become inflamed and fibrotic, particularly in early diffuse disease. Palpable tendon or bursal friction rubs are virtually pathognomonic of SSc and often are a harbinger of diffuse disease before widespread skin thickening has occurred. Destructive arthropathy is occasionally seen. Some patients develop a bland myopathy that manifests as nonprogressive, mild proximal muscle weakness and wasting. Other patients, particularly if they have overlapping features with other connective tissue diseases, can develop myositis.

Differential and Diagnosis

Raynaud disease, or “primary” Raynaud, is prominent in the differential for SSc. Two features that identify patients with Raynaud who have or may later develop SSc or another connective tissue disease are abnormal nailfold capillaries (dilation or dropout) and a positive antinuclear antibody

(ANA) test result. Neither of these features is found in Raynaud disease, which is more often familial.

When initially evaluating a patient with SSc features, it is important to determine whether she or he has SSc alone or overlapping with another connective tissue disease, such as systemic lupus erythematosus or polymyositis. Although these disorders are covered elsewhere, patients with these conditions (also referred to as *mixed connective tissue disease*) often will demonstrate SSc-like findings including scleroderma skin changes, Raynaud phenomenon, and esophageal dysmotility.

There are a number of scleroderma “mimics,” which at times can be confusing to distinguish from SSc (Table 83-2). These include eosinophilic fasciitis (EF), morphea, and the localized forms of scleroderma, such as linear scleroderma (more frequently seen in children). Nephrogenic systemic fibrosis (NSF) is a recently described disorder now recognized to be a complication of gadolinium administration for radiographic studies in the setting of renal failure. EF is distinguished by peripheral blood eosinophilia with thicken-

ing of the forearm fascia leading to clawing of the hands, but lack of skin thickening of the fingers. Morphea reveals isolated patches of induration followed by atrophic skin, often in a dermatomal pattern. Linear scleroderma more frequently affects children. NSF manifests as symmetrical, bilateral fibrotic indurated papules, plaques, or subcutaneous nodules, which can be erythematous, on the lower legs or hands. The lesions are often preceded by edema and may initially be misdiagnosed as cellulitis. This diagnosis should be considered in any patient being evaluated for a fibrotic disorder who has renal failure, regardless of the cause of renal disease. All SSc mimics lack Raynaud phenomenon, characteristic SSc internal organ involvement, and SSc-associated serum antibodies.

Patient Care and Treatment

As no single therapy exists for SSc, it is vital that patients with SSc be appropriately monitored for organ manifestations, thereby allowing for early identification and therapy targeted at specific organ complications (Table 83-3). Consultation with a rheumatologist is helpful in this respect. In general, all patients should undergo screening evaluation for ILD and pulmonary hypertension at the time of diagnosis and every 2 to 3 years thereafter. Patients with active diffuse cutaneous disease should undergo weekly monitoring of blood pressure, evaluating for increases suggestive of renal crisis. These patients should also have skin thickness scores assessed for progression or regression of cutaneous disease. Both patients with diffuse disease and those with limited disease can develop gastrointestinal manifestations as noted previously, and objective studies can be ordered as warranted by symptoms. Education of patients and family members regarding the disease and the patient’s classification (early or late diffuse or limited disease) can be helpful in alleviating patient anxiety.

RAYNAUD PHENOMENON

Calcium channel blockers have been widely used for decades and are generally well tolerated by patients. Long-acting nifedipine is effective in over half of patients, and newer agents such as amlodipine are also frequently prescribed. The angiotensin receptor blocking agent losartan has been shown to reduce the severity and frequency of Raynaud attacks in a placebo-controlled trial. In patients who experience digital ulcerations, more aggressive therapy may be warranted. Sildenafil has been studied and found to be helpful in uncontrolled studies. Topical nitroglycerin administered to the hand may be a useful adjunct. Bosentan has been shown in randomized placebo-controlled trials to prevent the formation of new digital ulcerations in patients with SSc and Raynaud, although it has not yet been approved by the U.S. Food and Drug Administration (FDA) for this indication. Although used more frequently in Europe, monthly intravenous (IV) prostacyclins have also been used to treat and prevent digital ulcerations. Surgical interventions include sympathectomy of the digital, radial, or ulnar artery and venous bypass for ulnar or radial artery occlusion.

Table 83-2 Scleroderma-like Syndromes

Other Diseases	Distinguishing Features
Morphea	Patchy or linear distribution
Eosinophilic fasciitis	Sparing of hands Biopsy shows involvement extending to fascia and muscle
Scleredema (of Buschke)	Prominent involvement of neck, shoulders, and upper arms; hands spared Associated with diabetes
Scleromyxedema	Association with gammopathy; skin lichenoid and thickened but not tethered May have Raynaud phenomenon
Graft-versus-host disease	Skin changes similar to scleroderma; vasculopathy
Nephrogenic-fibrosing dermopathy	Indurated plaques or nodules on the legs or arms, sparing the face, often preceded by edema
Environmental Agents and Drugs	
Bleomycin	Skin and lung fibrosis similar to scleroderma
L-Tryptophan	Eosinophilia-myalgia; from contaminant or metabolite (described in the 1980s) Fever, eosinophilia, neurologic manifestations, pulmonary hypertension
Organic solvents	Trichloroethylene and others implicated Clinically indistinguishable from idiopathic systemic sclerosis
Pentazocine	Localized lesions at injection sites
Toxic oil syndrome	Contaminated rapeseed oil (Spanish epidemic, 1981) Similar to eosinophilia myalgia syndrome
Vinyl chloride disease	Vascular lesions, acro-osteolysis, sclerodactyly No visceral disease
Gadolinium	Nephrogenic systemic fibrosis

Table 83-3 Therapeutic Approaches to Systemic Sclerosis

Manifestation	Pathophysiologic Features	Treatment
Raynaud phenomenon	Vascular hyperreactivity and obliteration	Calcium channel blocker Angiotensin receptor blockers, vasodilators, and smoking cessation
Digital ulcers	Vascular changes leading to ischemia	Raynaud treatment as above or treatment with sildenafil or monthly prostanoids. Bosentan may reduce new digital ulcerations. Digital sympathectomy or vascular bypass when there is evidence of radial or ulnar vasculopathy.
Esophageal reflux	Loss of lower esophageal sphincter function	Proton-pump inhibitors; H ₂ -blockers
Intestinal hypomotility	Damage to the myenteric plexus; intestinal fibrosis and atrophy	Promotility agents
Malabsorption	Bacterial overgrowth	Rotating antibiotics Monitoring and supplementation of fat-soluble vitamins and iron
Interstitial lung disease	Inflammation; fibrosis	Cyclophosphamide, mycophenolate mofetil corticosteroids
Pulmonary hypertension	Vascular obliteration	Prostacyclin analogs, endothelin-receptor antagonists, sildenafil
Cardiac arrhythmia	Myocardial ischemia and fibrosis	Anti-arrhythmic agents
Renal crisis	Vasculopathy with upregulated renin-angiotensin system	Angiotensin-converting enzyme (ACE) inhibitors
Myositis	Inflammation	Corticosteroids; methotrexate or other immunosuppressive agents
Skin thickening	Inflammation, Fibrosis	D-Penicillamine, mycophenolate, mofetil, or other investigational drugs

In patients with SSc with recurrent digital ulcerations or other thrombotic events with Raynaud disease, evaluation for a hypercoagulable state, particularly for lupus anticoagulant, should be performed. If a hypercoagulable state is present, the use of aspirin or other anticoagulants should be considered.

CUTANEOUS DISEASE

No therapeutic agent has been found to improve skin thickening in diffuse scleroderma patients in a randomized, placebo-controlled trial. There are several methodologic issues that may have contributed to the negative findings, including the drugs chosen, patient populations, and trial designs. In the past, considerable attention was given to methotrexate and D-penicillamine. Methotrexate provided conflicting results, and D-penicillamine, unfortunately, was never studied in a placebo-controlled fashion. Currently several drugs are undergoing clinical trials. These agents act by either reducing collagen synthesis or increasing collagen breakdown. Several reports on the benefit of autologous stem cell transplantation have been published, and two multicenter randomized, controlled trials of cyclophosphamide versus stem cell transplantation are currently enrolling patients.

SCLERODERMA RENAL CRISIS

Early identification and treatment with ACE inhibitors have dramatically improved survival and outcomes of scleroderma renal crisis. ACE inhibitors should be titrated to maintain a “normal” blood pressure, preferably <125/75. Even if a patient with renal crisis becomes dialysis-depend-

ent initially, if ACE inhibitor therapy is maintained, some patients may experience a slow reversal of renal vascular damage and can discontinue dialysis during the first 2 years after the onset of this complication.

INTERSTITIAL LUNG DISEASE

Early recognition of inflammatory ILD is important if treatment is to prevent progression to distortion of lung architecture and irreversible fibrosis. A recent large U.S. randomized, placebo-controlled trial demonstrated statistically significant but modest benefit with the use of cyclophosphamide at 1 year. However, after an additional year off therapy, cyclophosphamide-treated patients lost their benefit, suggesting other treatment options are needed. Small case series suggest potential benefit of mycophenolate mofetil, but this drug has not been tested in a randomized trial. Lung transplantation can be considered for end-stage ILD.

PULMONARY ARTERIAL HYPERTENSION

In recent years, several agents have been approved for the treatment of pulmonary arterial hypertension in patients with SSc. Subset analyses of several placebo-controlled drug trials have shown improvement in established SSc or connective tissue disease-related pulmonary hypertension. These have included sildenafil, bosentan, ambrisentan, treprostenil, and epoprostenol. Theoretically, treatment of patients with early, less severe disease would improve outcomes, but such studies are only beginning to be reported. Because patients with SSc-related pulmonary hypertension have a worse prognosis than those with primary pulmonary

hypertension, we strongly recommend referring patients with SSc with pulmonary hypertension to a tertiary care facility with a dedicated pulmonary hypertension clinic.

CARDIAC MANIFESTATIONS

Diastolic dysfunction, which is often underrecognized in SSc, can be evaluated on echocardiogram when performed for pulmonary hypertension screening. Many SSc deaths occur suddenly, possibly because of ventricular arrhythmias. Therefore it is prudent to obtain a resting electrocardiogram early in the disease course. Palpitations noted by the patient should be addressed with a formal cardiac arrhythmia evaluation.

GASTROINTESTINAL MANIFESTATIONS

Gastroesophageal reflux, which is present in nearly all patients with SSc, can be treated with proton pump inhibitors and conservative measures including elevation of the bed and avoidance of alcohol and caffeine. If untreated, reflux esophagitis can progress to stricture. Patients experiencing severe esophageal, gastric, or small bowel dysmotility may improve with the use of prokinetic drugs, such as

metoclopramide, erythromycin, or octreotide. If bacterial overgrowth is present, rotating antibiotics may be of assistance. In advanced small bowel involvement with malabsorption, supplementation of iron, calcium, and fat-soluble vitamins may be required. Occasionally, total parenteral nutrition is necessary. Unexplained iron deficiency anemia in patients with SSc should suggest the possibility of gastric antral vascular ectasias, which are treated with laser photocoagulation, and requires initial surveillance. Patients with this particular condition should be routinely monitored for iron deficiency anemia.

SKELETAL MUSCLE, JOINT, AND TENDON

Bland myopathy is generally nonprogressive and is treated with physical therapy. If myositis is suspected, as evidenced by elevation of serum muscle enzymes, abnormal electromyogram, or muscle biopsy, steroids and immunosuppressive therapy (such as methotrexate or azathioprine) may be helpful. Of note, both patients with limited disease and those with diffuse disease can develop contractures of the hands owing to tendon involvement. Physical therapy with daily stretching exercises directed at the finger joints should be instituted.

Prospectus for the Future

Effective therapy for both vascular and skin disease in scleroderma has been lacking. A multitude of potential reasons include lack of specific identified molecular targets, inadequate trial design, and difficulty in patient recruitment. An important clinical research emphasis should be defining and understanding clinical and serologic disease subsets. The SSc research community is working toward this. In the last few years,

additional potential molecular targets have been identified. Many of these are involved with the fibrotic process, which affects virtually all organ systems in the disease. Clinical trial consortia in both the United States and Europe are now working together to develop trials to test potential agents, increasing hope that important treatment advances will be made in the future.

Idiopathic Inflammatory Myopathies

Larry W. Moreland

The idiopathic inflammatory myopathies (IIMs) include polymyositis, dermatomyositis, myositis associated with malignancy, myositis associated with other connective tissue disease, and inclusion body myositis. These conditions have in common the clinical features of progressive symmetrical proximal weakness, elevation of muscle enzymes, muscle histologic features demonstrating mononuclear inflammatory cell infiltrates and muscle fiber necrosis, and characteristic electromyographic abnormalities. The IIMs differ in their association with extramuscular manifestations and with certain autoantibody profiles (Tables 84-1 and 84-2). The presence of mononuclear cell infiltration in muscle and frequent immune abnormalities, including autoantibodies, in patients with IIM has resulted in most of these disorders being thought of as autoimmune or immune-mediated diseases. This has also been the basis for the major therapeutic approaches for IIM that have been directed toward decreasing inflammation in the many organs that may be affected in these diseases.

The IIMs as a group and individually are relatively rare conditions, with estimated prevalence rates of 2 to 10 cases per million and incidence rates of 0.5 to 8.4 cases per million. The male-to-female ratio is approximately 2:1 for polymyositis and dermatomyositis; inclusion body myositis predominates in men. The age distribution of IIMs is bimodal, with a peak at ages 10 to 15 years in children with dermatomyositis and another peak at ages 40 to 60 years. Both myositis associated with malignancy and inclusion body myositis are more common after the age of 50 years.

Pathologic and Pathophysiologic Features

The hallmark of the IIMs is inflammatory infiltrate within muscle tissue. The infiltrate is primarily lymphocytic, but macrophages, plasma cells, and sometimes eosinophils,

basophils, and neutrophils are present. In polymyositis the infiltrate typically clusters in the endomysial area around muscle fibers, whereas in dermatomyositis the infiltrate predominates in the perimysial area around the fascicles and small blood vessels. Perifascicular atrophy occurs more frequently in dermatomyositis (Fig. 84-1). Necrotizing vasculitis is uncommon. Inclusion body myositis is characterized by the presence of intracellular vacuoles, which under electron microscopy appear as intracytoplasmic, intranuclear tubular, or filamentous inclusions.

The association of IIMs with other autoimmune disorders (including Hashimoto's thyroiditis, myasthenia gravis, primary biliary cirrhosis, and connective tissue diseases), in some cases with autoantibodies (see Table 84-2), and the response to corticosteroids suggest an autoimmune pathogenesis. This hypothesis is also supported by the identification of T cells cytotoxic to muscle in biopsy specimens and in the peripheral blood of patients with polymyositis and dermatomyositis. Autoimmunity is also suggested by the finding of immunoglobulin deposition and complement components in the capillaries and small arterioles in dermatomyositis. In addition, antibodies to autoantigens have been associated with IIMs and their complications. For example, antibodies to Mi2 (a nuclear helicase) are found in patients with dermatomyositis and skin rash, and antibodies to Jo-1 (a histidine transfer RNA [tRNA] synthetase) are found in patients with polymyositis and interstitial lung disease. Inclusion body myositis probably represents a special case, given its distinctive pathologic features, because amyloid deposits have been identified in the vacuoles that characterize this condition. A wide variety of proinflammatory cytokines (e.g., interferon- γ , interleukin-1, tissue necrosis factor- α), chemokines (e.g., monocyte chemoattractant protein), and cell adhesion molecules (e.g., platelet endothelial cell adhesion molecule-1, vascular cellular adhesion molecule) appear to be upregulated in the inflammatory myopathies. However, the sequence of events involved in the production of these molecules, their targets, and their precise role in muscle fiber damage and repair remain uncertain.

Table 84-1 Classification of the Idiopathic Inflammatory Myopathies

Primary idiopathic polymyositis
Primary idiopathic dermatomyositis
Polymyositis or dermatomyositis associated with malignancy
Juvenile dermatomyositis (or polymyositis)
Overlap syndrome of polymyositis or dermatomyositis with another autoimmune rheumatic disease
Inclusion body myositis

Table 84-2 Myositis Syndromes and Associated Autoantibodies

Autoantibody	Clinical Features	Treatment Response
Anti-Jo 1 (also known as antisynthetase)*	Polymyositis or dermatomyositis Acute interstitial lung disease Fever Arthritis Raynaud phenomenon	Moderate with persistent disease
Anti-SRP [†]	Polymyositis Abrupt onset Severe weakness Palpitations	Poor
Anti-Mi2 [‡]	Dermatomyositis V sign and shawl sign Cuticular overgrowth	Good

*Anti-Jo 1 is the most common myositis-specific autoantibody. It is known as *antisynthetase* because the putative antibody target is an RNA synthetase. The prevalence of anti-Jo 1 is approximately 20%. Other antisynthetase antibodies include anti-PL-7, anti-PL-12, anti-EJ, and anti-OJ, each of which has a prevalence of less than 3%.

[†]Prevalence is approximately 5%.

[‡]Prevalence is approximately 10%.

SRP, signal recognition particle.

Clinical Presentation

Patients with polymyositis are representative of the IIMs in their presentation and clinical features. The onset of the disease is typically insidious over a period of months, with proximal muscle weakness; in rare cases the presentation is more fulminant, with both proximal and distal muscle weakness. A more indolent onset over years with both proximal and distal involvement suggests inclusion body myositis. The symmetrical proximal muscle weakness often impairs performance of specific tasks such as getting up from a sitting position, getting out of a car, and reaching overhead or combing the hair, and it should be distinguished from conditions that produce a generalized fatigue or loss of energy that rarely interferes with these functions. Approximately one third of patients with polymyositis have upper esophageal involvement, which produces dysphagia and, occasionally, aspiration of oral contents. Myalgia occurs in approximately one half of patients, but it is generally mild, although it may cause confusion with polymyalgia rheumatica in older patients.

The assessment of muscle strength should include active resistive testing; the physician should keep in mind that this

testing should also be supplemented by asking the patient to perform specific tasks such as getting up from a low chair without using his or her arms, raising the arms over the head, and lifting the head from the examining table when in the supine position. The examiner should be aware that assessment of motor power may be confounded by the fatigue or pain of arthritis or myalgia.

In dermatomyositis, a characteristic skin eruption occurs, usually preceding the development of myositis. In rare cases, patients have the classic skin manifestations without the myositis (*dermatomyositis sine myositis* or *amyopathic dermatomyositis*). The rash has several distinctive varieties: Gottron lesions, the erythematous or poikilodermatous rash, and the heliotrope rash. *Gottron papules* consist of erythematous, sometimes scaly papules, plaques, or macules (Gottron sign) over the metacarpophalangeal and proximal interphalangeal joints. The *poikilodermatous eruption* of dermatomyositis consists of an erythematous or violaceous rash on the face, trunk, neck, extremities, or scalp. Occasionally, a characteristic distribution in the shape of a V appears on the anterior chest, or the so-called *shawl sign* (back of neck, upper torso, and shoulders). The *heliotrope (lilac-colored) rash* occurs in 30% to 60% of patients with dermatomyositis and is located characteristically on the upper eyelids, but it may be difficult to detect in dark-skinned patients.

Various nonmuscular and nondermatologic manifestations of the IIM may occur (Table 84-3). Pulmonary involvement in polymyositis and dermatomyositis may take several forms, including respiratory muscle weakness, interstitial lung disease, pulmonary hypertension, pulmonary vasculitis, and aspiration pneumonia. Respiratory muscle involvement may include the chest wall musculature and the diaphragm and is clinically significant in approximately 5% of patients. Respiratory failure necessitating ventilatory assistance is fortunately rare. Esophageal and tongue involvement appears to be a risk factor for this complication. Interstitial lung disease occurs in approximately 10% to 30% of patients with either polymyositis or dermatomyositis and in the case of polymyositis is frequently associated with the presence of antisynthetase (Jo-1) antibodies, fever, Raynaud phenomenon, and arthritis (*antisynthetase syndrome*) (see Table 84-2). Curiously, the severity of the interstitial lung disease may be independent of the severity of myositis.

Cardiac involvement in IIM may include conduction blocks, arrhythmias, and myocarditis; it appears to be more common than previously estimated (up to 70% in one series) and, as in interstitial lung disease, may be independent of the severity of myositis. Dysphagia, the result of myositis of striated muscle in the upper one third of the esophagus, occurs in up to 30% of patients with IIM. Less common involvement includes cricopharyngeal muscle dysfunction and, in children with dermatomyositis, intestinal vasculitis.

The relationship of IIM with malignant disease has been clarified by population-based studies showing a modest increase in risk (approximate twofold relative risk) within 1 to 2 years of the diagnosis of dermatomyositis and possibly polymyositis. The malignancies associated with dermatomyositis include those that occur most commonly in the general population. They include cancers of the lung, breast,

Experts recommend a thorough history, examination, and screening rectal examination; Papanicolaou stain in women; urinalysis; blood chemistry studies; chest radiograph; and prostate-specific antigen measurement in men. Serial gynecologic examinations, transvaginal ultrasonography, and serial CA-125 determinations to screen fully for ovarian cancer in women with recently diagnosed dermatomyositis may also be reasonable.

Diagnosis

When most of the known causes of myopathy are excluded by the clinical context and nature of the symptoms, the physical examination and laboratory testing should be directed at narrowing further the diagnostic possibilities and determining if more invasive procedures are needed. Muscle weakness needs to be distinguished from fatigability or pain that might limit function. The distribution of skeletal muscle tenderness or atrophy should be noted. Involvement of other muscles, including the heart, oropharynx, gastrointestinal tract, or ocular and respiratory muscles, as well as any other nonmuscle abnormalities, should be documented. Rashes need to be carefully evaluated and, in some cases, biopsied. The diagnosis of IIM is suggested by the typical history and physical examination. Muscle enzymes such as creatine phosphokinase and aldolase are significantly elevated. The diagnosis is confirmed by muscle biopsy, ideally an open biopsy to allow the optimal assessment of muscle architecture, although needle biopsy may be adequate for the diagnosis of polymyositis or dermatomyositis in many cases. The ideal muscle to sample for biopsy is one that is involved but not atrophic. Most commonly, the quadriceps or deltoid muscle is examined by biopsy. Magnetic resonance imaging (MRI) can detect muscle inflammation and damage and may improve the yield of biopsy diagnosis by directing the site of biopsy. Electron microscopy is helpful to establish the diagnosis of inclusion body myositis, and special stains to

identify excess glycogen or lipid are useful to exclude metabolic myopathies. With the possible exception of Jo-1 antibodies and the identification of the antisynthetase syndrome (see Table 84-2), the role of myositis-specific antibodies remains limited because they lack sensitivity, and not all are commercially available.

Electromyography alone cannot enable one to establish the diagnosis, but it can indicate muscle involvement in patients with dermatologic or nonmuscular features. Typical electromyographic features are listed in Table 84-4.

Differential Diagnosis

Patients with complaints of weakness or muscle pain are very common in clinical practice. Many different conditions should be considered in the differential diagnosis of myositis (Table 84-5). These include other myopathies (infectious myositis, drug-induced disorders, muscular dystrophies, metabolic myopathies, and endocrine disorders) and/or neurologic conditions (e.g., myasthenia gravis, Guillain-Barré syndrome).

Treatment

The mainstay of treatment for the IIMs consists of the corticosteroids. Initially, prednisone is begun at a high dose (e.g., 60 mg/day) until the creatine phosphokinase level has returned to normal or muscle strength has significantly improved. Occasionally, extremely high doses of intravenous corticosteroids are used for severely ill patients. Subsequently, corticosteroids are gradually tapered, depending on the clinical response. Approximately one third to one fourth of patients require additional immunosuppressive agents such as methotrexate or azathioprine because of steroid resistance, intolerable side effects, or inability to taper corticosteroids without inducing a flare-up in disease. Cyclophosphamide and cyclosporine have proved effective in patients who are resistant to steroid therapy; however, the toxicity of these agents limits widespread use. Mycophenolate mofetil is emerging as a promising and well-tolerated agent. Clinical trials have established the efficacy and low toxicity of intravenous gamma globulin in dermatomyositis. This therapy appears to work by blocking deposition of acti-

vated complement fragments and thereby protecting muscle capillaries from complement-mediated injury. Although intravenous gamma globulin is attractive because of its low toxicity, its long-term efficacy is unknown, and its long-term use is limited by its expense.

Prospectus for the Future

- The genetic factors that predispose individuals to develop dermatomyositis and polymyositis must be identified.
- The environmental triggers of myositis must be determined.
- Genetic, serologic, and other markers must be identified to predict treatment responses.

Sjögren Syndrome

Fotios Koumpouras

Sjögren syndrome is a chronic immune-mediated, inflammatory disorder of exocrine gland dysfunction. The syndrome can occur as a primary disorder or secondary to another connective tissue disease. The main exocrine glands that are affected include the lacrimal gland and the salivary glands, which can lead to dry eyes (keratoconjunctivitis sicca or xerophthalmia) and dry mouth (xerostomia). In addition, Sjögren syndrome can have systemic features including fatigue, fever, weight loss, and lymphadenopathy. The most common manifestations include inflammation of the exocrine glands by infiltration of mononuclear cells, resulting in gland destruction. Infiltration of visceral organs and skin can result in hepatitis, interstitial lung disease, vasculitis, and lymphoma, among others. Sjögren syndrome is associated with various autoantibodies, particularly antinuclear antibodies.

Patients are considered to have *secondary* Sjögren syndrome if they have another immunologic disorder, such as systemic lupus erythematosus, rheumatoid arthritis, systemic sclerosis (scleroderma), or primary biliary cirrhosis, and to have *primary* Sjögren syndrome if no underlying immunologic disorder is present. Although more common among women, Sjögren syndrome does affect men and is found among people of all ages, races, and ethnicities.

Clinical Features

The clinical features of Sjögren syndrome can be divided into those associated with exocrine gland dysfunction (Table 85-1) and those associated with extraglandular manifestations (Table 85-2). Dry eyes and mouth are by far the most common problems and can be very troubling to patients. Severe xerostomia can lead to tooth loss. Severe dry eyes can lead to corneal lesions and vision impairment. Many of the extraglandular manifestations, although often rare, can be life or organ threatening. The most common extraglandular feature is articular and the presence of Raynaud phenomenon.

The clinical association with Sjögren syndrome with lymphoma is well described. These lymphomas (usually B-cell

types) may involve malignant transformation of clinically involved exocrine glands or may involve sites not clinically apparent, such as cervical lymph nodes. Maintaining a low threshold in considering the diagnosis of lymphoma is prudent in patients with Sjögren syndrome who develop new masses, exhibit constitutional features, or experience persistent glandular swelling that is either resistant to treatment or changes in character.

Neurologic involvement in Sjögren syndrome can be overlooked. Five percent to 25% of patients with Sjögren syndrome have neurologic involvement, and it can be a presenting symptom. Sjögren syndrome can affect the central nervous system, but more commonly it affects the peripheral nervous system. The most common central nervous system manifestation is focal or multifocal brain involvement, which can mimic multiple sclerosis. Spinal cord involvement also can occur. Less common is the presence of optic neuritis. Peripheral nervous system involvement most commonly manifests as neuropathy with dysesthesias. Traditional electromyogram and nerve conduction velocity studies can identify about half of these patients. However, identification of small sensory fiber involvement requires quantitative sudomotor autonomic testing and should be pursued if traditional nerve conduction velocities and electromyogram studies are negative.

Diagnosis

A number of different diagnostic criteria sets have been proposed for Sjögren syndrome without consensus on any one set. Common to each set of criteria is the requirement to demonstrate the following:

1. Subjective and objective evidence of both keratoconjunctivitis sicca and xerostomia
2. Presence of at least one of the following four autoantibodies: antinuclear antibodies, rheumatoid factor, anti-Ro antibodies, or anti-La antibodies (these last two types of autoantibodies are also known as SS-A and SS-B

antibodies, respectively, and are so named for Sjögren syndrome)

3. Exclusion of underlying diseases that may mimic Sjögren syndrome

Leukopenia is common. Biopsy specimens from salivary glands, which are easily obtainable from the lower lip, may

Table 85-1 Clinical Features of Sjögren Syndrome Associated with Exocrine Gland Dysfunction

Problems Secondary to Lacrimal Gland Dysfunction

Dry, irritated eyes with foreign-body sensation
Corneal abrasions
Erythematous eyes

Problems Secondary to Salivary Gland Dysfunction

Dry mouth
Oral sores
Dental caries
Thrush
Lingual and labial fissures
Dysphagia
Gastroesophageal reflux
Parotid and/or submandibular gland swelling

Problems Secondary to Other Exocrine Dysfunction

Dyspareunia
Pancreatic malabsorption

demonstrate characteristic findings of focal lymphocytic infiltration of predominantly CD4 T cells. These histologic features imply that cell-mediated processes are essential in the pathogenesis of Sjögren syndrome, although the precise antigenic target is unknown.

Keratoconjunctivitis sicca can be objectively documented by either measuring decreased tear production with the Schirmer filter paper test (>5 mm of wetting in 5 minutes after placement in the lower eyelid) or viewing corneal abrasions by rose-bengal staining and slit-lamp examination. Reduced salivary production can be demonstrated by provocative sialometry.

The differential diagnosis of Sjögren syndrome includes a variety of infectious and infiltrative diseases that may cause keratoconjunctivitis sicca symptoms and/or lacrimal and salivary gland enlargement. Human immunodeficiency virus causes diffuse infiltrative lymphadenopathy syndrome (DILS), which closely mimics Sjögren syndrome. DILS, however, involves predominantly CD8 T cells and tends to cause more xerostomia instead of keratoconjunctivitis sicca. Both conditions can cause bilateral parotitis and parotid gland swelling. Additional infections to consider in patients with sicca symptoms include hepatitis B and C, human T-cell leukemia virus, syphilis, and infection with mycobacteria. Infiltrative diseases may involve lacrimal and salivary glands and appear in a fashion similar to Sjögren syndrome. These infiltrative diseases include sarcoidosis, the amyloidoses, and hemochromatosis. Diseases that result in abnormal

Table 85-2 Extraglandular Clinical Features of Sjögren Syndrome

Skin and Mucous Membranes

Lower extremity purpura, associated with hyperglobulinemia and/or leukocytoclastic vasculitis on biopsy
Photosensitive lesions, indistinguishable from those of subacute cutaneous lupus erythematosus

Pulmonary

Chronic bronchitis secondary to dryness of the tracheobronchial tree
Lymphocytic interstitial pneumonitis, interstitial pulmonary fibrosis, chronic obstructive lung disease, bronchiolitis obliterans organizing pneumonia, pseudolymphoma with intrapulmonary nodules

Musculoskeletal

Polymyositis
Polyarthralgias, polyarthritis

Renal

Tubulointerstitial nephritis, type 1 renal tubular acidosis

Central Nervous System

Focal defects including multiple sclerosis, stroke
Diffuse deficits including dementia, cognitive dysfunction
Spinal cord involvement including transverse myelitis

Peripheral Nervous System

Peripheral sensorimotor neuropathy
Trigeminal sensory neuropathy

Reticuloendothelial System

Splenomegaly
Lymphadenopathy and development of pseudolymphoma

Liver

Hepatomegaly
Primary biliary cirrhosis

Vascular

Raynaud phenomenon
Small-vessel vasculitis, with either a mononuclear perivascular infiltrate or leukocytoclastic changes on biopsy

Endocrine

Hypothyroidism caused by Hashimoto thyroiditis
Other autoimmune endocrinopathies

neural input to exocrine glands, such as multiple sclerosis, must also be considered in a patient with keratoconjunctivitis sicca symptoms.

Many drugs from various pharmaceutical classes have anticholinergic properties that result in clinically significant symptoms of dry eyes and dry mouth and mimic Sjögren syndrome. Such medication classes include antidepressants, decongestants, and antihypertensives. The list of medications with anticholinergic side effects is quite long, and all medications, including over-the-counter products, should be carefully reviewed in any patient with signs or symptoms of Sjögren syndrome. Alcohol and marijuana are common substances of abuse that can cause xerophthalmia and xerostomia.

Treatment

Treatment of Sjögren syndrome consists of either symptomatic care to ameliorate the exocrine deficiencies or systemic therapy for extraglandular involvement. Treatment options are outlined in Table 85-3. The interest in the potential therapeutic role of immunomodulatory biologic agents is increasing, especially B-cell–depleting agents. Patient education is important, and some measures outlined can be considered prophylactic.

Table 85-3 Treatment Options for Sjögren Syndrome

Local Treatment of Exocrine Dysfunction

Xerophthalmia

Artificial tears, preservative free
Eyeglasses and/or goggles
Punctal occlusion by means of plugs or electrocautery

Xerostomia

Artificial saliva
Salivary stimulators, either mechanical or electrical
Fluoride treatments and/or fastidious dental care
Avoid glucose lozenges and/or candies

Dyspareunia

Vaginal lubricants

Systemic Treatment of Exocrine Dysfunction

Pilocarpine or cevimeline
When possible, avoid or discontinue medications with anticholinergic effects

Treatment of Systemic Manifestations

Nonsteroidal anti-inflammatory drugs
Antimalarial agents: hydroxychloroquine or chloroquine
Glucocorticoids
Immunosuppressive agents, including methotrexate, azathioprine, mycophenolate mofetil, and gamma globulin

Prospectus for the Future

It is important to increase awareness of Sjögren syndrome, as it is often unrecognized. Atypical presentations of thrush, neuropathy, and multiple sclerosis–like disease all can occur with Sjögren syndrome.

Cytokine therapy, used in other rheumatic disorders such as rheumatoid arthritis and psoriatic arthritis, may be effective

for Sjögren syndrome. Large placebo-controlled randomized trials will be necessary to further evaluate these therapies for Sjögren syndrome. In addition, cell-based therapies, such as the use of stem cells to replace depleted acinar tissue of salivary glands, lies in the future as a potential permanent therapy for patients with Sjögren syndrome.

Systemic Vasculitis

Kathleen Maksimowicz-Mckinnon

The primary systemic vasculitides are a group of chronic inflammatory disorders characterized by immune-mediated injury of blood vessels. Inflammation leading to vessel necrosis, often accompanied by vessel thrombosis, results in subsequent ischemic tissue and organ injury. All organ systems are vulnerable to the vasculitides, although different preferential vessel and tissue targeting characterize each disorder. Although these disorders are rare, they can often be organ and life threatening. Because these consequences frequently can be averted by timely diagnosis and treatment, it is necessary for physicians to be able to promptly recognize these disorders. In this chapter, general concepts of classification and disease pathogenesis are reviewed, and disease features, diagnosis, and therapy for the more common vasculitides are outlined.

Classification

The classification and nomenclature of the vasculitides is based on the 1990 American College of Rheumatology Classification criteria and the Chapel Hill Consensus Conference definitions. These systems are based on affected vessel size, preferential organ involvement, and, when applicable, the presence of characteristic autoantibodies.

Identifying criteria that are both sensitive and specific for the classification of the vasculitides remains an ongoing challenge. There is remarkable diversity in disease presentation, and, as demonstrated in Figure 86-1, significant overlap exists among diseases when considering vessel involvement. Despite these limitations, classification systems are necessary to conduct clinical research, design treatment strategies and protocols, and determine patient prognosis.

Pathogenesis

For the majority of the vasculitides, the cause and pathogenesis of disease are unknown. It has been proposed that a number of diverse mechanisms act in concert to result in

vascular inflammation and consequent injury, and that it is likely that a sequence of events initiates this cascade against a background of genetic vulnerability (Fig. 86-2). Proposed triggers of disease include infection and environmental exposures (chemicals, pollutants). The best example of this purported relationship is the association that has been demonstrated between hepatitis B and C infections and the development of polyarteritis nodosa (PAN). However, for the majority of the vasculitides, these associations remain speculative.

Current evidence suggests that both humeral and cellular immune responses, cytokine and chemokine activation, and immune complex deposition are important in disease pathogenesis. However, it has become clear that normal protective and repair processes in the vessel can also contribute to injury and ischemia. For example, after injury, cellular migration and proliferation occurring as part of vessel repair can result in intimal hyperplasia, and the pro-coagulant milieu that is protective against hemorrhage may lead to thrombosis. So rather than a unidirectional “attack” directed against an innocent bystander, vasculitis is instead a dialogue between the immune system and the vessel, where both parties participate and contribute to disease pathogenesis.

Clinical manifestations of the vasculitides result primarily from the impairment of blood flow in injured vessels, which results in tissue and organ ischemia and subsequent injury. Flow can be interrupted by obliteration from destructive processes, thrombosis, or remodeling after injury. These changes can occur along a broad spectrum of severity; vary depending on the type of vasculitis and type and location of vessels involved; and are unique in any individual patient.

Clinical Features

Manifestations of the vasculitides are diverse and differ not only among disorders but also among patients. Often disease features are influenced by the vessel size and location. Common associations between the size of the affected vessel

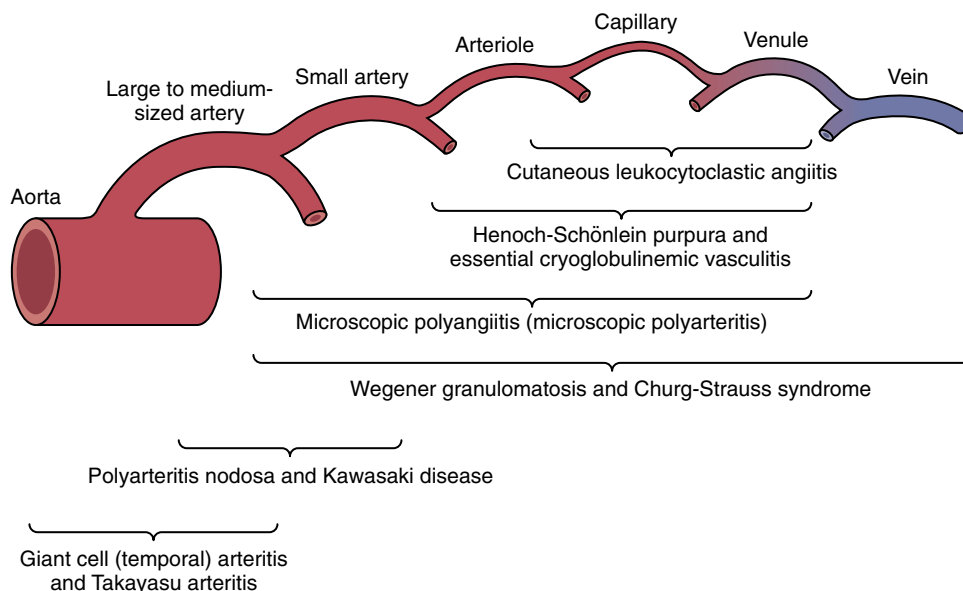

Figure 86-1 The vascular spectrum of the vasculitides. (From Jennette JC, Falk RJ, Andrassy K, et al: Nomenclature of systemic vasculitides. Proposal of an international consensus conference. *Arthritis Rheum* 37:187-192, 1994.)

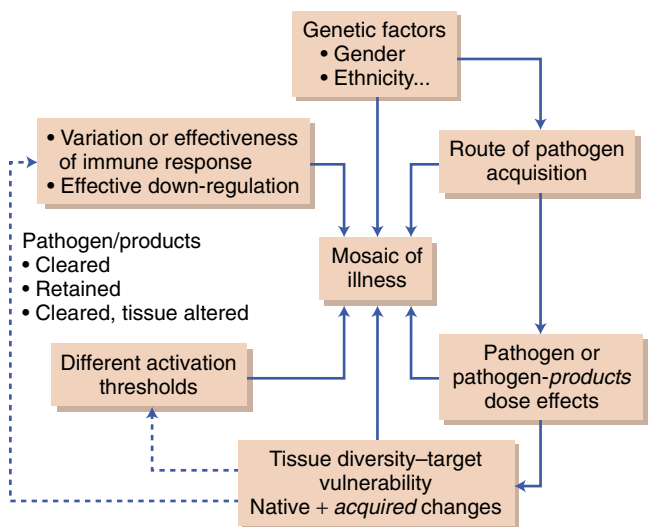

Figure 86-2 Factors affecting disease vulnerability and expression.

Table 86-1 Typical Clinical Features Based on Vessel Size		
Large	Medium	Small
Limb claudication	Cutaneous nodules	Purpura
Asymmetrical blood pressures	Ulcers	Vesiculobullous lesions
Absence of pulses	Livedo reticularis	Urticaria
Bruits	Digital gangrene	Glomerulonephritis
Aortic dilatation	Mononeuritis multiplex	Alveolar hemorrhage
	Microaneurysms	Cutaneous extravascular necrotizing granulomas
		Splinter hemorrhages
		Scleritis, episcleritis, uveitis
Constitutional symptoms in all: fever, weight loss, malaise, arthralgias		

and clinical manifestations are detailed in Table 86-1. It is important to be cognizant that patients generally do not manifest all of these features, and some patients may initially have only nonspecific constitutional signs and symptoms. The lack of specificity and diversity of signs and symptoms in any individual patient undoubtedly contribute to delays in diagnosis.

Small Vessel Vasculitis

ANTINEUTROPHIL CYTOPLASMIC ANTIBODY-ASSOCIATED VASCULITIDES

Wegener Granulomatosis

Wegener granulomatosis (WG) is a small to medium vessel granulomatous vasculitis that can affect nearly all organ

systems. However, the most common sites affected are the sinuses and upper airway, the lungs, and the kidneys. Chronic refractory sinusitis, nasal crusting, and otitis media are common manifestations. Patients may also have cartilaginous inflammation and destruction, leading to the characteristic “saddle nose” deformity. Lung involvement in WG can include pulmonary nodules, often cavitary, infiltrates, or hemorrhage. Orbital pseudotumors are seen in WG and can cause optic nerve compression or proptosis and can impinge on extraocular muscles. In addition, neurologic, cutaneous and musculoskeletal signs and symptoms are common and encompass a wide variety of manifestations.

Patients can experience weeks to months of more subtle symptoms, such as sinusitis, arthralgias, or fatigue, before

fulminant, organ-threatening disease occurs. However, presenting signs may be at the other end of the spectrum, with rapidly progressive glomerulonephritis or alveolar hemorrhage that may rapidly lead to organ damage, or even death.

The diagnosis of WG is most frequently established by tissue biopsy. Results of antineutrophil cytoplasmic antibody (ANCA) testing can be positive in nearly 90% of patients with renal disease but are less often positive in patients with limited involvement. Most patients with WG are found to have cytoplasmic ANCA (C-ANCA) anti-proteinase-3 type, but perinuclear ANCA (P-ANCA) anti-myeloperoxidase type has also been identified in WG patients. It is important to be cognizant that ANCA can be present in other conditions that can mimic WG, such as pulmonary infections (fungal, bacterial, or mycobacterial) and other autoimmune conditions. Hence, ANCA positivity is never adequate in itself to establish the diagnosis of WG or any other vasculitis. Conversely, patients with limited WG, which is generally described as disease restricted to the upper respiratory tract, are less likely to show ANCA positivity, so the absence of ANCA does not rule out the diagnosis of WG.

Churg-Strauss Syndrome

Churg-Strauss syndrome (CSS), also known as *allergic granulomatosis* and *angiitis*, is a small and medium vessel vasculitis differentiated from the other forms of small vessel vasculitis by its association with asthma and allergy. The majority of patients have asthma present for months to years before the onset of CSS, but some patients may manifest CSS and asthma simultaneously. In CSS patients with a preexisting asthma diagnosis, it is not infrequent for patients with stable, well-controlled asthma to note worsening or refractory asthma heralding the onset of CSS. Although patients with CSS often have sinusitis and pulmonary infiltrates, which are also seen in WG, in CSS the sinus disease is generally not destructive, and pulmonary infiltrates, unlike in WG, may be fleeting. CSS also often manifests with gastrointestinal, nervous system, and myocardial involvement.

As with WG, the diagnosis of CSS is made based on tissue biopsy in concert with appropriate history and clinical findings. Peripheral eosinophilia is a hallmark of CSS, and eosinophils are frequently seen in biopsy specimens of affected tissues. ANCA testing results are frequently positive in patients with CSS, but in contrast to WG, the majority of patients have P-ANCA anti-myeloperoxidase antibodies.

Microscopic Polyangiitis

Microscopic polyangiitis (MPA) is a predominantly small vessel vasculitis that preferentially affects the kidneys and lungs. Disease onset may be insidious, with constitutional symptoms such as fever, weight loss, and arthralgias present for months before diagnosis. Patients with renal involvement may have microscopic hematuria and proteinuria, or renal insufficiency resulting from glomerulonephritis. Alveolar hemorrhage is a characteristic manifestation of pulmonary involvement in MPA and may cause cough, dyspnea, and hemoptysis. Cutaneous and neurologic involvement are also frequent in MPA.

Diagnosis is established by tissue biopsy in the appropriate clinical scenario, similar to the other ANCA vasculitides.

ANCA are also frequent in MPA, and are most often P-ANCA/anti-myeloperoxidase type.

THERAPY FOR ANCA-ASSOCIATED VASCULITIS

Glucocorticoids are uniformly used in the treatment of ANCA-associated vasculitis. These disorders are characterized by relapsing disease, occurring in one third to one half of patients, so frequently a steroid-sparing immunosuppressive agent such as cyclophosphamide, azathioprine, or methotrexate is necessary to aid in maintaining disease remission. In general, daily oral cyclophosphamide is used in combination with glucocorticoid therapy in patients with fulminant organ- or life-threatening disease. Although the use of plasmapheresis remains controversial, it is often used as part of initial treatment in combination with immunosuppressive therapy in patients with alveolar hemorrhage or rapidly progressive glomerulonephritis, based on small studies suggesting potential benefit with regard to renal recovery and mortality.

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura (HSP) is a small vessel vasculitis that occurs most frequently in young children, with a median age of onset of 4 years, but can develop at any age. HSP is characterized by the presence of palpable purpura (seen in 100% of patients), arthritis (generally large joint), and abdominal pain, which results from vascular inflammation, ischemia, and associated bowel wall edema. Renal involvement most often manifests as hematuria, with progression to clinically overt glomerulonephritis requiring directed therapy much less commonly noted. Central nervous system involvement and pulmonary hemorrhage have also been reported but are rare.

The diagnosis of HSP is most often made on clinical and laboratory grounds. Given that other vasculitides (and other conditions) can manifest with purpura, arthritis, and abdominal pain, obtaining tissue to aid in diagnosis is strongly recommended. Immunoglobulin A deposition can be seen in affected tissues and organs and is helpful in establishing the diagnosis of HSP in the appropriate clinical setting.

In the vast majority of patients, HSP is a self-limited condition, and treatment is supportive. Glucocorticoid therapy can aid in more rapid resolution of symptoms, but whether treatment can decrease the risk of relapsing disease or more serious manifestations remains controversial. Glucocorticoid therapy is generally used in patients who develop overt glomerulonephritis, with steroid-sparing immunosuppressive agents also considered in the setting of steroid-requiring or relapsing disease.

Medium Vessel Vasculitis

POLYARTERITIS NODOSA

PAN is a medium vessel vasculitis characterized by arterial aneurysmal and stenotic lesions of muscular arteries, often located at segmental and branch points. Although all organ

systems are vulnerable to PAN, the most common systems affected include the gastrointestinal, renal, and nervous systems. Unlike what is seen in small vessel vasculitis, renal involvement in PAN is not characterized by glomerulonephritis, but rather manifests with aneurysms and/or stenoses of renal arteries.

The diagnosis of PAN is made based on angiographic and/or biopsy findings in the appropriate clinical setting. Constitutional symptoms are frequent in PAN, including fever, fatigue, and weight loss. Anemia and hypertension are also common in PAN. ANCA generally are absent in PAN. PAN is frequently associated with hepatitis B and C and has also been documented in patients with human immunodeficiency virus (HIV) infection.

Glucocorticoid therapy and other immunosuppressive agents are used in the treatment of PAN. Although not all patients with PAN have chronic viral infection, testing for these infections when PAN is suspected is imperative, because antiviral therapy may be required not only for attaining control of the viral infection but also in the treatment of the associated vasculitis.

KAWASAKI DISEASE

Kawasaki disease (KD) is a medium vessel vasculitis most often seen in children under the age of 5. It is the most common cause of acquired heart disease in children in the United States and Japan. The diagnosis of KD is made based on the presence of four of the following characteristics plus fever >5 days: conjunctival injection, oropharyngeal changes (strawberry tongue, mucous membrane desquamation), peripheral extremity changes (cutaneous desquamation), polymorphous rash, and cervical lymphadenopathy. Arthralgias, abdominal pain, hepatitis, aseptic meningitis, and uveitis have also been reported in patients with KD. Coronary artery aneurysms, one of the most serious comorbidities of KD, generally appear within the first 4 weeks after onset of disease and are often detectable with echocardiography. Although areas of ectasia and small aneurysms may regress, larger aneurysms often persist and can result in coronary ischemia at any time after development, even into adulthood.

Intravenous immunoglobulin has significantly decreased the incidence of coronary artery aneurysms and is standard therapy for patients with KD. Because patients often manifest significant thrombocytosis, with platelet counts that can be over 1 million, aspirin is also used in the treatment of KD. Children with coronary aneurysms require long-term follow-up by a cardiologist even into adulthood for monitoring and sequential imaging because complications such as coronary stenosis or thrombosis may occur.

Large Vessel Vasculitis

TAKAYASU ARTERITIS

Takayasu arteritis (TA) is a rare large vessel vasculitis initially identified in East Asia but found worldwide. It preferentially affects young women of childbearing age but can be found in both sexes and encompasses a broader age range. TA affects the aorta and its primary branches and most often

results in stenotic lesions, although aneurysms are also seen. The most common sites of involvement in the United States include the subclavian and carotid arteries and the aorta. Hypertension can result from renal artery stenosis in TA and may be missed in patients who have bilateral upper extremity arterial stenoses. TA can manifest with mild nonspecific and self-limited constitutional symptoms, so the diagnosis may not be made until late in the disease course when vascular stenosis and subsequent claudicatory symptoms manifest. Patients can also have abrupt onset of fever, arthralgias, myalgias, weight loss, and fatigue. About 20% of patients have monophasic disease, whereas the remainder of patients have at least one relapse.

Diagnosis of TA is often based on vascular imaging studies, often demonstrating long, tapering stenotic lesions and/or aneurysmal lesions in the aorta and primary branches, after infectious and other causes of large vessel vasculitis have been eliminated. Some patients are diagnosed after vascular surgical procedures (e.g., aortic valve replacement) when vasculitis is detected on pathologic studies of the excised tissue. Detecting disease relapse in TA can be challenging, because patients may have active vasculitis even without clinical signs and symptoms and normal acute phase reactants. Generally, as part of disease surveillance, patients undergo sequential vascular imaging studies—magnetic resonance imaging (MR) or computed tomography (CT) angiography—to identify active disease. Because vascular injury often leads to progressive stenosis, disease activity is defined by identifying new vascular lesions in previously unaffected areas.

Because hypertension is an important factor contributing to disease-associated morbidity and mortality, it is imperative to obtain central arterial pressure measurements by catheter-directed angiography if patients demonstrate or develop arterial lesions affecting all four extremities; peripheral blood pressure measurements may be unreliable.

In most patients, glucocorticoid therapy is efficacious in attaining disease control. Patients with relapsing disease frequently require other immunosuppressive agents, such as methotrexate or azathioprine, to minimize steroid exposure and aid in maintaining disease remission. However, disease relapse often occurs even while patients are receiving these therapies. There are data suggesting that anti-tumor necrosis factor can aid in maintaining disease remission; however, larger prospective studies are needed to better define the role of such agents in the treatment of TA.

Surgical intervention is undertaken in TA when organ-threatening ischemia is present or peripheral claudicatory symptoms warrant operative intervention. Elective interventions should be performed when disease is quiescent, because restenosis occurs more frequently in patients with active disease at the time of surgery. Data from the National Institutes of Health (NIH) and Cleveland Clinic cohorts demonstrate better long-term outcomes in TA from arterial bypass surgery than from angioplasty with or without stent placement.

GIANT CELL ARTERITIS OF THE ELDERLY (TEMPORAL ARTERITIS)

Giant cell arteritis (GCA) is a large vessel vasculitis that primarily affects white patients over the age of 50, often

affecting the extracranial arteries. Patients frequently manifest new onset of headache, which is continuous, scalp or temporal artery tenderness, jaw claudication, visual disturbances, fatigue, and arthralgias. Patients can have an insidious or explosive onset of disease and can manifest primarily cranial or constitutional symptoms. Blindness occurs in about 15% of patients with GCA, even with appropriate therapy, and can occur at disease onset.

The diagnosis of GCA should be confirmed with a superficial temporal artery biopsy. Whether or not bilateral biopsies should be obtained initially remains an area of controversy, because a few cases have been reported in which the symptomatic temporal artery biopsy was negative but the asymptomatic contralateral artery demonstrated arteritis. Anemia and elevated acute phase reactants are commonly seen in patients with GCA.

Large vessel disease, similar to that seen in TA, has been reported in GCA. Aortitis is one of the most common manifestations of large vessel involvement in patients with GCA and leads to an increased risk of aortic aneurysm and subsequent dissection and rupture. Given this potential catastrophic complication, it has been suggested that GCA patients undergo yearly surveillance with chest radiography to look for aortic enlargement, but the potential impact of this intervention on outcomes in GCA remains speculative.

Glucocorticoids are the cornerstone of therapy in GCA. Patients often experience disease relapses with steroid tapering, but other immunosuppressive agents overall have not demonstrated steroid-sparing activity in GCA. Although many patients with relapsing disease are still given trials of other immunosuppressive agents, given the toxicities associated with long-term steroid use, most patients continue to require steroid therapy for maintaining disease remission.

Polymyalgia rheumatica (PMR), a syndrome characterized by pain and stiffness in the muscles of the neck, shoulder girdle, and hip girdle with other signs and symptoms of systemic inflammation, is associated with GCA. However, not all patients with GCA manifest PMR symptoms, and not all patients with PMR develop GCA. However, because the prevalence of GCA is higher in patients with PMR, they should be educated regarding signs and symptoms of GCA.

LEUKOCYTOCLASTIC VASCULITIS

Leukocytoclastic vasculitis (LCV) describes microscopic changes seen in a biopsy specimen of the skin including vessel wall infiltration, fibrin deposition, and necrosis. LCV can be noted in a variety of conditions, so although a diagnosis of systemic vasculitis should be entertained when LCV is found, other conditions should also be considered, based on the clinical scenario.

Primary vasculitic conditions that may manifest with LCV include HSP, the ANCA-associated vasculitides, and PAN. Secondary vasculitides, including those associated with other rheumatic diseases (systemic lupus erythematosus, Sjögren syndrome, rheumatoid arthritis), paraneoplastic syndromes, medications, and infections can also manifest with LCV.

As the definition implies, the diagnosis of LCV is established by tissue biopsy. The treatment of LCV depends on its underlying cause; hence, appropriate and thorough inves-

tigations to seek a cause should be undertaken when the diagnosis of LCV is made.

When no clear underlying cause is found, a variety of agents can be used to alleviate symptoms and rash including antihistamines, dapsone, colchicine, and glucocorticoids. These patients need be monitored carefully in case LCV is the initial manifestation of a systemic process in evolution, and the threshold for further evaluation and/or reevaluation for an underlying disorder in the setting of treatment failure or the emergence of new signs or symptoms should be low.

Differential Diagnosis

Many conditions can manifest similarly to the primary vasculitides, and misdiagnosis or delayed diagnosis is not uncommon when these disorders are being considered. Table 86-2 outlines general categories and examples of disorders that can mimic the primary systemic vasculitides.

Given that immunosuppressive therapy has significant associated risks and toxicities, and that it may be harmful in

Table 86-2 Differential Diagnosis for Primary Systemic Vasculitis

Infection

Fibromuscular dysplasia
Ehlers-Danlos syndrome
Marfan syndrome

Other Disorders

Buerger disease
Calciphylaxis
Amyloidosis

other conditions that may mimic vasculitis (e.g., infection), it is critical that a thorough investigation be undertaken to exclude other diagnoses.

Additional Considerations in Treatment

Immunosuppressive therapy is associated with an increased risk of infection, with more intensive therapy leaving patients also vulnerable to opportunistic infections. Patients receiving combination therapy with moderate- to high-dose glucocorticoid therapy and another immunosuppressive agent generally are placed on prophylaxis for *Pneumocystis jirovecii* pneumonia (previously known as *PCP*). Furthermore, infectious conditions can often mimic or result in flares of systemic vasculitis. Careful evaluation is necessary to determine whether illness in a patient with known systemic vasculitis is caused by infection, active vasculitis, or both processes. Glucocorticoid therapy should never be abruptly discontinued, even in the setting of infection, because of the risk of adrenal crisis and also of disease relapse. In most cases, other immunosuppressive agents should be discontinued if infection is suspected or diagnosed and should not be resumed until antimicrobial therapy is completed and infection has

been eradicated. The dose of glucocorticoids may need to be adjusted to maintain disease control in this setting.

Glucocorticoid therapy is a common cause of bone loss in patients with systemic vasculitis and frequently results in osteopenia and osteoporosis. Studies have demonstrated that significant bone loss can occur even within the first 6 months of therapy, so calcium and vitamin D therapy should be initiated with the institution of glucocorticoid therapy, and a baseline bone density study obtained. Consideration should be given to additional preventative therapies in patients with decreased bone density at baseline, or those with other risk factors for bone loss.

Several immunosuppressive agents, including methotrexate and cyclophosphamide, used in the treatment of systemic vasculitis are teratogenic. Furthermore, cyclophosphamide therapy can result in premature ovarian failure. These factors need be considered when one chooses immunosuppressive therapy for the treatment of systemic vasculitis in women of childbearing age.

Immunosuppressive medications can be associated with additional long-term risks. One example of this is the known association between prolonged administration of cyclophosphamide and bladder hemorrhage and malignancy. Patients receiving immunosuppressive therapy should be under the care of physicians experienced in monitoring patients on these medications for associated risks and toxicities.

Prospectus for the Future

Understanding the cause and pathogenesis of the vasculitides is essential for scientific progress in the assessment and treatment of patients affected by these disorders. This knowledge will help generate:

- More precise diagnostic and classification criteria
- Diagnostic and monitoring studies with improved sensitivity and specificity
- Less toxic, better tolerated therapies
- Interventions for prevention of disease

Crystal Arthropathies

Dana P. Ascherman

Gout

First described by Hippocrates approximately 2500 years ago, gout is a metabolic disorder that results from monosodium urate crystal formation after supersaturation of extracellular fluids. Clinical manifestations include acute and chronic arthritis, soft tissue deposits of monosodium urate (tophi), nephrolithiasis, and, rarely, urate nephropathy. Collectively, these abnormalities reflect overproduction or underexcretion of uric acid, a metabolic byproduct of purine metabolism. Working knowledge of purine synthesis and salvage pathways as well as predominantly renal clearance mechanisms affecting uric acid turnover is therefore critical in understanding the pathogenesis of gout.

EPIDEMIOLOGIC FACTORS

Gout is principally a disease of men over the age of 35 but clearly affects postmenopausal women as well as specialized populations that include organ transplant recipients. The prevalence of gout correlates with serum uric acid levels, which are typically low until puberty but increase thereafter in an age-dependent manner. Given the significant overlap in levels between patients with and without clinical manifestations of gout, however, serum uric acid remains a poor screening tool for this disorder. Despite this caveat, the risk of symptomatic gout increases from less than 1% in individuals with normal serum uric acid to 20% to 30% in those with levels 2 to 3 mg/dL above normal. For a given level of uric acid, the risk of developing gout appears similar between men and women; however, women typically have lower levels of serum uric acid than men (particularly before menopause, when estrogen appears to enhance urate excretion), explaining the gender discrepancy in this metabolic disorder. Overall, gout occurs in 2% to 3% of the adult male population, with a clear dependence on age. Whereas 0.24% of males with gout are younger than 44 years of age and 3.4% are in the 45- to 64-year-old age group, the prevalence increases to 5% in males older than 65 years of age. In contrast, prevalence rates are less than 0.1% in women younger

than 44, increasing to 1.4% in women 45 to 64 years of age and 1.9% in those older than age 65.

URIC ACID METABOLISM AND PREDISPOSITION TO GOUT

Uric acid is the breakdown product of the purines adenine and guanine. The low solubility of uric acid, which at neutral pH is largely in the form of monosodium urate, allows for accumulation of monosodium urate crystals in the body of susceptible individuals possessing an imbalance of uric acid production and excretion. Total body uric acid stores are approximately 1800 mg, with a daily turnover of roughly 600 mg. Two thirds of daily input comes from de novo purine synthesis and/or salvage pathways, whereas one third comes from dietary sources. Two thirds of daily uric acid excretion occurs in the kidney, with the balance largely eliminated in the gastrointestinal tract.

Purine biosynthetic pathways have three basic features: (1) de novo synthesis driven by 5'-phosphoribosyl 1-pyrophosphate (PRPP) and glutamine, (2) purine interconversion (e.g., adenylic acid–inosinic acid–guanylic acid), and (3) reutilization pathways in which the intermediate breakdown products of adenine, guanine, and hypoxanthine are recaptured by reaction with PRPP rather than undergoing further degradation to xanthine and uric acid (Fig. 87-1). Recapture is catalyzed by the enzymes adenine phosphoribosyl transferase (APRT) and hypoxanthine-guanine phosphoribosyl-transferase (HGPRT). Abnormalities of these enzymes lead to an overaccumulation of PRPP that drives purine synthesis, resulting in increased serum levels of uric acid. Severe homozygous deficiency of HGPRT results in Lesch-Nyhan syndrome, a rare X-linked disorder characterized by self-mutilation, hyperuricemia, and gout. Heterozygous deficiency of HGPRT results in both hyperuricemia and gout at an early age without the neurologic complications of choreoathetosis, spasticity, dystonia, and developmental retardation observed in homozygotes. Some glycogen storage diseases and abnormalities of pentose shunt metabolism can also lead to the overproduction of uric acid.

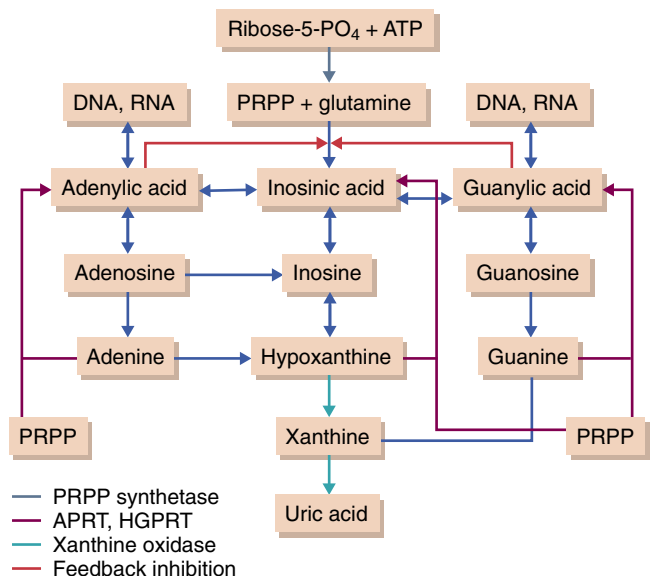

Figure 87-1 Biochemical pathways of purine synthesis, interconversion, and degradation. PRPP, 5'-phosphoribosyl 1-pyrophosphate; APRT, adenine phosphoribosyl transferase; HGPRT, hypoxanthine-guanine phosphoribosyltransferase.

Overall, 10% to 20% of gout stems from increased uric acid production, of which less than 2% results from a defined enzyme deficiency. Secondary causes of uric acid overproduction include lymphoproliferative diseases (e.g., leukemias and lymphomas), disorders of hematopoiesis (e.g., sickle cell disease, thalassemia), and widespread psoriasis—each of which is associated with increased cell turnover and release of intracellular uric acid (Table 87-1). Clinically, however, the most significant stimulus to uric acid overproduction is alcohol, which can dramatically increase *de novo* synthesis through effects on adenosine triphosphate (ATP) metabolism.

Although these causes of uric acid overproduction are important, more than two thirds of individuals with gout (up to 90% in some series) have normal production levels of uric acid but have some impairment in renal clearance of uric acid (the primary route of uric acid excretion). Under normal circumstances, uric acid is filtered at the renal glomerulus, almost completely reabsorbed in the proximal tubule, and then actively secreted and reabsorbed in the distal and collecting tubules. Secondary gout may result from (1) any disorder leading to decreased renal blood flow and glomerular filtration; (2) diminished urine flow and acidosis, which favor urate reabsorption; or (3) drugs that compete for organic acid transport. Diuretics (including thiazides and furosemide), aspirin (which at low doses preferentially inhibits urate secretion), dehydration, and acidosis all lead to decreased urate clearance. Lead has long been associated with gout (saturnine gout), acting as a tubular toxin and thereby impairing urate clearance.

PATHOGENESIS OF ACUTE ARTHRITIS

When an imbalance between uric acid production and excretion leads to supersaturation of extracellular fluid and monosodium urate crystal deposition, an acute inflammatory monoarticular or oligoarticular arthritis may ensue.

Table 87-1 Causes of Hyperuricemia

Decreased Urate Excretion	Increased Urate Production
Impaired renal function	Ethanol
Dehydration	Myeloproliferative diseases
Acidosis	Ineffective erythropoiesis (sickle cell, thalassemia)
Low-dose salicylates	Widespread psoriasis
Diuretics	Cytotoxic drugs
Pyrazinamide	Glycogen storage diseases
Cyclosporine	G6PD deficiency
Levodopa	HGPRTase deficiency
Ethambutol	Increased PRPP synthetase activity
Nicotinic acid	
Lead	
Ethanol	
Many other drugs	
Hypothyroidism	

G6PD, glucose-6-phosphate dehydrogenase; HGPRTase, hypoxanthine-guanine phosphoribosyltransferase; PRPP, 5'-phosphoribosyl 1-pyrophosphate.

Attacks of gouty arthritis can arise from *de novo* precipitation of microcrystals but often follow local trauma and shedding of crystals from previously formed intra-articular and periarticular deposits. Repetitive trauma to the first metatarsophalangeal (MTP) joint from weight-bearing activities may therefore underlie the predominant involvement of this joint. Beyond these physical factors, significant fluctuations in uric acid levels may also precipitate attacks. For example, dehydration, acidosis, alcohol ingestion, and extensive cell death from chemotherapy all lead to temporary increases in serum uric acid and are consequently linked with flares of gout. Alternatively, rapid lowering of uric acid levels likely leads to partial solubilization or breakdown of tophi and crystal shedding, potentially explaining the paradoxical association between gouty arthritis and the initiation of uric acid-lowering therapy with agents such as allopurinol.

Once formed and shed into the synovial fluid, monosodium urate crystals may activate complement (depending on the relative balance of proinflammatory and anti-inflammatory factors coating these crystals), leading to polymorphonuclear leukocyte (PMN) chemotaxis and crystal phagocytosis (Fig. 87-2). In turn, PMN activation triggers a cascade of intracellular events that ultimately lead to the release of degradative enzymes as well as an array of inflammatory mediators consisting of various cytokines, chemokines, prostaglandins, leukotrienes, and reactive-oxygen species. Specific chemotactic leukotrienes (leukotriene B_4) and chemokines (interleukin [IL]-8) promote further influx of PMNs in the setting of increased vascular permeability, perpetuating the local inflammatory response. This proinflammatory milieu persists until the synovial fluid cell profile shifts from PMNs to mature cells of monocyte and macrophage lineage.

CLINICAL PRESENTATION

Acute gouty arthritis is characterized by a rapid crescendo onset. Typically, affected patients go to sleep without

Figure 87-2 Pathogenesis of acute gout. Shedding of crystals leads to leukocyte activation and the release of inflammatory mediators. IgG, immunoglobulin G; PMN, polymorphonuclear leukocyte.

symptoms and subsequently awaken with severe pain, erythema, and swelling in the affected joint. The first MTP joint is the most commonly involved, resulting in an inflammatory condition termed *podagra*. Pain, warmth, and erythema often extend to the skin and surrounding soft tissue, producing a cellulitic appearance. As described by Sydenham in the 1800s, an inability to “bear the weight of bedclothes” develops, and patients frequently cannot put on a sock or cover the foot with a sheet. Although any joint may be affected in acute gout, the MTP, foot, ankle, and knee are most commonly involved. Inflammation of elbows, wrists, and small joints of the hands may also occur, but involvement of the hips, shoulders, and apophyseal joints is unusual. Hydrostatic factors may cause the predominant involvement of lower extremity joints. During the day when the legs are in a dependent position, transudation of plasma into the interstitial space occurs; at night, water is more quickly reabsorbed than uric acid, leading to higher concentrations of uric acid in the interstitial fluid and subsequent precipitation of crystals. The lower temperature in distal joints may also contribute to monosodium urate precipitation.

On examination, the skin overlying affected joints appears erythematous or even violaceous. The joint and surrounding soft tissue is warm or hot to touch and exquisitely tender, yielding extreme pain with passive as well as active range of motion. As indicated by the physical appearance of overlying skin and soft tissue, inflammation commonly extends beyond the confines of the joint. Occasionally, two or more joints are simultaneously involved. At times the process of gouty arthritis may be even more widespread, leading to a smoldering, chronic polyarthritis that can masquerade as rheumatoid arthritis or other inflammatory arthritides. Apart from the joints, an acute inflammatory process may occur in nonarticular structures such as bursae, sometimes causing confusion with septic bursitis.

DIAGNOSIS

The acute onset of inflammatory monoarthritis in a joint of the lower extremity is likely to be gout, particularly when the first MTP joint is affected in a middle-aged or older man. The differential diagnosis includes septic arthritis, pseudogout (calcium pyrophosphate dihydrate [CPPD] deposition disease), reactive arthritis (Reiter disease), monoarticular presentations of rheumatoid arthritis or other inflammatory arthritides, Lyme disease, viral arthritis, and sarcoidosis. Infectious arthritis is obviously the most important and usually the most difficult entity to differentiate at presentation. Both conditions, for example, can be associated with fever. Low-grade fever is relatively common in acute gout, but occasionally the patient’s temperature may reach 39° C (102.2° F). Patients with septic arthritis may have a more insidious onset than patients with gout, are usually systemically ill with chills and sweats accompanying fever, and often develop peripheral leukocytosis with toxic granulation of peripheral blood PMNs. Nevertheless, none of these clinical features is pathognomonic for crystalline or septic arthritis, underscoring the importance of synovial fluid analysis.

The joint fluid in gout is classified as inflammatory, with more than 10,000 white blood cells (WBCs) per milliliter (sometimes >50,000 WBCs/mL) and more than 90% PMNs. Polarized light microscopic examination of synovial fluid is the key to diagnosis. Intracellular, needle-shaped, negatively birefringent crystals are both pathognomonic for, and essential to, the definitive diagnosis of acute gouty arthritis (Fig. 87-3). Viewed under polarized light with a red compensator, urate crystals are yellow when parallel to the compensator axis and blue when perpendicular. Crystals may range in length from 1 to 2 μm to 15 to 20 μm , appearing similar to a lance that has pierced the neutrophil (colloquially referred to as the “martini glass” sign). Extracellular crystals of typical size and shape are supportive, but not diagnostic,

Figure 87-3 Polarized microscopy of (A) strongly negative birefringent monosodium urate crystals and (B) weakly positive CPPD crystals. Arrows indicate axis of polarization. (A, Adapted from the ACR Slide Collection on the Rheumatic Diseases; B, adapted from Saadeh C, Malacara JC: Calcium Pyrophosphate Deposition Disease. Available at: <http://www.emedicine.com/med/topic1938.htm>, May 4, 2006.)

of acute gouty arthritis. Urate crystals may also be seen in the white toothpaste-like material obtained from tophaceous deposits and occasionally from a joint into which a tophus has ruptured.

In 5% to 10% of gouty arthritis cases, crystals are not isolated from the affected joint. In other instances, particularly in small joints such as the MTP joint, synovial fluid may be difficult to aspirate. In a patient with known gout, a presumptive diagnosis is reasonable unless clinical features suggest septic arthritis. As previously indicated, serum uric acid is not a useful diagnostic screen, given that many patients have normal levels at the time of an acute attack and that elevated levels of uric acid are found in a high proportion of individuals lacking clinical manifestations of gout. Radiographs may show tophi or typical juxta-articular, “rat bite” erosions with sclerotic borders and overhanging edges (Martel sign). Mild peripheral blood leukocytosis, elevated erythrocyte sedimentation rate, and increased acute phase proteins may be seen but are entirely nonspecific.

CHRONIC POLYARTICULAR GOUT AND EXTRA-ARTICULAR MONOSODIUM URATE DEPOSITION

Gout may evolve into a chronic polyarthritis with or without acute attacks of arthritis. Patients with this form of gout often have multiple juxta-articular tophi and can develop destructive, erosive joint disease. Occasionally, polyarticular gout may appear similar to rheumatoid arthritis, and tophi may be mistaken for rheumatoid nodules. As indicated earlier, radiographs in chronic gout typically show sclerotic changes at erosive borders in a *juxta-articular* distribution, contrasting with the *peri-articular*, nonsclerotic, marginal erosions characteristic of rheumatoid arthritis. Synovial fluid analysis is diagnostic, justifying the examination of synovial fluid for crystals in patients with polyarthritis.

When significant monosodium urate crystal deposition does occur in the body, visible tophi may be present. Tophi most commonly form adjacent to joints, in bursae, on extensor surfaces of tendons, and, less commonly, on cartilaginous structures such as the pinnae of the ear. In severe cases, deposition may occur in other tissues, including the renal interstitium, where higher concentrations of uric acid are

Table 87-2 Treatment of Acute Gout

Drug	Route	Side Effects
Colchicine	PO	Diarrhea, cramps
	IV	Bone marrow failure, neuromyopathy
NSAIDs	PO	Gastritis, bleeding, renal insufficiency
Glucocorticoids	PO, IV, IM	Increased blood sugar
	Intra-articular	Mask infection

IM, intramuscular; IV, intravenous; NSAIDs, nonsteroidal anti-inflammatory drugs; PO, oral.

achieved. Individuals who overproduce *and* overexcrete uric acid are at risk for developing renal stones; in general, those eliminating greater than 700 mg/day of urinary uric are at risk. Stones may be composed of uric acid, or uric acid may form a nidus for calcium and other types of stones.

TREATMENT

Acute Arthritis

A variety of treatments are effective for acute gouty arthritis (Table 87-2). Joint drainage per se has a therapeutic effect in removing degenerating PMNs and in relieving joint distension. Nonsteroidal anti-inflammatory drugs (NSAIDs) are highly effective when adequate anti-inflammatory doses are used and are often the first drug of choice; however, NSAIDs should be avoided in patients with renal insufficiency, a common association with gout. Colchicine prevents the release of PMN chemotactic factors and inhibits phospholipase activation, which is needed for prostaglandin synthesis. This medication is particularly effective early in a gout attack, resulting in rapid resolution of symptoms, but is much less effective after 24 hours. Colchicine can be given by repeated dosing every 1 to 2 hours with a strict total dose limit of 6 mg. However, the practice of using hourly administration until abdominal cramps or diarrhea supervene is to be discouraged. Intravenous colchicine is effective and rapid in onset of effect but must be used with extreme caution, particularly in the setting of hepatic or renal dysfunction. Given reported cases of fatal arrhythmia and bone marrow

failure associated with use of intravenous colchicine, its use has been largely abandoned.

Alternatives to NSAIDs and colchicine include intra-articular glucocorticoids that have a rapid onset of action and are almost free of side effects. If the diagnosis of gout is fairly certain, various preparations of glucocorticoids may be instilled at the time of joint aspiration. Oral glucocorticoids in moderate-to-high doses may also be used; however, in patients with underlying diabetes or glucose intolerance, hyperglycemia may ensue. Nonetheless, in many patients with other comorbid medical conditions such as peptic ulcer disease and renal insufficiency, systemic glucocorticoids may be the best treatment option for acute gout. Parenteral adrenocorticotropic hormone and parenteral glucocorticoids are both effective treatments but are more costly. To prevent recurrent attacks after an acute attack of gout, colchicine prophylaxis for several weeks is a reasonable treatment option (see later discussion).

Intercritical and Chronic Gout

After a single attack of gout, the physician must decide whether to recommend long-term therapy. A substantial number of patients will have rare attacks, even if left untreated, leaving little rationale for immediate institution of lifelong therapy. On the other hand, patients with very high levels of serum uric acid or whose first attack occurs at a young age are at greatest risk of frequent attacks and subsequent development of chronic gouty arthritis, tophaceous gout, and/or destructive joint disease. If patients do have frequent recurrent attacks, then prophylactic treatment is advised (Table 87-3). In patients with mild gout and occasional attacks, prophylaxis with colchicine alone may be sufficient. However, in patients who have renal stones, tophi, erosive joint disease, polyarticular disease, or frequent, recurrent attacks of gout despite risk factor modification and prophylactic use of colchicine, long-term uric acid-lowering therapy is clearly indicated. The choice of agent depends (in part) on whether the patient overproduces uric acid or fails to efficiently eliminate this biochemical byproduct, a determination that rests on assessment of 24-hour urinary uric acid excretion occurring with a low-purine diet.

Uric acid-lowering agents fall into two general categories—uricosurics and xanthine oxidase inhibitors. Theoretically, uricosurics should be most commonly employed based on the distribution of uric acid underexcretion (90%) versus overproduction (10%) in the setting of gout. Probenecid, the prototypical uricosuric used in the United States, inhibits urate reabsorption in the distal tubule and promotes excretion. However, the effectiveness of probenecid hinges on intact renal function (glomerular filtration rate [GFR] >50 mL/min), and use of this medication may be impractical in many patients because of the requirement for increased fluid intake needed to prevent uric acid crystal formation in the renal tubules or urinary tract. Therefore, in patients who cannot tolerate probenecid or already have urate nephropathy or nephrolithiasis, allopurinol is a more appropriate choice. Allopurinol inhibits xanthine oxidase, the enzyme that catalyzes the formation of xanthine from hypoxanthine and uric acid from xanthine. It is effective in lowering the levels of uric acid whether they result from impaired clearance or from overproduction. Allopurinol, although generally safe, has greater toxicity than probenecid and has

Table 87-3 Treatment of Intercritical Gout

Drug	Mechanism of Action	Side Effects
Colchicine	Destabilizes microtubules Inhibits neutrophil chemotaxis, adhesion, and phagocytosis No effect on uric acid	Very safe (low dose); rare neuromyopathy
NSAIDs	Inhibit cyclo-oxygenase No effect on uric acid	Peptic ulcer disease, renal insufficiency
Probenecid	Uricosuric No anti-inflammatory activity	Very safe
Allopurinol	Inhibits uric acid synthesis	Dermatitis, hepatitis, interstitial nephritis, marrow failure

NSAIDs, nonsteroidal anti-inflammatory drugs.

been associated with a severe hypersensitivity syndrome characterized by acute interstitial nephritis, hepatitis, and severe skin reactions. Recent studies suggest that febuxostat, a nonpurine inhibitor of xanthine oxidase, may be a potential alternative for patients with hyperuricemia and gout who are intolerant of allopurinol.

Once the decision is made to institute allopurinol or probenecid, concomitant colchicine prophylaxis should be initiated and continued for several months. Allopurinol, in particular, can precipitate gouty attacks when first administered, presumably because of the rapid lowering of uric acid levels that mobilizes tissue deposits and facilitates shedding of preformed crystals. For this reason, neither allopurinol nor probenecid should be started in the setting of an acute attack. In patients with persistent, chronic arthritis despite urate-lowering therapy, chronic use of nonsteroidal agents (other than aspirin) may be required for the control of pain and inflammation. Occasionally, surgical removal of tophi may be beneficial, particularly in locations where they become irritated, inflamed, or infected.

Although dietary modification is recommended as an adjunct to pharmacologic therapy, dietary purine intake accounts for a relatively small proportion of daily uric acid turnover. Therefore little clinical effect will likely occur from drastic dietary alterations. Nevertheless, anchovies, sweetbreads, organ meats, and cellular leafy vegetables such as spinach are particularly high in purines and should be excluded from the diet. Most importantly, alcohol should be avoided because of its dual impact on uric acid overproduction and impairment of renal tubular function.

Asymptomatic Hyperuricemia

In patients who are to receive chemotherapy, short-term prophylaxis with allopurinol may prevent both gout and renal tubular precipitation of uric acid. Newer agents, including intravenous pegylated uricase, are also helpful in preventing the “tumor lysis” syndrome. Beyond this clinical situation, the significance of “asymptomatic” hyperuricemia

has been the subject of detailed investigation based on associations with hypertension, renal dysfunction, cardiovascular disease, and the metabolic syndrome. Although a number of clinico-epidemiologic studies, animal models, and in vitro experimental systems collectively provide a compelling case that hyperuricemia is an independent risk factor for vascular endothelial and smooth muscle dysfunction, routine treatment of asymptomatic hyperuricemia is not currently recommended.

Calcium Pyrophosphate Dihydrate Deposition Disease

CPPD deposition disease results from the formation of CPPD crystals in articular cartilage and fibrocartilage as well as other periarticular structures. Such deposits are common and increase in incidence with advancing age, affecting over 30% of individuals older than 80 years of age. In most individuals with CPPD deposition, an asymptomatic radiographic finding termed *chondrocalcinosis* is observed. Typical areas of involvement include the menisci of the knee, the triangular fibrocartilage of the wrist, and the symphysis pubis. Articular cartilage may be involved anywhere, but the knee, wrist, and ankle are the most commonly affected sites.

Acute goutlike attacks of arthritis may result when crystals are shed from such deposits, particularly when these crystals are bound by opsonins such as immunoglobulin G (IgG); hence, the disease is often called *pseudogout*. In middle-aged women, a chronic, smoldering polyarthritis may be associated with CPPD deposition. Referred to as *chronic pyrophosphate arthropathy*, this entity has clinical and radiographic characteristics overlapping those of rheumatoid arthritis and osteoarthritis. For unknown reasons, chronic pyrophosphate arthropathy has a predilection for knees, wrists, shoulders, elbows, hips, ankles, midtarsal joints, and small joints of the hands—many of which are atypical sites for primary osteoarthritis. More rarely, chronic pyrophosphate arthropathy can be associated with hemorrhagic arthritis.

Although the vast majority of CPPD deposition disease is idiopathic, approximately 20% of cases are associated with

underlying metabolic disorders such as hyperparathyroidism, hypomagnesemia, hypophosphatasia, and hemochromatosis. These associations undoubtedly stem from the roles of calcium, magnesium, alkaline phosphatase, and iron in chondrocyte-mediated pathways of ATP metabolism (magnesium, alkaline phosphatase) as well as crystal formation (calcium, iron). Of note, secondary forms of CPPD deposition disease may be the presenting clinical finding of the associated systemic disorder, typically occurring at an earlier age than idiopathic cases and often involving specific joints such as the second and third metacarpophalangeal joints.

DIAGNOSIS AND TREATMENT

Detection of chondrocalcinosis on radiographs suggests, but does not establish, the diagnosis of CPPD arthropathy. Synovial fluid aspiration with demonstration of intracellular, positively birefringent, rhomboid-shaped crystals is therefore necessary to confirm the diagnosis of pseudogout or chronic pyrophosphate arthropathy (see Fig. 87-3). However, crystals may be small, fragmented, and difficult to detect, partly reflecting their susceptibility to degradation. Acute attacks of CPPD arthropathy are effectively treated with NSAIDs or with intra-articular glucocorticoids, although joint aspiration alone can be therapeutic. Low-dose colchicine may be effective in preventing recurrent attacks of pseudogout or managing persistent inflammation in chronic pyrophosphate arthropathy.

Other Crystal Disorders

Hydroxyapatite crystals are composed of basic calcium phosphates and deposit at soft tissue sites, particularly tendons and bursae. Although hydroxyapatite deposition in peri-articular structures such as the supraspinatus tendon and subacromial bursa can result in calcific tendinitis, shedding of crystals into the actual joint space can produce exuberant synovitis and a destructive arthropathy (including the “Milwaukee shoulder” syndrome). Oxalate crystals, on the other hand, may deposit in cartilage and intervertebral discs.

Prospectus for the Future

Future studies of long-term use will help define the role of new agents such as pegylated uricase and febuxostat in the prevention and management of gout.

Osteoarthritis

C. Kent Kwoh

Epidemiology

Osteoarthritis (OA), also known as degenerative joint disease (DJD), is the most common arthritis and musculoskeletal disease. Over 26.9 million Americans over the age of 25 have some form of OA, and the prevalence of OA increases with age. The prevalence of radiographic OA varies by the joint involved, with 27.2% of all adults and over 80% of those over 65 having evidence of hand OA. With regard to knee OA, 37.4% of those over age 60 have radiographic evidence of disease. The prevalence of symptomatic OA is lower, with 6.8% of all adults having evidence of symptomatic hand OA and 16.7% of those over age 45 having evidence of symptomatic knee involvement. Hand and knee OA is more common among women, especially after age 50, and also is more common among African Americans. Nodal OA, involving the distal and proximal interphalangeal joints, is significantly more common in women and also is more common among female first-degree relatives.

OA is associated with major morbidity and is the leading cause of long-term disability in the United States. Lower extremity OA is the most common cause of difficulty with walking or climbing stairs, preventing an estimated 100,000 elderly Americans from independently walking from bed to bathroom. OA has a large economic impact as the result of both direct medical costs (e.g., physician visits, laboratory tests, medications, surgical procedures) and indirect costs (e.g., lost wages, home care, lost wage-earning opportunities). With the aging of the U.S. population, the burden of OA is expected to increase throughout the coming years.

Pathologic Factors

The causes of OA are complex and heterogeneous, and there is limited understanding of its pathophysiology. Its cardinal feature is progressive loss of articular cartilage with associated remodeling of subchondral bone. OA is best defined as joint failure, a disease process that involves the total joint including the subchondral bone, ligaments, joint capsule, synovial membrane, periarticular muscles, and articular car-

tilage. Joint failure may result from a variety of pathways subsequent to bone trauma and repetitive injury: joint instability caused by muscle weakness and ligamentous laxity; nerve injury and neuronal sensitization and/or hyperexcitability; low-grade systemic inflammation caused by subacute metabolic syndrome; or local inflammation resulting from synovitis.

OA is a complex disorder with one or more identifiable risk factors, which range from biomechanical, metabolic, or inflammatory processes, to congenital or developmental deformities of the joint, to genetic factors. As noted previously, age, sex, and race are prominent risk factors for OA. Biomechanical contributors include repetitive or isolated joint trauma related to certain occupations or physical activities that involve repeated joint stress and thus predispose an individual to early OA. Obesity may contribute from a biomechanical perspective or a systemic perspective related to a subacute metabolic syndrome. Certain metabolic disorders such as hemochromatosis and ochronosis are also associated with OA. High bone mineral density (BMD) has been shown to be associated with hip or knee OA. Estrogen deficiency may be a risk factor for hip or knee OA. Candidate gene studies and genome wide scans have identified a number of potential genetic markers of OA. Inflammatory joint diseases such as rheumatoid arthritis may result in cartilage degradation and biomechanical factors that lead to secondary OA. The destruction of the joint, including wearing away of articular cartilage, is therefore best viewed as the final product of a variety of possible etiologic factors.

The earliest finding in OA is fibrillation of the most superficial layer of the articular cartilage. With time, the disruption of the articular surface becomes deeper, with extension of the fibrillations to subchondral bone, fragmentation of cartilage with release into the joint, matrix degradation, and, eventually, complete loss of cartilage, leaving only exposed bone. Early in this process the cartilage matrix undergoes significant change, with increased water and decreased proteoglycan content. This progression is in contrast to the dehydration of cartilage that occurs with aging. The *tidemark* zone, separating the calcified cartilage from the radial zone, becomes invaded with capillaries. Chondrocytes initially are

metabolically active and release a variety of cytokines and metalloproteinases, contributing to matrix degradation, which in the later stages results in the penetration of fissures to the subchondral bone and the release of fibrillated cartilage into the joint space. An imbalance between tissue inhibitors of metalloproteinases and the production of metalloproteinases may be operative in OA. Subchondral bone increases in density and cystlike bone cavities containing myxoid, fibrous, or cartilaginous tissue occur. Osteophytes, or bony proliferations at the margin of joints at the site of bone-cartilage interface, may also form at capsule insertions. Osteophytes contribute to joint-motion restriction and are thought to be the result of new bone formation in response to the degeneration of articular cartilage, but the precise mechanism for their production remains unknown.

A variety of crystals has been identified in synovial fluid and other tissues from osteoarthritic joints, most notably calcium pyrophosphate dihydrate and apatite. Although these crystals clearly have potent inflammatory potential, their role in the pathogenesis of OA remains unclear. Frequently these crystals are asymptomatic and do not correlate with extent or severity of disease.

The diversity of risk factors predisposing to OA suggests that a wide variety of insults to the joints, including biomechanical trauma, chronic articular inflammation, and genetic and metabolic factors, can contribute to or trigger the cascade of events that results in the characteristic pathologic features of OA described earlier. At some point, the cartilage degradative process becomes irreversible, perhaps the result of an imbalance of regulatory molecules such as tissue inhibitors of metalloproteinases. With progressive changes in articular cartilage, joint mechanics become altered, in turn perpetuating the degradative process.

Clinical Features and Diagnosis

Pain is the characteristic clinical feature of OA. Recent research has found that pain in OA may be reported as either a constant aching or as a more severe, intermittent pain. Pain is generally worse with activity and/or weight bearing and better with rest. In later stages pain may also occur at rest. Pain tends to be localized to the specific joint involved but may also be referred to a more distant site. The cause of the pain is unclear and is likely to be heterogeneous. Pain may be the result of an interaction among structural pathology; the motor, sensory, and autonomic innervation of the joint; and pain processing at both the spinal and cortical levels, as well as specific individual and environmental factors. Stiffness may be present, particularly after prolonged inactivity, but is not a major feature and is of short duration, usually lasting for <30 minutes. Examination of an involved joint may reveal joint-line tenderness and bony enlargement of the joint. Joint effusion and/or soft-tissue swelling may be present with knee involvement but tends to be intermittent. Persistent inflammation with joint warmth, effusion, and soft-tissue swelling is generally not seen. Crepitus with movement, limitation of joint motion, joint deformity, and/or joint laxity are additional characteristic features that may be present. Several subtypes of generalized OA have

been identified. The nodal form of OA, involving primarily the distal interphalangeal joints, is most common in middle-aged women, typically with a strong family history among first-degree relatives. Erosive, inflammatory OA is associated with prominent erosive, destructive changes, especially in the finger joints, and may suggest rheumatoid arthritis, although systemic inflammatory signs and other typical features of rheumatoid arthritis (e.g., nodules, proliferative synovitis, extra-articular features, rheumatoid factor) are absent.

The diagnosis of OA is based on history, physical examination, and characteristic radiographic features. The physician must distinguish OA from other inflammatory joint diseases such as rheumatoid arthritis. Distinguishing OA from inflammatory joint diseases involves identifying the characteristic pattern of joint involvement and the nature of the individual joint deformity. Joints commonly involved in OA include the distal interphalangeal joints, proximal interphalangeal joints, first carpometacarpal joints, facet joints of the cervical and lumbar spine, hips, knees, and first metatarsophalangeal joints. Heberden and Bouchard nodes may be present in the hands. Involvement of the wrist, elbows, shoulders, and ankles is uncommon, except in the case of trauma, congenital disease, or endocrine or metabolic disease. The characteristic radiographic features of OA include subchondral sclerosis, joint-space narrowing, subchondral cysts, and osteophytes. The advent of magnetic resonance imaging (MRI) has demonstrated that additional morphologic abnormalities such as bone marrow lesions and meniscal degeneration may also be important features of OA.

Treatment

The natural history of OA is quite variable, with periods of relative stability interspersed with rapid deterioration. The management of OA should therefore be tailored to the individual patient and may include a combination of nonpharmacologic, pharmacologic, and surgical approaches. Patients should be educated regarding the objectives of treatment and the importance of changes in lifestyle, exercise, pacing of activities, and other measures to unload the damaged joint(s). The initial focus should be on self-help and patient-driven treatments rather than on passive therapies. Emphasis should be placed on encouraging adherence to both nonpharmacologic and pharmacologic therapies. Physical therapists may be helpful in providing instruction in appropriate exercises to reduce pain and preserve functional capacity. For knee and hip OA, assistive devices such as walking aids may be useful. Regular aerobic, muscle-strengthening and range-of-motion exercises may also be beneficial. Overweight patients with knee or hip OA should be encouraged to lose weight. A knee brace can reduce pain, improve stability, and diminish the risk of falling for patients with knee OA and mild or moderate varus or valgus instability. Advice concerning appropriate footwear is also important. For example, lateral wedged insoles can be of symptomatic benefit for some patients with medial tibiofemoral compartment OA. Spinal orthoses may provide benefit to patients with significant cervical or lumbar OA. Local applications of heat, ultrasound, or transcutaneous

electrical nerve stimulation (TENS) may provide short-term benefit. Acupuncture may also be of symptomatic benefit in patients with knee OA.

Pharmacologic therapy for OA provides symptomatic relief but has not been shown to successfully alter the course of the disease. Pharmacologic therapy should therefore be selected based on its relative efficacy and safety. The use of concomitant medications and the presence of comorbidities also need to be taken into account. Acetaminophen (up to 4 g/day) may be an effective initial oral analgesic for treatment of mild to moderate pain in OA. In patients with symptomatic OA, nonsteroidal anti-inflammatory drugs (NSAIDs) should be used at the lowest effective dose, although their long-term use should be avoided if possible. If patients have risk factors for increased gastrointestinal toxicity, either a cyclo-oxygenase (COX)-2 selective agent or a nonselective NSAID with co-prescription of a proton pump inhibitor (PPI) or misoprostol for gastroprotection should be considered. It is important to note that all NSAIDs, including both nonselective and COX-2 selective agents, should be used with caution in patients with cardiovascular risk factors. Topical NSAIDs and capsaicin may be effective alternatives to oral analgesic or anti-inflammatory agents in

knee OA and may also be used as adjunctive agents. Oral glucosamine and/or chondroitin sulfate may provide symptomatic benefit in patients with knee OA but may be slow acting, taking up to 6 months to show benefit. They should be discontinued if there has been no benefit after 6 months of therapy. If other interventions have been ineffective and/or contraindicated, weak opioids and narcotic analgesics may be considered for the treatment of refractory pain. Stronger opioids should be used for the management of severe pain only in exceptional circumstances. Injection of intra-articular corticosteroids may provide modest short-term symptomatic benefit with minimal toxicity, especially in the knee. Patients with moderate to severe pain and effusion and/or other local signs of inflammation may be more responsive. Intra-articular hyaluronate appears to have little if any benefit based on current evidence. Surgical management of OA includes total joint replacement, which has been shown to be extremely effective in relieving pain, decreasing disability, and improving function. With improvements in surgical technique and technology, the indications for total joint replacement have expanded to include both younger and older age groups. Other surgical options include osteotomy and unicompartmental knee replacement.

Prospectus for the Future

- Better understanding of the molecular events leading to cartilage loss in osteoarthritis will permit the development of novel therapies.

Nonarticular Soft Tissue Disorders

Niveditha Mohan

The nonarticular soft tissue disorders account for the majority of musculoskeletal complaints in the general population. These disorders include a large number of anatomically localized conditions (bursitis and tendinitis), as well as a more generalized pain disorder, fibromyalgia syndrome. The majority of these nonarticular soft tissue conditions include common syndromes in which the etiologic factors and pathogenesis are poorly understood. Thus the nonarticular soft tissue syndromes are generally best classified according to the anatomic region involved, for example, *shoulder pain*. Once the region is defined, an attempt is made to identify the structure at fault, such as supraspinatus tendon, bicipital tendon, and subacromial bursa, among others. In the case of back pain, precise anatomic delineation of the structure involved (e.g., intervertebral disk, facet joint, ligament, paraspinal muscle) is frequently impossible. Precise data on prevalence or incidence of most nonarticular soft tissue syndromes are not available, but these conditions account for up to approximately 30% of all outpatient visits.

Etiologic Factors and Pathogenesis

The precise pathophysiologic factors of most cases of nonarticular soft tissue disorders remain unknown, although in many cases predisposing factors can be identified, such as *overuse* or repetitive activities (e.g., *tennis elbow*, lateral epicondylitis) or biomechanical factors (e.g., leg-length discrepancy in trochanteric bursitis). The term *tendinitis* implies that an inflammatory process is present in the involved tendon sheath; however, small tendon tears, peritonitis, and even nerve entrapment have been postulated as potential mechanisms. Similarly, although bursitis implies bursal inflammation, demonstrable inflammation is difficult to find. In some cases (e.g., acute bursitis of the olecranon or prepatellar bursa), the mechanism is an acute inflamma-

tory response to sodium urate crystals deposited in the soft tissue, an extra-articular manifestation of gout. The favorable response of tendinitis and bursitis syndromes to anti-inflammatory agents, including corticosteroids, supports the view that at least one component of these syndromes is the result of an inflammatory process. In myofascial pain syndrome the causes are even more obscure. Frequently, overuse and trauma are cited as etiologic factors; however, many cases lack antedating mechanical considerations. In the case of fibromyalgia syndrome, recent research strongly suggests that alterations in central processing of sensory input contribute to the cardinal symptoms of persistent widespread pain and enhanced pain sensitivity. Exposure to psychosocial and environmental stressors, as well as altered autonomic nervous system and neuroendocrine responses, also may contribute to alterations in pain perception or pain inhibition.

Classification of Bursae

Many of the soft tissue rheumatic syndromes involve bursae. Bursae are closed sacs lined with mesenchymal cells that are similar to synovial cells; these sacs are strategically located to facilitate tissue gliding. Most bursae develop concurrently with synovial joints during embryogenesis, although new ones can develop in response to mechanical stress or inflammation (e.g., iliopsoas bursa, trochanteric bursa, semimembranous bursa). In general, bursae do not communicate with joints. An exception is the semimembranous or popliteal bursa in the knee, which communicates with the anterior knee in approximately 40% of individuals. The subacromial or subdeltoid bursa communicates with the glenohumeral joint only if a complete tear of the rotator cuff tendon occurs. Bursae are anatomically divided into the *superficial* bursae (e.g., suprapatellar, olecranon) and the *deep* bursae (e.g., subacromial, iliopsoas, trochanteric). Although most forms of bursitis involve isolated, local conditions, some may be the result of systemic conditions such as gout.

Table 89-1 Differentiating Nonarticular Soft Tissue Disorders from Articular Disease

	Nonarticular Soft Tissue Disorders	Articular Disease
Limitation of motion	Active > passive	Active = passive
Crepitus of articular surfaces (structural damage)	0	+/0
Tenderness		
Synovial (fusiform)	0	+
Local	+	0
Swelling		
Synovial (fusiform)	0	+
Local	+/0	0

+, present; 0, absent.

Diagnosis of Nonarticular Soft Tissue Disorders

Tendinitis, bursitis, and myofascial disorders should be distinguished from articular disorders. In most cases, this can be accomplished by a careful examination of the involved structure (Table 89-1). General principles of the musculoskeletal examination are as follows:

1. Observation: If deformity or soft tissue swelling is present, then is it fusiform (surrounding the entire joint in a symmetrical fashion) or is it localized? Local rather than fusiform deformity distinguishes nonarticular disorders from articular disorders.
2. Palpation: Is tenderness localized or in a fusiform distribution? Is an effusion present? Local, not fusiform or joint-line, tenderness distinguishes nonarticular disorders from articular disorders. The presence of an effusion almost always indicates an articular disorder.
3. Assessing range of motion: The musculoskeletal examination includes the assessment of both *active* range of motion (i.e., the patient attempts to move the symptomatic structure) and *passive* range of motion (i.e., the examiner moves the symptomatic structure). Articular disorders are generally characterized by equal impairment in both active and passive movements as a result of the mechanical limitation of joint motion resulting from proliferation of the synovial membrane, the presence of an effusion, or the derangement of intra-articular structures. Impairment of active movement characterizes nonarticular disorders to a much greater degree than passive movement.

Bursitis

CLINICAL PRESENTATION

Septic Bursitis

Superficial forms of bursitis, particularly olecranon bursitis and prepatellar and occasionally infrapatellar bursitis, are more frequently infected or involved with crystal deposition

Table 89-2 Bursitis Syndromes

Location	Symptom	Finding
Subacromial	Shoulder pain	Tender subacromial space
Olecranon	Elbow pain	Tender olecranon swelling
Iliopectineal	Groin pain	Tender inguinal region
Trochanteric	Lateral hip pain	Tender at greater trochanter
Prepatellar	Anterior knee pain	Tender swelling over patella
Infrapatellar	Anterior knee pain	Tender swelling lateral or medial to patellar tendon
Anserine	Medial knee pain	Tender medioproximal tibia (below joint line of knee)
Ischiogluteal	Buttock pain	Tender ischial spine (at gluteal fold)
Retrocalcaneal	Heel pain	Tender swelling between Achilles tendon insertion and calcaneus
Calcaneal	Heel pain	Tender central heel pad

than are deep forms of bursitis. Presumably, these infections or involvements are the result of direct extension of organisms through subcutaneous tissues. Most commonly, *Staphylococcus aureus* is isolated from infected superficial bursae. Septic bursitis should be suspected where there is cellulitis, erythema, fever, and peripheral leukocytosis. Definitive diagnosis and especially exclusion of infection of subcutaneous bursae generally require aspiration of the distended bursa. The bursal fluid should be assessed for cell count, Gram stain, and culture and examined for crystals.

Nonseptic Bursitis

Nonseptic bursitis frequently appears as an overuse condition associated with sudden or unaccustomed repetitive activity of the associated extremity. The two most common types of bursitis are subacromial and trochanteric bursitis (Table 89-2). Subacromial bursitis is the most common overall cause of shoulder pain over the lateral upper arm or deltoid muscle that is exacerbated with abduction of the arm. Subacromial bursitis is the result of compression of the inflamed rotator cuff tendon between the acromion and humeral head. Because the rotator cuff forms the floor of the subacromial bursa, bursitis in this location often results from tendinitis of the rotator cuff. Occasionally, subacromial bursitis or rotator cuff tendinitis results from osteophyte compression of the rotator cuff tendon originating from the acromioclavicular joint. The differential diagnosis includes tears of the rotator cuff, intra-articular pathologic mechanisms of the glenohumeral joint, bicipital tendinitis, cervical radiculopathy, and referred pain from the chest.

Trochanteric bursitis is the result of inflammation at the insertion of the gluteal muscles at the greater trochanter and produces lateral thigh pain, which is often worse when the subject lies on the affected side. Women seem to be more prone to develop this condition, perhaps because of increased traction of the gluteal muscles as a result of the relatively broader female pelvis. Other potential risk factors include weight gain, local trauma, overuse activities such as jogging, and leg-length discrepancies (primarily on the side with the

Table 89-3 Tendinitis Syndromes

Location	Symptom	Finding
Extensor pollicis brevis and abductor pollicis longus (de Quervain tenosynovitis)	Wrist pain	Pain on ulnar deviation of the wrist, with the thumb grasped by the remaining four fingers (Finkelstein test)
Flexor tendons of fingers	Triggering or locking of fingers in flexion	Tender nodule on flexor tendon on palm over metacarpal joint
Medial epicondyle	Elbow pain	Tenderness of medial epicondyle
Lateral epicondyle	Elbow pain	Tenderness of lateral epicondyle
Bicipital tendon	Shoulder pain	Tenderness along bicipital groove
Patella	Knee pain	Tenderness at insertion of patellar tendon
Achilles	Heel pain	Tender Achilles tendon
Tibialis posterior	Medial ankle pain	Tenderness under medial malleolus with resisted inversion of the ankle
Peroneal	Lateral midfoot or ankle pain	Tenderness under lateral malleolus with passive inversion

longer leg). These factors are thought to lead to increased tension of the gluteus maximus on the iliotibial band, producing bursal inflammation. The differential diagnosis of trochanteric bursitis includes lumbar radiculopathy (particularly of the L1 and L2 nerve roots), meralgia paresthetica (entrapment of the lateral cutaneous nerve of the thigh as it passes under the inguinal ligament), true hip joint disease, and intra-abdominal pathologic processes. Other bursitis syndromes are less common and listed in Table 89-2.

TREATMENT

Septic bursitis is treated with a combination of serial aspirations of the infected bursa and antibiotics, initially directed against *S. aureus* and then adjusted depending on the results of bursal fluid cultures. Recurrent septic bursitis may need surgical excision of the bursa in recalcitrant cases. The approach to nonseptic bursitis should include rest, local heat, and, unless contraindicated (e.g., by peptic ulcer disease, renal disease, advanced age), nonsteroidal anti-inflammatory drugs (NSAIDs). Usually, the most effective approach is a local injection of a corticosteroid. Superficial bursae with obvious swelling should be aspirated before the corticosteroid is injected. For deep bursae, such as the subacromial or trochanteric bursae, aspiration yields little if any fluid, and direct injection of a corticosteroid without attempted aspiration is reasonable. Caution is advised in attempted aspiration or injection of the iliopsoas bursa, the ischiogluteal bursa, and the gastrocnemius-semimembranosus bursa (Baker cyst). These bursae lie close to important neural and/or vascular structures, and aspiration under radiologic (ultrasound) guidance may be a safer option.

Tendinitis

CLINICAL PRESENTATION

Most tendinitis syndromes are the result of inflammation in the tendon sheath. Overuse with microscopic tearing of the tendon is the most common risk factor for tendinitis, but tendon compression by an osteophyte may occur, for

example, in the rotator cuff tendon compressed by an osteophyte originating from the acromioclavicular joint.

One of the most common forms of tendinitis is lateral epicondylitis, also known as *tennis elbow* (Table 89-3). This is a common overuse syndrome among tennis players, but it can be seen in many other settings requiring repetitive extension of the forearm (e.g., painting overhead). The diagnosis is confirmed by exclusion of elbow joint pathology and the finding of local tenderness at the lateral epicondyle, which is typically exacerbated by forearm extension against resistance. Enthesopathies such as Achilles tendinitis and peroneal and posterior tibial tendinitis may occur in the setting of an underlying seronegative arthropathy such as Reiter disease or psoriatic arthritis. A history and clinical evaluation for these disorders should be pursued in the appropriate patient.

TREATMENT

Therapy for tendinitis—NSAIDs, local heat, and corticosteroid injection—is similar to that for bursitis. Rest, physical therapy, occupational therapy, and occasionally ergonomic modification are useful adjuncts. The goal of corticosteroid injection in tendinitis is to infiltrate the tendon sheath rather than the tendon itself, because direct injection into a tendon may result in rupture of the tendon. Corticosteroid injection of the Achilles tendon should be avoided because of the propensity of this tendon to rupture. Surgical management of tendinitis is indicated only with failures of conservative treatment. For example, chronic impingement of the supraspinatus tendon that is refractory to conservative treatment may require subacromial decompression.

Fibromyalgia Syndrome

Fibromyalgia syndrome, formerly known as *fibrositis*, is a controversial chronic pain condition characterized by persistent, widespread pain and tenderness to palpation at anatomically defined tender points located in soft tissue musculoskeletal structures. Associated systemic symptoms can include insomnia, cognitive dysfunction, depression, anxiety, recurrent headaches, dizziness, fatigue, morning

stiffness, extremity dysesthesia, irritable bowel syndrome, and irritable bladder syndrome. Although the syndrome has only recently been the subject of investigation, descriptions of it exist far back in the medical literature. Controversy persists, however, because of the lack of objective diagnostic or pathologic findings.

PATHOPHYSIOLOGIC FEATURES

Fibromyalgia syndrome as defined by the American College of Rheumatology 1990 definition for clinical trials is a chronic widespread pain condition with characteristic tender points on physical examination, often associated with a constellation of symptoms such as fatigue, sleep disturbance, headache, irritable bowel syndrome, and mood disorders.

Investigators have examined diverse mechanisms in fibromyalgia syndrome, including studies of muscle, sleep physiologic processes, neurohormonal function, and psychological status. Although the pathophysiologic mechanisms remain unknown, an increasing body of literature points to central (central nervous system) rather than peripheral (muscle) mechanisms. Muscle tissue has been a focus of investigation for many years. Initial studies, including histologic and histochemical studies, suggested a possible metabolic myopathy; however, carefully controlled studies indicated that these abnormalities were simply the result of deconditioning. Sleep studies suggested that disruption of deep sleep (stage IV) by so-called *alpha-intrusion* (the normal awake electroencephalographic pattern) may play a causal role, but this finding was later observed in other disorders, more likely indicating effect rather than cause. In some cases, musculoskeletal injury has been implicated as a trigger for fibromyalgia, but social and legal issues cloud its causative role. Several studies have suggested that subtle hypothalamic-pituitary-adrenal axis hypofunction may occur in fibromyalgia syndrome, although it remains uncertain whether these changes are constitutive or are the result of fibromyalgia. A prevailing theory of pathogenesis is dysregulation of pain pathways leading to central sensitization and marked by neurotransmitter, neurohormone, and sleep physiology irregularities.

Fibromyalgia has long been linked to psychological disturbance. Most studies have confirmed high lifetime rates of major depression, which range from 34% to 71%, associated with fibromyalgia syndrome. High lifetime rates of migraine, irritable bowel syndrome, and panic disorder have also been associated with fibromyalgia syndrome, suggesting that fibromyalgia may be part of an *affective spectrum* group of disorders.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The clinical presentation of fibromyalgia syndrome is generally that of the insidious onset of chronic, diffuse, poorly localized musculoskeletal pain, typically accompanied by fatigue and sleep disturbance. The physical examination shows a normal musculoskeletal examination, with no deformity or synovitis; however, widespread tenderness occurs, especially at tendon insertion sites, indicating a general reduction in pain threshold. The American College of Rheumatology has published the results of a multicenter

Table 89-4 American College of Rheumatology Classification Criteria for Fibromyalgia Syndrome

For classification purposes, patients are said to have fibromyalgia if both criteria are satisfied.

1. *History of chronic, widespread pain:* Pain is considered widespread when present above and below the waist on both sides of the body. *Chronic* is defined as greater than 3 months in duration.
2. *Pain in 11 of 18 tender points on digital palpation:* Points include occiput, low cervical, trapezius, supraspinatus, second rib, lateral epicondyle, gluteal, greater trochanter, knee.

study to identify clinical classification criteria for fibromyalgia syndrome, which were shown to have high sensitivity and specificity (Table 89-4). These criteria have facilitated population-based studies, which suggest that fibromyalgia syndrome affects approximately 2% of the population and up to 7% of women. Approximately 10% of surveyed patients are disabled to varying degrees by their symptoms; therefore the economic impact is large. The prevalence of fibromyalgia appears to be similar in most ethnic and racial groups.

Approximately one third of the patients identify antecedent trauma as a precipitant for their symptoms, one third of patients describe a viral prodrome, and one third have no clear precipitant. A variety of less typical presentations has been described, including a predominantly neuropathic presentation with paresthesias (numbness and tingling) in a nondermatomal distribution, an arthralgic rather than myalgic presentation, and an axial skeletal presentation (resembling degenerative disk disease). Many patients may have undergone invasive diagnostic tests and in some cases inappropriate procedures such as carpal tunnel release or cervical or lumbar laminectomies.

Conditions that should be considered in the differential diagnosis of fibromyalgia syndrome include polymyalgia rheumatica (in older patients), hypothyroidism, polymyositis, and early systemic lupus erythematosus or rheumatoid arthritis. In general, however, symptoms are exhibited for many months or years without evidence of other signs or symptoms of an underlying connective tissue disease, making other possible diagnoses unlikely. Laboratory and radiographic studies are usually normal in patients with fibromyalgia syndrome. Exclusion of other conditions, such as osteoarthritis, rheumatoid arthritis, and systemic lupus erythematosus, by radiography, erythrocyte sedimentation rate, assays for rheumatoid factor or antinuclear antibody, and other tests is no longer considered a necessary preliminary to the diagnosis of fibromyalgia syndrome, which should be diagnosed on the basis of positive criteria.

TREATMENT

The treatment of fibromyalgia includes reassurance that the condition is not a progressive, crippling, or life-threatening entity. A combination of treatment options, including medication and physical measures, is helpful in most patients. Medications shown to be helpful in short-term, double-blind, placebo-controlled trials include amitriptyline

and cyclobenzaprine. Low doses of these medications (e.g., 10 to 30 mg of amitriptyline, 10 to 30 mg of cyclobenzaprine) are moderately effective and generally well tolerated. Studies have also shown that newer antidepressants of the serotonin-norepinephrine reuptake inhibitors (e.g., duloxetine, venlafaxine, bupropion) and $\alpha_2\delta$ ligands (gabapentin, pregabalin) are also effective, particularly in combination with low doses of tricyclic antidepressants. Patients should

also be encouraged to take an active role in the management of their condition. They should, if possible, begin a progressive, low-level aerobic exercise program to improve muscular fitness and a sense of well-being. A combination approach is effective in most patients in alleviating symptoms, although a small minority of patients require more intensive treatment strategies, such as psychiatric treatment or referral to a pain center.

Prospectus for the Future

Better understanding of pathophysiology and improved trial design and outcome measures will facilitate the development of more effective therapies in soft tissue disorders.

Rheumatic Manifestations of Systemic Disorders

Fotios Koumpouras

Many systemic disorders can express themselves through the musculoskeletal system. These often can be the presenting clue for the true nature of the underlying disorder (Table 90-1).

Rheumatic Syndromes Associated with Malignancy

HYPERTROPHIC OSTEOARTHROPATHY

Hypertrophic osteoarthropathy (HOA) is a syndrome that includes clubbing of fingers and toes, periostitis of the long bones, and arthritis. HOA can be primary, which is a hereditary form appearing in childhood and usually self-limited, or secondary. The secondary form can be either generalized or localized. Secondary generalized HOA is most often associated with neoplastic disease or infectious disease but can be seen in congenital heart disease, inflammatory bowel disease, cirrhosis, or Graves disease. Approximately 90% of cases are associated with lung cancer. Secondary localized HOA has been associated with hemiplegia, aneurysms, infective arteritis, and patent ductus arteriosus. In addition, isolated digital clubbing is associated with pleuropulmonary disease in approximately 80% of patients, but cancer is present in only a small minority of patients. Chronic digital clubbing does not appear to lead to the development of HOA. The long bones most commonly involved in HOA are the distal femur, tibia, and radius. The pathogenesis is unknown, although platelet-endothelial interactions with production of von Willebrand factor are thought to be important mechanisms.

HOA typically produces bone and joint pain with swelling that results from peri-articular periostitis. Joints appear swollen, but no proliferative synovium or inflammation develops, and joint fluid is noninflammatory. Radiographic features can be diagnostic and include periostitis with peri-

osteal new bone formation, especially along the distal and/or proximal portion of long bones. Treatment of the underlying disorder ameliorates HOA.

LEUKEMIA AND LYMPHOMA

Leukemia may simulate various rheumatic syndromes by producing synovitis or bone pain resulting from direct invasion of the synovium or marrow expansion. Approximately 6% of adult patients with leukemia exhibit rheumatic manifestations, which precede the diagnosis of leukemia by an average of 3 months. The most common presentation is an asymmetric large-joint oligoarthritis, often accompanied by low back pain. Up to 60% of children with acute leukemia have been diagnosed with either monoarthritis or polyarthritis. Although lymphoma is frequently associated with bone lesions, arthritis is a rare presentation. The combination of nocturnal bone pain, hematologic abnormalities, and radiographic features such as periosteal elevation should suggest the possibility of leukemia. Treatment of the leukemia usually results in resolution of the musculoskeletal manifestations.

Vasculitis may also occur with leukemia, lymphoma, and other myelodysplastic disorders. Leukocytoclastic vasculitis is the most common clinical vasculitic paraneoplastic presentation. In addition, a polyarteritis nodosa–like vasculitis is the most common rheumatologic manifestation of hairy cell leukemia. The presentation of vasculitis may proceed or follow the malignancy diagnosis. The most common malignancies associated with vasculitis include hairy cell leukemia, leukemia, multiple myeloma, non-Hodgkin lymphoma, Hodgkin lymphoma, sarcoma, cervical carcinoma, breast carcinoma, prostate carcinoma, and colon cancer.

Sweet syndrome is an acute febrile neutrophilic dermatosis that mimics vasculitis and is associated with malignancy in approximately 15% of patients. It is most commonly seen with acute myelogenous leukemia but has been described with other types of malignancies. It can be associated with an acute, self-limited polyarthritides in 20% of the cases.

Hematologic Disorders

HEMOPHILIA

Hemarthrosis is the most common bleeding complication of either hemophilia A (factor VIII deficiency) or hemophilia B (factor IX deficiency) and occurs in up to two thirds of patients. Hemarthrosis may occur spontaneously or as the result of minor trauma, and the level of factor deficiency determines its frequency and age at onset. Acute, painful swelling of the knees, elbows, and ankles is the most common presentation. A chronic arthropathy with persistent synovitis may also occur, perhaps as a result of excessive iron deposition in synovial membrane and cartilage. Radiographic findings are those of degenerative joint disease, with joint space narrowing, subchondral sclerosis, and cyst formation. Widening of the femoral condylar notch is a late, diagnostic radiographic finding. Treatment consists of prompt administration of factor VIII or IX concentrate or recombinant forms, intra-articular corticosteroid injections, local ice application, rest, and later physical therapy. Aspiration is indicated only if concomitant sepsis is suggested or if the joint is unusually tense and only after factor replacement. No evidence suggests that prophylaxis for acute hemarthrosis may reduce the incidence of chronic synovitis and future joint damage.

SICKLE CELL DISEASE

Of the sickle cell hemoglobinopathies, sickle cell (SS) anemia, sickle cell- β -thalassemia, sickle cell-hemoglobin C (SC) disease, and sickle cell-hemoglobin D (SD) disease all produce musculoskeletal complications, which include painful crises, arthropathy, dactylitis, osteonecrosis, osteomyelitis, and gout. SS crises are the most common musculoskeletal features, producing pain in the chest, back, and joints. Involvement of joints may produce a painful arthritis,

typically of the large joints. The mechanism of the arthropathy is thought to be an articular reaction to juxta-articular bone infarction or infarction of the synovial membrane by vascular occlusion from sickled erythrocytes. The synovial fluid is typically noninflammatory. Dactylitis resulting from vaso-occlusion in bone may occur in infants and young children, producing acute, painful, nonpitting edema of the hands and feet (hand-foot syndrome). This usually resolves spontaneously in a few weeks. Osteonecrosis of the femoral head, shoulder, and tibial plateau (in decreasing frequency) may also result from repeated crises and is most common in SS disease.

An increased incidence of septic arthritis and osteomyelitis has been associated with SS disease; *Salmonella* is the bacterial genus most frequently isolated in the patient with osteomyelitis (approximately 50%). Predisposition to *Salmonella* species is thought to be caused by functional asplenia. Osteomyelitis may be subtle and is often confused with sickle crisis. Bandemia is more suggestive of osteomyelitis. Combined technetium and gallium nuclear scans can be employed to help diagnosis.

In addition, hyperuricemia caused by renal tubular damage secondary to sickle cell disease can be seen in up to 40% of adult patients. Therefore gout can occur in patients with sickle cell disease, although it is uncommon. In children with sickle cell disease, hyperuricosuria without hyperuricemia occurs, presumably resulting from the increased marrow turnover and urate production.

Noninflammatory joint effusions adjacent to areas of bony crisis can occur, particularly at the knees and ankles. Focal muscle necroses as well as rhabdomyolysis are uncommon to rare manifestations.

MULTIPLE MYELOMA AND AMYLOIDOSIS

Multiple myeloma is one of the most common plasma cell dyscrasias and is frequently accompanied by musculoskeletal manifestations, which include bone pain resulting from lytic bone lesions, pathologic fractures, and osteoporosis. The diagnosis of multiple myeloma should be suggested in any of these clinical settings and is confirmed with the finding of a monoclonal gammopathy and sheets of immature neoplastic plasma cells on bone marrow biopsy. Primary (AL) amyloidosis accompanies approximately 15% of patients with myeloma. Alternatively, AL amyloidosis occurs without significant plasma cell proliferation on bone marrow biopsy, but patients have evidence of a plasma cell dyscrasia by virtue of the presence of a serum monoclonal gammopathy. AL amyloidosis results when amyloid protein, consisting of microscopic fibrils derived from monoclonal light chains, is deposited in organs such as the kidneys, heart, peripheral nerves, and gastrointestinal tract. It should be considered in the differential diagnosis of a patient older than 40 years of age who has nephritic syndrome, unexplained heart failure, idiopathic peripheral neuropathy, or hepatomegaly. Infrequently, amyloid joint infiltration produces a symmetrical, small-joint polyarthritis-simulating rheumatoid arthritis. Occasionally, significant infiltration of the shoulder joints with amyloid deposits produces an anterior glenohumeral soft tissue deformity known as the *shoulder pad sign*. Macroglossia and submandibular gland infiltration may also

occur. The diagnosis of this form of amyloidosis is the most easily established, with the demonstration of apple-green birefringent fluorescence on Congo red staining of an abdominal fat pad aspirate, or rectal mucosal biopsy. Biopsy of affected areas, such as gastric mucosa in those with stomach involvement, also has a high yield. In addition, immunoelectrophoresis and immunofixation of serum and urine should be performed. Optimal treatment of AL amyloidosis now consists of high-dose chemotherapy with stem cell transplantation.

The three other principal systemic forms of amyloidosis are (1) secondary (AA) amyloidosis, (2) hereditary (familial amyloid polyneuropathy) amyloidosis, and (3) β_2 -microglobulin-associated (β_2 M) amyloidosis. AA amyloidosis is a rare complication of chronic inflammatory conditions such as rheumatoid arthritis, inflammatory bowel disease, and familial Mediterranean fever. Certain chronic infections such as leprosy, tuberculosis, and osteomyelitis are also associated with this form of amyloidosis. The amyloid fibrils are derived from the acute phase reactant, serum amyloid A protein. The disease usually causes proteinuria or gastrointestinal symptoms because of infiltration of the kidney or gastrointestinal tract. The diagnosis generally requires organ biopsy because the sensitivity of the abdominal fat pad aspirate is considerably lower in AA amyloidosis than it is in the AL form. Treatment consists of controlling the underlying disorder, producing the chronic inflammatory process.

Hereditary (familial amyloid polyneuropathy) amyloidosis is the least common form of amyloidosis. This rare autosomal dominant disease is the result of single-point mutations in the gene coding for transthyretin, a thyroid-transport protein. Transthyretin is synthesized principally in the liver. Amyloid fibrils in this disease are composed of fragments of mutant transthyretin that have a propensity to form amyloid fibrils. The condition typically causes an axonal and/or autonomic neuropathy late in life. Abdominal fat aspiration has high sensitivity in the diagnosis of this type of amyloidosis. Studies suggest that the optimal treatment is orthotopic liver transplantation, which prevents further production of the mutant transthyretin.

β_2 M-associated amyloidosis occurs almost exclusively in patients on long-standing hemodialysis. This disease typically causes carpal tunnel syndrome and flexor tendon deposits in the hands or in the rotator cuff. Cystic bone deposits in the carpal bones, hips, shoulders, and cervical spine have also been described. The pathogenesis of β_2 M-associated amyloidosis is not completely understood but may in part be the result of altered proteolysis of β_2 -microglobulin in long-standing hemodialysis. Treatment includes physical measures such as splinting for carpal tunnel syndrome and physical therapy for shoulder involvement. Anti-inflammatory agents may provide additional symptomatic relief. Surgical removal of carpal or shoulder deposits may be required. Renal transplantation may be the most effective way to halt progression.

Gastrointestinal Diseases

WHIPPLE DISEASE

Whipple disease is a rare, multisystemic disease of late middle-aged to older men and is characterized by the

presence of fever, abdominal pain, steatorrhea with weight loss, lymphadenopathy, and arthritis, the last of which is now known to be the result of infection with *Tropheryma whipplei*. Polyserositis, arterial hypotension, hyperpigmentation, and various central nervous system manifestations, such as personality changes, memory loss, dementia, and spastic paraparesis, may also occur. The organism's DNA can be detected in duodenal biopsy specimens. Biopsy has long been used to detect this unculturable organism in histiocytes of the lamina propria, which show intracytoplasmic inclusions of irregular granular material that is positive on periodic acid-Schiff staining. This last finding is not specific for Whipple disease, and therefore polymerase chain reaction assay to detect the organism's DNA is now the preferred technique for diagnosis.

The arthritis of Whipple disease occurs in 60% to 90% of patients and is the most common prodrome. Classically, the arthritis is an intermittent migratory oligoarthritis lasting from a few hours to days with spontaneous remission. Some patients have only arthralgia, whereas others have a florid polyarthritis. Synovial fluid findings are typically inflammatory with a high percentage of mononuclear cells. Treatment consists of antibiotic therapy with tetracycline, which results in complete resolution within 1 week to 1 month.

HEMOCHROMATOSIS

Hereditary hemochromatosis is an autosomal recessive disorder associated with increased iron absorption and deposition that, via hemosiderin, eventually produces multiorgan damage. Hemochromatosis is among the most common genetic diseases among Europeans, with a homozygous prevalence of 0.3% to 0.5% and a heterozygote frequency of 6.7% to 10%. Approximately 90% of white patients with hereditary hemochromatosis are homozygous for the same mutation (C282Y) in the *HFE* gene. *HFE* protein forms complexes with the transferrin receptor, which is important in iron transport, and mutations in *HFE* decrease the protein's affinity for the receptor, impairing iron transport and resulting in iron overload.

The classic clinical features of hemochromatosis include hepatic cirrhosis, cardiomyopathy, diabetes mellitus, pituitary dysfunction, hypogonadism, skin pigmentation, and sicca syndrome. Symmetrical arthropathy of the second and third metacarpal joints is a disabling complication that occurs in approximately 50% of patients. Radiographic manifestations are similar to those of osteoarthritis (see Chapter 88) and include characteristic "bird-beak" osteophytes arising from the radial side of the metacarpal. In addition, the presence of chondrocalcinosis can be seen in the wrists, as hemochromatosis is associated with calcium pyrophosphate deposition disease. Occasionally, superimposed attacks of pseudogout dominate the clinical picture. Osteoarthritis-like disease occurring in a middle-aged man with involvement of the metacarpophalangeal joints should indicate the possibility of hemochromatosis. Joint changes are irreversible. The diagnosis may be established with the identification of the mutated gene sequence in DNA obtained from peripheral blood.

PRIMARY BILIARY CIRRHOSIS

Primary biliary cirrhosis is an inflammatory disease of the intrahepatic bile ducts that is frequently associated with other disorders presumed to be autoimmune, including limited scleroderma (see Chapter 83), rheumatoid arthritis (see Chapter 79), Sjögren syndrome (see Chapter 85), autoimmune thyroiditis, and renal tubular acidosis. Approximately 90% of patients have detectable immunoglobulin G–antimitochondrial antibodies, which are rare in other forms of liver disease. Up to 50% of patients with primary biliary cirrhosis have secondary Sjögren syndrome, which represents the most common rheumatic disorder associated with primary biliary cirrhosis. Other musculoskeletal complications include (1) osteomalacia caused by reduced vitamin D absorption and (2) accelerated osteoporosis. The diagnosis of primary biliary cirrhosis should be suggested in the patient with unexplained pruritus or elevated levels of serum alkaline phosphatase. A positive antimitochondrial antibody test provides strong evidence, which should then be confirmed with a liver biopsy.

Endocrine Disorders

DIABETES

Many musculoskeletal complications of diabetes exist (Table 90-2). One of the most common complications is the so-called *diabetic stiff-hand syndrome*, which is characterized by waxy thickening of the skin in long-standing type 1 or 2 diabetes. Occasionally, it may develop before the onset of overt diabetes and may create confusion because of the similarity of its appearance to that of scleroderma-like sclerodactyly. These changes are thought to be the result of excess sugar alcohols, such as sorbitol, producing excess water content in the skin and leading to increased stiffness. Joint contractures, flexor tendon contractures (including Dupuytren contractures), and joint thickening produce a condition known as *diabetic cheiroarthropathy* or the *syndrome of limited joint mobility*; these conditions appear to be related to the duration of diabetes. Although it is most common in the fingers, limited mobility may also occur in the shoulders. Diabetic periartthritis of the shoulders also referred to as *adhesive capsulitis* or *frozen shoulder*. It occurs in 10% to 30% of patients with diabetes mellitus and typically affects patients with non–insulin-requiring diabetes of long duration. About half the patients have bilateral involvement, although, curiously, the nondominant shoulders frequently are more severely involved. In many instances, adhesive capsulitis in diabetics can remit spontaneously in several weeks. When adhesive capsulitis is accompanied by vasomotor changes of the same upper extremity, this can be referred to as *shoulder-hand syndrome*, which is similar to reflex sympathetic dystrophy.

Charcot joints or neuropathic arthropathy may occur with any neuropathy but are most commonly associated with diabetes, although defects are present in less than 1% of all patients with diabetes. The condition affects men and women with equal frequency. Most patients are over age 40 years and have long-standing disease. Poorly controlled diabetes associated with diabetic peripheral neuropathy is the strongest risk factor. Tarsal and tarsometatarsal joints

Table 90-2 Musculoskeletal Manifestations of Endocrine Disease

Endocrine Disease	Musculoskeletal Manifestation
Diabetes mellitus	Carpal tunnel syndrome Charcot arthropathy Adhesive capsulitis Syndrome of limited joint mobility (cheiroarthropathy) Diabetic amyotrophy Diabetic muscle infarction
Hypothyroidism	Proximal myopathy Arthralgias Joint effusions Carpal tunnel syndrome Chondrocalcinosis
Hyperthyroidism	Myopathy Osteoporosis Thyroid acropachy
Hyperparathyroidism	Myopathy Arthralgias Erosive arthritis Chondrocalcinosis
Hypoparathyroidism	Muscle cramps Soft tissue calcifications Spondyloarthropathy
Acromegaly	Carpal tunnel syndrome Myopathy Raynaud phenomenon Back pain Premature osteoarthritis
Cushing syndrome	Myopathy Osteoporosis Avascular necrosis

are most commonly involved, and trauma together with diminished pain perception, proprioception, and position sense are major factors in the genesis of this arthropathy. The most common presentation is swelling of the foot with little or no pain. Treatment consists of avoiding weight-bearing activities and application of a Charcot boot or soft cast. Prevention of skin oral ulceration over bony prominences is critical. End-stage Charcot deformity of the foot is referred to as “rocker-bottom feet.”

Carpal tunnel syndrome is associated with diabetes. Up to 15% of all patients with carpal tunnel syndrome have diabetes. The condition causes typical paresthesias in median nerve distribution.

Diffuse idiopathic skeletal hyperostosis occurs in approximately 20% of non–insulin-requiring diabetic patients. Typically patients have neck and back stiffness associated with loss of motion. Pain tends not to be prominent. Spine radiographs demonstrating calcification of the anterior longitudinal ligament of four contiguous vertebrae are diagnostic. Lack of involvement of the apophyseal joints distinguishes this disorder from ankylosing spondylitis and osteoarthritis. Physical therapy and nonsteroidal anti-inflammatory medications are the mainstays of treatment.

HYPOTHYROIDISM

Almost one third of patients with frank hypothyroidism can exhibit objective musculoskeletal findings. Myxedematous

arthropathy usually affects large joints. Patients may demonstrate swelling and stiffness, synovial membrane thickening, ligamentous laxity, and joint effusions. Synovial fluid is noninflammatory. In addition, hypothyroidism is associated with carpal tunnel syndrome, Raynaud phenomena, fibromyalgia-like muscle pain, and proximal muscle weakness with stiffness and increased creatinine kinase.

Pseudogout may also be a presenting manifestation of hypothyroidism. Myopathy, especially proximal, occurs in hypothyroidism and is often associated with elevated levels of creatine kinase. Muscle biopsy specimens show atrophy of type II fibers but no inflammation. Thyroid replacement results in gradual improvement of both the arthropathy and myopathy of hypothyroidism.

HYPERTHYROIDISM

Four principal rheumatic manifestations occur in thyrotoxicosis: proximal myopathy, shoulder peri-arthritis, thyroid acropachy (thickened skin with periosteal new bone formation), and osteoporosis. Myopathy is common, occurring in 70% of patients with hyperthyroidism, but it is seldom a presenting manifestation. Myopathy tends to be more common in elderly patients with apathetic hyperthyroidism. The concurrence of new onset atrial fibrillation should be a clue. Peri-arthritis of the shoulder (especially bilateral) occurs in up to 10% of patients. Thyroid acropachy is a rare complication of Graves disease and consists of clubbing and soft tissue swelling of the hands and feet. Radiographs show periosteal new bone formation, which is best seen on the radial aspect of the second and third metacarpals. It is strongly associated with ophthalmopathy and pretibial myxedema. The symptoms of thyroid acropachy occur as patients achieve euthyroidism. Osteoporosis is produced by increased bone turnover, which accompanies the hyperthyroid state.

HYPERPARATHYROIDISM

Musculoskeletal manifestations are common in hyperparathyroidism and are the initial manifestations in up to 15% of patients. Pseudogout is the most common rheumatic complication, occurring in up to 10% of patients with hyperparathyroidism, although radiographic chondrocalcinosis is seen in up to 40% of patients. A rheumatoid,

arthritis-like disorder has also been described with involvement of the knees, wrists, hands, and shoulders, showing radiographic erosions. In contrast to rheumatoid arthritis, however, synovial proliferation is absent, the joint space is preserved, and erosions are characteristically on the ulnar side, as opposed to rheumatoid arthritis, in which the erosions are typically on the radial side.

Secondary hyperparathyroidism is common in patients with chronic renal failure and is a component of renal osteodystrophy. Musculoskeletal features are similar to those described earlier.

Sarcoidosis

Sarcoidosis is a multisystemic inflammatory disorder exhibited by the formation of noncaseating granulomas. It may be associated with both acute and chronic rheumatic manifestations. The acute syndrome is known as *Löfgren syndrome* and consists of the classic triad of hilar adenopathy, erythema nodosum, and arthritis. It occurs in approximately 15% of those patients with sarcoidosis. The arthritis is usually symmetrical and migratory; it frequently involves the ankles, although it may be difficult to distinguish from erythema nodosum and peri-arthritis of the ankle. Joint effusions are typically noninflammatory. The arthritis is nondeforming, nonerosive, and self-limiting, usually not lasting more than 3 to 4 months. Patients with the nonarticular manifestations of Löfgren syndrome have an excellent prognosis.

Chronic arthropathy involving the knees, ankles, wrists, and elbows occurs less frequently and is generally associated with active multisystemic disease. Synovial thickening and effusions are common; a synovial biopsy specimen may show the typical noncaseating granulomas. Treatment of acute sarcoid arthropathy includes the use of nonsteroidal anti-inflammatory drugs or, occasionally, a short course of corticosteroids. Treatment of the chronic arthropathy is dependent on the severity of the extra-articular manifestations that usually accompany it. Corticosteroids and other immunosuppressive agents are generally needed to control the systemic disease, which in turn can control the arthropathy. Bony involvement by sarcoidosis leads to lytic lesions, particularly over the phalanges, and can cause a pathologic fracture.

Prospectus for the Future

The future of recognizing rheumatic syndromes as part of systemic diseases relies on accurate diagnosis. With the employment of new cell-based assays, autoantibody tests, and physician recognition, the recognition of systemic disease with rheumatic manifestations can be facilitated. In addition, increasing the rheumatology workforce allows for rapid refer-

ral of patients who have rheumatic complaints that may be secondary to other systemic disorders, which in turn may lead to earlier diagnosis. Lastly, interdisciplinary care, such as in Centers of Excellence, allows for rapid referral among subspecialists when the diagnosis is in question.

Organisms That Infect Humans

Benigno Rodríguez and Michael M. Lederman

Of diseases affecting humans, most that are curable and preventable are caused by infectious agents. The infectious diseases that capture the attention of physicians and the public periodically shift—for example, from syphilis to tuberculosis to acquired immunodeficiency syndrome (AIDS)—but the challenges of dealing with these processes endure. To the student, an understanding of infectious diseases offers insights into medicine as a whole. Osler’s adage (with updating) remains relevant: “He [or she] who knows syphilis [AIDS], knows medicine.”

Viruses

Viruses produce a wide variety of clinical illnesses. A virus consists of either DNA or RNA (in rare cases, both) wrapped within a protein nucleocapsid. The nucleocapsid may be covered by an envelope composed of glycoproteins and lipids; pathogenic viruses that lack an envelope tend to survive better in the environment and are more often transmitted by the fecal-oral route, whereas those that possess an envelope are more often transmitted by the parenteral route or through the genital or respiratory mucosae. Viral genes can code for only a limited number of proteins, and viruses possess no metabolic machinery. They are entirely dependent on host cells for protein synthesis and replication and are therefore obligate intracellular parasites. Some viruses are dependent on other viruses to replicate or produce active infection. Such is the case with the delta agent, which produces disease only in the presence of hepatitis B infection. All must attach to receptors on the host cell and achieve entry into the cell through mechanisms that include receptor-mediated endocytosis, fusion, pinocytosis, or, in the case of certain nonenveloped viruses, direct penetration of the cell membrane. Once within the cells, the virus uncoats, allowing its nucleic acid to use host cellular machinery to reproduce (productive infection) or to integrate into the host cell (latent infection). Some viruses, such as influenza virus, cause disease by lysis of infected cells. Others, such as hepatitis B virus, do not directly cause cell destruction

but may involve the host immune responses in the pathogenesis of disease. Still others, such as the human T-lymphotropic virus type 1, promote neoplastic transformation of infected cells.

Viruses have developed several mechanisms for evading host defense mechanisms. By multiplying within host cells, viruses can avoid neutralizing antibodies and other extracellular host defenses. Some viruses can spread to uninfected cells by intercellular bridges. Others, especially the herpes group and human immunodeficiency virus (HIV), are capable of persisting latently without multiplication in a metabolically inactive form within host cells for prolonged periods. The influenza virus is capable of extensive gene rearrangements, resulting in significant changes in surface antigen structure. This allows new strains to evade host antibody responses directed at earlier strains.

Some viruses, as they exit the host cell during productive infection, may carry antigens of host cell origin, thus providing another potential mechanism for evading host defenses, whereas others block host immune defense mechanisms (such as expression of human leukocyte antigens). HIV induces both specific and nonspecific escape mechanisms by selectively deleting HIV-reactive T-cell clones and coating itself with a host-derived “glycan shield” that hinders neutralizing antibody attachment, while also causing profound global immune dysfunction that paralyzes host defenses.

Prions

Prions are a group of host-encoded transmissible proteins devoid of nucleic acid material that cause disease through accumulation of a pathogenic isoform of the prion protein. They are thought to be responsible for a number of progressive and ultimately fatal neurologic diseases in humans, including kuru, Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker syndrome and familial fatal insomnia, and animal diseases such as scrapie and bovine spongiform encephalopathy (“mad cow disease”). Although some prion diseases (e.g., familial CJD) are inherited, others,

including kuru and new variant CJD, are acquired through consumption of infected neural tissue. There is no known treatment for these disorders.

Bacteria

Bacteria comprise a tremendously varied group of organisms that are generally capable of cell-free growth, although some produce disease as intracellular parasites. There are numerous ways of classifying bacteria, including morphology, ability to retain certain dyes, growth in different physical conditions, ability to metabolize various substrates, and antibiotic sensitivities. Although combinations of these methods are used to identify bacteria in clinical bacteriology laboratories, relatedness for taxonomic purposes is established by DNA homology.

CHLAMYDIAE

Chlamydiae are obligate intracellular parasites; they always contain both DNA and RNA, divide by binary fission (rather than multiplying by assembly), can synthesize proteins, and contain ribosomes. Although classified as a unique family of bacteria, they are unable to synthesize adenosine triphosphate and thus depend on energy from the host cell to survive. The three chlamydial species known to cause disease in humans are *Chlamydia trachomatis*, *Chlamydophila pneumoniae*, and *Chlamydia psittaci*. *C. trachomatis* causes trachoma, the major cause of blindness in the developing world, and a variety of sexually transmitted genitourinary disorders, including urethritis, salpingitis, and lymphogranuloma venereum. *C. pneumoniae* is a common cause of atypical pneumonia, bronchitis, and sinusitis. *C. psittaci*, the cause of a common infectious disease of birds, can produce a serious systemic illness with prominent pulmonary manifestations in humans. Chlamydiae are susceptible to tetracyclines, rifampin, macrolides and related compounds, ketolides, and certain quinolones.

RICKETTSIAE AND EHRLICHIAE

Rickettsiae and ehrlichiae are also small bacterial organisms that, like chlamydiae, are obligate intracellular parasites. They are primarily animal pathogens that generally produce disease in humans through the bite of an insect vector, such as a tick, flea, louse, or mite. Most of these organisms specifically infect vascular endothelial cells. With the exception of Q fever and human ehrlichiosis, rash caused by vasculitis is a prominent manifestation of these often disabling febrile illnesses. These organisms are susceptible to tetracyclines and chloramphenicol.

MYCOPLASMAS

Mycoplasmas are the smallest free-living organisms. In contrast to viruses, chlamydiae, rickettsiae, and ehrlichiae, mycoplasmas can grow on cell-free media and produce disease without intracellular penetration. Like other bacteria, these organisms have a membrane, but unlike other bacteria, they have no cell walls. Thus antibiotics that are active against bacterial cell walls have no effect on mycoplas-

mas. At least 14 species of mycoplasma may cause disease in humans. *Mycoplasma pneumoniae* is an agent of pharyngitis and pneumonia. Although *Mycoplasma hominis*, *Ureaplasma urealyticum*, and the newly described *Mycoplasma genitalium* are primarily agents of genitourinary disease, they may also cause systemic infections, particularly in compromised hosts. Mycoplasmas are sensitive to erythromycin, tetracycline, a combined regimen of both, and most quinolones.

SPIROCHETES

Spirochetes are slender, motile, spiral organisms that are not readily seen under the microscope unless stained with silver or viewed under darkfield illumination. Many of these organisms cannot yet be cultured on artificial media or in cell culture. Four genera of spirochetes cause disease in humans. *Treponema* species include the pathogens of syphilis and the nonvenereal, endemic, syphilis-like illnesses of yaws, pinta, and bejel. The illnesses caused by these organisms are chronic and characterized by prolonged latency in the host. Penicillin is active against *Treponema*. *Leptospira* species are the causative agents of leptospirosis, an acute or subacute febrile illness occasionally resulting in aseptic meningitis, jaundice, and (in rare cases) renal insufficiency. *Borrelia* species are arthropod-borne spirochetes that are the causative agents of Lyme disease (see Chapter 95) and relapsing fever. During afebrile periods in relapsing fever, these organisms reside within host cells and emerge with modified cell surface antigens. These modifications may permit the bacterium to evade host immune responses and produce relapsing fever and recurrent bacteremia. *Spirillum minus* is one of the causative agents of rat-bite fever. *Helicobacter pylori* is a spirochete of the upper gastrointestinal tract that plays an important role in the pathogenesis of duodenal and gastric ulcers and also in certain neoplasms of the gastrointestinal tract.

ANAEROBIC BACTERIA

Anaerobes are organisms that cannot grow in atmospheric oxygen tensions. Some are killed by very low oxygen concentrations, whereas others are relatively aerotolerant. As a general rule, anaerobes that are pathogens for humans are not as sensitive to oxygen as nonpathogens. Anaerobic bacteria are primarily commensals. They inhabit the skin, gut, and mucosal surfaces of all healthy individuals. In fact, the presence of anaerobes may inhibit colonization of the gut by virulent, potentially pathogenic bacteria. Anaerobic infections generally occur in two circumstances:

- Contamination of otherwise sterile sites with anaerobes laden contents. Examples include (1) aspiration of oral anaerobes into the bronchial tree, producing anaerobic necrotizing pneumonia; (2) peritonitis and intra-abdominal abscesses after bowel perforation; (3) fasciitis and osteomyelitis after odontogenic infections or oral surgery; and (4) some instances of pelvic inflammatory disease.
- Infections of tissue with lowered redox potential as the result of a compromised vascular supply. Examples include (1) foot infections in diabetic patients, in whom vascular disease may produce poor tissue oxygenation; and (2)

infections of pressure sores, in which fecal anaerobic flora gain access to tissue whose vascular supply is compromised by pressure.

The pathogenesis of anaerobic infections—that is, soilage by a complex flora—generally results in polymicrobial infections. Thus the demonstration of one anaerobe in an infected site generally implies the presence of others. Often, facultative organisms (organisms capable of anaerobic and aerobic growths) coexist with anaerobes. Certain anaerobes, such as *Clostridium*, produce toxins that cause well-defined systemic illnesses such as food poisoning, tetanus, and botulism. Other toxins may play a role in soft tissue infections (cellulitis, fasciitis, and myonecrosis) occasionally produced by *Clostridium* species. *Clostridium difficile* is the causative agent of pseudomembranous colitis, a diarrheal disease of varying severity (sometimes fatal) that has emerged as a major cause of morbidity in patients receiving antibiotic therapy and those in health care facilities. *Bacteroides fragilis*, the most numerous bacterial pathogen in the normal human colon, has a polysaccharide capsule that inhibits phagocytosis and promotes abscess formation. Clues to the presence of anaerobic infection include a foul odor; the presence of gas, which may be seen radiographically or manifested by crepitus on examination (although not all gas-forming infections are anaerobic); and the presence of mixed gram-positive and gram-negative flora on a Gram stain of purulent exudate, especially when there is little or no growth on plates cultured aerobically. Many pathogenic anaerobes are sensitive to penicillin. Exceptions are strains of *B. fragilis* (usually sensitive to metronidazole, clindamycin, or ampicillin-sulbactam) and *C. difficile* (which is almost always sensitive to metronidazole and vancomycin). Strains of *Fusobacterium* may also be relatively resistant to penicillin. As a general rule, infections caused by anaerobes originating from sites above the diaphragm are more often (but not always) penicillin sensitive, whereas infections below the diaphragm are often caused by penicillin-resistant organisms, notably *B. fragilis*.

GRAM-NEGATIVE BACTERIA

The cell walls of gram-negative bacteria, which appear pink on a properly prepared Gram stain, contain lipopolysaccharide, a potent inducer of cytokines such as tumor necrosis factor, and are associated with fever and septic shock. These organisms cause a wide variety of illnesses. Gram-negative bacteria are the most common cause of cystitis and pyelonephritis. *Haemophilus* species are common pathogens of the respiratory tract and cause otitis media, sinusitis, tracheobronchitis, and pneumonia. Lower respiratory tract infections with these organisms are particularly common in adults with chronic obstructive pulmonary disease. *Haemophilus* can be an important cause of meningitis, particularly in children. Except for *Haemophilus* and *Klebsiella* species, gram-negative bacteria are uncommon causes of community-acquired pneumonia but are common causes of nosocomial pneumonia.

Except for the peculiar risk of *Pseudomonas* infection in intravenous drug users, gram-negative organisms are rare causes of endocarditis on natural heart valves but are occasional pathogens on prosthetic valves. The Enterobacteria-

ceae include *Escherichia coli*, *Klebsiella*, *Enterobacter*, *Serratia*, *Salmonella*, *Shigella*, and *Proteus*. These are large gram-negative rods. Except for the occasional presence of a clear space surrounding some *Klebsiella* representing a large capsule, these organisms are not readily distinguished from one another on Gram stain. The Enterobacteriaceae can be thought of as gut-related or genitourinary pathogens. *Salmonella*, a relatively common cause of enteritis, may occasionally infect atherosclerotic plaques or aneurysms. *Shigella* is an agent of bacterial dysentery. *Proteus* species, which split urea, are the agents associated with staghorn calculi of the urinary collecting system. Increasingly, gram-negative bacteria that are often resistant to multiple antibiotics are important causes of nosocomial infection. The genus *Bartonella* contains a group of emerging pathogens that cause uncommon, unique infections including bacillary angiomatosis, cat-scratch disease, and South American bartonellosis.

Gram-negative cocci that cause disease in humans include *Neisseria* and *Moraxella* species. These kidney bean-shaped diplococci are not distinguishable from one another on Gram stain. *Neisseria meningitidis* is an important cause of meningitis, and *Neisseria gonorrhoeae* causes gonorrhoea. *Moraxella catarrhalis*, which is part of the normal oral flora, is a cause of lower respiratory tract infection.

GRAM-POSITIVE BACTERIA

Although these organisms (which appear deep purple on Gram stain) lack endotoxin, infections with gram-positive bacteria also produce fever and cannot be reliably distinguished on clinical grounds from infections caused by gram-negative bacteria.

Gram-Positive Rods

Infections caused by gram-positive rods are relatively uncommon outside certain specific settings. Diphtheria is rare (although epidemics have occurred in recent years), but other corynebacteria produce infections in the immunocompromised host and on prosthetic valves and shunts. Because corynebacteria are regular skin colonizers, they often contaminate blood cultures; in the appropriate setting, however, they must be considered potential pathogens. *Listeria monocytogenes* resembles *Corynebacterium* on initial isolation, and this food-borne pathogen is an increasingly important cause of meningitis and bacteremia in the immunocompromised patient. *Bacillus cereus* is a recognized cause of food poisoning. Serious infections with this and other *Bacillus* species occur among intravenous drug users. Infections with *Clostridium* species were discussed earlier.

Gram-Positive Cocci

Staphylococcus aureus is a common pathogen that can infect any organ system. It is a common cause of bacteremia and sepsis. The organism often colonizes the anterior nares, particularly among insulin-treated diabetics, hemodialysis patients, and injection drug users; these populations therefore have a greater frequency of infections with this organism. Hospital workers colonized with *S. aureus* have been responsible for hospital epidemics of staphylococcal disease.

Generally protected by an antiphagocytic polysaccharide capsule, staphylococci also possess catalase, which inacti-

vates hydrogen peroxide—a mediator of bacterial killing by neutrophils. Staphylococci tend to form abscesses; the low pH within an abscess cavity also limits the effectiveness of host defense cells. Staphylococci elaborate several toxins that mediate specific manifestations of disease. A staphylococcal enterotoxin is responsible for staphylococcal food poisoning. Staphylococcal toxins also mediate the scalded skin syndrome and the multisystem manifestations of toxic shock syndrome. Most staphylococci are penicillinase producing, and an increasing proportion are resistant to penicillinase-resistant penicillin analogues. Although commonly referred to as *methicillin-resistant S. aureus* (MRSA), they are resistant to all β -lactams. Once found almost exclusively in hospitalized patients, MRSA strains that express novel pathogenic determinants, such as the Panton-Valentine leukocidin (PVL), and exhibit a distinctive antimicrobial resistance pattern have now become established in the community and are the cause of thousands of severe community-acquired infections each year. At the same time, the role of MRSA as a nosocomial pathogen continues, and MRSA has been responsible for widespread epidemics in health care institutions worldwide. Vancomycin remains active against most strains, but strains with reduced susceptibility and even complete resistance to this and other glycopeptides have recently been isolated from clinical cases. Resistance in these strains is the result of acquisition of mobile genetic elements from *Enterococcus* species, likely in the hospital setting. These strains are still uncommon but can cause severe disease, including bloodstream infections. Strains with decreased susceptibility to the oxazolidinone linezolid have now also been described.

Other staphylococci are distinguished from *S. aureus* primarily by their inability to produce coagulase. Some of these coagulase-negative staphylococci produce urinary tract infection (*Staphylococcus saprophyticus*). Another, *Staphylococcus epidermidis*, is part of the normal skin flora and an increasingly important cause of infection on foreign bodies such as prosthetic heart valves, ventriculoatrial shunts, and intravascular catheters. Like *Corynebacterium*, *S. epidermidis* may be a contaminant of blood cultures but in the appropriate setting should be considered a potential pathogen. *S. saprophyticus* is sensitive to a variety of antibiotics used in the treatment of urinary tract infection; *S. epidermidis* is usually resistant to all β -lactams but sensitive to vancomycin.

Streptococci are classified into groups according to the presence of serologically defined carbohydrate capsules (Lancefield typing). Group A streptococci produce skin infections, pharyngitis, and systemic infections. These organisms are also associated with the immunologically mediated poststreptococcal disorders—glomerulonephritis and acute rheumatic fever. Streptococci are further classified according to the pattern of hemolysis on blood agar— α for incomplete hemolysis (producing a green discoloration on the agar), β for complete hemolysis, and γ for nonhemolytic strains. An important α -hemolytic species is *Streptococcus pneumoniae* (pneumococcus), the most common cause of community-acquired pneumonia and an important cause of meningitis and otitis media. Penicillin resistance in pneumococcal isolates is an increasingly important problem and is often associated with concomitant resistance to other agents. Whereas pneumococcal pneumonia caused by

strains with intermediate penicillin resistance can still be successfully treated with very high doses of penicillin, other antimicrobial agents must now be used for pneumococcal meningitis (see Chapter 97). Penicillin-resistant *S. pneumoniae* generally remains susceptible to vancomycin. A heterogeneous group of streptococci, often improperly referred to as *viridans* (green) streptococci (these organisms may show α - or γ -hemolysis), includes several species of streptococci that are common oral or gut flora and are important agents of bacterial endocarditis, abscesses, and odontogenic infections.

Formerly classified as members of the *Streptococcus* genus, enterococci are facultative anaerobes that, unlike the streptococci, exhibit variable degrees of resistance to penicillins and are uniformly resistant to cephalosporins. Vancomycin-resistant strains of enterococci are increasingly prevalent causes of serious hospital-acquired infections, particularly in immunocompromised and postsurgical patients, that are exceedingly difficult to treat.

MYCOBACTERIA

Mycobacteria comprise a group of rod-shaped bacilli that stain weakly gram positive. These organisms are rich in lipid content and are recognized in tissue specimens by their ability to retain dye after washing with acid alcohol (acid fast). These bacteria are generally slow-growing (some require up to 6 weeks to demonstrate growth on solid media), obligate aerobes. They generally produce chronic disease and survive for years as intracellular parasites of mononuclear phagocytes. Some escape intracellular killing mechanisms by blocking phagosome and lysosome fusion or by disrupting the phagosome. Almost all provoke cell-mediated immune responses in the host, and clinical disease expression may be related in large part to the nature of the host immune response. Tuberculosis is caused by *Mycobacterium tuberculosis*. Other mycobacteria (nontuberculous mycobacteria) can cause diseases resembling tuberculosis. Certain rapid-growing mycobacteria cause infections after surgery or implantations of prostheses, as well as epidemic and sporadic skin and soft tissue infections. *Mycobacterium avium* complex (MAC) is an important cause of disseminated infection among patients with AIDS. MAC is frequently resistant to drugs usually used in the treatment of tuberculosis. Leprosy is a mycobacterial disease of skin and peripheral nerves caused by the noncultivable *Mycobacterium leprae*.

ACTINOMYCETALES

Nocardia and *Actinomyces* are weakly gram-positive filamentous bacteria. *Nocardia* is acid fast and aerobic; *Actinomyces* is anaerobic and not acid fast. *Actinomyces* inhabits the mouth, gut, and vagina and produces cervicofacial osteomyelitis and abscess, pneumonia with empyema, and intra-abdominal and pelvic abscess, the last often associated with intrauterine contraceptive devices. *Nocardia* most commonly produces pneumonia and brain abscess. Approximately half of patients with *Nocardia* infection have underlying impairments in cell-mediated immunity. Infections with either of these slow-growing organisms require long-term treatment. *Actinomyces* is relatively sensitive to

many antibiotics; penicillin is the treatment of choice. *Nocardia* infections are treated with high doses of sulfonamides, but serious or resistant infections may require combinations of carbapenems, aminoglycosides, and cephalosporins.

Fungi

Fungi are larger than bacteria. Unlike bacteria, they have rigid cell walls that contain chitin as well as polysaccharides. They grow and proliferate by budding, by elongation of hyphal forms, and/or by spore formation. Except for *Candida* and related species, fungi are rarely visible on Gram-stained preparations but can be stained with Gomori methenamine silver stain. They are also resistant to potassium hydroxide and can often be seen on wet mounts of scrapings or secretions to which several drops of a 10% solution of potassium hydroxide have been added. Fungi are resistant to most antibiotics used in the treatment of bacterial infections and are typically treated with drugs active against their unusual cell wall. Most fungi can exist in a yeast form (round to ovoid cells that may reproduce by budding) and a mold form, a complex of tubular structures (hyphae) that grow by branching or extension.

Candida species are oval yeasts that often colonize the mouth, gastrointestinal tract, and vagina of healthy individuals. They may produce disease by overgrowth and/or invasion. *Candida* stomatitis (thrush) often occurs in individuals who are receiving antibiotic or corticosteroid therapy or who have impairments of cell-mediated immunity. Vulvovaginitis caused by *Candida* may occur in these same settings but can also occur in women with no apparent predisposing factors and more commonly in women with diabetes mellitus. *Candida* can also colonize and infect the urinary tract, particularly in the presence of an indwelling urinary catheter. *Candida* species may also gain entry into the bloodstream and produce fungemia with or without seeding of solid tissues, especially in hospitalized patients, in whom *Candida* species are now the fourth leading cause of intravascular infection. This most frequently occurs in the setting of neutropenia after chemotherapy, where the portal of entry is the gastrointestinal tract, or in individuals with intravascular catheters, which provide a route for cutaneous *Candida* to enter the systemic circulation (see Chapter 106). Largely as a consequence of widespread use of empiric and targeted antibiotic therapy, as well as more frequent immunosuppressive conditions, *Candida* species other than *Candida albicans* have become increasingly common causes of invasive disease in hospitals. These non-*C. albicans* species (e.g., *Candida glabrata*, *Candida krusei*, *Candida tropicalis*) are more often resistant to commonly used antifungals such as fluconazole and have therefore skewed the landscape of empiric antifungal therapy, especially in immunosuppressed patients, toward broader-spectrum agents such as amphotericin B and the echinocandins.

Histoplasma capsulatum is a dimorphic fungus endemic to the Ohio and Mississippi River valleys that produces asymptomatic infection or a mild febrile syndrome in most individuals and a self-limited pneumonia in some. In predisposed individuals, it can cause cavitary pulmonary disease

and mediastinal fibrosis. Infants and immunosuppressed individuals, such as those with AIDS or neutropenia, are susceptible to the progressive disseminated form of the infection, which is potentially fatal (see Chapter 108). Systemic or progressive disease is treated with parenteral amphotericin B or itraconazole.

The dimorphic fungus *Coccidioides immitis* is endemic in the southwestern United States and, like *H. capsulatum*, produces a self-limited respiratory infection or pneumonia in most infected individuals. Immunocompromised individuals are at greatest risk for fatal systemic dissemination or meningitis. Fluconazole, itraconazole, or amphotericin B is used for progressive or extrapulmonary disease.

Cryptococcus neoformans is a yeast with a large polysaccharide capsule. It produces a self-limited or chronic pneumonia, but the most common clinical manifestation of infection with this fungus is a chronic meningitis. Although patients with impairment in cell-mediated immunity are at risk for cryptococcal meningitis, some patients with this syndrome have no identifiable immunodeficiency. Treatment is with amphotericin B combined with flucytosine. Long-term oral fluconazole therapy is effective in preventing relapse in persons with AIDS (see Chapter 108).

Blastomyces dermatitidis is a dimorphic organism also endemic in the Ohio and Mississippi River basins. Acute self-limited pulmonary infection is followed in rare instances by disseminated disease. Skin disease is most common, but bones, the central nervous system, and the genitourinary tract may be involved as well. Amphotericin B is used for treating systemic disease; itraconazole is appropriate for immunocompetent hosts.

Aspergillus is a mold that produces several clinical illnesses in humans. Acute bronchopulmonary aspergillosis is an immunoglobulin E-mediated hypersensitivity to *Aspergillus* colonization of the respiratory tract. This condition produces wheezing and fleeting pulmonary infiltrates in patients with asthma. Occasionally, *Aspergillus* will colonize a preexistent pulmonary cavity and produce a mycetoma or fungus ball. Hemoptysis is the most serious complication of such infection. Invasive pulmonary aspergillosis is a rare cause of chronic illness in marginally compromised hosts; more often, it is a cause of acute, life-threatening pneumonia or disseminated infection in patients with neutropenia or in recipients of organ transplants. Voriconazole is now the drug of choice for most cases of invasive aspergillosis; amphotericin B and the echinocandins remain important alternatives or concomitant agents.

The zygomycetes (Mucorales) are molds with ribbon-shaped hyphae that produce disease in patients with poorly controlled diabetes mellitus or hematologic malignancy or in recipients of organ transplantation. Invasive disease of the palate and nasal sinuses, which may extend intracranially, is the most common presentation, but pneumonia may be seen as well. These infections are generally treated with surgical excision plus high-dose amphotericin B.

Pneumocystis jiroveci (formerly *Pneumocystis carinii*) was once thought to be a protozoan; genetic analyses have classified *P. jiroveci* as a fungus. This organism causes life-threatening pneumonia in patients with impaired cell-mediated immunity; it is the most common major opportunistic pathogen in persons with AIDS (see Chapter 108).

Table 91-1 Some Protozoal Diseases of Humans

Protozoan	Clinical Illness	Transmission	Diagnosis
<i>Plasmodium</i>	Malaria: fever, hemolysis	Mosquito, transfusion	Peripheral blood smear
<i>Babesia microti</i>	Fever, hemolysis	Tick, transfusion	Peripheral blood smear
<i>Trichomonas vaginalis</i>	Vaginitis	Sexual contact	Vaginal smear
<i>Toxoplasma gondii</i> *	Fever, lymph node enlargement; encephalitis, brain abscess in compromised host	Raw meat, cat feces	Serologies, tissue biopsy
<i>Entamoeba histolytica</i>	Colitis, hepatic abscess	Fecal-oral	Stool smear, serologies
<i>Giardia lamblia</i>	Diarrhea, malabsorption	Fecal-oral	Stool smear, small bowel aspirate
<i>Cryptosporidium</i> *	Diarrhea	Fecal-oral	Sugar flotation, acid-fast stain of stool, biopsy
<i>Isospora belli</i> *	Diarrhea, malabsorption	Fecal-oral	Wet mount or acid-fast stain of stool
<i>Microsporidium</i> *	Diarrhea, malabsorption, dissemination	Fecal-oral	Small bowel biopsy Electron microscopy

*Important opportunistic pathogens in persons with acquired immunodeficiency syndrome (see Chapter 108).

Protozoans

The protozoal pathogens listed in Table 91-1 are all important causes of disease within the United States. Infections caused by these organisms are diagnosed as indicated in Table 91-1 and are discussed in the relevant disease-oriented chapters.

Helminths

Diseases caused by helminths are among the most prevalent diseases in the developing world but are uncommon causes

of illness in North America. In contrast to the pathogens discussed previously, helminths are multicellular parasites. Helminthic pathogens found in the United States include the roundworm *Ascaris* species (malnutrition and obstruction), the hookworm *Necator americanus* (intestinal blood loss), the pinworm *Enterobius vermicularis* (anal pruritus), and the threadworm *Strongyloides stercoralis* (gastroenteritis and dissemination in the immunocompromised host). It is important to recognize the risk of other helminthic diseases in travelers returning from endemic regions (see Chapter 110).

Prospectus for the Future

Clinicians should anticipate the identification of “novel” pathogens causing disease, as follows:

- Prevalent microbes not previously recognized as pathogenic
- “Discovery” of prevalent pathogens not previously identified
- Influx into new communities of pathogens prevalent elsewhere
- Increased frequency and distorted clinical presentation of uncommon pathogens as a consequence of immunosuppressive conditions and treatments
- Emergence of resistant strains of common pathogens

Host Defenses Against Infection

Benigno Rodríguez and Michael M. Lederman

Host Defenses versus Mechanisms of Microbial Pathogenesis: The Struggle for Survival

As our experience suggests and as fossil records indicate, life is a continuous struggle for survival. Pathogenic and host defense evasive mechanisms of microbes are countered by multiple and overlapping host innate and adaptive immune defense mechanisms. In some cases, the pathogen “wins,” with destruction of the host; in others, the host immune response prevails, with eradication of the microbe. Often there is a standoff characterized by latent infection or colonization without substantial morbidity to the host; sometimes the relationship is actually symbiotic, with both host and pathogen gaining from it. In settings of latent or colonizing pathogens, microbes have the capacity to activate and cause disease if host defenses become impaired. Much of our understanding of host defenses and their relationship to microbial pathogenesis has been derived from recognizing the spectrum of infections experienced by individuals with specific impairments of host defenses. Thus, persons with neutrophil depletion or defects in neutrophil function tend to experience bacterial and fungal infections, those with antibody defects are particularly at risk for infections caused by encapsulated bacteria, and persons with impairments in cell-mediated immunity tend to be at particular risk for infection with pathogens that replicate within host cells. Reflecting the importance of these insights, in the early days of the acquired immunodeficiency syndrome (AIDS) epidemic, astute clinicians recognized immediately that the kinds of infections seen in the first AIDS patients implicated an acquired impairment of cell-mediated adaptive immune defenses; this insight accelerated research on the pathogenesis and etiology of AIDS.

Evolutionary Advantage of Adaptable Organisms

Fundamental to our understanding of evolution is the concept that organisms most capable of adaptation to environmental stresses are most likely to survive, to propagate, and to persist. Thus, random mutations in the germline that confer survival advantage are passed on to adapting, succeeding generations. With this in mind, it is astounding that complex organisms such as humans can compete for survival with microbes much more capable of rapid genetic adaptation to challenge. The number of germline mutations over time is dependent on generation time, the number of offspring per generation, and the mistake rate of the DNA or RNA polymerase required for genomic replication. In each of these indices, microbes have the clear adaptive advantage. As an example, humans must survive at least 10 years or more before they are even capable of reproduction, and then they generate only a small number of offspring before dying. In contrast, bacteria can grow exponentially, with generation times measured in minutes to hours, and viruses express thousands of progeny with replication cycles that can be completed within hours to days. Human DNA polymerases have an error rate of approximately one base pair per 10^{12} per cellular division; bacterial DNA polymerases have an error rate of approximately one base pair per 10^6 , and the reverse transcriptase of human immunodeficiency virus type 1 (HIV-1) has an error rate of approximately one base pair per 10^3 to 10^4 per replication. These mutations are to a large extent random, and most result in decreased function or are incompatible with survival. Because of the limited number of offspring humans produce, a faithful DNA polymerase that maximizes survival of an individual's descendants is important to our species. In contrast, microbes can generate many defective organisms with null mutations and still maintain a self-sustaining

population of organisms arising from the small subset that harbor the rare mutations that confer a survival advantage. The rapid emergence of resistance to antimicrobials is reflective of the genetic flexibility of microbes. The ability to recognize and respond nonspecifically to foreign organisms has existed for millions of years and can be demonstrated even in relatively primitive life forms. But to survive in the struggle for the environment against microbes and their seemingly unending ability to replicate and evolve over short intervals of time, more complex species (including humans) with slow and infrequent germline evolution events require a system that can efficiently adjust to protect the individual against the constantly changing onslaught of microbial pathogens. Thus, with the appearance of the gnathostomes, or jawed vertebrates, an adaptable immune defense system emerged that for the first time permitted a rapid “evolution” of host defense to infectious agents without the need for reproduction or germline mutation. This “real-time evolution” is achieved through rearrangement (and, in the case of B lymphocytes, somatic mutation) of the genes encoding the receptors of T and B lymphocytes and the ability to expand clones of these microbe-specific cells—the directors of adaptive immune recognition.

Categories of Host Defenses and Risks for Infection

Over the course of species development, numerous mechanisms have evolved to protect larger organisms from infection or parasitization by another. These mechanisms can be categorized according to the primary defense mechanism as anatomic, humoral, or cellular, and according to their specificity and phylogenetics as innate or adaptive. Anatomic defenses are primarily innate or nonadaptive, whereas humoral and cellular defenses can be either innate or adaptive. Innate defenses, present in many primitive organisms, comprise a rapid, “already primed” response to microbial invasion, whereas adaptive responses may be more delayed in their onset but ultimately are both more specific in their targets and capable of providing “memory” of prior encounters to protect against recurrence of infection. Although it is important to distinguish between these two kinds of host defenses, both innate and adaptive immune mechanisms are intimately interactive, thereby providing, in most instances, remarkable synergistic protection against infection.

ANATOMIC DEFENSES

Anatomic defenses protect directly against microbial colonization and infection and are primarily located at sites with proximate environmental contact. Thus skin and mucosal surfaces are enriched with defenses ranging from the tightness of epithelial junctions to resist microbial penetration, to the presence of cough and gag reflexes to expel aspirated secretions, and to the presence of chemical agents such as acids and defensins with antimicrobial properties. Permissiveness to colonization of these surfaces by microbes of low pathogenicity prevents colonization and infection by more

virulent organisms. In some clinical settings, interference with anatomic defense mechanisms may increase the risk of infection. Therefore burns that denude the epithelial barrier, illnesses or intoxicants that suppress gag and cough reflexes, treatment with agents that decrease gastric pH, and treatment with antibiotics that disturb the commensal mucosal flora can increase the risks of microbial infection.

HUMORAL DEFENSES AGAINST INFECTION

Complement System

Humoral defenses, consisting of soluble compounds found in blood plasma and in other extracellular fluids, also play important roles in defense against microbes. One of the most important of these humoral defenses is the complement system. Complement activity results from the sequential interaction of a large number of plasma and cell membrane proteins. A simplified diagram of the most important steps in the complement cascade is shown in Figure 92-1. The *classic complement pathway* is activated by antibody-coated targets or antigen-antibody complexes through the interaction of the initial protein, C1, with the Fc receptor of the antigen-activated immunoglobulin (Ig) molecule. The *alternative pathway* is activated in the absence of antibody by constituents of the microbial surface, including polysaccharides. Finally, the sugar-binding protein *mannose-binding lectin* can also activate the complement cascade after binding to surface mannose residues on viruses and other pathogens. All three pathways converge with the formation of C3 convertase, which leads to the production of the effector components of the complement system. C3b or iC3b deposited on the surface of microbes binds to complement receptors (CR1, CR3, and CR4) on neutrophils and macrophages and

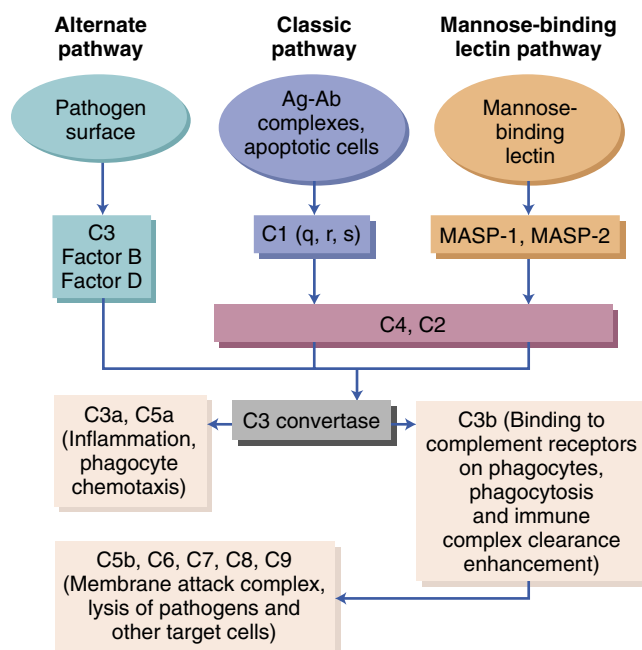

Figure 92-1 Simplified diagram of the complement system. The final effector components are shown in clear symbols at the bottom of the graphic, with a summary of their most important biologic activities. Not all molecular events leading to the final effector components are shown.

Table 92-1 Properties of Human Immunoglobulins

	IgG	IgA	IgM	IgD	IgE
H chain class	γ	α	μ	δ	ε
Molecular weight (approximate)	150,000	170,000	900,000	180,000	190,000
Complement fixation (classic)	++	0	++++	0	0
Opsonic activity (for binding)	++++	++	0	0	0
Reaginic activity	0	0	0	0	++++
Serum concentration (approximate mg/dL)	1500	150-350	100-150	2	2
Serum half-life (days)	23	6	5	3	2.5
Major functions	Recall response; opsonization; transplacental immunity	Secretory immunity	Primary response; complement fixation	?	Allergy; anthelmintic immunity

promotes phagocytosis. Moreover, C3b furthers clearance of immune complexes by linking them to CR1 on the erythrocyte surface. C5a is a chemotaxin for neutrophils and activates oxidative burst activity. C5a and C3a also stimulate histamine release from mast cells and thus promote inflammation. The ultimate effector element of the complement system is the membrane attack complex, which involves C5 to C9. This complex produces pores in the membrane of microbes and subjects them to osmotic lysis. Thus, the complement system can opsonize microbes, can directly damage them, and can also induce inflammation through liberation of chemotactically active fragments. Persons with complement deficiencies, particularly deficiencies in terminal components, are especially at risk for repeated infections with gram-negative encapsulated bacteria, especially *Neisseria* species.

Antibodies

Antibodies are large polypeptides produced by B lymphocytes and plasma cells that are key components of the adaptive immune response (Table 92-1). Antibody molecules recognize structural elements of microbial surfaces and, when bound, may block the ability of that structure to interact with and infect a cell (neutralization), may facilitate ingestion of the microbe by phagocytes (opsonization), or may bind and activate complement (discussed earlier), resulting in killing of certain microbes. Finally, antibodies may recognize microbial or other foreign antigens expressed on a cell surface and facilitate the destruction of that cell by host defense cells with cytolytic capabilities (antibody-dependent cellular cytotoxicity [ADCC]). The five classes of antibodies are summarized in Table 92-1. IgM constitutes the earliest immune response to antigenic challenge and often predominates in response to polysaccharides; IgG is the most prevalent Ig class in blood; IgA is present both in blood and at mucosal surfaces and is a key element in mucosal immune protection; IgD and IgM may serve as B-lymphocyte antigen receptors; IgE plays an important role in allergy by triggering mast cell activation and is also important in mediating responses to parasitic infestation. As components of the adaptive immune response, antibodies have great diversity in their recognition domains, and the generation of this diversity permits both targeted investment of

immune “energy” and the generation of immune memory. Antibodies provide protection against microbes primarily when these organisms are in the extracellular space. Once within cells that they infect, microbes are largely (but not always; see ADCC, earlier) invisible to antibody-mediated defenses. Persons with defects in antibody formation are at greatest risk for infection with encapsulated bacteria such as pneumococci.

CELLULAR DEFENSES AGAINST INFECTION

Phagocytic Cells

Phagocytic cells—neutrophils and macrophages—are rapidly recruited to sites of microbial invasion by chemoattractant cytokines called *chemokines*, among other mechanisms. These cells are able to ingest (phagocytose) microbes directly and, even more efficiently, when the microbes are opsonized (coated with antibody or complement), through attachment to specific receptors on the phagocyte cell surface. Once ingested, microbes are killed by a system of enzymes and other antimicrobial systems. These cells are efficient mediators of defense against many bacteria and fungi; decreases in the numbers or function of neutrophils place persons at risk for bacterial and fungal infection. Macrophages also serve as “professional antigen-presenting cells” (see later) and can activate cell-mediated immune defenses by presenting digested microbial peptides to T cells.

T Lymphocytes

T lymphocytes are critical effector and helper cells of the adaptive cell-mediated immune response that are generated through a complex process of selection in the thymus gland. In the thymus, the genes encoding the T-cell antigen receptor are rearranged, generating an enormous diversity of T-cell receptor (TCR) structures. T cells recognize peptide antigen bound by host cell surface human leukocyte antigens (HLAs). T cells with insufficient affinity or too great an affinity for host HLAs fail to survive thymic development. Thus the population of T cells with intermediate affinity for host HLA molecules that survive thymic maturation maintains a diverse yet selected repertoire of TCRs capable of recognizing a wide array of peptides when bound by cell surface HLA

molecules. The TCR of CD4⁺ T cells recognizes ingested peptides bound by class II HLA molecules, whereas class I HLA molecules bind peptides typically synthesized within the cell by invading pathogens for recognition by the TCRs of CD8⁺ T cells. Not surprisingly, therefore, after TCR engagement, CD8⁺ T cells destroy infected cells expressing the foreign peptides, whereas CD4⁺ T cells are activated largely to express T-helper cytokines that enhance the function of other immune cells such as CD8⁺ T cells, natural killer (NK) cells, macrophages, and B lymphocytes. On encountering antigen for the first time in lymph nodes, naive CD4⁺ T cells proliferate and differentiate into effector cells with one of several functional phenotypes: T_H1 CD4⁺ T cells produce predominantly interleukin (IL)-2 and interferon (IFN)- γ , tend to activate macrophages and induce B cells to produce opsonizing antibodies, and are central to an effective cellular immune response. T_H2 cells, on the other hand, produce mainly IL-4, IL-10, and IL-13, activate mast cells, induce IgM, IgE, and IgA production by B cells, and shift the system toward the humoral immune response. The balance between these two profiles is particularly important in infections caused by certain intracellular organisms, which require a vigorous T_H1 response to be eliminated, among other aspects of the immune response. A third functional phenotype is that of the T regulatory cell (Treg). T regulatory cells express high levels of the IL-2 receptor CD25 and the forkhead box transcription factor P3 (FOXP3) and typically serve to modulate immune responsiveness. A third differentiation subset of CD4⁺ T cells, termed T_H17 because of its preferential expression of proinflammatory molecules of the IL-17 family (as well as IL-22), has recently been described and is important in protection against extracellular bacteria and fungi. Selective depletion of T_H17 cells in the intestinal mucosa may also play a role in the pathogenesis of progressive HIV-related immunodeficiency through interference with the epithelial barrier function against microorganisms in the intestinal lumen. Destruction of target cells by cytolytic CD8⁺ T cells can be mediated by receptor-ligand interaction, whereby binding of receptors on the target cell (such as Fas) by ligand on the effector cell results in activation of programmed cell death (apoptosis) of the target. Perhaps more important, cytolytic cells are enriched for perforin, which, like the terminal components of complement, produces pores in the target cell membrane, and granzymes that gain entry to target cells through these pores and induce programmed cell death of the target. Impairments in T-cell numbers or function place persons at particular risk for infection with pathogens that replicate within host cells. Because of their central role in mediating immunologic help, decreases in CD4⁺ T cells or their function also diminish many other aspects of host defense, such as antibody responses.

Natural Killer Cells

NK cells are large granular lymphocytes that, like CD8⁺ T cells, have cytolytic function. These cells can kill tumor cells or normal cells infected by viruses. They are most active against target cells with low-level expression of class I HLA molecules, which, when present, activate inhibitory molecules on the NK cell surface. Because many viruses decrease host HLA class I expression as a means to evade host cytotoxic T-lymphocyte recognition, it is thought that NK cells

may serve to identify and lyse cells resistant to antigen-specific T-cell-mediated cytotoxicity. As an effector of innate or nonadaptive host defense, NK cells are thought to be important also in early responses to viral infections and in defense against malignancy. NK cells also have receptors for IgG that, when binding the NK cells to target cells expressing viral antigens on the surface, can activate target cell lysis by the NK cell (ADCC). Rarely, persons with dramatic decreases in numbers of NK cells have been found to experience repeated and severe herpesvirus infections.

How Cells Communicate with Other Cells

Cellular interactions are critical for host defense against microbes. Cells need to signal other cells in order to attract them to sites of infection; cells can also arm and activate other cells to perform their function more effectively, and cellular interactions are essential to generate and amplify host adaptive immune responses. Cells establish these communications in two basic ways: by direct contact and by the expression of soluble factors—cytokines that bind to cellular receptors and result in the generation of intracellular signals that affect the function of the cell. Some cytokine receptors are very specific for a single cytokine (e.g., the high-affinity IL-2 receptor and IL-2), whereas others can be triggered by multiple cytokines (as is often the case for chemokine receptors). Chemokines are cytokines that induce cellular movement and play important roles in trafficking cells to appropriate sites. Different cell types may express the same cytokine, and one cytokine may target several cell types, resulting in different effects in each. Thus the network of cellular interactions in host defense can be quite complex.

INTERFERONS

IFNs are antiviral cytokines that can be induced as a response to viral infection; these cytokines also have potent effects on host defense cells and the priming of adaptive immune defenses. Type I IFNs (α and β) are produced by virus-infected cells, whereas type II IFN (IFN- γ) is produced by T cells and NK cells. The type I IFNs are induced by a variety of stimuli including double-stranded RNA that is not present in uninfected cells; therefore immediately after viral infection takes place, IFN is expressed by the infected cell and acts on IFN receptors to activate a number of host antiviral mechanisms, thereby rapidly attenuating viral replication. Hundreds of host genes can also be activated by type I IFNs, and thus IFNs not only activate antiviral defenses but also induce a complex array of cellular genes that prime and activate host defenses. IFN- γ also activates cytolytic activity of T cells and NK cells and activates monocytes.

How Enormous Diversity in Immune Recognition Is Possible

Because there is enormous diversity in the structure and sequence of microbial pathogens, host defenses must have

Figure 92-2 Diagram of the overall structure of immunoglobulin G, which is the basic structural pattern for all immunoglobulins (see text), drawn to highlight the various reactive areas and to emphasize the globular domain features of the immunoglobulin molecule. (From Bennett JC: Approach to the patient with immune diseases. In Bennett JC, Plum F [eds]: Cecil Textbook of Medicine, 20th ed. Philadelphia, WB Saunders, 1996, p 1394.)

the ability to generate and maintain a diverse repertoire of defenses against potential invaders. Both the humoral (B-cell driven) and cellular (T-cell driven) arms of the adaptive immune response are activated by the specific interaction of foreign antigen with cellular receptors. In the case of B cells, the receptor is a surface Ig (antibody) molecule that recognizes three-dimensional structures; in the case of the T cells, the receptor recognizes short foreign peptides from 8 to 20 amino acids in length that are bound to host HLA molecules. It is the flexibility of T-cell and B-cell receptor rearrangements that permits the adaptive immune system to respond to a large number of antigenic structures. B cells and T cells appear to use similar mechanisms to generate and express the diversity required for such a broad range of specific antigenic responses.

Five classes of antibodies (isotypes) are recognized (see Table 92-1). An *IgG antibody* (Fig. 92-2) consists of two light (κ or λ) chains and two heavy chains. Each antibody has constant regions, which are identical in structure to all antibodies of that class, and distinctive antigen recognition sites whose structures are variable. An *IgG₁* molecule has two such antigen-combining sites. The antigen-combining sites of antibody molecules recognize the three-dimensional structure of an antigen and bind to it in a lock-and-key manner through multiple weak, noncovalent interactions. The variable regions consist of the approximately 110 amino-terminal amino acids of each chain. Three short, hypervariable regions are present in each of the light and heavy chains. The six hypervariable regions form the antigen-combining site.

Antibody diversity is generated as B lymphocytes mature and is understood at the molecular level. The variable portion of the heavy chain is encoded by three different genes: V, D, and J; investigators have identified 500 to 1000 different V genes, 10 D genes, and 4 J genes. The variable

portions of the light chains are encoded by V and J genes; investigators have identified 200 possible V genes and 6 J genes. During the differentiation of B cells in the bone marrow, somatic translocations randomly select the V, D, and J heavy chain genes and the V and J light chain genes that will be transcribed in that cell. The diversity achieved by this means is enormous. Somatic mutations in B cells as they divide after encountering antigen in lymphoid tissue (see later) allow the possibility of improving the fit between antibody and antigen; repeated or sustained exposure to antigen selects B cells capable of producing antibody with the highest binding affinity. These circulate as *memory cells*.

T lymphocytes can be divided into two subpopulations based on the polypeptide chains constituting the antigen receptor. The $\alpha\beta$ T cells, constituting the larger population (approximately 95%), possess a receptor consisting of a heterodimer of α and β polypeptide chains. The variable portion of the $\alpha\beta$ TCR is composed of the approximately 100 amino-terminal amino acids. The generation of diversity is by translocation of V, D, and J genes; this takes place as the cells mature within the thymus. During thymic maturation, T cells are selected for survival and exportation into the periphery according to their affinity for self-HLA molecules. Those with too great an affinity for self-peptides and HLA molecules and those with too low an affinity for self-HLA do not survive. Thus T cells that may have “autoimmune” reactivity and those with affinities too low to recognize any peptide bound to host HLA molecules are largely deleted from the circulating T-cell pool.

The TCR is directed at the foreign peptides bound by cell surface HLA molecules. $\alpha\beta$ T cells can be divided by their surface expression of glycoproteins into CD4 and CD8 subpopulations. CD4 and CD8 cells also differ in their genetic restriction and function. Peptides bound by class I HLA are recognized by CD8⁺ T cells, whereas peptides bound by HLA class II molecules are recognized by CD4⁺ helper T cells. The TCR recognizes linear peptides of 8 to 20 amino acids in length. Importantly, in addition to their crucial role in recognizing antigens presented in this manner, T cells also provide costimulatory signals that enable the maturation and proliferation of naive B cells as they encounter antigen (discussed earlier), and thus link the humoral and cellular immune response (see discussion of the antibody response, later). Another subpopulation of T lymphocytes, $\gamma\delta$ T cells, constitutes fewer than 5% of circulating and lymphoid T cells. These cells do not express CD4 or CD8; their TCRs contain heterodimers of γ and δ chains. Although there is diversity in the rearrangement of these chains, it is far less than that seen among $\alpha\beta$ T cells. $\gamma\delta$ T cells may not respond to peptides bound to major HLA molecules but instead tend to be activated directly by phospholipid antigens, by heat shock proteins, and by minor HLA molecules. Thus these cells comprise a defense intermediate between the intrinsic and adaptive host defenses.

Host-Microbe Interaction

THE PRIMARY ENCOUNTER AND ROLE OF INNATE DEFENSES

The skin and mucosal surfaces represent the primary interface with the external world and microbes. At these sites,

anatomic barriers that also include certain intrinsic defenses and the normal microbial colonists as well as secretory antibody help to defend against the development of invasive disease. Mucosal colonization by pathogenic microbes, such as pneumococcal colonization of the oropharynx, can induce an adaptive immune response. If this response develops before tissue invasion takes place, colonization may result in acquisition of a protective antibody response. However, factors that disrupt normal host defenses, such as a depressed sensorium blocking gag and cough reflexes, cigarette smoking suppressing ciliary clearance, or intercurrent influenza virus infection denuding the tracheal epithelium, can increase the likelihood that colonization with a pathogenic microbe will result in invasive infection. Once anatomic barriers are breached and an invading microbe gains access to tissues, other intrinsic host defenses come into play rapidly. These rapid responders are phagocytic cells that express “toll-like” receptors for microbial elements such as cell wall lipopolysaccharide, other cell wall products, flagellins, or microbial nucleotide sequences. Phagocytic cells are then activated to ingest nearby microbes and to induce expression of chemotactic cytokines that facilitate entry of additional inflammatory cells to the site of microbial breach. Some microbes are armed to resist these defenses, as is the case for bacteria with capsules that resist phagocytosis. Host complement can be activated to bind to these capsules, helping to opsonize the bacterium to enhance phagocytosis and also to enhance ingress of inflammatory cells to the site. Because it generally takes several days to a few weeks for the adaptive immune system to mobilize and generate sufficient effector activity to protect the host, one key role of the innate immune system is to provide a method of limiting microbial replication and pathogenesis until the more potent and specific adaptive immune response can be mobilized. Activation of microbicidal phagocytic cells, complement and NK cell activation, and induction of antiviral IFNs all may play a role in the early innate defense against microbial invasion. It should be emphasized, however, that there are many collaborative interactions between innate and adaptive defense mechanisms to ensure optimal arming of host defenses.

GENERATION OF ADAPTIVE IMMUNE RESPONSES

Cell-Mediated (T-Cell) Responses

Skin and mucosal tissue contain large numbers of dendritic cells, such as Langerhans cells, that also express toll-like receptors. These cells ingest foreign antigens and foreign microbes and also may ingest dying inflammatory cells that have themselves ingested invading microbes. As they migrate to lymphoid tissues, these dendritic cells mature, degrading the ingested antigens and expressing these microbial peptides on cell surface HLA molecules. At the same time, these cells lose the ability to ingest additional material and begin to express numerous co-receptors that enhance their ability to interact with and activate T lymphocytes. In lymphoid tissues, these professional antigen-presenting cells encounter “naïve” T cells that have undergone TCR gene rearrangement in the thymus, and a small number of these cells will (by chance) express a TCR configuration that recognizes an HLA-bound peptide. What largely restricts the breadth of immune recognition is the ability of peptide to bind to that

Figure 92-3 The molecular events in antigen presentation. Peptides within human leukocyte antigen (HLA) molecules on the antigen-presenting cell (APC) are bound weakly by T-cell receptor α and β chains. This interaction is stabilized and facilitated by interactions between the adhesion molecules LFA-1 on the T cell and its ligand ICAM-1 on the APC. T-cell and APC interactions between costimulatory molecules CD80 and CD86 on the APC and receptors such as CD28 or CTLA-4 on the T cell can result in T-cell activation or suppression, respectively.

particular HLA molecule. Thus different HLA molecules can bind different peptides, and this variable binding ability (and not so much the recognition by the T cell) determines an individual's ability to recognize a foreign peptide and mount an immune response to it. As discussed earlier, T cells with high affinity for self-peptides or too low an affinity for self-HLA molecules have already been deleted within the thymus. The relatively low-affinity interactions between TCR and HLA-bound peptide are supported by multiple co-receptor–ligand and adhesion molecule interactions between the T cell and antigen-presenting cell that also result in activation of the T cell (Fig. 92-3). The naïve T cell is thus activated to divide time and time again, rapidly expanding the number of T cells with the same clonal antigenic specificity. T cells thus activated are no longer antigen “naïve” but are now activated to express cytokines and/or to have cytolytic activity, and some will develop long-lived “memory” function. Cytokines expressed by $CD4^+$ T-helper cells enhance the activity of other immune cells such as cytolytic $CD8^+$ T cells and NK cells and are also critical to the development and maturation of B lymphocytes to result in the generation of antibody responses. T-helper cells also interact directly with dendritic cells, affecting their maturation and function.

Antibody Response

In lymphoid tissues, more complex antigens, including whole microbes, can be bound in an antigen-specific fashion by B lymphocytes, which have as their antigen receptor membrane-bound immunoglobulins (IgD and IgM). Thus bound, a particle can be ingested by the B cell and degraded, and then these microbial peptides are expressed on the B-cell surface HLA class II molecules. Thus, B lymphocytes may serve as professional antigen-presenting cells for recognition by $CD4^+$ T cells. For most antigens, therefore, attraction of $CD4^+$ T-cell help is essential to permit B lymphocyte expansion and ultimately antibody synthesis. As is the case for the interaction between the $CD4^+$ T cell and other professional

antigen-presenting cells, multiple receptor-ligand interactions stabilize the interaction between the TCR and the peptide HLA molecule that it recognizes on the B-cell surface. At the site of this intimate interaction, the CD4⁺ T cell is activated to express T-helper cytokines that in turn activate the B cell, promoting cellular division and maturation. In this fashion microbial peptides that are recognized by CD4⁺ T cells induce the “help” that is needed to result in generation and amplification of an antibody response to that microbe. Recognition of this basic principle has resulted in the development of “conjugate vaccines” that, through linkage of immune help inducing peptides to microbial sugars (which themselves do not induce T-cell responses) can enhance the antibody responses to these sugars. Conjugate vaccines are now used to prevent *Haemophilus* and pneumococcal infection.

The B lymphocytes thus activated by binding antigen to their surface receptors and helped by their interaction with CD4⁺ T cells begin clonal replication and maturation. Replication amplifies the “mass” of antigen-reactive B cells, and maturation involves both transformation of B cells into antibody-secreting plasma cells and the induction of “class-switching,” wherein the variable antigen-binding domains of the antibody are “switched” by gene rearrangements onto constant domains of different classes of antibody molecules. Thus an initial IgM response is followed later by an IgG response with the same specificity in terms of antigen recognition (hence the utility of a high-level IgM response to a microbial antigen as a clinically meaningful indicator of recent infection). These events take place largely in germinal centers within lymphoid tissue that is enriched also with follicular dendritic cells. These follicular dendritic cells can, for periods of years, trap and hold intact antigens on their surfaces and facilitate B-lymphocyte maturation. During the early course of antibody generation, the affinity of antibody molecules for their antigens can increase. This affinity maturation takes place during the rapid expansion of B lymphocytes and is the consequence of somatic hypermutation of sequences within the hypervariable regions of the antibody genes. Progeny B lymphocytes with greater surface immunoglobulin (receptor) affinity for antigen will be more rapidly activated to divide and will “outcompete” B lymphocytes with lower affinity receptors. The antibodies thereby secreted by progeny plasma cells become increasingly capable of binding microbial antigens with higher affinity. Thus the humoral immune response “evolves” in real time, selecting for B cells producing antibodies with progressively higher affinity for microbial pathogens.

Microbial Pathogenesis versus Host Defenses—the Continuing Drama

RESISTANCE TO EXTRACELLULAR BACTERIA: ENCAPSULATED ORGANISMS

Streptococcus pneumoniae

The type-specific polysaccharide capsule is a major virulence factor because of its antiphagocytic properties. Antibody to the polysaccharide is itself capable of preventing pneumo-

coccal disease, as reflected by experimental studies and the efficacy of pneumococcal polysaccharide vaccines.

In the absence of immunity, pneumococci reaching the alveoli are not effectively contained by the host. Their phagocytosis by neutrophils is inefficient, because organisms must be trapped against a surface to be ingested (*surface phagocytosis*). The pneumococcus does, however, elicit a neutrophilic inflammatory response. The organism activates complement by the alternative pathway and interactions of C-reactive protein in serum with pneumococcal C-polysaccharide. Activated complement fragments (C3a, C5a, and C567) are chemotactic for neutrophils. Opsonic complement fragments (C3b) coating pneumococci favor their attachment to neutrophils but are less effective in promoting phagocytosis and killing than is specific antibody. Clinical observations also directly support the primal role of antibody in immunity. The development of specific antibody on days 5 to 9 of untreated pneumococcal pneumonia may produce a clinical “crisis,” with dramatic resolution of symptoms. Opsonization of *S. pneumoniae* by type-specific anti-polysaccharide antibody promotes ingestion and oxidative burst activity, with destruction of the organism.

Neisseria meningitidis

Capsular polysaccharide also represents an important virulence factor for meningococci. In addition, pathogenic *Neisseria* species produce an IgA protease that dissociates the Fc fragment from the Fab portion of secretory and serum IgA and thus interferes with effector properties of the antibody molecule. Antibody-dependent, complement-mediated bacterial killing is the most critical host defense against meningococci. Therefore the presence of bactericidal antibody is associated with protection against the meningococcus. In epidemic situations, 40% of persons who become colonized with the epidemic strain but who lack bactericidal antibodies develop disease. Protective serum antibody is elicited by colonization with the following: (1) nonencapsulated and encapsulated strains of meningococci of low virulence, which elicit antibodies cross-reactive with virulent strains, and (2) *Escherichia coli* and *Bacillus* species with cross-reacting capsular polysaccharides. The lack of bactericidal activity in the serum of adolescents and adults manifesting susceptibility to *N. meningitidis* may be a result of blocking IgA antibody. Susceptibility of patients lacking C6, C7, or C8 to meningococcal infection provides important evidence that the dominant protective mechanism against this organism involves complement-mediated bacteriolysis.

RESISTANCE TO FACULTATIVE INTRACELLULAR PARASITES: MYCOBACTERIUM TUBERCULOSIS

Activation of host phagocytes provides the critical defense mechanism against *M. tuberculosis*. Primary infection progresses locally in the nonhypersensitive host, because ingested organisms persist and multiply within mononuclear phagocytes. The bacteria escape intracellular digestion by secreting products that inhibit phagolysosomal fusion. Antibody-coated mycobacteria do not evade phagolysosomal fusion but nonetheless resist degradation, probably because of shielding provided by their rich lipid content. The development of cellular immunity leads to T-

lymphocyte–dependent macrophage activation and to the killing of the intracellular tubercle bacillus organism. The lesions of primary tuberculosis regress. However, latent foci persist, and delayed reactivation remains a threat throughout the lifetime of the host.

RESISTANCE TO OBLIGATE INTRACELLULAR PARASITES: VIRUSES

Host antiviral defense is characterized by overlap and redundancy, which allow an effective response to most viral agents. The key element of the response varies with the virus, the site, and the timing. Initially, infection is limited at the local site by type I IFNs, which increase the resistance of neighboring cells to spread of the infection. Complement directly neutralizes some enveloped viruses. NK cells destroy infected cells, a process enhanced by IFNs. As specific antibody is produced, IgA may neutralize the virus at mucosal surfaces; IgG may neutralize virus that has spread systemically to extracellular sites and also may allow uptake and destruction by FcR-bearing effector cells. Later, effector cytotoxic T

lymphocytes are expanded and activated to lyse host cells expressing viral peptides in the context of HLA antigens. The host thus directs several defenses against viral infection. Humoral defenses are active against extracellular viruses and, if neutralizing antibody is present at high enough levels before infection, may prevent clinical infection entirely. Cell-mediated defenses largely play more critical roles in attenuating the magnitude of viral replication during chronic infection. Viruses at the same time have evolved numerous mechanisms to blunt or block host antiviral defenses. Many viruses can decrease the expression of class I HLA molecules on cells they infect, thereby limiting recognition of these cells by CD8⁺ cytotoxic T lymphocytes. Many viruses that cause chronic infection, such as herpesviruses and HIV, can maintain a latent infection whereby, in the absence of viral protein synthesis, there are no viral peptide targets for recognition by cytotoxic T lymphocytes. Other viruses have acquired gene sequences that encode homologues of host cytokine or cytokine receptor genes that may help viruses escape from host immune surveillance or contribute to viral pathogenesis.

Prospectus for the Future

- Increased understanding of the molecular and cellular mechanisms responsible for the establishment and regulation of the immune response
- More accurate and reproducible techniques to quantify and evaluate the different components of the immune response
- Expanding role of genomics and proteomics as techniques to map the biochemical profiles that characterize the immune response to various pathogens, as well as prevalent antigens
- Innovative therapeutic interventions aimed at modulating specific components of the immune response selectively, and increased interest in clinically meaningful ways to evaluate the effectiveness of those interventions

Laboratory Diagnosis of Infectious Diseases

Benigno Rodríguez and Michael M. Lederman

Five basic laboratory techniques can be used in the diagnosis of infectious diseases: (1) direct visualization of the organism, (2) detection of microbial antigen, (3) a search for “clues” produced by the host response to specific microorganisms, (4) detection of specific microbial nucleotide sequences, and (5) isolation of the organism in culture or propagation in cell culture. Each technique has its use and its pitfalls. The laboratory can usually provide the clinician with prompt, accurate, and, if the techniques are used judiciously, inexpensive diagnosis.

Diagnosis by Direct Visualization of the Organism

In many infectious diseases, pathogenic organisms can be directly visualized by microscopic examination of readily available tissue fluids. With the use of Gram or acid-fast stains, bacteria, mycobacteria, and *Candida* can be readily identified. An India ink preparation can often identify *Cryptococcus*, and potassium hydroxide (KOH) preparations can occasionally identify other fungal pathogens. Although antigen detection techniques are rapidly supplanting conventional staining and microscopy for identification of organisms such as *Giardia* in stool samples and *Cryptococcus* in cerebrospinal fluid (CSF) specimens (see later) because of their greater sensitivity and their decreased susceptibility to interobserver variation, the expediency of traditional direct visualization techniques in the presence of a large organism burden remains unmatched by these approaches. Examples of positive specimens prepared by conventional staining techniques are shown in Figures 93-1 and 93-2. Other techniques can also reveal clinically relevant pathogens. Silver staining using the Gomori methenamine technique can identify most fungi, including *Pneumocystis jirovecii*. Experienced pathologists can also identify *P. jirovecii* on Giemsa-stained specimens of induced sputum. Darkfield microscopy

can identify *Treponema pallidum*, and electron microscopy can sometimes detect viral particles in infected cells.

INDIA INK PREPARATION

A drop of centrifuged CSF is placed on a microscope slide next to a drop of artist's India ink. A coverslip is placed over the drops, and the area of mixing of CSF and India ink is examined at 100× magnification. Cryptococci are identified by their large capsules, which exclude the India ink (see Fig. 93-1).

Diagnosis by Detection of Microbial Antigens

Certain pathogens can be detected by examination of specimens for microbial antigens (Table 93-1). These studies can be performed rapidly—often within 1 hour. The diagnosis of meningitis caused by *Streptococcus pneumoniae*, *Cryptococcus neoformans*, some strains of *Haemophilus influenzae*, and *Neisseria meningitidis* can be made rapidly by detection of specific polysaccharide antigen in the CSF. Although these diagnoses may also be made by Gram stain or India ink preparation, antigen detection is especially helpful when attempts at direct visualization of the pathogen are not diagnostic (e.g., in the patient with partially treated bacterial meningitis). Immunofluorescence techniques (Fig. 93-3) using antibodies directed against the organisms identify pathogens such as *Legionella pneumophila* and *Bordetella pertussis* in respiratory secretions. Immunofluorescence can also be used to identify cells infected with influenza virus, respiratory syncytial virus, and adenovirus. Detection of urinary pneumococcal antigen can enhance the diagnostic capabilities of direct visualization and culture techniques in community-acquired pneumonia. Quantitation of cytomegalovirus (CMV) antigen in blood may help predict the development of active disease in immunocompromised patients.

The demonstration of hepatitis B surface antigen in blood establishes the presence of infection by this virus.

Diagnosis by Examination of Host Immune or Inflammatory Responses

Histopathologic examination of sampled or excised tissue often shows patterns of the host inflammatory response that

Figure 93-1 India ink preparation of cerebrospinal fluid revealing encapsulated cryptococci. Note the large capsules surrounding the smaller organisms.

Figure 93-2 Tzanck preparation for diagnosis of herpesvirus infection. Note the multicolored giant cell (bottom) characteristic of herpes infection.

can narrow down diagnostic possibilities. As a general rule, a polymorphonuclear leukocytic infiltrate suggests an acute bacterial process. A lymphocytic infiltrate suggests a more chronic process and is characteristically seen in viral, mycobacterial, and fungal infections. Similarly, examination of infected fluids such as CSF may provide clues to possible causes. Bacterial infections generally provoke a polymorphonuclear leukocytosis with elevated protein and depressed glucose concentrations. Viral infections most often provoke a lymphocytic pleocytosis; protein elevations are less marked, and glucose levels are usually normal. Eosinophilia suggests helminthic infestations or certain fungal infections, such as coccidioidomycosis or aspergillosis, particularly the allergic forms of the latter. Granuloma formation suggests a mycobacterial cause. Certain parasites (such as *Schistosoma* species) and fungi (such as *Histoplasma*, *Cryptococcus*, and *Blastomyces*) can also lead to granuloma formation. Some diseases, such as syphilis (obliterative endarteritis), cat-scratch disease (mixed granulomatous, suppurative, and lymphoid hyperplastic changes), and lymphogranuloma venereum (stellate abscesses), have fairly characteristic histologic features.

Several viral infections produce characteristic changes in host cells, which are detectable by cytologic examination. Skin or respiratory infection with herpesviruses, or pneumonia caused by CMV or measles virus, for example, can be diagnosed with reasonable accuracy by cytologic examination (e.g., Tzanck preparation for herpesvirus infection).

Host cell-mediated immune responses can be used to help make certain diagnoses. A positive skin test for delayed-type hypersensitivity to mycobacterial or fungal antigens indicates active or previous infection with these agents. A negative skin test may be seen despite active infection in individuals with depression of cell-mediated immunity (anergy). Control skin tests using commonly encountered antigens (e.g., *Candida*, mumps, *Trichophyton*) have been used in an attempt to exclude global anergy as the reason for a negative skin reaction, but their value as a diagnostic tool is questionable and they are therefore not routinely recommended. The QuantiFERON-TB test is an assay for detection of interferon- γ production by *Mycobacterium tuberculosis*-specific lymphocytes, and is an example of a clinically useful in vitro diagnostic procedure based on detection of the cellular immune response to a specific pathogen.

Host humoral responses may be used to diagnose certain infections, particularly those caused by organisms whose cultivation is difficult (e.g., *Ehrlichia chaffeensis*) or hazardous to laboratory personnel (e.g., *Francisella tularensis*). In general, two sera are obtained at intervals of at least 2

Table 93-1 Diseases Often Diagnosed by Detection of Microbial Antigens

Disease	Assay	Agent Detected
Meningitis	Latex agglutination	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Neisseria meningitidis</i> , <i>Cryptococcus</i>
Respiratory tract infection	Immunofluorescence Enzyme immunoassay	<i>Bordetella pertussis</i> , <i>Legionella pneumophila</i> , influenza virus, respiratory syncytial virus, adenovirus
Genitourinary tract infection	Enzyme immunoassay	<i>Chlamydia</i> species, herpes simplex viruses 1 and 2
Hepatitis B	Radioimmunoassay	Hepatitis B surface antigen

Figure 93-3 Diagram of the steps in the enzyme-linked immunosorbent assay (ELISA). Shown here is the form of ELISA used to detect antibodies (such as the test used to detect HIV infection); other forms of ELISA detect antigens. The process begins by adding the specimen to a well that has a purified antigen adsorbed to its inner surface, along with irrelevant proteins to cover the remaining well surface and prevent nonspecific binding. If specific antibodies are present in the sample, they will bind to the antigen; an antibody directed against human immunoglobulin labeled with an enzyme is then added. In the final step, the substrate for the enzyme is added; if there is attached antibody in the well, the linked enzyme will interact with the substrate and produce a color change that is proportional to the amount of antibody and can be read by a spectrophotometer.

weeks, and a fourfold or greater rise (or fall) in antibody titer generally suggests a recent infection. Antibodies of the immunoglobulin M class also suggest recent infection. Depending on the organism, assays may detect either specific (hepatitis viruses) or nonspecific, cross-reactive antibodies (syphilis non-treponemal tests). From another perspective, measurement of antibody levels in serum can determine if a person is likely protected from acquisition of infection or on the other hand might be a candidate for immunization. Measurement of serum antibodies to hepatitis A and hepatitis B virus is often used to determine if persons at risk are candidates for immunization.

Assays That Detect Microbial Nucleotide Sequences

Detection of microbial nucleotide sequences can provide a sensitive and specific means of identification of pathogens in clinical specimens. These genetic molecular diagnostic techniques can provide rapid speciation of slow-growing microbial isolates. In addition, these techniques can also provide rapid quantitation of pathogens that can establish the prognosis and also determine the effectiveness of modes of therapy. Finally, genetic analyses can identify genetic markers of antimicrobial resistance that can guide the selection of therapy.

The exquisite sensitivity and specificity of these techniques are consequences of the specificity of DNA base pairing and the dramatic amplifications of signals that can be provided by techniques such as the quantitative polymerase chain reaction (Fig. 93-4), nucleic acid sequence–based amplification, and branched-chain signal amplification analyses.

The sensitivity of these techniques has revolutionized laboratory diagnostics. For example, most standard techniques for detection of microbial antigens cannot reliably detect fewer than 100,000 molecules in clinical samples. In contrast, the genetic techniques discussed earlier are being routinely used now to identify as few as 20 to 50 molecules in clinical samples and can be modified to have even greater sensitivity. Table 93-2 lists some examples of diseases in which molecular diagnostic methods have represented a major advance in recent years.

Clinical Applications of Molecular Diagnostics

SPECIATION

The slow replication of mycobacteria limits rapid speciation of these organisms after their identification in clinical samples. In certain clinical settings, such as those that may occur in persons with human immunodeficiency virus (HIV) infection, the distinction between nontuberculous mycobacteria and *M. tuberculosis* may be particularly important. Genetic probes that distinguish among these organisms can provide rapid speciation after only limited growth.

DIAGNOSIS OF INFECTION

In acute HIV infection, detection of genomic HIV-1 RNA in plasma can provide diagnosis of this syndrome weeks before the development of diagnostic HIV specific antibodies (see Chapter 108). Nucleic acid amplification techniques are now routine for the diagnosis of gonorrhea and *Chlamydia* infections and can be performed on a single specimen, with a rapid turnaround time. Detection of herpes simplex virus sequences within CSF can provide a sensitive and specific diagnosis of herpes simplex encephalitis. Similar assays can be used for diagnosis of CMV, JC virus, Epstein-Barr virus, and *Bartonella henselae* infection. In certain anatomic

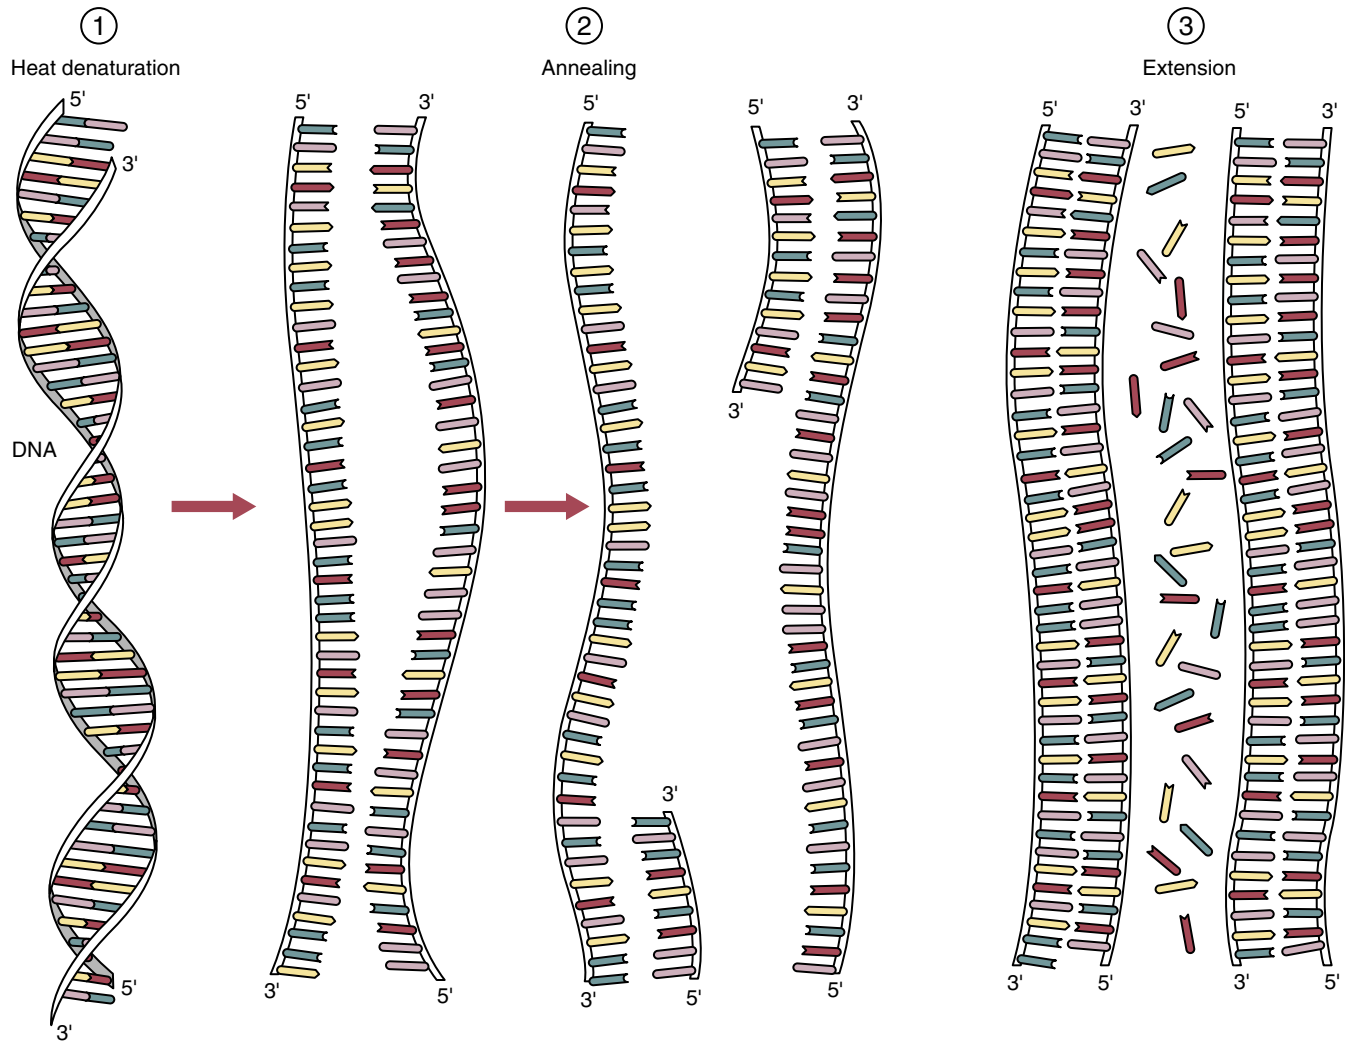

Figure 93-4 Schematic representation of polymerase chain reaction (PCR). The reaction solution contains the sample—presumably containing the target DNA, nucleotides, and primers, which will serve as building blocks for the amplified product, and polymerase enzymes that will catalyze the attachment of the nucleotides to the growing chain. (If the viral genome is composed of RNA, the genome must be first reverse transcribed to provide a complementary DNA template.) The first step in genomic amplification is denaturation, during which the solution is heated to 95°C to separate the two strands of DNA. The temperature is then lowered to allow the primers to attach to their complementary sequences on the single DNA strands, a process known as *annealing*. Finally, the mixture is heated again to a temperature at which the DNA polymerase catalyzes the attachment of further nucleotides to the primers (*extension*) until full double-stranded duplicates of the original DNA molecules are produced. If this process is repeated multiple times in a thermal cycler, a single DNA molecule can yield one million molecules after approximately 20 cycles.

locations such as the pericardium and the central nervous system, nucleic acid amplification may help in the diagnosis of tuberculosis. It is anticipated that numerous infectious diseases will soon be diagnosed with great sensitivity by means of these techniques. The exquisite sensitivity of this technique may, however, yield false-positive results unless the assays are carefully standardized.

QUANTIFICATION OF MICROBIAL BURDEN

Molecular diagnostic assays have been refined and standardized to permit reliable quantification of microbial genomic sequences in clinical samples. Quantification of CMV DNA, for example, has proven a useful tool in identifying individuals at risk for developing progressive CMV disease during chemotherapy-induced or organ transplantation-induced immunosuppression. These quantitative assays have also

provided evidence that the magnitude of microbial replication is predictive of disease progression in HIV infection, and sequential application of these techniques is now used routinely to monitor the activity of therapy for HIV and for hepatitis C virus infection.

DETECTING GENETIC MARKERS FOR ANTIMICROBIAL RESISTANCE

Microbial resistance to therapeutic interventions is an increasing problem in infectious diseases. When genetic sequences that confer resistance to therapies are known, assays to detect them can be applied rapidly to clinical samples, providing information that can be used to select treatment regimens. Direct analysis of plasma HIV sequences has provided genetic information that can predict the failure of specific modes of therapy; under certain circumstances, routine application of this information to the selection of

Table 93-2 Diseases in Which Molecular Diagnosis Techniques Are Commonly Used

Pathogen	Test	Clinical Situation
Hepatitis C virus	Quantitative PCR	Confirmation of chronic infection; monitoring of the effectiveness of therapy; documentation of sustained virologic response
Cytomegalovirus	PCR Hybrid capture DNA test, CMV pp67 NASBA	Diagnosis of CMV encephalitis, myelitis on CSF specimens Prediction of development of clinical disease in seropositive immunocompromised patients
<i>Chlamydia trachomatis</i> , <i>Neisseria gonorrhoeae</i>	PCR, ligase chain reaction	Diagnosis of sexually transmitted diseases on a single specimen—now the standard of care in many centers
Hepatitis B virus	PCR	Quantification of viral burden; monitoring of response to therapy; determination of infectiousness
HIV	PCR, branched DNA amplification, NASBA	Quantification of viral replication; monitoring of response to therapy; confirmation of diagnosis in acute infection and mother-to-child transmission
Enteroviruses	Real-time PCR	Etiologic diagnosis of viral meningitis
Herpes simplex virus	PCR	Reliable diagnosis of HSV encephalitis, a life-threatening disease

HIV, human immunodeficiency virus; HSV, herpes simplex virus; NASBA, nucleic-acid-sequence–based amplification; PCR, polymerase chain reaction.

treatment regimens has been shown to improve the success rates of antiretroviral treatment.

Diagnosis by Isolation of the Organism in Culture

Isolation of a single microbial species from an infected site is generally considered evidence that the infection is caused by this organism. However, information obtained from the culture must be interpreted according to the clinical setting. For example, cultures obtained from ordinarily contaminated sites (e.g., vagina, pharynx) may be overgrown with nonpathogenic commensals, and fastidious organisms such as *Neisseria gonorrhoeae* are difficult to recognize unless cultured on a medium that selects for their growth. Similarly, cultures of expectorated “sputum” may also be uninterpretable if heavily contaminated with saliva. The culture of an organism from an ordinarily sterile site is reasonable evidence for infection with that organism. Conversely, the failure to culture an organism may simply result from inadequate culture conditions (e.g., “sterile” pus from a brain abscess cultured only on aerobic media). Most brain abscesses are caused by anaerobic bacteria that do not grow under aerobic conditions. Thus, when submitting samples for culture, the physician must alert the laboratory to likely pathogens.

Gram stains of specimens submitted for culture are often invaluable aids to the interpretation of culture results. A Gram stain of “sputum” will readily detect contamination by saliva if numerous squamous epithelial cells are seen. In contrast, a Gram stain revealing bacteria despite negative cultures suggests infection by fastidious organisms. The presence of an organism in high density and within neutrophils strongly suggests that the corresponding bacterial isolate is causing disease rather than colonizing the patient or contaminating the specimen. Gram staining of the initial clinical specimen may also help determine the

relative importance of different isolates when cultures show mixed flora.

VIRAL ISOLATION

Because all viral pathogens that can be cultured require eukaryotic cells in which to grow, virus isolation is expensive and often laborious. Throat washings, rectal swabs, or cultures of infected sites should be transported immediately to the laboratory or, if this is not possible, placed in virus transport medium and refrigerated overnight until they can be cultured in the laboratory. Certain viruses such as HIV and CMV are often cultivated from whole blood samples. Notifying the laboratory of the suspected pathogens allows selection of the best cell lines or systems for culture. The clinician must be aware of the viruses that the hospital’s laboratory can isolate, and consideration should be given to the clinical circumstances in which the specimen was obtained to properly interpret a positive result. This is particularly true in the case of viruses that can be shed intermittently in the absence of active disease, such as the herpes simplex viruses and CMV.

ISOLATION OF RICKETTSIAE, CHLAMYDIAE, AND MYCOPLASMAS

Rickettsiae are cultivated primarily in reference laboratories. Diagnosis of rickettsial illness is generally made on clinical grounds and confirmed serologically. Although chlamydiae can be propagated in cell cultures used in most hospital virology laboratories, chlamydial infection is most often diagnosed through antigen detection techniques. Mycoplasmas will grow on selective media; however, the prolonged period of incubation results in little advantage over serologic diagnosis.

BACTERIAL ISOLATION

Isolation of common bacterial pathogens is achieved readily by most hospital laboratories. Specimens should be carried

promptly to the laboratory. In instances in which likely isolates may be fastidious (e.g., bacterial meningitis) and immediate processing cannot be ensured, the specimen should be placed directly onto the culture medium, with careful attention to sterile techniques. Widespread availability of transport media has minimized the need for this kind of approach. Blood culture is a special case of bacterial isolation technique, for which immediate inoculation into the culture medium is required. Blood culture samples are arguably some of the most critical specimen types processed by a microbiology laboratory, and errors in their collection and processing can have major clinical consequences. Common mistakes include insufficient blood volume (30 to 40 mL total is recommended for adults), collection of multiple specimens from the same venipuncture site or intravenous catheter (making it difficult to interpret the significance of normal skin colonizers and to estimate the persistence of the bacteremia), collection after antibiotic initiation, and less than meticulous aseptic technique (resulting in contaminant growth).

Isolation of anaerobic bacteria is often critically important for clinical diagnosis. When anaerobes are suspected, the specimen, if pus or liquid, can be drawn into a syringe, the air expelled, and the syringe capped before transport to the laboratory. Otherwise, specimens must be taken immediately to the laboratory or placed in an anaerobic transport medium appropriate for survival of pathogens. Because of contamination by oral anaerobes, sputum should not be cultured anaerobically unless the sample was obtained by transtracheal or percutaneous lung aspiration.

ISOLATION OF FUNGI AND MYCOBACTERIA

Specimens for fungal and mycobacterial culture must be processed and cultured by the microbiology laboratory. Although some fungi and rapidly growing mycobacteria grow readily on standard agars used for routine isolation of bacteria, others, such as *M. tuberculosis* and *Histoplasma capsulatum*, must be cultured on special media for as long as several weeks.

Prospectus for the Future

- Greater use of molecular methods for diagnosis and monitoring of infectious diseases
- Greater use of rapid bedside tests for the diagnosis of infectious diseases

Antimicrobial Therapy

Benigno Rodríguez and Michael M. Lederman

One of the most dramatic advances in medical practice in the twentieth century was the development of antimicrobial therapy. Antimicrobials are agents that interfere with microbial metabolism, resulting in inhibition of growth or death of bacteria, viruses, fungi, protozoa, or helminths. Some, like penicillin, are natural products of other microbes. Others, such as sulfa drugs, are chemical agents synthesized in the laboratory. Still others are semisynthetic, with chemical modifications of naturally occurring substances that result in enhanced activity (e.g., nafcillin) and/or diminished toxic effects.

The most effective antimicrobials are characterized by their relatively selective activity against microbes. Some, such as penicillins and amphotericin B, interfere with the synthesis of microbial cell walls that are absent in human cells. Others, such as trimethoprim and sulfa drugs, inhibit obligate microbial synthesis of essential nucleic acid intermediates, pathways not required by human cells. Still others, such as acyclovir, an antiviral agent, are relatively inactive until metabolized by pathogen-derived enzymes. Antiretroviral agents selectively inhibit viral elements that are essential for replication. More recently antiretroviral agents have been developed that inhibit host cellular factors necessary for viral replication. Antimicrobial agents, although typically selective in activity against microbes, have variable degrees of toxicity for human cells. Thus, monitoring for toxicity during antimicrobial therapy is always important.

Pathogen

If the pathogen has been clearly identified (see Chapter 93), a drug with a narrow spectrum of activity (i.e., highly selective for the particular pathogen) is usually the most reasonable choice. If the pathogen responsible for the patient's illness has not been identified, then the physician must choose a drug or combination of drugs active against the most likely pathogens in the specific setting. In either instance, the physician must be guided by patterns of antimicrobial resistance common in the community and in the

specific hospital. Some pathogens (e.g., group A streptococci) are almost always sensitive to narrow-spectrum antimicrobials such as penicillin. Other pathogens, such as staphylococci, are variably resistant to penicillins but almost always susceptible to vancomycin. Resistance patterns, particularly among hospital-acquired bacteria, may vary widely and are important in devising antimicrobial strategies. Broad-spectrum antimicrobial coverage for all febrile patients ("shotgunning") must not be substituted for carefully evaluating the clinical problem and pinpointing therapy directed toward the most likely pathogen or pathogens. Widespread use of broad-spectrum antimicrobials almost invariably leads to emergence of resistant strains or the emergence of potentially fatal pathogens such as *Clostridium difficile*. However, the greater the severity of a patient's illness and the less certain the physician is of the responsible pathogen, the more important initial, empirical, broad-spectrum coverage becomes. Initial empirical treatment is also frequently indicated in the immunocompromised febrile patient (e.g., the patient with severe neutropenia secondary to chemotherapy). Once the pathogen is isolated and its antimicrobial sensitivities are known, empirical therapy must be scaled down to a definitive regimen with optimal activity against the specific microorganism.

Site of Infection

The location of the infection is also important in determining the selection and dosage of an antimicrobial. Deep-seated infections and bacteremic infections generally require higher doses of antimicrobials than, for example, superficial infections of the skin, upper respiratory tract, or lower urinary tract. Penetration of antimicrobials into sites such as the meninges, eye, and prostate is quite variable. Therefore treatment of infections at these sites involves selection of an antimicrobial agent that penetrates these tissues in concentrations sufficient to inhibit or kill the pathogen. The meninges are relatively resistant to penetration by most antimicrobials; inflammation renders them somewhat more

permeable. High doses of antibiotics are therefore the rule when meningitis is treated. Bacterial infections of certain sites such as the heart valves or meninges must be treated with antibiotics that kill the microbe (bactericidal) as opposed to simply inhibiting growth (bacteriostatic). This is so because local host defenses at these sites are inadequate to rid the host of infecting organisms. Infections involving foreign bodies may be impossible to eradicate without removal of the foreign material.

Antimicrobials alone are often insufficient in the treatment of large abscesses. Although many drugs achieve reasonable concentrations in abscess walls, the low pH antagonizes the activity of some drugs (e.g., aminoglycosides), and some drugs bind to and are inactivated by the high concentrations of protein, white blood cells, and their products in these collections. The large number of organisms, their depressed metabolism in this unfavorable milieu, and the frequent polymicrobial nature of certain abscesses increase the likelihood that some organisms present may be resistant to antimicrobial therapy. Therefore most abscesses should be drained whenever anatomically possible.

Characteristics of the Antimicrobial

The physician must know the pharmacokinetics of the drug (i.e., its absorption, its penetration into various sites, and its metabolism and excretion) and its toxic effects, as well as its spectrum of antimicrobial activity, before selecting it for use (Table 94-1).

DISTRIBUTION AND EXCRETION

Lipid-soluble drugs, such as chloramphenicol and rifampin, penetrate most membranes, including the meninges, more readily than do more ionized compounds, such as the aminoglycosides. Understanding a drug's distribution, rate and site of metabolism, and route of excretion is essential in selecting the appropriate drug and dose. Drugs excreted unchanged in the urine may be particularly suitable for the treatment of lower urinary tract infection or for the treatment of systemic infection in the presence of renal insufficiency. Some antimicrobials are metabolized in the liver and must be adjusted appropriately in the presence of hepatic dysfunction.

ACTIVITY OF THE DRUG

The physician must understand the spectrum of activity of the drug against microbial isolates, the mechanism of activity of the agent, and whether it is bactericidal or bacteriostatic in achievable concentrations. It should be remembered, however, that the actual activity of an agent as bacteriostatic or bactericidal may depend on concentration at the anatomic site, the microorganism involved, or both. As a general rule, cell wall-active drugs are likely to be bactericidal. Bactericidal drugs are necessary for treatment of infections sequestered from effective host inflammatory responses, such as meningitis and endocarditis. With the exception of

aminoglycosides and certain azalide and macrolide antibiotics, agents inhibiting protein synthesis at ribosomal sites are generally bacteriostatic.

TOXIC EFFECTS OF THE DRUG

The physician must have a thorough understanding of the contraindications for use of the drug, as well as the major toxic effects and their general frequencies. This will help in evaluating the risks of treatment and will also assist in advising the patient about possible adverse reactions. History of drug hypersensitivity must be sought before any antimicrobial is prescribed. The presence or absence of previous reactions to penicillin should be documented for every patient. Patients with a history suggestive of immediate hypersensitivity to penicillin, such as hives, wheezing, hypotension, laryngospasm, or angioedema at any site, must be considered at risk for anaphylaxis. These patients should not receive penicillins or related drugs (cephalosporins or carbapenems) if adequate alternatives are available. Given the large number of currently available agents with activity against penicillin-susceptible organisms, the need for skin testing and desensitization is now much less common. In the rare cases when it is necessary, however, consultation with an experienced allergist is recommended. Examples of situations where desensitization using progressively larger doses of penicillin, either parenterally or orally, may be necessary include neurosyphilis and syphilis during pregnancy. Patients with a history of an uncomplicated morbilliform or delayed rash after penicillin therapy are not likely to be at risk for immediate hypersensitivity and may be treated with cephalosporins, for which the risk of cross-hypersensitivity to penicillins is likely to be in the range of 5%. Evidence suggests that cross-hypersensitivity to aztreonam is less common.

Route of Administration

Oral administration of antimicrobials can often prevent the morbidity and expense associated with parenteral (intravenous or intramuscular) administration. Although some antimicrobials (e.g., amoxicillin and the fluoroquinolones) are very well absorbed after oral administration, most patients hospitalized with severe infections should be treated, at least initially, with intravenous antibiotics. Gut absorption of antimicrobials can be unpredictable, and the intravenous route often permits administration of greater amounts of drug than can be tolerated orally. Intramuscular administration of some antimicrobials can result in excellent drug absorption but should be avoided in the presence of hypotension (erratic absorption) and coagulation disorders (hematomas). Repeated intramuscular injections are uncomfortable and for some drugs (e.g., pentamidine) can also result in the formation of sterile abscesses.

Duration of Therapy

Antimicrobial therapy should be initiated as part of a treatment plan of defined duration. In a few settings, the duration of optimal antimicrobial therapy is established (e.g., 10 days, but not 7 days, of oral penicillin will consistently prevent

Table 94-1 Characteristics of Commonly Used Antimicrobial Agents

Drug Class	Site of Action	Excretion/ Metabolism	Uses and Activity
Antibacterials			
<i>β</i>-Lactams			
Penicillins	Cell wall	Renal	Streptococci, <i>Neisseria</i> , oral anaerobes
<i>β</i> -lactamase-resistant penicillins (e.g., nafcillin)	Cell wall	Renal and/or hepatic	Methicillin-sensitive staphylococci
Amino penicillins (e.g., ampicillin)	Cell wall	Renal	Gram-positive organisms, not staphylococci, some gram-negative organisms
Extended-spectrum penicillins (e.g., piperacillin)	Cell wall	Renal	Broad-spectrum gram-positive organisms; gram-negative organisms, including <i>Pseudomonas</i> , not <i>Staphylococcus</i>
<i>β</i> -lactamase inhibitors (e.g., clavulanic acid)	Inactivate <i>β</i> -lactamase	Renal/metabolic	Used with ampicillin, amoxicillin, piperacillin, or ticarcillin; expand activity to include anaerobes, many gram-negative organisms, and methicillin-sensitive staphylococci
Cephalosporins^a			
First generation (e.g., cefazolin)	Cell wall	Renal	Gram-positive organisms, many common gram-negative bacteria
Second generation (e.g., cefuroxime)		Renal	Some with anaerobic activity (e.g., ceftiofex)
Third generation (e.g., ceftriaxone)		Renal or hepatic	Some active against <i>Pseudomonas</i> (e.g., ceftazidime)
Fourth generation (e.g., cefepime)		Renal	Broadest spectrum including resistant nosocomial gram-negative organisms, and gram-positive cocci, including methicillin-sensitive staphylococci
Monobactams			
Aztreonam	Cell wall	Renal	Aerobic gram-negative bacilli
Carbapenems			
Imipenem-cilastatin, meropenem, ertapenem, doripenem	Cell wall	Renal	Very broad-spectrum, many gram-negative, including resistant nosocomial organisms, some enterococci, and methicillin-sensitive staphylococci, anaerobes
Glycopeptides			
Vancomycin	Cell wall	Renal	Coagulase-positive and coagulase-negative staphylococci, other gram-positive bacteria
Streptogramins			
Quinupristin-dalfopristin	Ribosome	Hepatic, fecal	Gram-positive organisms, including methicillin-resistant staphylococci and non- <i>faecalis</i> vancomycin-resistant enterococci
Lipopeptides			
Daptomycin	Cell membrane (?)	Renal	Coagulase-positive and coagulase-negative staphylococci, other gram-positive bacteria, including glycopeptide-resistant enterococci
Oxazolidinones			
Linezolid	Ribosome	Renal	Coagulase-positive and coagulase-negative staphylococci, other gram-positive bacteria, including glycopeptide-resistant enterococci, certain mycobacteria, <i>Nocardia</i>
Sulfonamides, trimethoprim	Inhibit nucleic acid synthesis	Renal	Gram-negative bacilli, <i>Salmonella</i> , <i>Pneumocystis jirovecii</i> , <i>Nocardia</i>
Fluoroquinolones (e.g., ciprofloxacin, levofloxacin, moxifloxacin)	DNA gyrase	Some hepatic metabolism	Broad spectrum, including <i>Legionella</i> ; newer agents also active against streptococci or anaerobes
Metronidazole	DNA disruption	Hepatic metabolism	Anaerobes, <i>Clostridium difficile</i> , amebas, <i>Trichomonas</i>
Rifampin	Transcription	Hepatic metabolism/renal	<i>Mycobacterium tuberculosis</i> ; meningococcal and <i>Haemophilus influenzae</i> prophylaxis
Aminoglycosides	Ribosome	Renal	Gram-negative bacilli; no activity in anaerobic conditions

Table 94-1 Characteristics of Commonly Used Antimicrobial Agents—Cont'd

Drug Class	Site of Action	Excretion/ Metabolism	Uses and Activity
Chloramphenicol	Ribosome	Hepatic metabolism/ renal	Broad spectrum; active against <i>Salmonella</i> , anaerobes, <i>Rickettsia</i> , <i>Brucella</i> , <i>Bartonella</i> , but use limited by toxicity
Clindamycin	Ribosome	Hepatic metabolism/ renal	Anaerobes; gram-positive cocci
Tetracyclines	Ribosome	Renal/hepatic metabolism	Broad spectrum; especially useful for spirochetes, <i>Rickettsia</i>
Glycylcyclines			
Tigecycline	Ribosome	Renal/hepatic metabolism	Broad spectrum, including methicillin-resistant staphylococci, anaerobes, gram-negative organisms
Macrolides and Azalides			
Erythromycin	Ribosome	Hepatic	Gram-positive cocci, <i>Legionella</i> , <i>Mycoplasma</i>
Azithromycin, clarithromycin	Ribosome	Hepatic	High intracellular levels have enhanced activity against mycobacteria, <i>Toxoplasma</i>
Ketolides			
Telithromycin	Ribosome	Hepatic metabolism/ renal	Enhanced activity against gram-positive organisms, including methicillin-resistant staphylococci, intracellular respiratory pathogens, macrolide-resistant <i>Streptococcus pneumoniae</i>
Antifungals			
Polyenes			
Amphotericin B	Binds membrane ergosterol	Tissue breakdown	Most fungi; newer lipid formulations may be better tolerated
Flucytosine	Blocks DNA synthesis	Renal	Candidiasis; <i>Cryptococcus</i> with amphotericin B
Azoles			
Ketoconazole	Block ergosterol biosynthesis	Hepatic	Mucosal candidiasis, pulmonary histoplasmosis (nonmeningeal)
Itraconazole		Hepatic	Histoplasmosis, blastomycosis
Fluconazole		Renal	Candidiasis, cryptococcosis, coccidioidomycosis
Voriconazole		Hepatic	Invasive aspergillosis, <i>Fusarium</i> and <i>Scedosporium</i> infections, empiric for febrile neutropenia
Posaconazole		Hepatic	Prophylaxis of invasive fungal infections in immunosuppressed patients, zygomycosis (not FDA approved), refractory <i>Candida</i> infections
Echinocandins			
Caspofungin	Inhibit glucan synthesis	Chemical decay and degradation	<i>Candida</i> species, invasive aspergillosis
Micafungin			Esophageal candidiasis, prophylaxis of invasive <i>Candida</i> infections in bone marrow transplant recipients, empiric treatment in febrile neutropenia
Anidulafungin		Chemical decay and degradation	Candidemia, other systemic <i>Candida</i> infections, esophageal candidiasis
Antivirals			
Acyclovir	DNA polymerase	Renal	Herpes simplex, including encephalitis; herpes zoster
Famciclovir	DNA polymerase		Herpes simplex, zoster
Ganciclovir, valganciclovir	DNA polymerase	Renal	Cytomegalovirus, herpesviruses
Foscarnet	DNA polymerase	Renal	Cytomegalovirus, herpesviruses
Cidofovir	DNA polymerase	Renal	Cytomegalovirus, herpesviruses
Amantadine, rimantadine	Uncoating(?)	Renal	Influenza A treatment and prophylaxis
Zanamavir	Neuraminidase	Renal	Influenza A and B
Oseltamavir	Neuraminidase	Renal	Influenza A and B
Ribavirin	RNA synthesis(?)	Hepatic/renal	RSV, hepatitis C (together with interferon- α)
Interferon- α	Immunomodulator		Hepatitis B, C
Entecavir	DNA polymerase	Renal	Hepatitis B

Continued

Table 94-1 Characteristics of Commonly Used Antimicrobial Agents—Cont'd

Drug Class	Site of Action	Excretion/ Metabolism	Uses and Activity
Antiretrovirals			
Nucleoside or nucleotide reverse transcriptase inhibitors ^b	HIV-1 reverse transcriptase	Renal and/or hepatic	HIV-1
Non-nucleoside reverse transcriptase inhibitors ^c	HIV-1 reverse transcriptase	Hepatic	HIV-1
Protease inhibitors ^d	HIV-1 protease	Hepatic	HIV-1
Fusion inhibitors ^e	HIV-1 viral entry	Catabolism	HIV-1
Chemokine receptor inhibitors ^f	Cellular CCR5	Hepatic/renal	HIV-1
Integrase inhibitors ^g	HIV-1 integrase	Hepatic	HIV-1

^aAs a rule. First-generation cephalosporins have better activity against gram-positive cocci and minimal CNS penetration. Second-generation cephalosporins have somewhat better activity against gram-negative bacteria and may penetrate the CNS. Third-generation cephalosporins have broader activity against gram-negative bacteria and generally penetrate the CNS, but they are relatively less active against gram-positive cocci. Fourth-generation cephalosporins have the broadest spectrum of activity, regaining activity against gram-positive organisms.

^bThese include zidovudine, stavudine, didanosine, zalcitabine, lamivudine, emtricitabine, tenofovir, and abacavir.

^cThese include efavirenz, nevirapine, etravirine, and delavirdine.

^dThese include indinavir, nelfinavir, ritonavir, saquinavir, amprenavir, fosamprenavir, tipranavir, atazanavir, darunavir, and lopinavir-ritonavir.

^eThe only currently approved agent is enfuvirtide.

^fThe only currently approved agent is maraviroc.

^gThe only currently approved agent is raltegravir.

CNS, central nervous system; FDA, U.S. Food and Drug Administration; HIV, human immunodeficiency virus; RSV, respiratory syncytial virus.

rheumatic fever after streptococcal pharyngitis); in many others the duration of treatment is empirical and sometimes can be based on the clinical and bacteriologic course. Bloodstream infections without endocarditis or other focal infections can generally be treated for 10 to 14 days. Pneumococcal pneumonia can be effectively treated in 7 to 10 days.

Combinations

Combinations of antimicrobials are indicated in serious infection when they provide more effective activity against a pathogen than any single agent. In some instances, combinations of drugs are used to prevent the emergence of resistance (e.g., infections caused by *Mycobacterium tuberculosis* and the human immunodeficiency virus). In others, combinations are used because they provide synergistic action against the pathogen (e.g., penicillin, a cell wall-active antibiotic, facilitates uptake of aminoglycosides by enterococci). In still other instances, drug combinations are used in empirical therapies to cover a wide spectrum of potential pathogens when the causative agent is unidentified or when infection is likely to be from a mixture of organisms (e.g., fecal soilage of the peritoneum). The use of more than one drug increases the likelihood of toxic effects, increases costs, and often increases the risk of superinfection.

Monitoring of Antimicrobial Therapy

The physician and patient should be alert to potential toxic effects and should be prepared to halt the drug in the event of serious toxic effects. Similarly, in vitro susceptibility is not necessarily synonymous with clinical effectiveness, and repeated clinical evaluation for resolution of both systemic and local signs of infection is the single most important monitoring tool available to the clinician treating an infectious process. For some antimicrobials, such as aminoglycosides, the ratio of effective to toxic drug levels is low, requiring

monitoring of serum levels of the drug to ensure safe and effective dosing. Vancomycin is another antimicrobial that often requires measurement of serum levels to optimize dosing, particularly with prolonged treatment or in the presence of renal failure.

Antiviral Agents

As obligate intracellular pathogens, viruses depend on interactions with host cellular machinery for completion of the life cycle. Thus many potential antiviral treatment strategies are limited by toxic effects on host cells. Specificity for viruses or virus-infected cells can be obtained by interfering with the function of unique viral elements (e.g., the M2 protein of influenza virus that is the target of amantadine and rimantadine) or by developing drugs such as acyclovir that must be processed by viral enzymes (in this instance, phosphorylated by herpesvirus thymidine kinase) before becoming active. In contrast to antibacterial drugs, however, antiviral agents generally have a limited spectrum of activity, each agent being useful against a small number of viruses. In the 1990s there was a dramatic increase in the numbers and types of drugs effective in the treatment of viral infections. This has been particularly striking in the field of antiretroviral therapies (see Chapter 108), and new agents against influenza, hepatitis B, and cytomegalovirus are now part of the therapeutic armamentarium. Additional developments in therapies for other viruses (e.g., hepatitis C) are anticipated.

Antifungal Agents

A number of drugs are useful when applied topically or systemically in the treatment of fungal diseases. Most target the ergosterol-containing cell membrane either by inhibiting ergosterol synthesis (azoles) or by aggregating in proximity to ergosterol and increasing membrane permeability (polyenes). Flucytosine inhibits fungal DNA synthesis. Echinocandins inhibit glucan synthesis. Increasing

resistance to certain azoles and flucytosine among clinically relevant fungal isolates limits the utility of these agents in patients requiring chronic therapy.

Antimicrobial Resistance Testing

As treatment options expand, the emergence of antimicrobial resistance to therapies is predictable. Thus physicians

must be prepared to evaluate the resistance patterns of specific microbial isolates. Resistance testing is now routinely provided for bacterial pathogens and in the design of antiretroviral treatment strategies (see Chapter 108). Certain resistance assays are not yet fully standardized, and all require some level of expertise to facilitate their interpretation. Thus interpretation of resistance assay results to guide treatment decisions, whether for serious bacterial, fungal, or viral infections, should generally involve discussion with an expert in infectious diseases.

Prospectus for the Future

- Newer classes of antiviral medications targeting hepatitis and other viruses
- Newer classes of antiretroviral medications targeting different phases of viral replication
- Newer classes of antibacterials targeting antibiotic-resistant organisms
- Newer, less toxic antifungal agents
- Antimicrobial peptides and other “designer” drugs with innovative mechanisms of action
- Improved agents for the treatment of parasitic and other diseases that are uncommon in Western developed countries (e.g., malaria, leishmania)

Fever and Febrile Syndromes

Tracy L. Lemonovich and Robert A. Salata

Regulation of Body Temperature

Although normal body temperature ranges vary considerably, oral temperature readings in excess of 37.8°C (100.2°F) are generally abnormal. In healthy individuals, core body temperature is maintained within a narrow range, so that for each individual, daily temperature variations greater than 1° to 1.5°C are distinctly unusual. The hypothalamic nuclei that establish set points for body temperature control this homeostasis. Homeostasis is affected by a complex balance between heat-generating and heat-conserving mechanisms that raise or lower body temperature, respectively. Heat is regularly generated as a byproduct of obligate energy use (e.g., cellular metabolism, myocardial contractions, breathing). When an increase in body temperature is needed, shivering—nondirected muscular contractions—generates large amounts of heat. Cutaneous blood vessels constrict to diminish heat lost to the environment. At the same time, the person feels cold; this heat preference promotes heat-conserving behavior, such as wrapping up in a blanket.

Similarly, when a lower body temperature is needed, obligate heat loss to the environment occurs through the skin and by evaporation of water through sweat and respiration. Vasodilation flushes the skin capillaries, temporarily raising skin temperature but ultimately lowering core body temperature by increasing heat loss through the skin to the cooler environment. Sweating promotes rapid heat loss through evaporation, and at the same time the person feels warm and sheds blankets or initiates other activities to promote heat loss.

Fever and Hyperthermia

Fever is an elevated body temperature that is mediated by an increase in the hypothalamic heat-regulating set point. Although exogenous substances such as bacterial products may precipitate fever, the increase in body temperature is achieved through physiologic mechanisms. In contrast,

hyperthermia is an increase in body temperature that overrides or bypasses the normal homeostatic mechanisms. As a general rule, body temperatures in excess of 41°C (105.8°F) are rarely physiologically mediated and suggest hyperthermia. Hyperthermia may occur after vigorous exercise, in patients with heat stroke, as a heritable reaction to anesthetics (malignant hyperthermia), as a response to phenothiazines (neuroleptic malignant syndrome), and occasionally in patients with central nervous system disorders such as paraplegia (see also Chapter 118). Some patients with severe dermatologic conditions are also unable to dissipate heat and therefore experience hyperthermia.

Fever is usually a physiologic response to infection or inflammation. Monocytes or tissue macrophages are activated by various stimuli to liberate various cytokines with pyrogenic activity (Fig. 95-1). Interleukin (IL)-1 is also an essential cofactor in initiating the immune response. Another pyrogenic cytokine, tumor necrosis factor (TNF)- α , activates lipoprotein lipase and may also play a role in immune cytolysis; TNF- β , or lymphotoxin, has similar properties. A fourth cytokine, interferon (IFN)- α , has antiviral activity (see Chapter 92). IL-6, a cytokine that potentiates B-cell immunoglobulin (Ig) synthesis, also has pyrogenic activity. Endogenous pyrogens activate the anterior preoptic nuclei of the hypothalamus to raise the set point for body temperature. Newer data suggest that there is also a more immediate stimulatory effect of exogenous pyrogens (e.g., bacterial lipopolysaccharide) in the production of fever. This occurs when exogenous pyrogens induce the release of prostaglandin E₂ (PGE₂), which either directly stimulates the anterior preoptic nuclei or causes excitation of vagal afferent nerves that transmit signals to these nuclei. Infection with all types of microorganisms can be associated with fever. Tissue injury with resulting inflammation, as observed in patients with myocardial or pulmonary infarction or after trauma, can produce fever. Certain malignancies such as lymphoma and leukemia, renal cell carcinoma, and hepatic carcinoma are also associated with fever. In some instances, fever is related to the liberation of endogenous pyrogens by monocytes in the inflammatory response surrounding the tumor; in other

Figure 95-1 Pathogenesis of fever.

patients, the malignant cell may release an endogenous pyrogen. Many immunologically mediated disorders, such as connective tissue diseases, serum sickness, and some drug reactions, are characterized by fever. In most patients with drug-induced fevers, the mechanisms are unknown. Virtually any disorder associated with an inflammatory response (e.g., gouty arthritis) can be associated with fever. Certain endocrine disorders such as thyrotoxicosis, adrenal insufficiency, and pheochromocytoma can also produce fever.

The association of fever with infections or inflammatory disorders raises the question of whether fever is beneficial to the host. For example, IL-1 (an endogenous pyrogen) is critical for initiating the immune response, elevated temperatures marginally enhance certain *in vitro* immune responses, and some infectious organisms prefer cooler temperatures. It is not certain, however, that fever is helpful to humans in any infectious disease, with the possible exception of neurosyphilis. Fever is deleterious in certain situations. Among individuals with underlying brain disease and even in healthy older persons, fever can produce disorientation and confusion. Fever and the associated tachycardia may compromise patients, especially older individuals with significant cardiopulmonary disease. Fever should be controlled with antipyretics if the patient is particularly uncomfortable or whenever it poses a specific risk to the patient, such as with underlying severe congestive heart failure or myocardial infarction.

Heat stroke almost always results from prolonged exposure to high environmental temperatures and humidity, usually occurring in otherwise healthy individuals after strenuous exercise. Heat stroke is characterized by a body temperature greater than 40.6°C (105°F) and is associated with altered sensorium or coma and with cessation of sweating. Rapid cooling is critical to the patient's survival. Covering the patient with cold (11°C), wet compresses until the core temperature reaches 39°C is the most effective initial therapeutic approach and should be followed by intravenous infusions of fluids appropriate to correct the antecedent fluid and electrolyte losses.

FEVER PATTERNS

The normal diurnal variation in body temperatures results in a peak temperature in the late afternoon or early evening.

This variation often persists when patients have fever. In certain individuals, fever patterns may be helpful in suggesting the cause of fever. Rigors—true shaking chills—often herald a bacterial process (especially bloodstream infection), although they may occur in patients with viral infections, as well as in those with drug or transfusion reactions. Hectic fevers, which are characterized by wide swings in temperature, may indicate the presence of an abscess, disseminated tuberculosis, or collagen vascular diseases. Patients with non-*falciparum* malaria may have a relapsing fever with episodes of shaking chills and high fever, which are separated by 1 to 3 days of normal body temperatures and relative well-being. Medications that may have been recently initiated may cause high, constant fevers. Patients with tuberculosis may be relatively comfortable and unaware of a significantly elevated body temperature. Patients with uremia, diabetic ketoacidosis, or hepatic failure generally have a lower body temperature; thus, normal temperature readings in these settings may indicate infection. Similarly, older patients with infection often fail to mount a febrile response and may experience instead a loss of appetite, confusion, or even hypotension without fever. The administration of nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., aspirin, ibuprofen) or corticosteroids also blunts or ablates the febrile response.

Acute Febrile Syndromes

Fever is one of the most common complaints that bring patients to a physician. The challenge is in discerning the few individuals who require specific therapy from among the many with self-limited benign illness. The approach is simplified by considering patients in three groups: (1) those with fever without localizing symptoms and signs, (2) those with fever and rash, and (3) those with fever and lymphadenopathy. This chapter deals only with fever caused by microbial agents; however, autoimmune, neoplastic, and other disease processes are important causes of fever as well.

FEVER ONLY

Most patients with fever as their sole complaint defervesce spontaneously or exhibit localizing clinical or laboratory

Table 95-1 Infections Exhibiting Fever as the Sole or Dominant Feature

Infectious Agent	Epidemiologic Exposure and History	Distinctive Clinical and Laboratory Findings
Viral		
Rhinovirus, adenovirus, parainfluenza	None (adenovirus in epidemics)	Often URI symptoms; throat and rectal cultures, viral antigen testing
Enteroviruses	Summer, epidemic	Occasionally, aseptic meningitis, rash, pleurodynia, herpangina; serologic or nucleic acid testing
Influenza	Winter, epidemic	Headache, myalgias, arthralgias; nasopharyngeal culture, viral antigen testing
EBV, CMV	See text	See text; monospot test, quantitative nucleic acid testing
Colorado tick fever	Southwest and northwest tick exposure	Biphasic illness, leukopenia; blood, CSF cultures, serologic or nucleic acid testing
Bacterial		
<i>Staphylococcus aureus</i>	IV drug users, IV catheters, hemodialysis, dermatitis	Must exclude endocarditis; blood cultures
<i>Listeria monocytogenes</i>	Depressed cell-mediated immunity	Meningitis may also be present; blood, CSF cultures
<i>Salmonella</i> Typhi, <i>Salmonella</i> Paratyphi	Food or water contaminated by carrier or patient	Headache, myalgias, diarrhea or constipation, transient rose spots; blood, bone marrow, or stool cultures
Streptococci	Valvular heart disease	Low-grade fever, fatigue; blood cultures
After Animal Exposure		
<i>Coxiella burnetii</i> (Q fever)	Infected animals	Headache, occasionally pneumonitis, hepatitis, culture-negative endocarditis; serologic testing
<i>Leptospira interrogans</i>	Water contaminated by urine from dogs, cats, rodents, small mammals	Headache, myalgias, conjunctival suffusion, biphasic illness, aseptic meningitis; serologic testing
<i>Brucella</i> species	Exposure to cattle or contaminated dairy products	Occasionally epididymitis, sacroiliitis, endocarditis; blood cultures, serologic testing
<i>Ehrlichia chaffeensis</i>	South and southeast deer or dog tick exposure	Acute onset of headache, fever, myalgias; leukopenia and thrombocytopenia; blood smear, serologic or nucleic acid testing
Granulomatous Infection		
<i>Mycobacterium tuberculosis</i>	Exposure to patient with tuberculosis, known positive tuberculin skin test result	Back pain suggests vertebral infection; sterile pyuria or hematuria suggests renal infection; liver or bone marrow cultures, histology
<i>Histoplasma capsulatum</i>	Mississippi and Ohio River valleys	Pneumonitis, oropharyngeal lesions; culture and histology of bone marrow and oral lesions, serologic or antigen testing

CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; IV, intravenous; URI, upper respiratory infection.

findings within 2 to 3 weeks of the onset of illness (Table 95-1). Beyond 3 weeks, the patient can be considered to have a fever of unknown origin (FUO), a designation with its own circumscribed group of management considerations, as discussed later in this chapter.

Viral Infections

In young, healthy individuals, acute febrile illnesses generally represent viral infections. The causative agent is rarely established, largely because establishing the precise diagnosis seldom has major therapeutic implications. Rhinovirus, coronavirus, parainfluenza, and adenovirus infections are usually, but not invariably, associated with symptoms of coryza or upper respiratory tract infection (e.g., rhinorrhea, sore throat, cough, hoarseness). Respiratory syncytial virus (RSV) and human metapneumovirus (hMPV) infections can range from upper respiratory tract infection to bronchiolitis and severe pneumonia. Human bocavirus is a newly described cause of respiratory tract infections, primarily occurring in children. Enterovirus infections occur predominantly in the summer, usually in an epidemic setting.

Undifferentiated febrile syndromes account for the majority of enteroviral infections, but the etiologic features are more likely to be established definitively when a macular rash, aseptic meningitis, pericarditis, or a characteristic syndrome such as herpangina (vesicular pharyngitis caused by coxsackievirus A) or acute pleurodynia (fever, chest wall pain, and tenderness caused by coxsackievirus B) is present. Serologic surveys also indicate that many arthropod-borne viruses (California encephalitis virus; eastern, western, and Venezuelan equine encephalitis viruses; St Louis encephalitis virus) usually produce mild, self-limited febrile illnesses. West Nile virus, in particular, has recently become a common cause of febrile syndrome (less commonly associated with neurologic manifestations) during the summer months throughout the United States. Influenza causes sore throat, cough, myalgias, arthralgias, and headache in addition to fever; it most often occurs in an epidemic pattern during the winter months. It is unusual, however, for fever to persist beyond 5 days in uncomplicated influenza.

The mononucleosis syndromes caused by Epstein-Barr virus (EBV), primary human immunodeficiency virus (HIV)

(see Chapter 108), cytomegalovirus (CMV), and (in rare cases) *Toxoplasma gondii* may sometimes manifest in a typhoidal manner—that is, with high fever but little or no detectable lymph node enlargement. Diagnosis and management are discussed later in the section on generalized lymphadenopathy and mononucleosis syndromes, in keeping with the more typical presentation of these processes. The mononucleosis syndromes are generally self-limited. The need to establish a specific diagnosis therefore is usually not urgent with the exception of acute HIV infection. Viral cultures of the throat and rectum and virus-specific antibodies in acute and convalescent serum samples may allow diagnosis of the specific viral cause. Acute retroviral syndrome (HIV) may require diagnosis through plasma p24 antigen or DNA or RNA polymerase chain reaction (PCR) assays because antibodies are frequently not detectable in the early stages (see Chapter 108).

The recognition of other viral syndromes, however, can be critically important. The outbreak of severe acute respiratory syndrome (SARS) in Southeast Asia highlights the importance of early recognition. In the spring of 2003, several people in local hospitals exhibited a variety of complaints that typically included fever and dry cough. Only through the combined efforts of the global medical community was the epidemic contained and the SARS coronavirus identified as the causative agent. Avian influenza is the latest in a series of emerging viruses to pose the threat of widespread infection. Fever is an important element in the early stages of this disease as well.

Bacterial Infections

Pathogenic bacteria most commonly cause sepsis or disseminated bloodstream infection (see Chapter 96). *Staphylococcus aureus* (Web Fig. 95-1) frequently causes sepsis without an obvious primary site of infection. Fever may be the predominant clinical manifestation of the illness. *S. aureus* sepsis should be considered in patients undergoing intravenous therapy with an indwelling catheter, patients on hemodialysis, intravenous drug users, and patients with severe chronic dermatoses. In the patient with *S. aureus* bacteremia, the question of whether intravascular infection exists is key in determining the length of therapy. The following risk factors are associated with infective endocarditis (IE): long duration of symptoms, underlying valvular disease, prior endocarditis, absence of removable focus of infection (e.g., intravenous catheter, soft tissue abscess), metastatic sites of infection (e.g., septic pulmonary emboli, arthritis), younger age, history of injection drug use, and new heart murmur. Transesophageal echocardiogram is frequently necessary to evaluate for an endovascular focus in *S. aureus* bacteremia, especially in patients at high risk for IE (see Chapter 100). *Listeria monocytogenes* bacteremia is seen predominantly in patients with depressed cell-mediated immunity and is the most common presentation of listeriosis in these hosts. Occasionally a relatively indolent clinical syndrome belies the bacterial cause of *S. aureus* and *L. monocytogenes* bacteremia.

Enteric fever—typhoid or paratyphoid fever—may also have fever alone as the primary clinical manifestation. The major species producing this syndrome are *Salmonella* Typhi and *Salmonella* Paratyphi, both of which have humans as their only reservoir. *Salmonella* Paratyphi usually produces

less severe disease than *Salmonella* Typhi. Disease is acquired by ingesting food or water contaminated with fecal material from a chronic carrier or a patient with typhoid or paratyphoid fever. A large number of bacteria (10^6 to 10^8) must be ingested to cause disease in the normal host. Major host risk factors are achlorhydria, malnutrition, malignancy (particularly lymphomas), sickle cell anemia, and other defects in cellular and humoral immunity. *Salmonella* Typhi penetrates the gut wall and enters the lymphoid follicles (Peyer patches), where it multiplies within mononuclear phagocytes. Primary bacteremia occurs with spread to the reticuloendothelial system (liver, spleen, and bone marrow). After further multiplication at those sites, secondary bacteremia can occur and localize to lesions such as tumors, aneurysms, and bone infarcts. Infection of the gallbladder, particularly in the presence of gallstones, leads to a chronic carrier state. Approximately 2 weeks after exposure, patients develop prolonged fever with chills, headache, and myalgias. Diarrhea or constipation may be present but usually does not dominate the clinical picture. Occasionally, crops of rose spots (2- to 4-mm salmon-colored maculopapular lesions) appear on the upper abdomen but are evanescent. Typhoid fever usually resolves in about 1 month if left untreated. However, complication rates are high because of bowel perforation, metastatic infection, and the general debility of patients, which may last for months. *Salmonella* Typhi or Paratyphi may be isolated from blood, bone marrow, stool, or rose spots to confirm the diagnosis. Typhoid fever should be treated with third-generation cephalosporins or fluoroquinolones.

Localized bacterial infection can be clinically occult and can develop as an undifferentiated febrile syndrome. Intra-abdominal abscess, vertebral osteomyelitis, streptococcal pharyngitis, urinary tract infection, IE, and early pneumonia may all cause fever with surprisingly few clinical clues to the location of the infection. Therefore urinalysis, throat and blood cultures, and chest radiography should be performed in the patient who is febrile with features suggestive of a bacterial infection.

Eleven cases of inhalational anthrax in the United States in 2001 highlighted this bacterial infection as an important cause of fever without early localizing signs. The illness appeared biphasically with an initial influenza-like illness, followed by sepsis syndrome and severe respiratory distress. All patients had abnormal chest radiographs, with the majority demonstrating pleural effusions, mediastinal widening, and pulmonary infiltrates, with a high rate of positive blood cultures. Early recognition and initiation of appropriate antimicrobial therapy are essential to decreasing mortality. Antimicrobial prophylaxis for individuals with potential exposure is critical, combined with adjunctive postexposure vaccination.

Febrile Syndromes Associated with Animal Exposure

Q fever, brucellosis, and leptospirosis are diseases associated with exposure to fluids from infected animals and may have similar clinical presentations.

Q Fever

Q fever is an under-recognized cause of acute febrile illness. *Coxiella burnetii*, the causative agent, produces mild

infection in livestock. Humans are infected by inhalation of aerosolized particles or by contact with hides, placenta, or amniotic fluids from infected animals. The source of animal exposure may go unnoticed.

A self-limited febrile illness is the most common presentation of Q fever. Other clinical syndromes include pneumonia, hepatitis, osteomyelitis, and neurologic manifestations. Pneumonia may be found incidentally during the initial febrile illness and is often accompanied by headache. Definitive diagnosis is usually based on a fourfold rise in titer of complement-fixing antibodies between acute and convalescent samples, as *C. burnetii* is difficult to isolate in culture. The treatment of choice for Q fever is doxycycline. Chronic Q fever may also cause endocarditis, often in the setting of underlying valvular disease or a prosthetic valve. The presence of hepatomegaly, splenomegaly, anemia, and purpuric rash caused by vasculitis in a patient with culture-negative endocarditis may be a clue to this diagnosis. Diagnosis is most often serologic; therapy usually involves prolonged combination antimicrobial therapy including doxycycline.

Leptospirosis

Humans are infected with *Leptospira* species, primarily *Leptospira interrogans*, by exposure to urine from infected animals, usually rodents, small mammals, livestock, dogs, and cats. Indirect exposure is most frequent, occurring by contact with contaminated wet soil or water. Direct contact also occurs in veterinarians, farm workers, hunters, and animal handlers. After an incubation period of approximately 1 week, patients develop chills, high fever, headache, and myalgias. The illness often follows a biphasic course. During the second phase of illness, fever is less prominent, but headache and myalgias are severe; aseptic meningitis is the most important manifestation of the second or immune phase of the illness. Suffusion of the bulbar conjunctivae with visible corkscrew vessels surrounding the limbus is a useful early sign of leptospirosis. Lymphadenopathy, hepatomegaly, and splenomegaly may also occur. Leptospirosis may also pursue a more severe clinical course characterized by renal and hepatic dysfunction and hemorrhagic diathesis (Weil syndrome). Laboratory studies in leptospirosis are often nonspecific but may reveal mild transaminase elevation and increase in serum creatine kinase. Darkfield examination can reveal leptospire in body fluids but has low sensitivity and specificity. Leptospire may also be isolated by culture of blood or cerebrospinal fluid (CSF). The diagnosis is most commonly made serologically by a fourfold rise in the microscopic agglutination test (MAT) antibody titer between acute and convalescent sera. Early antibiotic treatment shortens the duration of fever and may reduce complications. However, to be effective, antibiotics must be initiated presumptively, before serologic confirmation. Intravenous penicillin or ceftriaxone is used for severe disease, and oral doxycycline is effective for mild disease.

Brucellosis

Brucella species infect cattle (*Brucella abortus*), pigs (*Brucella suis*), sheep, and goats (*Brucella melitensis*). Humans are most commonly exposed occupationally via broken skin, aerosolized particles, or inoculation in the conjunctiva or by ingestion of unpasteurized dairy products. Acute disease is nonspecific and is often characterized by chills, fever, head-

ache, and arthralgias and sometimes by lymphadenopathy, hepatomegaly, and splenomegaly. During the associated bacteremia, any organ may be seeded. Epididymo-orchitis, spondylitis (Web Fig. 95-2) or sacroiliitis, granulomatous hepatitis, and bone marrow involvement are characteristic localized findings. With or without antibiotic treatment of acute infection, brucellosis may relapse or enter a chronic phase, although treatment does reduce the incidence of complications and relapse. *Brucella* species can be isolated from blood or other normally sterile fluids; however, the diagnosis is often made serologically. Treatment consists of combination therapy with doxycycline plus either rifampin or streptomycin.

Granulomatous Infection

Tuberculosis

Extrapulmonary and miliary tuberculosis (Web Fig. 95-3) may cause a febrile syndrome. In disseminated tuberculosis, initial chest radiographs may be normal and tuberculin skin tests are often nonreactive. This finding is particularly true in older or immunocompromised patients. Protracted FUO should always suggest this possibility. Liver biopsy and bone marrow biopsy have a high yield in miliary disease. Genitourinary and vertebral tuberculosis may also develop as unexplained fever. However, careful history, urinalysis, intravenous pyelography, and radiographs of the spine should reveal the site of tissue involvement. Extrapulmonary tuberculosis should be treated for the first 2 months with four-drug therapy with isoniazid, rifampin, ethambutol, and pyrazinamide given orally. Thereafter, isoniazid and rifampin are continued for 7 months (longer in patients with skeletal tuberculosis). The ethambutol can be discontinued once the organism is shown to be sensitive to isoniazid. Corticosteroids may be a useful adjunctive measure in the patient with severe systemic toxicity or central nervous system involvement (see Chapter 97). The dose of corticosteroids should be tapered as soon as the patient shows symptomatic improvement.

Histoplasmosis

Most individuals living in endemic areas in the Mississippi and Ohio River valleys who become infected with *Histoplasma capsulatum* (Web Fig. 95-4) have a subclinical, self-limited febrile illness as a manifestation of acute pulmonary histoplasmosis (Web Fig. 95-5). Although patients may complain of chest pain or cough, physical examination of the chest is usually unremarkable despite radiographic findings of diffuse infiltrates and mediastinal or hilar adenopathy. Therefore, in the absence of chest radiographs, the lower respiratory tract component of the illness is easily overlooked. Cavitory pulmonary histoplasmosis occurs more insidiously with low-grade fever, productive cough, dyspnea, and weight loss. This syndrome is most likely to occur in older men with underlying chronic lung disease such as emphysema. Isolation of *H. capsulatum* in culture is variable and depends on specimen source and burden of disease. Serology is often used diagnostically, with a complement fixation (CF) antibody titer of at least 1:32 or a fourfold rise in titer being consistent with the diagnosis of acute histoplasmosis. Although spontaneous resolution of symptoms is normal in acute pulmonary histoplasmosis, unusually prolonged illness (more than 4 weeks) may require antifungal

treatment with itraconazole or amphotericin B for more severe disease.

Progressive disseminated histoplasmosis may occur as a consequence of reactivation of latent infection in immunosuppressed individuals (e.g., those with acquired immunodeficiency syndrome [AIDS]) (see Chapter 108) or may reflect an uncontrolled primary infection. The febrile illness in such patients is protracted. Oropharyngeal nodules and ulcerative lesions are commonly found in disseminated histoplasmosis, biopsy of such lesions permits rapid diagnosis. Serologic studies are less helpful in disseminated histoplasmosis because they are positive in less than one half of patients. Cultures and Gomori-methenamine or Grocott silver stains of bone marrow biopsy specimens can establish the diagnosis. *Histoplasma* urine antigen detection is a sensitive predictor of disseminated infection. Disseminated histoplasmosis is initially treated with amphotericin B, but patients can often be switched to itraconazole to complete therapy once symptoms resolve. Duration of therapy is often 6 to 12 months, but immunosuppressed patients may require lifelong suppressive therapy.

Other Infections

Malaria characteristically produces febrile paroxysms that occur every 48 (*Plasmodium vivax*) to 72 (*Plasmodium malariae*) hours in some patients. However, during the first few days of illness, the fever may be low grade and sustained or intermittent. The diagnosis should therefore be suggested in all febrile travelers who have returned from endemic areas. Malaria may also occur, albeit rarely, in intravenous drug users and recipients of blood transfusions. *Plasmodium falciparum* (Web Fig. 95-6) causes a high level of parasitemia and is associated with a high mortality rate unless recognized and treated promptly. Daily fever often occurs in this form of malaria. Although *P. vivax* and *Plasmodium ovale* may cause relapsing infection long after primary infection because of latent extra-erythrocytic infection in the liver, the course is milder. Demonstration of parasites in blood smears establishes the diagnosis of malaria.

Many, if not most, infectious diseases may exhibit fever as an early finding with subclinical or eventual clinical involvement of specific organ systems. Examples include cryptococcosis, coccidioidomycosis, psittacosis, infection with *Legionella* species, and *Mycoplasma pneumoniae* infections. Pulmonary involvement by these infectious agents often produces few signs on physical examination; chest radiographs often reveal more prominent abnormalities than are clinically suggested.

FEVER AND RASH

Many of the febrile syndromes already discussed may occasionally be associated with a rash (Table 95-2). This section, however, considers diseases in which rash is a prominent feature of the presentation. The most life-threatening infections associated with fever and rash include meningococemia, staphylococcal toxic shock syndrome (TSS), and Rocky Mountain spotted fever (RMSF).

Bacterial Diseases

Petechial lesions, purpura, and ecthyma gangrenosum are lesions associated with bacteremia (see Chapter 96). Dis-

Table 95-2 Differential Diagnosis of Infectious Agents Producing Fever and Rash

Maculopapular Erythematous

Enterovirus
EBV, CMV, *Toxoplasma gondii*
Acute HIV infection
Colorado tick fever virus
Salmonella Typhi
Leptospira interrogans
Measles virus
Rubella virus
Hepatitis B virus
Treponema pallidum
Parvovirus B19
Human herpesvirus 6

Vesicular

Varicella-zoster virus
Herpes simplex virus
Coxsackievirus A
Vibrio vulnificus

Cutaneous Petechiae

Neisseria gonorrhoeae
Neisseria meningitidis
Rickettsia rickettsii (Rocky Mountain spotted fever)
Rickettsia typhi (murine typhus)
Ehrlichia chaffeensis
Echoviruses
Viridans streptococci (endocarditis)

Diffuse Erythroderma

Group A streptococci (scarlet fever, toxic shock syndrome)
Staphylococcus aureus (toxic shock syndrome)

Distinctive Rash

Ecthyma gangrenosum—*Pseudomonas aeruginosa*
Erythema migrans—Lyme disease

Mucous Membrane Lesions

Vesicular pharyngitis—coxsackievirus A
Palatal petechiae—rubella, EBV, scarlet fever (group A streptococci)
Erythema—toxic shock syndrome (*Staphylococcus aureus* and group A streptococci)
Oral ulceronodular lesion—*Histoplasma capsulatum*
Koplik spots—measles virus

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus.

seminated gonococemia (Web Fig. 95-7) causes sparse vesiculopustular, hemorrhagic, or necrotic lesions on an erythematous base, typically on the extremities and particularly their dorsal surfaces (see Chapter 107). Meningococemia is also an important cause of fever and a rash that may range from a few petechiae to, in the most severe cases, purpura fulminans (Web Fig. 95-8).

Bacterial toxins produce characteristic clinical syndromes. Pharyngitis or other infections with an erythrogenic toxin-producing *Streptococcus* (Web Fig. 95-9) may lead to scarlet fever. Diffuse erythema begins on the upper part of the chest and spreads rapidly, although sparing palms and soles. Small red petechial lesions are found on the palate, and the skin has a sandpaper texture caused by occlusion of the sweat glands. The tongue at first shows a yellowish coating and then becomes beefy red. The rash of scarlet fever (Web Fig. 95-10) heals with desquamation. *Arcanobacterium haemolyticum* can also produce pharyngitis and rash.

Streptococcal TSS may also occur as a complication of group A streptococcal soft tissue infections. Major manifestations include cellulitis and/or fasciitis with shock, adult respiratory distress syndrome, renal failure, liver abnormalities, coagulopathy, and a generalized erythematous macular rash. Treatment consists of high-dose penicillin and clindamycin, early surgical intervention, supportive measures, and possibly intravenous immunoglobulin (IVIG). The mortality remains high (>30%) even with optimal current therapy.

Staphylococcal TSS (Web Figs. 95-11 and 95-12) was first recognized as a distinct clinical entity in 1978, with an increased number of cases seen in the early 1980s associated with the use of hyperabsorbable tampons. *S. aureus* strains producing TSS toxin (TSST-1) or other closely related exotoxins cause the syndrome. TSST-1 acts as a superantigen by directly binding T lymphocytes to antigen-presenting cells via MHC class II receptors, causing an immense cytokine release and ensuing inflammatory response. Previously, most patients have been 15- to 25-year-old girls and women who use tampons. Emerging settings in which nonmenstrual TSS occurs include use of contraceptive diaphragms, vaginal or cesarean deliveries, nasal surgery, influenza, and recalcitrant desquamating syndrome in patients with AIDS. Superficial staphylococcal infections and abscesses often cause TSS in men. Patients with TSS develop the abrupt onset of high fever (temperature >40°C [104°F]), hypotension, nausea and vomiting, severe watery diarrhea, and myalgias, followed in severe cases by confusion and oliguria. Characteristically, diffuse erythroderma (a sunburn-like rash) with erythematous mucosal surfaces is apparent. Later, intense scaling and desquamation of the skin occur, particularly on the palms and soles. Laboratory abnormalities include elevated levels of liver and muscle enzymes, thrombocytopenia, and hypocalcemia. Diagnosis is based on the clinical findings and requires specific exclusion of RMSF, leptospirosis, measles, and blood or CSF cultures negative for organisms other than *S. aureus*. Management of the patient consists of restoring an adequate circulatory blood volume by the administration of intravenous fluids, drainage of abscesses or débridement of affected tissues if necessary, and treatment of the staphylococcal infection with vancomycin or nafcillin. Vancomycin is the therapy of choice for known methicillin-resistant *S. aureus* (MRSA) or until susceptibilities are known. Prevention of recurrence targets avoidance of further tampon use and eliminating staphylococcal colonization of skin and mucosal sites. Decolonization regimens may include intranasal antibiotics such as mupirocin, antiseptic body washes, and systemic antibiotics such as rifampin along with other agents.

Rickettsial Diseases

In the United States, several rickettsial diseases are endemic including RMSF (Web Fig. 95-13), rickettsialpox, and murine typhus. Of these, RMSF is the most virulent, with a case-fatality rate of greater than 20% if early appropriate therapy is not given. Although originally described in the western United States, most cases occur in the South Atlantic south-central states. The causative organism, *Rickettsia rickettsii*, is transmitted from dogs or small wild animals to ticks and then to humans. Infection occurs primarily during warmer months, the periods of greatest tick activity. The tick transmits infection after 6 to 10 hours of feeding and may

be unnoticed. The fulminant onset of severe frontal headache, chills, fever, myalgias, and conjunctivitis occurs after 2 to 14 days; cough and shortness of breath develop in one fourth of patients. The diagnosis may be obscure at the onset. Rash characteristically begins on the third to fifth day of illness as 1- to 4-mm erythematous macules on the hands, wrists, feet, and ankles. Palms and soles may also be involved. The rash may be transient, but it usually spreads to the trunk and may become petechial. Intravascular coagulopathy develops in some patients who are severely ill. Diagnosis and the institution of appropriate therapy must be based on the clinical and epidemiologic findings; delay in treatment may be fatal. Confirmation of the diagnosis is usually retrospective by using an indirect immunofluorescence assay showing detectable serum antibodies during convalescence. Treatment is with doxycycline, given orally or parenterally, or oral tetracycline for 7 days.

Human Ehrlichiosis

Human ehrlichiosis is an acute, febrile illness caused most frequently by *Ehrlichia chaffeensis* (Web Fig. 95-14) (human monocytic ehrlichiosis [HME]) or *Anaplasma phagocytophilum* (human granulocytic anaplasmosis [HGA]). *E. chaffeensis* is transmitted by the dog tick *Amblyomma americanum* (the Lone Star tick) and causes illness with peak incidence in the summer months. Since the disease was first recognized in 1986, cases of HME have been identified most frequently in 21 contiguous southeastern states from Maryland to Texas, but have been documented in 47 states. The illness characteristically begins with fever, chills, headache, and myalgias, with a maculopapular rash occurring in less than one third of cases. Although a wide spectrum of illness exists, roughly one half of clinically recognized cases are associated with pulmonary infiltrates. Laboratory studies often reveal leukopenia, thrombocytopenia, and elevated liver transaminases. Acute respiratory distress syndrome often associated with renal failure may develop, most often occurring in older patients. If the disease is left untreated, the mortality rate may exceed 10% in hospitalized patients. More severe illness is usually associated with older age and immunocompromised status (e.g., from HIV, corticosteroid therapy, organ transplantation).

HGA peaks in July and occurs in areas where infected *Ixodes* ticks are found, including the Northeast, parts of the Midwest, and California. Nine percent of patients have concurrent Lyme disease or babesiosis because the same tick vector transmits these diseases. HGA usually exhibits a nonspecific influenza-like illness with fever, chills, malaise, headache, nausea, and vomiting. As in HME, leukopenia, thrombocytopenia, and elevations in hepatic transaminases are important laboratory features. Older patients tend to have more severe disease.

Presumptive diagnosis of HME or HGA is made on clinical grounds in patients with acute febrile illnesses, which are generally associated with decreasing leukocyte and platelet counts after tick exposure. Peripheral blood smears may show intracellular organisms called *morulae* in infected leukocytes, particularly in HGA. Serodiagnosis is sensitive but helpful only in retrospective confirmation of diagnosis. PCR methods for amplifying nucleic acids of *E. chaffeensis* and *A. phagocytophilum* appear to be effective for a timely diagnosis of active infection. Treatment with doxycycline or

tetracycline is effective in decreasing both the duration and the severity of illness.

Major clinical distinctions between human ehrlichiosis and RMSF include the earlier, more frequent, and more severe cutaneous manifestations of RMSF and the more common pulmonary manifestations and characteristically decreasing leukocyte counts in ehrlichiosis.

Lyme Disease

Lyme disease is a common, multisystem spirochetal infection caused by *Borrelia burgdorferi* (Web Fig. 95-15) and is transmitted by the *Ixodes* species of ticks, *Ixodes scapularis* in the East and Midwest US and *Ixodes pacificus* in California. The largest number of cases are distributed in areas that correspond to distribution of the *Ixodes* vectors (the Northeast, Wisconsin, Minnesota, California, and Oregon); however, the infection is distributed broadly throughout North America and Western Europe. Between 3 days and 3 weeks after the tick bite, of which most individuals are unaware, patients develop a mild febrile illness, usually associated with headache, stiff neck, myalgias, arthralgias, and erythema migrans (EM) (Web Fig. 95-16). EM begins as a red macule or papule at the site of the tick bite; the surrounding bright red patch expands to a diameter of up to 15 cm. Partial central clearing is often seen. The centers of lesions may become indurated, vesicular, or necrotic, and several red rings may be found within the outer border. Smaller secondary lesions that are caused by disseminated spirochetes may appear within several days. Lesions are warm but nontender. Enlargement of regional lymph nodes is common. The rash usually fades in several weeks without treatment.

Several weeks after the onset of symptoms, important neurologic manifestations occur in more than 15% of patients. Most characteristic is meningoencephalitis with cranial nerve involvement and peripheral radiculoneuropathy. Bell palsy may occur as an isolated phenomenon; when associated with fever, this finding is strongly suggestive of Lyme disease. The CSF at this time shows a lymphocytic pleocytosis of approximately 100 cells/mL. Heart involvement may also exhibit as atrioventricular block, myopericarditis, or cardiomegaly.

Joint involvement eventually occurs in 60% of untreated patients. Early in the course, arthralgias and myalgias may be quite severe. Months later, arthritis often develops with significant swelling and little pain in one or two large joints, typically the knee. Episodes of arthritis may recur for months or years; in about 10% of patients the arthritis becomes chronic, and erosion of cartilage and bone occurs.

Diagnosis is usually based on a compatible clinical syndrome, potential exposure in an endemic area, and positive serologic testing. Serologic testing should not be performed in the setting of EM, as antibodies are likely to be negative in the first 1 to 2 weeks of disease. Serologic testing is performed in a two-step approach with an initial enzyme-linked immunosorbent assay (ELISA), followed by a confirmatory Western blot in those with positive or equivocal ELISA results. By 1 month of disease, essentially all patients with active infection have positive immunoglobulin G (IgG) titers. Antibody responses wane slowly after treatment but may remain present for years after infection. Antibodies to *B. burgdorferi* may also be detected in CSF in acute neu-

roborreliosis. In Lyme arthritis, synovial fluid contains an average of 25,000 cells/mL, mostly neutrophils. Synovial fluid PCR for *B. burgdorferi* DNA provides a moderately sensitive means of diagnosis before antibiotic treatment.

Treatment with doxycycline 200 mg orally within 72 hours of a deer tick bite in an endemic area appears to decrease the subsequent development of Lyme disease. Treatment of the early manifestations of Lyme disease with doxycycline or amoxicillin for 14 to 21 days usually prevents late complications. Neurologic and cardiac involvement should be treated with intravenous aqueous penicillin G or ceftriaxone for 14 to 28 days; first-degree atrioventricular block or an isolated facial palsy can usually be treated with an oral regimen. Arthritis can be treated with oral therapy for 30 to 60 days or intravenously for 14 to 28 days.

Viral Infections

The rashes associated with viral infections may be so typical as to establish unequivocally the cause of the febrile syndrome (Web Table 95-1). Varicella-zoster requires special consideration because of the availability of effective antiviral drugs. In normal children under the age of 12, antiviral therapy is not required for the treatment of chickenpox. However, for patients over age 12, those with chronic cutaneous or pulmonary disease, those receiving salicylate therapy, and immunocompromised hosts should receive antivirals because these patients are at higher risk for complications. Dermatomal herpes zoster should be treated in those older than age 50 to decrease the incidence, severity, and duration of post-herpetic neuralgia (PHN). Immunocompromised patients with herpes zoster should also be treated to prevent dissemination of infection. In addition, ophthalmic zoster demands antiviral treatment because of its association with vision loss related to the development of keratitis, iridocyclitis, or secondary glaucoma. In general, more severe disease with either chickenpox or herpes zoster requires intravenous acyclovir therapy, whereas milder disease may be treated orally with acyclovir or valacyclovir. Acute onset of high fever characterizes viral hemorrhagic fevers, along with, in some cases, bleeding complications and high mortality rates. Arthropod vectors usually transmit these infections; in some patients, they are acquired by direct contact with the reservoir animal or with infected persons and their body fluids. These illnesses include dengue, Marburg hemorrhagic, Ebola hemorrhagic, and Lassa fevers.

FEVER AND LYMPHADENOPATHY

Many infectious diseases are associated with some degree of lymph node enlargement. However, in some diseases, lymphadenopathy is a major manifestation. Lymph node enlargement can be further divided according to whether the enlargement is generalized or regional.

Generalized Lymphadenopathy: Mononucleosis Syndromes

The mononucleosis syndromes are important causes of fever and generalized lymph node enlargement.

Epstein-Barr Virus Infection

Approximately 90% of American adults have serologic evidence of EBV infection; most infections are subclinical and

Table 95-3 Most Common Infectious Causes of Heterophil-Negative Atypical Lymphocytosis

Infectious hepatitis

occur before the age of 5 years or midway through adolescence. EBV causes approximately 80% of clinical cases of infectious mononucleosis. This acute illness usually develops late in adolescence after intimate contact with asymptomatic oropharyngeal shedders of EBV. Patients develop sore throat, fever, and generalized lymphadenopathy and sometimes experience headache and myalgias. From 5% to 10% of patients have a transient rash that may be macular, petechial, or urticarial. Palatal petechiae are often present, as is pharyngitis, which may be exudative. Cervical lymph node enlargement, particularly involving the posterior lymphatic chains, is prominent, although some involvement elsewhere is common. The spleen is palpably enlarged in about 50% of patients. Thrombocytopenia and hepatitis are common laboratory abnormalities. Autoimmune hemolytic anemia, encephalitis or aseptic meningitis, Guillain-Barré syndrome, and splenic rupture are rare but severe complications of EBV infection. The enlarged spleen may be very fragile, necessitating avoidance of contact sports and caution in splenic palpation. Three fourths of patients exhibit an absolute lymphocytosis. At least one third of their lymphocytes are atypical in appearance: large, with vacuolated basophilic cytoplasm, rolled edges often deformed by contact with other cells, and lobulated, eccentric nuclei. Immunologic studies indicate that some circulating B cells are infected with EBV and that the cells involved in the lymphocytosis are mainly reactive cytotoxic T cells. Atypical lymphocytes may also be seen in other viral illnesses (Table 95-3).

B-cell infection with EBV is a stimulus to the production of polyclonal antibodies. Heterophile antibody tests such as the Monospot rapid diagnostic test are sensitive and specific; false-positive results occur in rare cases in patients with lymphoma or hepatitis. Virus-specific antibodies also are produced in response to infection. The presence of IgM antibody to viral capsid antigen (VCA) is virtually diagnostic of acute infectious mononucleosis. The appearance of antibody to EBV nuclear antigen occurs late in the course of infection and is also indicative of recent EBV infection. These antibodies persist lifelong.

Infectious mononucleosis usually has a benign course with complete recovery even in patients with neurologic involvement, and fatalities are rare. The fever resolves after

1 to 2 weeks, although residual fatigue may be protracted. In general, patients should be managed symptomatically. Antibiotics, particularly ampicillin, should be avoided as the use of ampicillin causes a classic rash in almost all patients with EBV infection. This phenomenon can also be a diagnostic clue to the occurrence of EBV infection. Because EBV infection is predominantly latent, there is no role or available antiviral therapy directed against EBV. Corticosteroids are indicated in the rare individual with serious hematologic involvement (e.g., thrombocytopenia, hemolytic anemia) or impending airway obstruction as a result of massive tonsillar swelling. Acute bacterial superinfections of the pharynx and peritonsillar tissues should be considered when the course is unusually septic. Rarely, patients can have a persistent or recurrent syndrome with evidence of ongoing organ dysfunction including hemophagocytosis, lymphadenitis, hepatitis, and interstitial pneumonia with serologic evidence of chronic active EBV infection. In contrast to the majority of patients with acute infectious mononucleosis, these patients have a poor prognosis.

The differential diagnosis of Monospot-negative mononucleosis is shown in Table 95-4.

Cytomegalovirus

Serologic surveys indicate that by adulthood most people have been infected with CMV, but seroprevalence varies by country. In the United States, 60% to 70% of the population has been infected, and this approaches 100% in some parts of Africa. The ages of peak incidence of CMV infection are in the perinatal period (transmission via the birth canal or by breast milk) and during the second to fourth decades of life. Congenital CMV acquired in utero is usually a result of primary infection in the mother and can be fatal. Like other herpesviruses, CMV can establish latency after primary infection, leading to a potential for reactivation. This is often related to immune suppression.

There are several important modes of transmission in adults. CMV can be transmitted sexually, and virus can be isolated from both semen and the uterine cervix. The frequency of antibody to CMV and active viral excretion has been shown to correlate with number of sexual partners. Contact with oral secretions and fecal-oral transmission are the main sources of CMV infection within households and in child day-care workers. In addition, blood transfusions carry a risk of approximately 3% per unit of blood for transmitting CMV infection. This risk becomes substantial in the setting of open-heart surgery or multiple transfusions for other indications. The use of seronegative or

leukocyte-depleted blood products can minimize the risk of CMV transmission, particularly in high-risk CMV seronegative hematopoietic stem cell transplant recipients.

Primary infection with CMV causes a major proportion of cases of Monospot-negative mononucleosis (see Table 95-4). The distinction between CMV and EBV may be impossible on clinical grounds alone. However, CMV tends to involve older patients (mean age 29) and often produces milder disease, is less likely to cause pharyngitis, and often causes high fever with little or no peripheral lymph node enlargement. The infrequent but serious forms of neurologic and hematologic involvement that develop in EBV infection occur less commonly with CMV. As with EBV infection, hepatitis (which is usually mild and may be granulomatous) is common. Diagnosis of primary infection is usually made serologically by indirect fluorescent or CF antibody testing. The IgM antibody in particular is specific for primary infection. Isolation of CMV from body fluids or tissues can also be diagnostic in primary or reactivation of latent infection. CMV hybrid capture and PCR techniques have been developed to provide rapid laboratory diagnosis of CMV viremia and can be useful in certain patient groups such as solid organ or hematopoietic stem cell transplant recipients. CMV mononucleosis is usually a self-limited disease that does not require specific therapy. CMV infection in the immunocompromised host may be life threatening; in this setting it usually responds to therapy with ganciclovir, valganciclovir, or foscarnet.

Primary HIV Infection (Acute Retroviral Syndrome)

Typical presenting features of primary HIV infection overlap those of the mononucleosis syndrome (see Chapter 108). Although most patients with the acute retroviral syndrome seek medical attention, the correct diagnosis is missed in a large number of cases because of physician failure to consider HIV infection. Because it is of critical importance to both the patient and his or her sexual partners to establish this diagnosis (see Chapter 108), primary HIV infection must be considered in all patients with mononucleosis syndromes.

Toxoplasmosis

T. gondii is a parasite of cats and other felids. *T. gondii* is acquired in humans by ingestion of tissue cysts in undercooked meat, by ingestion of food or water contaminated by oocysts, or congenitally. Seroprevalence of *T. gondii* infection varies geographically, with rates in Western Europe and Africa being much higher than in the United States. Overall age-adjusted seroprevalence in the United States has been reported to be 22.5%. Seropositivity in HIV-infected patients in the United States is similar to that in the non-HIV-infected population. Only between 10% and 20% of infections in normal adults are symptomatic. Presentation may take the form of a mononucleosis-like syndrome, although maculopapular rash, abdominal pain caused by mesenteric and retroperitoneal lymphadenopathy, and chorioretinitis may also occur. Striking lymph node enlargement and involvement of unusual chains (occipital or lumbar) may necessitate lymph node biopsy to exclude lymphoma. More commonly, cervical adenopathy is observed in symptomatic patients. Overall, however, toxoplasmosis accounts for less than 1% of mononucleosis-like illnesses. Histologically,

focal distention of sinuses with mononuclear phagocytes, histiocytes blurring the margins of germinal centers, and reactive follicular hyperplasia indicate *Toxoplasma* infection. Acute acquired toxoplasmosis is suggested by the conversion of *T. gondii*-specific IgG and IgM antibodies from negative to positive; several different serologic tests are available including the Sabin-Feldman dye test, indirect fluorescent antibody test, and ELISA. Acute acquired toxoplasmosis is generally self-limited in the immunologically intact host and does not require specific therapy. Significant involvement of the eye or viscera is an indication for treatment with pyrimethamine plus sulfadiazine. Infection in immunocompromised hosts usually reflects reactivation of latent infection rather than acute acquired infection. Clinical manifestations are protean and often severe, the most common being encephalitis, pneumonitis, and myocarditis. Treatment with combination antimicrobial therapy is necessary.

Granulomatous Disease

Disseminated tuberculosis, histoplasmosis, and sarcoidosis may be associated with generalized lymphadenopathy, although involvement of certain lymph node chains can predominate. Lymph node biopsy shows granulomas or nonspecific hyperplasia.

Regional Lymphadenopathy Pyogenic Infection

S. aureus and group A streptococcal infections produce acute suppurative lymphadenitis. The most frequently affected lymph nodes are submandibular, cervical, inguinal, and axillary, in that order. Involved nodes are large (>3 cm), tender, and firm or fluctuant. Pyoderma, pharyngitis, or periodontal infection may be present at the presumed primary site of infection. Patients are febrile and have leukocytosis. Fluctuant nodes should be aspirated. Otherwise, antibiotic therapy should be directed toward the most common pathogens. Penicillin G therapy is appropriate if pharyngeal or periodontal origin implicates a streptococcal or mixed anaerobic infection. Skin involvement suggests possible staphylococcal infection and is an indication for vancomycin or an oral antimicrobial with activity against MRSA (e.g., clindamycin, doxycycline, or trimethoprim-sulfamethoxazole) until susceptibilities are known. The dose and route of administration of the drug should be determined by the severity of the infection.

Tuberculosis

Scrofula, or tuberculous cervical adenitis, develops in a subacute to chronic fashion. Fever, if present, is low grade. A large mass of matted lymph nodes is palpable in the neck. In children, if *Mycobacterium tuberculosis* is the causative organism, then other sites of active infection are usually present from ongoing primary infection. In adults, extranodal disease is rare. The most common causative agent of lymphadenitis in children in the United States is *Mycobacterium avium* complex, followed by *Mycobacterium scrofulaceum*. Surgical excision is the treatment of choice and usually does not require chemotherapy.

Cat-Scratch Disease

Chronic regional lymphadenopathy after exposure to a cat scratch, lick, or bite should suggest the diagnosis. About 1

week after contact with the cat, a local papule or pustule may develop. One week later, regional adenopathy appears, usually of the head, neck, or upper extremity. Lymph nodes may be tender (sometimes exquisitely so) or just enlarged (1 to 7 cm). Fever is low grade if present at all. Lymph node enlargement usually persists for several months. The diagnosis can usually be established on clinical grounds. Lymph node biopsy shows necrotic granulomas with giant cells and stellate abscesses surrounded by epithelial cells. Pleomorphic gram-negative bacilli of *Bartonella henselae* can be identified in the lymph node biopsy specimens by a Warthin-Starry stain during the first 4 weeks of illness. Serologic testing can confirm the diagnosis. The course is usually self-limited and benign in immunocompetent individuals even without antimicrobial therapy but may be life threatening in persons with severe immunodeficiency. The best approach to the treatment of cat-scratch disease in the immunocompromised patient is not known, but erythromycin, azithromycin, or doxycycline may be helpful.

Ulceroglandular Fever

Tularemia is the classic cause of ulceroglandular fever. The syndrome is acquired by contact with tissues or fluids from an infected animal (including rabbits, beavers, squirrels, or birds) or the bite of an infected tick. Patients have chills, fever, an ulcerated skin lesion at the site of inoculation, and painful regional adenopathy. When infection is acquired by contact with animals, the skin lesion is usually on the fingers or hand, and lymph node involvement is epitrochlear or axillary. In tick-borne transmission, the ulcer is on the lower extremities, perianal region, trunk, head, or neck and the adenopathy is inguinal, femoral, occipital, or cervical. Most cases are diagnosed serologically, because Gram-stained preparations are usually negative; however, the causative organism, *Francisella tularensis*, may be isolated from blood, lymph nodes, and other body fluids if supportive media are used. *F. tularensis* is hazardous to laboratory personnel, who should be notified if this organism is suspected. A fourfold rise in agglutination titer between acute and convalescent serum confirms the diagnosis. PCR techniques for rapid diagnosis have also been developed and may be more sensitive than culture. Patients should be treated with streptomycin as the drug of choice for 7 to 14 days. Quinolones, doxycycline, and chloramphenicol are alternative agents with activity against *F. tularensis*.

Oculoglandular Fever

Conjunctivitis with preauricular lymphadenopathy can occur in tularemia, cat-scratch disease, sporotrichosis, lymphogranuloma venereum infection, listeriosis, and epidemic keratoconjunctivitis caused by adenovirus.

Inguinal Lymphadenopathy

Inguinal lymphadenopathy associated with sexually transmitted diseases (see Chapter 107) may be bilateral or unilateral. In primary syphilis, enlarged nodes are discrete, firm, and nontender. Early lymphogranuloma venereum causes tender lymphadenopathy with later matting of involved nodes and sometimes fixation to overlying skin, which assumes a purplish hue. The lymphadenopathy of chancroid is most often unilateral, is very painful, and is composed of fused lymph nodes. Tender inguinal lymphadenopathy

also occurs in primary genital herpes simplex virus infection.

Plague

Bubonic plague usually causes fever, headache, and a large mat of inguinal, axillary, or cervical regional lymph nodes near the site of the infected flea bite, which go on to suppurate and drain spontaneously. Plague, caused by *Yersinia pestis*, is an important consideration in the acutely ill patient in the southwestern United States with possible exposure to fleas and rodents. If plague is suggested, then blood cultures and aspirates of the buboes should be obtained, and streptomycin therapy should be instituted. Gram-stained preparations of the aspirate reveal gram-negative coccobacilli in two thirds of patients. A Wayson stain will reveal the characteristic safety-pin appearance of *Y. pestis* with dark blue staining polar bodies. Various serologic tests also allow for a rapid specific diagnosis as soon as 5 days after the onset of illness. Both plague and tularemia are potential bioterrorism agents.

Fever of Unknown Origin

Fever of unknown origin is the term applied to febrile illnesses with temperatures exceeding 38.3°C (101°F) that are of at least 3 weeks' duration and remain undiagnosed after 3 days in the hospital or after three outpatient visits. Improvements in noninvasive diagnostic testing have resulted in newly proposed categories of FVO (Table 95-5). They include (1) classic FVO, for which the common causes are infections, malignancy, rheumatologic or connective tissue diseases, and drug fever; (2) nosocomial FVO; (3) neutropenic (<500 neutrophils/mm³) FVO; and (4) HIV-associated FVO (see later discussion). The evaluation of FVO remains among the

Table 95-5 Fever of Unknown Origin—Definitions

Classic FVO

Fever $\geq 38.3^{\circ}\text{C}$ (101°F) on multiple occasions
Duration ≤ 3 weeks
Uncertain diagnosis after investigations (3 hospital days or 3 outpatient visits)

Nosocomial FVO

Fever $\geq 38.3^{\circ}\text{C}$ (101°F) on multiple occasions in hospitalized patient
Infection not incubating on admission
Uncertain diagnosis after 3-day evaluation, including 2-day microbiologic culture incubation

Neutropenic FVO

Fever $\geq 38.3^{\circ}\text{C}$ (101°F) on multiple occasions
Absolute neutrophil count < 500 cells/mm³
Uncertain diagnosis after 3-day evaluation, including 2-day microbiologic culture incubation

HIV-Associated FVO

Fever $\geq 38.3^{\circ}\text{C}$ (101°F) on multiple occasions
Confirmed diagnosis of HIV infection
Fever 1 month (outpatients) or > 3 days (inpatients)
Uncertain diagnosis after 3-day evaluation, including 2-day microbiologic culture incubation

FVO, fever of undetermined origin; HIV, human immunodeficiency virus.

most challenging problems facing the physician. Many illnesses that cause FUO are treatable, making the pursuit of the diagnosis particularly rewarding. No substitute for a meticulous history taking and physical examination exists; both should be repeated frequently during both the patient's hospital course and outpatient visits because recurrent questioning of the patient may reveal an important historical clue, and important physical findings may develop after the initial evaluation. These clues may direct the next series of diagnostic studies. Patients with FUO should always be offered HIV testing. Directed biopsy specimens of lesions should be stained and cultured for pathogenic microbes. In many instances, however, localizing clues are not present or fail to yield rewarding information. In these patients, bone marrow biopsy can reveal granulomatous or neoplastic disease, even in the absence of clinical evidence of bone marrow involvement. Similarly, liver biopsy may also reveal the cause of FUO but seldom in the absence of any clinical or laboratory evidence of liver disease. Exploratory laparotomy is rarely needed for diagnosis of FUO, as most anatomic abnormalities are able to be detected by computed tomography (CT) when used in combination with symptoms, signs, and laboratory abnormalities suggestive of an abdominal source of FUO. If tuberculosis remains a reasonable possibility after careful workup fails to establish a diagnosis, then an empiric trial of antituberculous therapy may be initiated while one awaits results of bone marrow, liver, and urine cultures.

Table 95-6 indicates the final diagnoses in a study of over 100 patients with FUO observed in the decade from 1970 to 1980. More recent studies have shown decreases over time in infections and malignancies as the causes of FUO, with increases in rheumatologic and connective tissue diseases and undiagnosed fevers. In general, infections and connec-

tive tissue diseases currently each cause approximately 15% to 25% of FUO cases, with malignancy usually causing less than 20% of cases. Undiagnosed FUO cases vary widely among studies; however, patients who remained undiagnosed after a thorough evaluation have an overall good prognosis. Table 95-6 emphasizes the range of diagnostic possibilities to be considered. Numbers of patients in each category are not presented because regional and temporal variations in the frequency of specific diagnoses are great.

CAUSES OF FEVERS OF UNKNOWN ORIGIN

Infections

Abscesses account for approximately one quarter to one third of infectious causes of FUO. Most of these abscesses are intra-abdominal or pelvic in origin because abscesses elsewhere (e.g., lung, brain, superficial abscesses) are more readily identifiable radiographically or as a result of the signs or symptoms they produce.

Intra-abdominal abscesses generally occur as a complication of surgery or leakage of visceral contents, as might occur with the perforation of a colonic diverticulum or appendicitis. Surprisingly, large abdominal abscesses may be present with few localizing symptoms. This development is especially true in the older or immunocompromised patient. Abscesses of the liver (see Chapter 102) occur most often as a consequence of inflammatory disease of the biliary tract or of the bowel; in the latter instance, bacteria reach the liver through portal blood flow. Liver abscesses can also be amebic in cause, especially in a traveler returning from an endemic area. Occasionally, blunt trauma predisposes the liver or spleen to abscesses, but splenic abscesses are often hematogenous in origin. Hepatic, splenic, or subdiaphragmatic abscesses are generally readily detected by ultrasonography or a CT scan. However, diagnosis of intra-abdominal abscess may be challenging because even large abscesses in the pericolic spaces may be difficult to distinguish from fluid-filled loops of bowel on CT. Gallium or tagged white blood cell scanning, ultrasonography, or barium enemas may assist if the diagnosis is probable and a CT scan is not definitive.

Endovascular infections (IE, mycotic aneurysms, and infected atherosclerotic plaques) are uncommon causes of FUO because blood cultures are generally positive unless the patient has received antibiotics within the preceding 2 weeks. Infections of intravascular catheter sites are generally also associated with bacteremia unless the infection is limited to the insertion site. Diagnosis of endovascular infection is more difficult to make when blood cultures are negative because of infection with slow-growing or fastidious organisms, such as *Brucella* species, *C. burnetii* (Q fever), *Bartonella* species, or *Haemophilus* species. Diagnosis is especially difficult among patients who have been treated with antimicrobial agents. If endocarditis is suggested, then blood cultures should be repeated for at least 1 week after antimicrobial agents have been discontinued, the bacteriologic laboratory should be alerted to the possibility of infection with a fastidious organism, and evidence of valvular vegetations should be sought by transesophageal echocardiography (see Chapter 100). Occasionally, the suggestion of valvular infection is strong enough to warrant empiric antibiotic treatment of a presumed culture-negative endocarditis.

Data from Larson EB, Featherstone HJ, Petersdorf RG: Fever of undetermined origin: Diagnosis and follow-up of 105 cases, 1970-1980. *Medicine* 61:269-292, 1982.

Although most patients with osteomyelitis have pain at the site of infection, localizing symptoms are occasionally absent and patients have only fever. Technetium pyrophosphate bone scans and gallium scans demonstrate uptake at sites of osteomyelitis, but positive scans are not always specific for infection. Magnetic resonance imaging can be especially useful in differentiating between bone and soft tissue infections (see Chapter 101).

Mycobacterial infections, most frequently with *M. tuberculosis*, remain important causes of FOU. Patients with impaired cell-mediated immunity are at particular risk for disseminated tuberculosis, and occult infection with this organism is seen with particular frequency among older patients, AIDS patients, patients after organ transplantation, and those undergoing hemodialysis. Fever may be the only sign of this infection. Among both immunocompromised patients and previously healthy persons with disseminated tuberculosis, purified protein derivative skin test results are often negative. In some patients, careful review of chest radiographs reveals apical calcifications or upper lobe scars suggestive of remote tuberculous infection. A diffuse, often subtle radiographic pattern of *millet seed* densities, which is best visualized on the lateral chest views, is highly suggestive of disseminated tuberculosis. In this setting, transbronchial or open lung biopsy will establish the diagnosis, as sputum cultures may be positive in only 25%. Similar radiographic patterns may be seen in sarcoidosis, disseminated fungal infection (e.g., histoplasmosis), and some malignancies. Bone marrow or liver biopsy often reveals granulomas, and cultures of these samples are positive in 50% to 90% of patients with disseminated tuberculosis.

Viral infections, especially those caused by CMV or EBV, can produce prolonged fevers. Both infections may be seen in young, healthy adults. Recipients of blood are at risk for acute post-transfusion CMV infection. Recipients of solid organ or hematopoietic stem cell transplantation and other immunosuppressed patients may experience reactivation of latent CMV infection producing fever, leukopenia, and pulmonary and hepatic disease. Lymph nodes are often enlarged in EBV infection, and a peripheral blood smear usually reveals lymphocytosis with increased numbers of atypical lymphocytes. Occasionally, the atypical lymphocytosis is delayed several weeks after the onset of fever. A positive Monospot test result may clarify the diagnosis. Unexplained fever may be a complication of infection with HIV; most such fevers are attributable to concomitant opportunistic infections (see Chapter 108).

Simple lower urinary tract infections are readily diagnosed by symptoms and urinalysis. Complicated infections such as perinephric, renal, or prostatic abscess may be occult and result in FOU. In general, a history of antecedent urinary tract infection or disorder of the urinary tract is present. In prostatic abscess the prostate is usually tender on rectal examination. In suggested cases of perinephric, renal, or prostatic abscesses, the urinalysis should be repeated if it is initially normal because abnormalities of the sediment may be intermittent. Ultrasonography or a CT scan detects most of these lesions (see Chapter 105).

Although most patients with sinusitis have localizing symptoms, infections of the paranasal sinuses may occasionally exhibit fever only, particularly among hospitalized patients who have had nasotracheal and/or nasogastric intu-

bation. Sinus films reveal fluid in the sinuses. Infection of the sphenoidal sinus may be difficult to detect unless special views or CT scans are obtained.

Neoplastic Diseases

Neoplasms account for less than 20% of FUOs. Some tumors, particularly those of hematologic origin and hypernephromas, release endogenous pyrogens. In others, the mechanism of fever is less clear but it may result from pyrogen release by infiltrating or surrounding inflammatory cells. Lymphomas can cause FOU; usually enlargement of lymph nodes or the spleen is found. The presentation of some lymphomas is with intra-abdominal disease only. CT scans may be helpful in detecting these tumors. Leukemia may also cause FOU, sometimes with a normal peripheral blood smear. Bone marrow examination reveals an increased number of blast forms. Solid tumors more typically associated with fevers include renal cell carcinoma, atrial myxoma, sarcoma, primary hepatocellular carcinoma, and tumor metastatic to the liver. Liver function abnormalities (predominantly alkaline phosphatase) are common in all these tumors except in atrial myxoma. Myxoma can be suggested in the presence of heart murmur and multisystem embolization (mimicking endocarditis) and is readily diagnosed by echocardiogram. Radiographic studies of the abdomen and retroperitoneum (CT or ultrasonography) generally detect the other tumors. Colon carcinoma must also be considered in the differential diagnosis, because one third or more of patients with this diagnosis may have low-grade fever; in some this is the only sign of disease.

Other Causes

Collagen vascular diseases account for approximately one quarter of FUOs, and this proportion has increased over time. Systemic lupus erythematosus is readily diagnosed clinically and serologically and thus accounts for a small proportion of patients with FOU. Vasculitis remains an important cause of FOU and should be suggested in febrile patients with embolization, infarctions, or multisystem disease. Giant cell arteritis should be considered in older patients with FOU, particularly in the presence of polymyalgia rheumatica symptoms (see Chapter 86). Systemic onset juvenile rheumatoid arthritis, or Still disease, can cause FOU with joint symptoms. An evanescent rash, sore throat, adenopathy, and leukocytosis may occur in this disorder, which is diagnosed on the basis of clinical criteria in the absence of other potential causes of fever.

Granulomatous diseases without a defined cause have been associated with FOU. Sarcoidosis often involves the lungs, skin, and lymph nodes. The majority of patients are anergic to skin test antigens. Diagnosis is based on the exclusion of an infectious cause and the demonstration of discrete, noncaseating granulomas on biopsy of bone marrow, liver, lung, or other tissues. Granulomatous hepatitis can exhibit prolonged fevers, occasionally lasting for years. Serum alkaline phosphatase levels are generally elevated; liver biopsy reveals granulomas, and no underlying cause can be demonstrated.

A number of miscellaneous disorders, including inflammatory bowel disease, hereditary periodic fever syndromes, hematoma, hyperthyroidism and other endocrinologic causes, disordered heat homeostasis, and

hypertriglyceridemia make up the remainder of diagnosed FUO cases. Hereditary periodic fever syndromes include familial Mediterranean fever (FMF), TNF receptor-1 associated periodic syndrome (TRAPS), and hyper-IgD syndrome, as well as others. In the appropriate setting, drug-related fevers always demand consideration in the differential diagnosis. Fever may occur without other evidence of drug sensitivity such as rash or eosinophilia in more than 75% of cases. The fever may develop weeks to months after initiation of the drug. Although relatively more common with anticonvulsants (phenytoin and carbamazepine), antimicrobials (sulfonamides, penicillins, nitrofurantoin, and vancomycin), and antihypertensives (hydralazine and methyldopa), fever may occasionally result from any class of drug. A variable number of FUOs (10% to more than 50% in various studies) remains undiagnosed after careful evaluation. Most of these patients have experienced an indefinable but self-limited illness, with fewer than 10% developing an underlying serious disorder after several years of follow-up.

FEVER OF UNKNOWN ORIGIN IN SPECIAL GROUPS

Besides patients with *classic* FUO, several other groups of patients with fever in whom the diagnosis is not readily apparent deserve special attention. These special groups are encountered more frequently in clinical practice and include patients with nosocomial FUO (see Table 95-6).

Nosocomial Fever of Unknown Origin

Most patients with nosocomial FUO have significant underlying comorbidities that lead to hospitalization and complex treatment. The hospital environment, invasive procedures, foreign devices, antibiotic resistance, and alteration of host defenses by diseases or therapy set the stage for potentially unique infectious complications. Bacterial and fungal infections of the urinary tract, surgical wounds, respiratory tract, sinuses, bloodstream, and vascular catheter sites are significant concerns. A frequent cause of nosocomial FUO is *Clostridium difficile*-associated colitis, especially if diarrhea is minimal or absent. This disease is more often encountered in older patients, and a clue to the diagnosis can be an unexplained leukocytosis. Nosocomial FUO in the intensive care unit presents a unique challenge. Disorders to consider in this situation include cholesterol emboli syndrome or CMV postperfusion syndrome after open-heart surgery, nosocomial sinusitis related to nasotracheal or nasogastric intubation, intra-abdominal or pelvic abscess, invasive fungal infection (especially in patients on prolonged steroids), and nosocomial pneumonia. Patients with CMV postperfusion syndrome exhibit a mononucleosis-like syndrome several weeks after open-heart surgery. The risk of developing the condition is directly related to the number of blood units transfused during the procedure, and the diagnosis must be differentiated from Dressler syndrome, which is an autoimmune condition and more likely to occur 2 weeks after the procedure. Other causes of nosocomial FUO that are noninfectious in origin can be loosely divided into those in which the temperature exceeds 102°F and those in which the temperature is less than 102°F. Possible causes of nosocomial FUO with temperatures less than 102°F include tissue injury or infarction, thromboembolic disease, gastrointesti-

nal hemorrhage, and acute pancreatitis. Noninfectious conditions associated with temperatures greater than 102°F include adrenal insufficiency and drug fever. Temperatures greater than 106°F are rarely from infectious causes. The most common causes of high fevers of this nature are neuroleptic malignant syndrome, malignant hyperthermia, disordered heat homeostasis caused by central nervous system trauma, and drug fevers. Most drug fevers are caused by common medications; consequently, a close review of a patient's active medication list is essential to make the diagnosis.

Immune-Deficient Fever of Unknown Origin

Patients who are immunosuppressed have a higher likelihood of infectious complications. Neutropenic FUO is undiagnosed fever in the context of persistent and severe neutropenia. In general, most patients in this category will have received cytotoxic and/or immunosuppressive therapy for their underlying disease. Regardless of the cause, complicating infections are frequently encountered when the absolute neutrophil count (mature neutrophils and bands) falls below 1000 cells/mm³ (and especially below 500 cells/mm³). Occult bacterial infections are the most frequent causes of fever, and deterioration may be rapid; empiric broad-spectrum antibiotics are mandated in patients with febrile neutropenia after appropriate cultures are obtained. If the cultures are negative and the patient remains febrile, then the patient is considered to have neutropenic FUO.

In patients with impaired cell-mediated immunity, FUO caused by agents other than bacteria is being increasingly recognized. Populations of patients who are receiving chronic steroids or who are using immunomodulatory agents to control underlying disease processes are growing. In these patients, occult fungal infections and reactivation of viral or mycobacterial diseases need to be considered when unexplained febrile episodes develop. For example, opportunistic infections in patients receiving anticytokine therapy such as TNF inhibitors for rheumatologic conditions and inflammatory bowel disease are being increasingly recognized, particularly mycobacterial infections such as tuberculosis. Other etiologic considerations in these patients should also always include perirectal or periodontal disease, drug-induced fever, relapse of underlying disease (especially hematologic malignancy), and thromboembolic conditions.

HIV-Associated Fever of Undetermined Origin

Fever is one of the most common symptoms in patients infected with HIV. With advanced HIV disease, more frequent causes of FUO include mycobacterial disease (especially disseminated *M. avium* complex), CMV (retinitis or colitis) infection, drug reactions, and bacterial line infections (see Chapter 108).

Factitious or Self-Induced Fever

Patients with factitious or self-induced illness present unique ethical and therapeutic problems. Once the possibility of

factitious or self-induced illness is considered, the physician-patient relationship is changed. Typically the physician can rely on the good faith of the patient's history. In the case of factitious or self-induced illness, the physician must assume a more detached role to establish the diagnosis. Patients with factitious fever are typically young and often women. Many have been or are employed in health-related professions. Usually articulate and well educated, these patients are adept at manipulating their family, friends, and physicians. In these instances a consultant new to the patient may provide a detached and helpful perspective on the problem.

Clues to factitious fever include the absence of a toxic appearance despite high temperature readings, lack of an appropriate rise in pulse rate with fever, and absence of the physiologic diurnal variation in temperature. Suggested factitious readings can be evaluated by immediately repeating the reading with the nurse or physician in attendance. The use of electronic thermometers allows rapid and accurate recording of a patient's temperature (see also Chapter 118).

Self-injection of pyrogen-containing substances, usually bacteria-laden culture medium, urine, or feces, can produce bacteremia and high fever; usually these bacteremic episodes

are polymicrobial and intermittent, often suggesting a diagnosis of intra-abdominal abscess. However, patients with self-induced bacteremia may appear remarkably well between episodes of fever. The occurrence of polymicrobial bacteremia in an otherwise healthy person should suggest the possibility of self-induced infection. Illicit ingestion of medications known by the patient to produce fever can also present a difficult diagnostic problem. Clues to the presence of self-induced illness are subtle. The patients are often emotionally immature. Some fabricate unrelated aspects of their history. The most extreme form of factitious or self-induced illness is called the Munchausen syndrome. Some patients are surprisingly stoic about the apparent seriousness of their illness and the procedures used to diagnose or treat them. In some instances, interviewing family members can elicit clues to the possibility of factitious or self-induced illness. Confirming the diagnosis is crucial and, in many instances, requires a search of the patient's hospital room. Although most will deny their role in inducing or feigning illness, the diagnosis must be explained, and psychiatric care is essential. These complicated patients are at risk for inducing life-threatening disease; some respond to psychiatric counseling.

Prospectus for the Future

Advances in medical technology will allow for faster and more accurate diagnosis and treatment of febrile syndromes. For example, new and sophisticated radiographic imaging techniques will provide more detailed identification of internal abnormalities. Highly specific molecular techniques, such as immunohistochemistry, in situ hybridization, and nucleic acid amplification will improve the ability to diagnose infectious causes of fever and FUO. In addition, the sequencing of human and microbial genomes and advances in functional genomics will significantly affect the development of new vaccines and therapies for pathogens associated with febrile syndromes.

Nevertheless, medical progress will also change the spectrum of febrile syndromes and FUO. For example, it is likely that the increased numbers and types of compromised hosts created by the expansion of transplantation programs and new immunosuppressive medications will add significant challenges for the diagnosis and management of febrile syndromes. In addition, the creation of new organisms by chance or through bioterrorism and the spread of old organisms to new parts of the world through increased global communication will shape the evolution of this area of medicine.

Bacteremia and Sepsis Syndrome

Richard R. Watkins and Robert A. Salata

Sepsis syndrome is a leading cause of morbidity and mortality in hospitalized patients. There is a growing understanding of the pathophysiology of sepsis and recognition of the critical interdependence of the inflammatory and coagulation systems. Novel therapeutic approaches now being used and tested in sepsis syndrome are a direct result of the elucidation of the molecular mechanisms of sepsis and the practical applications of modern techniques of biochemistry and molecular biology to rational drug design.

The bases for current definitions of sepsis syndrome and related disorders are presented in Table 96-1 and Figure 96-1. Infection, defined by the presence of microbial pathogens in normally sterile sites, can be symptomatic or inapparent. Bloodstream infection (BSI) implies the presence of organisms that can be cultured from blood. Septicemia implies BSI with greater severity. Sepsis indicates clinical settings in which evidence of infection and a systemic response to infection exist (fever or hypothermia, tachycardia, tachypnea, leukocytosis or leukopenia). Sepsis syndrome emphasizes an even greater degree of severity, with evidence of altered organ perfusion with one of the following: hypoxemia, oliguria, altered mentation, or elevated serum lactate level. Severe sepsis represents a more advanced degree of organ dysfunction and is often associated with multi-organ failure. Septic shock indicates sepsis plus hypotension despite adequate intravenous fluid challenge. Refractory septic shock is defined as shock lasting more than 1 hour that is unresponsive to fluids and/or vasopressors. Noninfectious insults (e.g., thermal burns, severe trauma, severe pancreatitis, pulmonary contusion, certain toxins, therapy with monoclonal antibodies for solid organ transplant rejection) can also be associated with a severe systemic reaction simulating sepsis syndrome. The term *systemic inflammatory response syndrome* (SIRS) encompasses both infectious and noninfectious causes of a profound host inflammatory response with systemic symptoms and signs; sepsis syndrome is the predominant cause of SIRS.

Epidemiologic Factors

The incidence of sepsis and associated deaths has increased dramatically in the United States, and evidence suggests that this rise will continue. Septic shock is the most common cause of death in intensive care units and the thirteenth most common cause of death in the United States. More than 750,000 cases of sepsis occur in the United States each year, resulting in approximately 200,000 fatalities.

Historically, gram-negative organisms caused most cases of sepsis and septic shock. However, the National Nosocomial Infection Surveillance System indicates significant increases in the frequency of septicemia caused by gram-positive infections since 1985. Highest rates for hospital-acquired septicemias occur in patients with cancer and burn or trauma victims, as well as in high-risk nurseries. Hospital-acquired BSI is associated with 7.4 extra days of hospitalization and \$4000 of extra hospital charges per occurrence. The most commonly identified bloodstream pathogens include staphylococci, streptococci, *Escherichia coli*, *Enterobacter* species, and *Pseudomonas aeruginosa*. Fungal bloodstream isolates are found less frequently, but their incidence increased over the last decade. In particular, fungemia from non-*albicans* *Candida*, with increasing resistance to azoles, has become more frequent, which has important implications for empiric antimicrobial therapy.

Major epidemiologic factors that have contributed to the increased occurrence of sepsis include the growing number of immunocompromised hosts resulting from more intense chemotherapy regimens, an aging population, and the aggressive employment of increasingly invasive procedures and complex surgery. The incidence of sepsis is greatest in the winter, suggesting an associated respiratory cause. Mortality varies among ethnic groups with African American men at highest risk. Also, age-adjusted sepsis mortality rates are highest at the extremes of age.

Table 96-2 lists organisms important in sepsis syndrome as they relate to host factors. Factors that have negatively

Table 96-1 Definitions of Sepsis and Related Disorders

Disorder	Definition
Infection	Microorganisms in a normally sterile site; subclinical or symptomatic
Bacteremia	Bacteria present in bloodstream; may be transient
Septicemia	Same as bacteremia but greater severity
Sepsis	Clinical evidence of infection plus systemic response to infection
Sepsis syndrome	Sepsis plus altered organ perfusion (hypoxemia, oliguria, altered mentation)
Severe sepsis	Sepsis syndrome plus hypotension and hypoperfusion
Septic shock	Sepsis with hypotension despite adequate fluid resuscitation; patients on vasopressors may not be hypotensive at the time hypoperfusion abnormalities are evident
Refractory septic shock	Shock lasting more than 1 hr that is unresponsive to fluid administration and/or vasopressors
Systemic inflammatory response syndrome (SIRS)	Wide variety of insults (infectious response syndrome and noninfectious) that initiate profound systemic responses; sepsis syndrome is a subset of SIRS Current definition includes two or more of the following: temperature $>38^{\circ}\text{C}$ or $\leq 36^{\circ}\text{C}$; tachycardia >90 beats/minute; respiratory rate >20 breaths/minute; $\text{Paco}_2 \leq 32$; white blood cell (WBC) count $>12,000$ cells/ mm^3 or <4000 cells/ mm^3 , or $>10\%$ bands

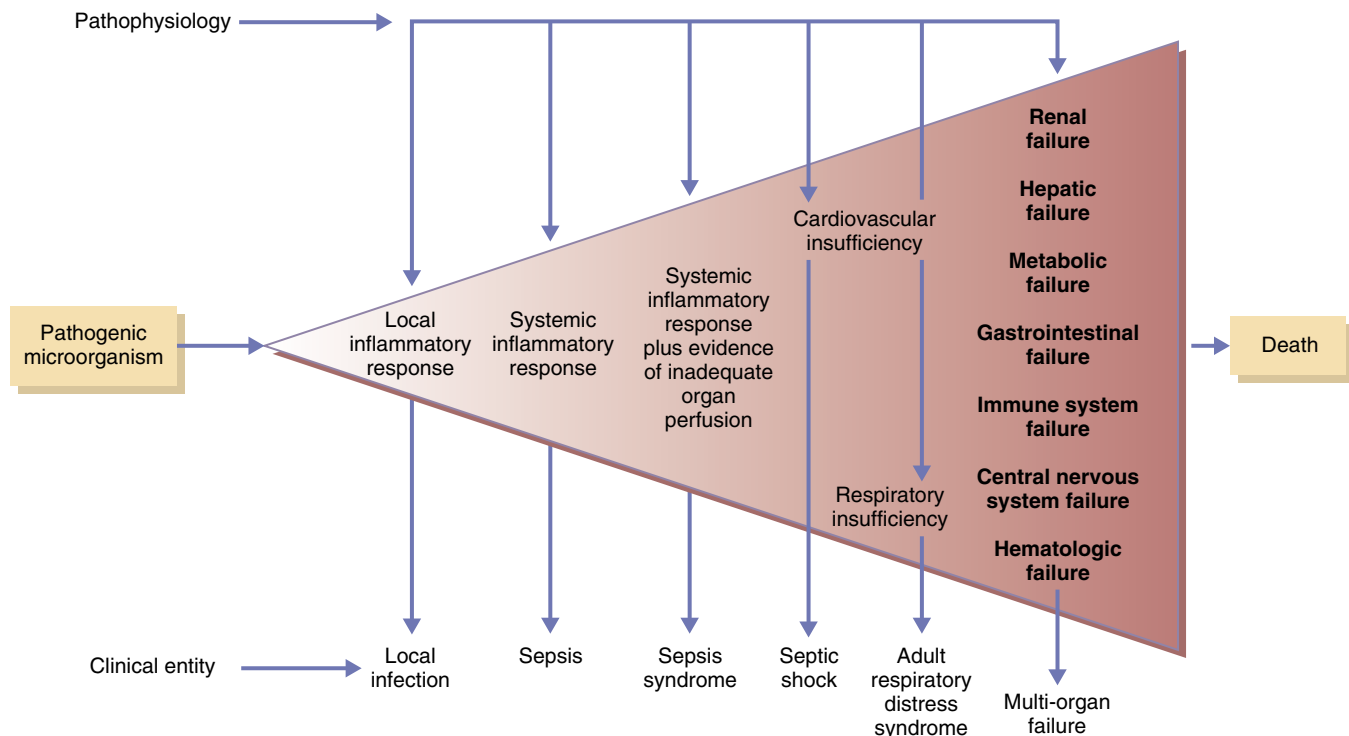

Figure 96-1 Natural history of the sepsis process.

influenced survival in the setting of BSI have included severity of underlying disease, delayed initiation of appropriate antimicrobial therapy, virulence of the pathogen (e.g., *P. aeruginosa*), extremes of age, site of infection (respiratory being more common than abdominal, which is more common than urinary), health care–associated infection, polymicrobial infection, and development of end-organ complications (acute respiratory distress syndrome, acute renal failure, disseminated intravascular coagulation [DIC], bowel ischemia or infarction, and coma). When evidence of dysfunction of two or more systems exists, the diagnosis of multi-organ system failure can be made. Mortality rises in proportion to the number of organ systems involved and is near 100% when four or more systems are dysfunctional.

Pathogenesis

The pathogenesis of sepsis is shaped largely by the infected host's complex response to the invading pathogen (Fig. 96-2). Sepsis with organ dysfunction occurs primarily when the host's responses to infection are inadequate. Gram-negative bacterial lipopolysaccharide (LPS), or endotoxin, is representative of a larger class of microbial products causally linked to septic shock syndrome. Cell wall products of gram-positive bacteria, such as teichoic acid and peptidoglycan, induce inflammatory responses similar to those produced by LPS. Sepsis syndrome may complicate infections with bacteria, viruses, fungi, rickettsiae, mycobacteria, and parasites. The pathogenesis of shock involves a series of

events initiated by the invading pathogen or its products, and shock is produced through a causally related sequence of host responses.

The sepsis cascade begins when a pathogenic microorganism penetrates a host barrier. Local host defense cells

(macrophages, mast cells, dendritic cells) detect molecules on the invader's cell wall by means of pattern-recognition receptors such as CD14 and toll-like receptors (TLRs). For example, TLR-2 recognizes the peptidoglycan of gram-positive bacteria, TLR-4 recognizes an LPS of gram-negative bacteria, and both TLR-2 and TLR-4 recognize the cell wall of *Aspergillus*. Binding of TLRs to epitopes on the microorganisms stimulates intracellular signaling and leads to the production of cytokines and inflammatory molecules such as tumor necrosis factor (TNF)- α and interleukin (IL)-1 β . These molecules in turn activate neutrophils and endothelial cells, which results not only in killing of microorganisms but also damaging of endothelium by release of mediators that increase vascular permeability. Edema fluid then flows into the lungs and other organs, causing acute organ injury. Activated endothelial cells also release nitric oxide, a potent vasodilator.

Microorganisms stimulate adaptive immune responses in the course of sepsis. B cells release immunoglobulins that bind the microorganisms and promote their delivery by antigen-presenting cells to natural killer cells and neutrophils. Type 1 helper T cells (Th1 cells) secrete proinflammatory cytokines, whereas type 2 helper T cells (Th2 cells) release anti-inflammatory cytokines such as IL-4 and IL-10, depending on the infecting organism and other complex cell-cell interactions (Table 96-3).

Systemic inflammation influences activity of the coagulation system by directly and indirectly modulating production of procoagulant and anticoagulant molecules. In response to proinflammatory cytokines, tissue factor released by endothelium and associated thrombin formation, respectively, activate the extrinsic and intrinsic pathways of coagulation. Simultaneous depletion of endogenous anticoagulant molecules occurs, including proteins C and S, tissue factor pathway inhibitor, and antithrombin III, as well as

Table 96-2 Microorganisms Involved in Sepsis Syndrome in Relation to Host Factors	
Host Factors	Organisms of Particular Importance
Asplenia	Encapsulated organisms: <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Neisseria meningitidis</i> , <i>Capnocytophaga canimorsus</i>
Cirrhosis	<i>Vibrio</i> , <i>Yersinia</i> , and <i>Salmonella</i> species, other gram-negative rods, encapsulated organisms
Alcoholism	<i>Klebsiella</i> species, <i>Streptococcus pneumoniae</i>
Diabetes	Mucormycosis, <i>Pseudomonas</i> species, <i>Escherichia coli</i>
Steroids	Tuberculosis, fungi, herpesviruses
Neutropenia	Enteric gram-negative rods, <i>Pseudomonas</i> , <i>Aspergillus</i> , <i>Candida</i> , <i>Mucor</i> species, <i>Staphylococcus aureus</i> , <i>Streptococcal</i> species
T-cell dysfunction	<i>Listeria</i> , <i>Salmonella</i> , and <i>Mycobacterium</i> species, herpesvirus group (herpes simplex virus, cytomegalovirus, varicella-zoster virus)
AIDS	<i>Salmonella</i> , <i>Staphylococcus aureus</i> (including MRSA), <i>Mycobacterium avium</i> complex

MRSA, methicillin-resistant *Staphylococcus aureus*.

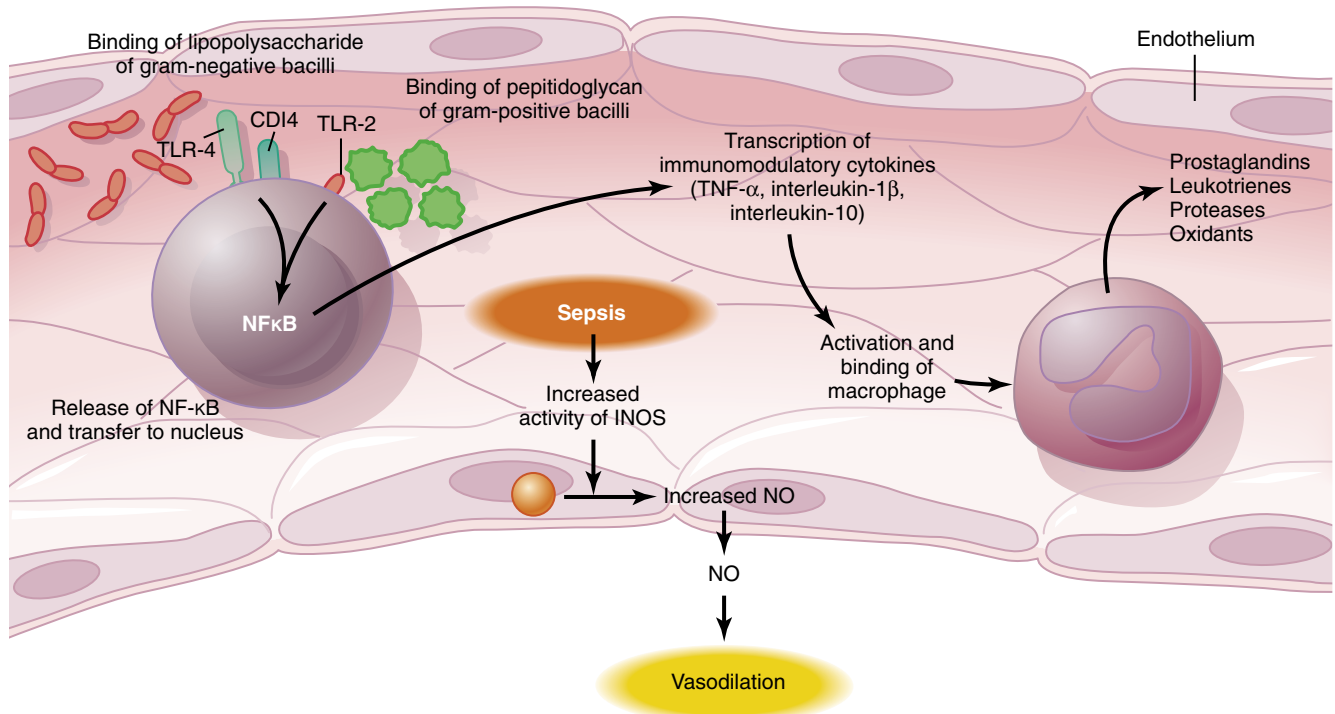

Figure 96-2 Inflammatory response to sepsis.

Table 96-3 Cytokines with a Potential Role in Systemic Inflammatory Response Syndrome

Cytokine	Source	Target Cell	Function
Granulocyte-macrophage colony-stimulating factor (GM-CSF)	T cells, macrophages, endothelial cells, fibroblasts	Myeloid precursor cells, neutrophils, eosinophils, macrophages	Proliferation of progenitor cells Differentiation and maturation of neutrophils and macrophages
Granulocyte colony-stimulating factor (G-CSF)	Monocytes, endothelial cells, fibroblasts, neutrophils	Neutrophils, promyelocytes	Proliferation of myeloid progenitor cells Enhanced neutrophil survival and function
IL-1 (α and β)	Macrophages, fibroblasts, T cells, endothelial cells, hepatocytes	Fibroblasts, T cells, monocytes, neutrophils	Induces cytokines (IL-2, IL-3, IL-6, TNF); induces B- and T-cell activation, growth, and differentiation Synthesis of acute phase reaction; induces fever, catabolism
IL-2	Activated T cells	Activated lymphoid cells	Enhances T- and B-cell immune responses Promotes cytotoxic T cells Induces IFN- γ and TNF
IL-4	Th2 T cells	B and T cells, macrophages, mast cells	Induces B-cell activation, proliferation, and differentiation and IgG ₁ and IgE production Enhances MHC class I and II receptors
IL-6	Macrophages, fibroblasts, Th2 T cells	Lymphocytes, monocytes	Stimulates B-cell growth, differentiation, and activation Induces synthesis of acute phase reactants
IL-8	Monocytes, fibroblasts, endothelial cells	Neutrophils, monocytes	Enhanced neutrophil activity and histamine release
IL-12	Macrophages, B cells	T cells	Induces differentiation of Th1 cells Initiates production of IFN- α
IFN- γ	T cells	Macrophages, monocytes, T and B cells	Pronounced monocyte and macrophage activation Increased MHC class II expression
TNF- α (cachectin), TNF- β (lymphotoxin)	Monocytes, macrophages, lymphocytes, mast cells	Monocytes, macrophages, lymphocytes, neutrophils, fibroblasts	Induces cascade of inflammatory reactions (fever, catabolism, acute phase reactants) Induces multiple cytokines (IL-1, GM-CSF) Increases MHC class I expression Enhances B-cell proliferation and immunoglobulin production

IFN, interferon; IgE, immunoglobulin E; IgG₁, immunoglobulin G₁; IL, interleukin; MHC, major histocompatibility complex; TNF, tumor necrosis factor.

inhibition of fibrinolysis via increases in plasminogen activator inhibitor and thrombin-activatable fibrinolysis inhibitor. Endotoxin stimulates membrane phospholipid metabolism, leading to the generation of platelet-activating factor and other bioactive metabolites of arachidonic acid, including prostaglandins and leukotrienes. These compounds, in turn, exert a variety of synergistic and antagonistic effects on vascular endothelium, smooth muscle, platelets, and leukocytes. The resultant exaggerated procoagulant state leads to microvascular thrombosis (often in association with DIC) and tissue ischemia and may ultimately cause multiple organ failure. These proinflammatory and procoagulant responses are amplified by secondary ischemia and hypoxia through the release of plasminogen-activator inhibitor 1. Proinflammatory cytokines can also lead to host immunosuppression by causing apoptosis of circulating and tissue lymphocytes.

The altered signaling pathways in sepsis eventually lead to tissue injury and multiple organ failure. It is therefore critical to interrupt the sepsis cascade early by containing and eliminating the source (e.g., through antibiotics, removal of

infected devices, and drainage of infected fluid or pus). Multiple studies have shown an association between high circulating levels of proinflammatory markers and survival.

Clinical Manifestations

The clinical manifestations of sepsis syndrome are protean and often nonspecific (Table 96-4). The clinician is faced with the challenge of early recognition and sorting through the various possible causes of SIRS so that appropriate therapy can be initiated. Patients with the clinical picture of sepsis of uncertain origin should be presumed to have BSI and treated accordingly. Prompt, thorough cultures of blood and suspicious local sites should be followed immediately by initiation of antibiotics appropriate for the most likely pathogens as well as control of the source of infection (removal of infected devices and drainage of infected collections) if at all possible.

Fever and chills are usually present, but older or debilitated patients (especially those with renal or liver failure or

Table 96-4 Signs and Symptoms Indicative of Sepsis Syndrome

Fever (core temperature >38° C)
Hypothermia (core temperature ≤36° C)
Chills
Hyperventilation (mixed venous oxygen saturation >70%)
Mental status changes
Hypotension (systolic blood pressure ≤90 mm Hg or mean arterial pressure ≤70 mm Hg)
Leukopenia (white blood cell count <4000 cells/mm ³)
Leukocytosis (white blood cell count >12,000 cells/mm ³ or >10% bands)
Thrombocytopenia (platelet count ≤100,000/mm ³)
End-organ failure: lung, kidney, liver, heart, disseminated intravascular coagulation, bowel
Hypoglycemia or hyperglycemia
Hyperlactatemia (>3 mmol/L)

those receiving systemic corticosteroids) may not develop fever. Hypothermia may occur and is associated with a poorer prognosis. One of the early clues to a systemic infectious process is the presence of hyperventilation and respiratory alkalosis.

Skin manifestations in sepsis can occur with any infectious agent and at times may represent the earliest signs of sepsis syndrome. Staphylococci and streptococci can be associated with cellulitis or diffuse erythroderma in association with toxin-producing strains. BSI with gram-negative bacteria can be associated with a skin lesion called *ecthyma gangrenosum* (round or oval 1- to 15-cm lesions with a halo of erythema and usually a vesicular or necrotic central area). Although *ecthyma gangrenosum* is most commonly associated with *P. aeruginosa*, other invaders such as *Aeromonas* organisms, *Klebsiella* organisms, *E. coli*, *Serratia* species, and fungal organisms may also cause *ecthyma gangrenosum* (see also Chapter 101). *Neisseria meningitidis* bacteremia is often heralded by petechial and hemorrhagic skin lesions and followed by rapidly progressive shock.

The sepsis syndrome is characteristically associated with hypotension and oliguria. In many patients, hypotension may initially respond to intravenous fluids. Other patients progress from an initial stage of hypotension, tachycardia, and vasodilation (warm shock) to deep pallor, vasoconstriction, and anuria (cold shock). Of all infectious causes of sepsis syndrome, gram-negative bacilli most often cause shock; up to 35% of patients with gram-negative sepsis develop shock, often with mortality rates between 40% and 70%.

As sepsis syndrome progresses, myocardial function can become profoundly depressed. This situation greatly complicates fluid management and necessitates continuous cardiopulmonary monitoring in an intensive care setting. Pulmonary complications of sepsis syndrome are frequent. Acute respiratory distress syndrome, characterized by arterial oxygen tension less than 50 mm Hg despite fractional inspired oxygen greater than 50%, diffuse alveolar infiltrates, and pulmonary capillary wedge pressure less than 18 mm Hg, occurs in 10% to 40% of patients with sepsis syndrome and is most frequently seen in conjunction with gram-negative

organisms. Increased pulmonary capillary permeability, resulting from inflammatory cytokines released during sepsis, is a major causative factor in acute respiratory distress syndrome and makes administration of intravenous fluids, often given in an attempt to improve cardiac output, extremely hazardous. Failure of respiratory muscles can also complicate sepsis and contribute significantly to morbidity and mortality.

Most patients with sepsis have a neutrophilic leukocytosis. Leukopenia may occur, most often with overwhelming bacteremias but also with severe systemic viral infections. Alcoholics and older adults are at increased risk for sepsis-associated neutropenia. A low platelet count and evidence of coagulopathy occur in up to 75% of patients with gram-negative bacillary bacteremia. DIC occurs in roughly 10% of patients with sepsis.

Renal insufficiency in sepsis syndrome is multifactorial and depends to varying degrees on the host, the microbe, and the therapy administered. Most often in sepsis, acute tubular necrosis is the basis for renal dysfunction and may be secondary to hypotension, volume depletion, or cytokines elaborated in sepsis syndrome. Acute renal failure associated with sepsis syndrome may be seen without overt hypotension. Tubulointerstitial disease caused by specific pathogens and/or antimicrobial therapy may also occur. Endocarditis may also be associated with immune complex-mediated glomerulonephritis.

Upper gastrointestinal tract bleeding may be a life-threatening complication in patients with sepsis who also have coagulopathy and thrombocytopenia. Liver dysfunction may occur with evidence of cholestatic jaundice or of hepatocellular injury. With bacteremia related to gram-negative bacilli, *hyperbilirubinemia of sepsis* often occurs, with little change in the other liver enzymes. Large increases in transaminase values usually indicate ischemia of the liver; these abnormalities usually resolve rapidly with restoration of blood pressure.

Increased serum lactate concentrations are seen in patients with severe sepsis and septic shock. Such increases occur as a consequence of increased glycolysis and pyruvate production. Impaired hepatic clearance of lactate and mitochondrial dysfunction also contribute to hyperlactatemia.

Hypoglycemia may complicate sepsis syndrome and can be a correctable cause of mental status change or seizures. Hypoglycemia occurs more frequently in individuals with underlying liver disease. Hyperglycemia may result during the body's acute metabolic response to infection, especially in diabetics or when glucose-containing intravenous fluids are given.

Diagnosis

The initial evaluation of the patient with possible sepsis syndrome ideally begins with a thorough history. However, in patients with fully developed sepsis syndrome, the working diagnosis is made on the basis of physical findings, and the detailed history must necessarily follow correction of hemodynamic problems, obtaining appropriate microbial culture samples, and empiric initiation of antimicrobial therapy. Attention should be focused on underlying diseases or predispositions to sepsis, previous infections and

antimicrobial therapy, available microbiologic information, and symptoms suggesting localization of infection. A history of travel, environmental exposure, and any contact with infectious agents should be thoroughly explored. Information on the complications of previous treatment (e.g., toxic effects of drugs or drug allergies) can be critical in the selection of therapy.

Physical examination should focus on discovering clues to infection and localizing sites thereof. Appropriate specimens for microbiologic evaluation must be obtained. Two or three sets of blood cultures from patients with bacteremia yield the organism in 89% and 99% of patients, respectively.

The selection of additional laboratory studies should be based on the clinical manifestations. Patients with diarrhea should have a stool sample sent for a cytotoxic assay against *Clostridium difficile* toxins A and B. Obtaining appropriate diagnostic studies expeditiously is critical. These studies are usually aimed at delineating the focus of infection (e.g., cerebrospinal fluid examination, computed tomography scans) and determining whether adjunctive surgical therapy (e.g., abscess drainage, foreign body removal) is indicated. Patients whose condition is too unstable for transport to the radiology department may benefit from ultrasonography at the bedside.

Therapy

The key to managing sepsis is the early recognition of the systemic response and initiation of therapy before hypotension and complications ensue (Table 96-5). Patients with sepsis syndrome, especially if hypotensive, are best managed in the intensive care unit. The essential therapies of sepsis syndrome and septic shock include judicious fluid administration, oxygen, vasopressors, and antibiotics.

Early goal-directed therapy focused on optimal oxygen delivery to tissues is associated with improved survival. This therapy includes crystalloid fluid resuscitation, red blood cell transfusion to maintain a hematocrit of at least 30%, careful hemodynamic monitoring, and the use of inotropes in select persons. Antibiotic choices should reflect epidemiologic concerns (see Table 96-2), antibiotic resistance patterns, and potential sites of infection. Time does not allow withholding antimicrobial therapy until bacteremia or an infectious source is proved in patients with sepsis syndrome. Until culture results and other diagnostic studies are completed, empiric broad-spectrum antimicrobial therapy (covering both gram-positive and gram-negative pathogens, as well as antifungal therapy in select patients) is necessary in patients with sepsis (Table 96-6). Initiation of appropriate empiric antimicrobial therapy has a major impact on survival of these patients. As soon as a specific microbial cause has been established by culture, antibiotics should be changed, if necessary, to target the causative agent. Duration of antibiotics depends on the clinical response, infecting pathogen, and initial site of infection, with most courses lasting 7 to 14 days. Attention should also be directed to serum glucose control because maintenance of glucose at 80 to 110 mg/dL using intensive insulin therapy is associated with reduced mortality.

Table 96-5 Recommended Management of Sepsis

Start resuscitation immediately in patients with hypotension or serum lactate >4 mmol/L.
Obtain appropriate cultures before starting antibiotics, provided it does not significantly delay therapy.
Evaluate for a focus of infection amenable to source control (e.g., abscess drainage).
Remove intravascular catheters if potentially infected.
Begin broad-spectrum antibiotics within the first hour of severe sepsis and septic shock.
Fluid-resuscitate using crystalloids or colloids.
Give fluid challenges of 1L of crystalloids or 300 to 500 mL of colloids over 30 minutes.
Maintain mean arterial pressure \geq 65 mm Hg.
Use norepinephrine and dopamine centrally administered as vasopressors of choice.
Use dobutamine in patients with myocardial dysfunction.
Give red blood cells when hemoglobin decreases to <7 g/dL to a target hemoglobin of 7 to 9 g/dL.
Target a tidal volume of 6 mL/kg in patients with acute respiratory distress syndrome.
Use intravenous insulin to keep blood glucose <150 mg/dL.
Give either low-molecular-weight heparin or unfractionated heparin for deep vein thrombosis prophylaxis.
Provide stress ulcer prophylaxis using H ₂ blockers or a proton-pump inhibitor.

Data from Dellinger RP, Levy MM, Carlet JM, et al: Surviving Sepsis Campaign: International guidelines for management of severe sepsis and septic shock: 2008. *Crit Care Med.* 2008;36(1):296-327.

The limitations of currently available therapy for sepsis and septic shock are demonstrated by the continued high mortality rates associated with this disease, despite improvement in antibiotic therapy and critical care techniques. Standard approaches to therapy for sepsis and septic shock are crucial. Of the various steps in the pathogenesis of septic shock, beginning with tissue invasion by the offending organism and culminating in pathophysiologic phenomena associated with septic shock syndrome, current therapy addresses only the initial and final steps of this process (see Figs. 96-1 and 96-2). Few currently employed therapies target intermediate steps in the pathogenesis of septic shock, even though these steps dominate the disease process in fully developed sepsis syndrome. Newer strategies entail attempts to amplify selectively or modulate the host responses to the invading pathogen or its pathogenic products. Targets include the bacterium, endotoxin (or other bacterial products), host cells that respond to endotoxin, mediators produced by these cells in response to endotoxin, and cells injured by endotoxin-induced mediators (see Fig. 96-2).

Numerous studies have attempted to clarify the role of steroids in sepsis and septic shock. Recently a multicenter, randomized, double-blind, placebo-controlled trial found no improvement in survival or reversal of shock in patients who received hydrocortisone for shock or in those who did not have a response to corticotrophin. The benefit of treatment for adrenal insufficiency using corticosteroids now seems limited to patients with vasopressor-dependent septic shock. Trials targeting cytokines in sepsis have failed to demonstrate clinical efficacy. These studies have

Table 96-6 Initial Antibiotic Recommendations for Septic Patients*

Empiric coverage	Vancomycin 15 mg/kg q12h plus either piperacillin-tazobactam [†] 3.375 g IV q6h or imipenem 0.5 g IV q6h or meropenem 1.0 g IV q8h with or without an aminoglycoside (e.g., tobramycin 5 mg/kg IV q24h). [‡]
Community-acquired pneumonia	Ceftriaxone 1 g IV q24h plus azithromycin 500 mg IV q24h or a fluoroquinolone (e.g., moxifloxacin 400 mg IV q24h or levofloxacin 750 mg IV q24h). [§]
Community-acquired urosepsis	Ciprofloxacin 400 mg IV q24h or ampicillin 2 g IV q6h plus gentamicin 5 mg/kg IV q24h.
Meningitis	Vancomycin 500-750 mg IV q6h plus ceftriaxone 2 g IV q12h plus dexamethasone 0.15 mg/kg IV q6h × 2-4 days preferably before antibiotics; add ampicillin 2 g IV q4h if <i>Listeria</i> is suspected.
Nosocomial pneumonia	Vancomycin 15 mg/kg q12h plus either piperacillin-tazobactam 4.5 g IV q6h or imipenem 0.5 g IV q6h or meropenem 1 g IV q8h or cefepime 2 g IV q12h plus either an aminoglycoside (e.g., amikacin 15 mg/kg IV q24h or tobramycin 7 mg/kg IV q24h) or levofloxacin (Levaquin) 750 mg IV q24h. Some authorities would substitute linezolid 600 mg IV q12h for vancomycin if MRSA is of significant concern or known to be the cause.
Neutropenia	Cefepime 2 g IV q8h; add vancomycin 15 mg/kg IV q12h if a central line is present and infection is a concern. Add antifungal coverage with liposomal amphotericin B 3-5 mg/kg q24h or caspofungin 70 mg IV × 1 then 50 mg IV q24h if fever persists ≥5 days. If invasive aspergillosis is highly suspected or proven, voriconazole 6 mg/kg IV q12h × 2 then 4 mg/kg IV q12h should be used.
Cellulitis and skin infections	Vancomycin 15 mg/kg IV q12h. Add piperacillin-tazobactam 4.5 g IV q6h in diabetics or immunocompromised patients. If necrotizing fasciitis is suspected, add clindamycin 900 mg IV; surgical débridement is crucial.

*Assumes normal renal function; dose adjustments required with impaired creatinine clearance.

[†]Substitute aztreonam 2 g IV q8h if penicillin allergic.

[‡]Monitor drug levels of aminoglycosides (i.e., peak and trough).

[§]Use ceftriaxone and azithromycin if the patient is admitted to the intensive care unit. MRSA, methicillin-resistant *Staphylococcus aureus*.

emphasized that targeting a specific molecule as adjunctive therapy for sepsis may be inadequate, given the complex cascade and temporal relationships of factors involved in the pathophysiologic parameters of SIRS. Currently the only adjunctive therapeutic agent to clearly show significant reduction in mortality in sepsis syndrome is recombinant human activated protein C (rhAPC). In a multicenter, randomized, double-blind, placebo-controlled trial for severe sepsis, infusion of rhAPC resulted in a 6.1% absolute risk reduction for mortality. The major adverse effect in this trial was bleeding, occurring in 3.5% of patients receiving the drug. Although clinical experience with this agent is limited and optimal target populations have not been fully identified, rhAPC is currently the only medication approved by the U.S. Food and Drug Administration specifically for the treatment of severe sepsis in adults (Table 96-7). The Surviving Sepsis Campaign Guidelines are a comprehensive, up-to-date set of recommendations for treatment of sepsis.

Table 96-7 Exclusion Criteria for Recombinant Human Activated Protein C

Pregnancy or breastfeeding
Age <18 years or weight >135 kg
Platelet count <30,000/mm ³
Conditions that increase the risk of bleeding:
Surgery within 12 hours before the infusion
A history of severe head trauma, stroke, or intracranial surgery within 3 months
History of intracerebral arteriovenous malformation, cerebral aneurysm, or mass lesion
History of congenital bleeding diathesis
Gastrointestinal bleeding within 6 weeks
Trauma considered to increase the risk of bleeding
A known hypercoagulable condition
Deep-vein thrombosis or pulmonary embolism within 3 months
Patient's family, physician, or both are not in favor of aggressive treatment or presence of an advance directive to withhold life-sustaining treatment

Prospectus for the Future

The evolving epidemiology of microbes causing bloodstream infection (BSI) and sepsis is a reflection of trends such as the increasing age of inpatients, higher numbers of immunocompromised individuals, and widespread antibiotic use. Technologic advances in microbe identification will therefore have an important role in the management of individuals with sepsis syndrome. The recent explosion in our understanding of microbial recognition by the immune system will lead to more rational immunomodulatory approaches to these patients.

Improved Diagnostics

Rapid diagnosis of the microbial cause of BSI and sepsis syndrome is essential to ensure both that antimicrobial therapy is directed against the appropriate pathogen and that coverage is not needlessly broad. Peptide nucleic acid–fluorescence in situ hybridization (PNA-FISH) can differentiate *Staphylococcus aureus* from the less pathogenic coagulase-negative staphylococci as well as different species of *Candida* sooner than

Prospectus for the Future—Cont'd

conventional methods. This may allow for earlier modification of antibiotics. Galactomannan and β -1,3-D-glucan testing may better identify fungi, such as *Aspergillus* and *Candida* species, respectively, than currently available techniques.

Immune-Based Therapies

Dysregulation of the immune response has long been the focus of novel therapies for sepsis syndrome. The identification of toll-like receptors and other pattern-recognition receptors as key players in host defense and the elucidation of subsequent intracellular signaling pathways have opened up new targets

for potential pharmacologic intervention. Furthermore, the fact that immune dysregulation in critical illness exists across a spectrum is increasingly recognized, from heightened immune activation associated with systemic inflammatory response syndrome to severe immunodepression characterized by impairments in antigen presentation and proinflammatory cytokine production. Immunostimulatory approaches, including cytokines and growth factors, are under further study. Inhibition of apoptosis with anticaspases has been shown to improve survival in an animal model of sepsis. Lipids may modify innate immunity by binding lipopolysaccharide and are under investigation as well.

Infections of the Nervous System

Scott A. Fulton and Robert A. Salata

Infections of the central nervous system (CNS) range from fulminant, readily diagnosed septic processes to indolent illnesses requiring exhaustive investigation to identify their presence and define their causes. Neurologic outcome and survival depend largely on the extent of CNS damage before effective treatment begins. Accordingly, it is essential that the physician move quickly to achieve a specific diagnosis and institute appropriate therapy. The initial evaluation must, however, take into account both the urgency of beginning antibiotic treatment in bacterial meningitis and the potential hazard of performing a lumbar puncture in the presence of focal neurologic infection or mass lesions.

Patients with CNS infection usually exhibit some combination of fever, headache, altered mental status, depressed sensorium, seizures, focal neurologic signs, and stiff neck. The history and physical examination, the results of lumbar puncture when applicable (Table 97-1), and the neuroradiographic images provide the mainstays of diagnosis. The order in which the last two procedures are performed is critical. A subacute history, evolving over 7 days to 2 months, of unilateral headache with focal neurologic signs and/or seizures implies a mass lesion that may or may not be infectious in nature. A brain-imaging procedure should be performed first; lumbar puncture is potentially dangerous because it may precipitate cerebral herniation, even in the absence of overt papilledema. However, patients with acute symptoms of fever, headache, lethargy, confusion, and stiff neck should have an immediate lumbar puncture, and if this test proves abnormal, then antibiotics should be instituted rapidly for presumed bacterial meningitis. If the distinction between focal and diffuse CNS infection is unclear or adequate evaluation is not possible, as in the comatose patient, then cultures of blood, throat, and nasopharynx should be obtained, antibiotic therapy started, and an emergency scanning procedure performed. If the last is not possible, then lumbar puncture should be delayed pending evidence that no danger of herniation exists. Inevitably, this approach means that some patients will receive empiric parenteral antibiotics several hours before a lumbar puncture is performed. In acute bacterial meningitis, 50% of cerebrospinal

fluid (CSF) cultures will be negative by 4 to 12 hours after antibiotics are instituted; negative CSF cultures are even more likely if the causative organism is a sensitive pneumococcus. Should the CNS infection actually represent acute bacterial meningitis, however, the characteristics of the CSF usually suggest the diagnosis because neutrophilic pleocytosis and some degree of hypoglycorrhachia (low CSF glucose) usually persist for at least 12 to 24 hours after antibiotics are instituted. Furthermore, Gram-stained preparation (or assay for microbial antigen in the CSF by latex agglutination) should indicate the causative organism even after antibiotics have rendered the CSF culture negative. Blood and nasopharyngeal cultures obtained before therapy are also likely to be positive in view of the high frequency of isolation of causative organisms from these sites. The approach of treating presumptive CNS infections promptly is often life saving and does not significantly compromise management. This approach to the use of scanning procedures is germane only for adults with community-acquired CNS infection. In children, technically adequate computed tomography (CT) requires heavy sedation; therefore scanning procedures must be reserved for more stringent indications.

Armed with the clinical presentation and the results of the lumbar puncture and CT scanning or magnetic resonance imaging, the clinician must decide on a probable cause and develop a plan for initial management and definitive evaluation. The task is simplified by addressing the following issues:

1. Is the host immunocompetent? The spectrum of CNS diseases and their causes shifts dramatically in the patient who is immunocompromised (**Web Table 97-1**). For example, the possibility of human immunodeficiency virus (HIV) infection must be determined expeditiously by serologic testing and polymerase chain reaction (PCR) if the likelihood is sufficiently high (see Chapter 108), because acute HIV infection may cause CNS signs and symptoms at seroconversion. Likewise, for patients who have been treated with immunosuppressive medications or immune response modifiers, cultures and PCR testing

Table 97-1 Typical Cerebrospinal Fluid Findings in Central Nervous System Infections

Infection	Cells	Neutrophils	Glucose	Protein
Bacterial meningitis	500-10,000/mcL	>90%	<40 mg/dL	>150 mg/dL
Aseptic meningitis	10-2000/mcL	Early >50%; late <20%	Normal	>100 mg/dL
Herpes simplex virus encephalitis	0-1000/mcL	>50%	Normal	<100 mg/dL
Tuberculous meningitis	50-500/mcL	Early >50%; late <50%	<30 mg/dL	>150 mg/dL
Syphilitic meningitis	50-500/mcL	<10%	<40 mg/dL	<100 mg/dL

for common and uncommon agents should be expedited if clinically indicated.

- Are there relevant exposures? Exposure to persons with tuberculosis or HIV infection may be associated with the acquisition of these diseases. Ticks may transmit Lyme disease or spotted fever, and mosquitoes may transmit arboviral encephalitis. Exposure to livestock or unpasteurized dairy products suggests brucellosis. Residence in the Ohio and Mississippi River valleys increases the risk of histoplasmosis and blastomycosis; coccidioidomycosis is endemic to semi-arid regions of the Southwest. Travel and particularly residence in developing countries may suggest cysticercosis, echinococcal cyst disease, tuberculosis, and cerebral malaria.
- Does the patient have meningitis, encephalitis, or meningoencephalitis? Is the disease acute, subacute, or chronic? These distinctions narrow and modify the differential diagnosis considerably and form the basis for the organization of the sections that follow. The meningitis syndrome consists of fever, headache, and stiff neck. Confusion and a depressed level of consciousness may occur as part of the encephalopathy in patients with acute bacterial meningitis. Seizures are rare and may indicate complicating processes such as cortical vein thrombosis. In contrast, encephalitis characteristically causes confusion, bizarre behavior, depressed levels of consciousness, focal neurologic signs, and seizures (generalized or focal). A presentation suggestive of encephalitis can raise a variety of issues quite different from those surrounding a patient with bacterial meningitis.

Meningitis

Meningitis is inflammation of the leptomeninges caused by infectious or noninfectious processes. The causes of infectious meningitis may be bacterial, viral, tuberculous, and fungal. The most common noninfectious causes are subarachnoid hemorrhage, cancer, and sarcoidosis. Infectious meningitis is considered in three categories: acute bacterial meningitis, aseptic meningitis, and subacute to chronic meningitis.

ACUTE BACTERIAL MENINGITIS

Epidemiologic Features

Three fourths of patients with acute bacterial meningitis are presented before the age of 15 years. *Neisseria meningitidis* causes sporadic disease or epidemics in closed populations. Closed population outbreaks often occur among students in primary and secondary schools and college students residing

in dormitories. However, most cases occur in winter and spring and involve children younger than 5 years of age. *Haemophilus influenzae* meningitis is even more selectively a disease of childhood, with most cases developing by the age of 10 years. Infections are sporadic, although secondary cases may occur in close contacts. The incidence of *H. influenzae* meningitis has significantly declined with the widespread use of effective conjugated vaccines. In contrast, pneumococcal meningitis is a disease observed in all age groups. In addition, pneumococcus is becoming increasingly resistant to penicillin, making therapy more challenging (see later discussion). Recent clinical series of hospitalized adults show a relative frequency of 40% to 55% pneumococcal, 3% to 13% meningococcal, 10% to 13% listerial, and 4% to 8% *H. influenzae* for community-acquired meningitis. The use of the conjugated pneumococcal vaccine in early childhood should decrease the incidence of meningitis caused by *Streptococcus pneumoniae* in all age groups.

Vaccination is particularly important for persons with inherited (e.g., complement deficiency, sickle cell anemia) and acquired (e.g., HIV infection, splenectomy) immunodeficiency (see **Web Table 97-1**).

Close contact with a patient with *N. meningitidis* or *H. influenzae* disease increases the incidence of secondary cases of meningitis, sepsis, and epiglottitis. For example, the risk of meningococcal disease is 500 to 800 times greater in a close contact of a patient with meningococcal meningitis than it is with no contact. Asymptomatic pharyngeal carriers of *H. influenzae* can also spread infection to their contacts. Thus, prophylactic therapy for close contacts is critical to prevent secondary cases (see discussion of treatment and outcome).

Pathogenesis and Pathophysiologic Features

The bacteria that cause most community-acquired meningitis transiently colonize the oropharynx and nasopharynx of healthy individuals. Meningitis may occur in nonimmune hosts after bacteremia from an upper respiratory site (*N. meningitidis* or *H. influenzae*) or pneumonia and by the direct spread from contiguous foci of infection (nasal or mastoid sinuses).

The pathogenesis of acute bacterial meningitis is best understood for meningococcal disease. The carrier state occurs when meningococci adhere to pharyngeal epithelial cells by means of specialized filamentous structures termed *pili*. The production of immunoglobulin A (IgA) protease by pathogenic *Neisseria* species favors adherence by inactivating IgA, a major host barrier to mucosal colonization. Organisms enter and pass through epithelial cells to subepithelial tissues, where they multiply in nonimmune individu-

als and produce bacteremia. The localization of organisms to the CSF is not well understood but presumably depends on invasive properties of the capsular polysaccharide, which permit penetration of the blood-brain barrier. Immunity is conferred by bactericidal antibody and presumably is acquired by earlier colonization of the pharynx with non-pathogenic meningococci and other cross-reacting bacteria. The presence of blocking IgA antibody may increase susceptibility transiently in some individuals. Bacterial meningitis usually remains confined to the leptomeninges and does not spread to adjacent parenchymal tissue. Focal and global neurologic deficits develop because of involvement of blood vessels coursing in the meninges and through the subarachnoid space. In addition, cranial nerves and cerebral tissue can be damaged by the attendant inflammation, edema, and scarring, as well as by the development of obstructive hydrocephalus.

Gram-negative bacterial meningitis occurs mainly in severely debilitated persons or in individuals whose meninges have been breached or damaged by head trauma, a neurosurgical procedure, or a parameningeal infection or tumor.

Clinical Presentation

Patients with bacterial meningitis may exhibit fever, headache, lethargy, confusion, irritability, and stiff neck. One of three principal modes of onset can occur. (1) Approximately 25% of cases begin abruptly with fulminant illness; mortality is very high in this setting. (2) More often, meningeal symptoms progress over 1 to 7 days. (3) Meningitis may superimpose itself on 1 to 3 weeks of an upper respiratory-type illness; diagnosis is most difficult in this group. Occasionally, no more than a single additional neurologic symptom or sign hints at disease more serious than a routine upper respiratory tract infection. Stiff neck is absent in roughly one half of all patients with meningitis, notably in the very young, the old, and the comatose. A petechial or purpuric rash is found in one half of patients with meningococcemia; although not pathognomonic, palpable purpura is very suggestive of *N. meningitidis* infection. Approximately 20% of patients with acute bacterial meningitis have seizures, and a similar fraction has focal neurologic findings.

Laboratory Diagnosis

In acute bacterial meningitis the CSF usually contains 500 to 10,000 cells/mL, mostly neutrophils (see Table 97-1). Glucose concentration falls below 40 mg/dL, and the protein level rises above 150 mg/dL in most patients. The Gram-stained preparation of CSF is positive in 80% to 88% of patients. However, certain cautionary notes are appropriate. Cell counts can be lower (occasionally zero) early in the course of meningococcal and pneumococcal meningitis or in patients with neutropenia. In addition, predominantly mononuclear cell pleocytosis may occur in patients who received antibiotics before the lumbar puncture. A similar mononuclear pleocytosis may be seen in meningitis caused by *Listeria monocytogenes*, *Mycobacterium tuberculosis*, and *Treponema pallidum* (secondary syphilis) (Table 97-2). Gram-stained preparations of CSF may be negative or misinterpreted when meningitis is caused by *H. influenzae*, *N. meningitidis*, or *L. monocytogenes* because gram-negative diplococci and coccobacilli may be difficult to visualize or

Table 97-2 Meningitis and Meningoencephalitis in the Immunocompromised Patient

discern. In addition, bacteria tend to be pleomorphic in CSF and may assume atypical forms. Compared with patients with acute meningitis caused by other bacterial pathogens, patients with *Listeria* infection have a significantly lower incidence of meningeal signs, and the CSF profile is significantly less likely to have a high white blood cell count or a high protein concentration. Gram stain is negative in two thirds of patients with listerial meningitis or meningoencephalitis. If interpretation of the Gram-stained CSF is not clear, then broad-spectrum antibiotics should be instituted while results of cultures are pending. If the initial Gram-stained preparation does not contain organisms, then examining the Gram-stained sediment prepared by concentrating up to 5 mL of CSF with a cytocentrifuge may reveal the causative organism.

Cultures of CSF, blood, fluid expressed from purpuric lesions, and nasopharyngeal swabs have a high yield. The last method is particularly valuable in patients who received antibiotic therapy before hospitalization because most antibiotics do not achieve substantial levels in nasopharyngeal secretions to eradicate the colonization state.

Recognition of meningitis may be difficult after head trauma or neurosurgery because the symptoms, signs, and laboratory findings of infection can be difficult to separate from those of trauma. A low level of CSF glucose usually indicates infection but can also be seen after subarachnoid hemorrhage. The causative organism, characteristically an enteric gram-negative bacillus (including *Pseudomonas aeruginosa*), may already have been cultured from an extraneural site such as a wound or urine. The known antibiotic sensitivities of such isolates therefore may provide a valuable guide to the initial treatment of meningitis in patients after neurosurgery.

All patients with meningitis caused by unusual agents or mixed infections and certain patients with meningitis

caused by *S. pneumoniae* and *H. influenzae* should undergo radiography of nasal and mastoid sinuses to exclude a parameningeal focus of infection.

Differential Diagnosis

Classic acute bacterial meningitis resembles few other diseases. Ruptured brain abscess should be considered, particularly if the CSF white blood cell count is unusually high and focal neurologic signs are present or if there is an abrupt loss of consciousness. Parameningeal infections usually cause fever, headache, and local neurologic signs. CSF characteristically shows modest neutrophilic pleocytosis and moderately increased protein, but the CSF glucose level is usually normal. The CSF may be sterile in patients with bacterial meningitis who have already received antibiotics, but neutrophils commonly are present in CSF and the glucose level is depressed. Early in the evolution of viral or tuberculous meningitis, the pleocytosis may be predominantly neutrophilic. Serial CSF examinations, however, will show a progressive shift to mononuclear cell predominance. Similarly, acute viral meningoencephalitis may be difficult to distinguish clinically from bacterial meningitis, but the evolution of CSF findings and the clinical course usually decide the matter.

Treatment and Outcome

Bacterial meningitis requires prompt administration of appropriate antibiotics. If the Gram-stained smear of CSF indicates pneumococcal or meningococcal disease, then penicillin G or a third-generation cephalosporin (e.g., ceftriaxone, 1 g every 12 hours) should be administered intravenously. Because the frequency of intermediate and highly penicillin-resistant *S. pneumoniae* has increased significantly, additional therapy with vancomycin is recommended until the results of sensitivity testing are available. Alternative drugs for patients with severe penicillin allergy are vancomycin and meropenem. Patients with suggested *H. influenzae* meningitis should be treated with ceftriaxone (1 g given intravenously every 12 hours). In a patient with probable community-acquired meningitis, if the Gram-stained preparation of CSF is negative but clinical and laboratory findings suggest bacterial meningitis, then penicillin (or ampicillin) and ceftriaxone therapy should be started. Third-generation cephalosporins are the indicated choice for treating sensitive gram-negative enteric organisms causing meningitis. Agents such as ceftazidime (2 g given intravenously every 6 to 8 hours) may be effective against *P. aeruginosa*. If the organism is resistant to cephalosporins, then the patient should be treated with meropenem. Regardless of the results of sensitivity testing, chloramphenicol is not an adequate drug for the treatment of gram-negative bacillary meningitis; its use has been associated with unacceptably high mortality rates.

Experimental studies have suggested that the morbidity and mortality associated with acute bacterial meningitis results from the detrimental effects of the host inflammatory response. Conversely, inflammation also enhances penetration of antimicrobial agents into the CSF, and in this regard inflammation is considered beneficial. Treatment or modulation of host inflammatory responses during meningitis has evolved as therapeutic targets and adjunctive use of corticosteroids now are recognized as a standard of care in the

initial treatment of suspected cases of bacterial meningitis in adults. However, corticosteroids have been shown to improve functional outcome and reduce mortality only in cases of acute pneumococcal meningitis. It is not known why corticosteroids do not offer similar benefits for infections caused by other encapsulated pathogens. Nonetheless, adjunctive use of corticosteroids (dexamethasone 10 mg administered with the first dose of antibiotic) should begin promptly in cases of suspected bacterial meningitis and should continue at 6-hour intervals for 4 days only when *S. pneumoniae* infection has been confirmed.

The management of bacterial meningitis extends beyond the patient. Contacts also must be protected because they are at substantial risk for developing meningococcal meningitis or serious *H. influenzae* disease. At the time when bacterial meningitis is first suggested, respiratory isolation procedures should be initiated. Antibiotic prophylaxis of contacts should begin when the clinical course or Gram-stained preparation of CSF suggests meningococcal or *H. influenzae* meningitis. The recommended drug for household and other intimate contacts of patients with meningococcal meningitis is rifampin, 10 mg/kg (up to 600 mg) twice daily for 2 days. The goal of prophylaxis of contacts of *H. influenzae* type B meningitis is to protect children younger than 4 years of age. Because the organism may be passed from patient to asymptomatic adults to an at-risk child, rifampin, 20 mg/kg (up to 600 mg) daily for 4 days, should be given to all members of the household and day care center of the index case who have contact with children younger than 4 years old. Alternatives to rifampin include intramuscular ceftriaxone or oral ciprofloxacin. Despite parenteral antibiotic therapy, patients with *N. meningitidis* or *H. influenzae* meningitis may have persistent nasopharyngeal carriage and should also receive rifampin treatment at the end of parenteral antibiotic therapy. Because *L. monocytogenes* is resistant to cephalosporins, ampicillin for a minimum of 15 to 21 days (with an aminoglycoside for the first 7 days) is the treatment of choice for *Listeria* meningitis.

Although hospital contacts of patients with meningococcal meningitis are at low risk for acquiring the carrier state and disease, secondary cases occasionally occur. Thus, personnel in close contact with the patient's respiratory secretions should receive prophylactic antibiotics. All persons receiving rifampin prophylaxis should be warned that their urine and tears will turn orange and that the anti-estrogen effects of the drug will temporarily inactivate oral contraceptives.

Approximately 30% of adults with bacterial meningitis die of the infection. In survivors, deafness (6% to 10%) and other serious neurologic sequelae (1% to 18%) are common. The prognosis in individual cases depends largely on the level of consciousness and extent of CNS damage at the time of the first treatment. Misdiagnosis (50% of patients) and delays in starting antibiotics are factors in morbidity that physicians must try to avoid. Patients with suggested bacterial meningitis should be treated with antibiotics within 30 minutes of reaching medical care. Even after antibiotic therapy and presumed cure, bacterial meningitis may recur. The pattern of recurrence usually suggests a parameningeal infection or dural defect (Table 97-3).

Because more effective protein-conjugated vaccines are now available for some strains of *N. meningitidis*, *S.*

pneumoniae, and *H. influenzae* type B, vaccination of susceptible individuals can reduce these common types of bacterial meningitis.

ASEPTIC MENINGITIS

Leptomeningitis associated with negative Gram stains of CSF and negative cultures for bacteria has been designated aseptic meningitis, a somewhat unfortunate designation that often implies a benign illness that resolves spontaneously. However, assuming a high level of vigilance with this group of patients is important because they may have a potentially treatable but progressive illness.

Epidemiologic Features

Viral infections are the most frequent cause of aseptic meningitis (Table 97-4). Of those cases in which a specific causal agent can be established, 97% are caused by enteroviruses (particularly coxsackievirus B, echovirus, mumps virus, and lymphocytic choriomeningitis virus), herpes simplex virus (HSV) I and II, and *Leptospira*. Viral meningitis is most often a disease of children and young adults (70% of patients are younger than 20 years of age). Seasonal variation reflects the predominance of enteroviral infection; most cases occur in summer or early fall. Mumps usually occurs in winter,

and lymphocytic choriomeningitis usually occurs in fall or winter.

Pathogenesis and Pathophysiologic Features

Localization to the meninges occurs during systemic viremia. The basis for the meningotropism of viruses that cause aseptic meningitis is not understood. HSV type 2 may cause meningitis during the course of primary genital herpes.

Clinical Presentation

The syndrome of aseptic meningitis of viral origin begins with the acute onset of headache, fever, photophobia, and meningismus associated with CSF pleocytosis. The headache is often described as the worst ever experienced and is exacerbated by sitting, standing, or coughing. In typical cases, the course is benign. The development of changes in sensorium, seizures, or focal neurologic signs shifts the diagnosis to encephalitis or meningoencephalitis. Additional clinical features may suggest a particular infectious agent. Patients with mumps may have concurrent parotitis or orchitis and usually give a history of appropriate contact. Lymphocytic choriomeningitis often follows exposure to mice, guinea pigs, or hamsters and causes severe myalgias; an infectious mononucleosis-like illness can ensue, with rash and orchitis. Leptospirosis often follows exposure to rats or mice or swimming in water contaminated by their urine; aseptic meningitis occurs in the second phase of the illness. Aseptic meningitis can also be seen in persons with HIV infection, either as a manifestation of the primary infection or as a later complication. The pleocytosis generally is modest, the protein level is only slightly elevated, and the glucose concentration is normal or slightly depressed. HIV serologic findings may be negative during acute HIV infection, but the diagnosis is readily established by detectable plasma HIV RNA (see Chapter 108).

Laboratory Diagnosis

In viral meningitis the CSF shows a pleocytosis of 10 to 2000 white blood cells/mL (see Table 97-1). Two thirds of patients have mainly neutrophils in the initial CSF specimen. However, serial lumbar punctures reveal a rapid shift (within 6 to 8 hours) in the CSF differential count toward mononuclear cell predominance. CSF protein is normal in one third of patients and almost always is less than 100 mg/dL. The level of CSF glucose is characteristically normal, although minimal depression occurs in mumps (30% of cases), in lymphocytic choriomeningitis (60%), and, less frequently, in echovirus and HSV meningitis. Serial lumbar punctures show a 95% reduction in cell count by 2 weeks. Stool cultures have the highest yield for enterovirus isolation (40% to 50%), whereas CSF and throat cultures are positive in approximately 15% of patients. Serologic studies also may indicate a specific causative agent; a fourfold rise in antibody titer is helpful in confirming the significance of a virus isolated from the throat or stool. Serologic studies are seldom useful in acute diagnosis, but PCR-based testing detects enteroviral RNA in CSF of approximately 70% of persons with aseptic meningitis.

Differential Diagnosis

Partially treated bacterial meningitis and a parameningeal focus of infection may be particularly difficult to distinguish

from aseptic meningitis. Serial lumbar punctures may be helpful in establishing the former, and radiographs of the paranasal sinuses, mastoids, and spine may help confirm the latter. In addition, the differential diagnosis includes infectious agents that are not cultured on routine bacterial media and are considered to be causes of subacute meningitis (see the following discussion). Infective endocarditis may cause aseptic meningitis and is an important diagnostic consideration in the appropriate setting (see Chapter 100). Although less common, true noninfectious causes of meningitis (e.g., nonsteroidal anti-inflammatory drugs; immunoglobulin and immune response modifiers) should be included in the differential for aseptic meningitis.

Treatment and Course

Viral meningitis is generally benign and self-limited. HSV meningitis associated with primary genital herpes occasionally causes sufficient symptoms to warrant treatment with acyclovir. Medication-induced meningitis resolves with withdrawal of the offending agent.

SUBACUTE AND CHRONIC MENINGITIS

Certain infectious and noninfectious diseases can develop as subacute or chronic meningitis. *Chronic meningitis* refers to a clinical syndrome that develops over a course of several weeks, clinically takes the form of meningitis or meningoencephalitis, and is associated with a predominantly mononuclear pleocytosis in the CSF. The infectious causes of this syndrome may develop as a subacute to chronic meningitis (Table 97-5).

At the outset, considering the possible role of HIV as directly causing this syndrome or predisposing the patient to specific opportunistic infections such as cryptococcosis or toxoplasmosis is important; these may develop as subacute meningitis, although the latter most often develops as a mass lesion. However, the incidence of HIV-associated CNS cryptococcal and toxoplasmic infection has diminished greatly in the era of highly active antiretroviral therapy (HAART) (see Chapter 108).

Tuberculous meningitis results from the rupture of a parameningeal focus into the subarachnoid space. The presentation is generally one of subacute meningitis, with a neurologic syndrome being present for less than 2 weeks in over one half of the patients. Headache, fever, meningismus, and altered mental status are characteristic, with papilloedema, cranial nerve palsies (II, III, IV, VI, or VII), and extensor plantar reflexes each occurring in about one fourth of patients. The initial CSF sample may show predominance of neutrophils, but the differential shifts to mononuclear cells within the next 7 to 10 days. Acid-fast bacilli are identified in the CSF sediment of 15% to 25% of patients. Because delayed treatment is associated with increased mortality, therapy is initiated before confirmation of the diagnosis by culture in most patients. More rapid diagnosis can be established by CSF PCR in the majority of patients. The clinical suggestion of tuberculous meningitis is heightened by a history of remote tuberculosis in one half of patients. Because concurrent pulmonary disease occurs in approximately one third of patients, smears or cultures of pulmonary secretions may support the diagnosis. Appropriate therapy consists of isoniazid, rifampin, ethambutol, and pyrazinamide. *Vascu-*

Table 97-5 Subacute to Chronic Meningitis

Causative Agent	Association
Human immunodeficiency virus	Direct involvement or opportunistic infection
<i>Mycobacterium tuberculosis</i>	May have extraneural tuberculosis
<i>Cryptococcus neoformans</i>	Compromised host
<i>Coccidioides immitis</i>	Southwestern United States
<i>Histoplasma capsulatum</i>	Ohio and Mississippi River valleys
<i>Treponema pallidum</i>	Acute syphilitic meningitis, secondary meningovascular syphilis
Lyme disease	Tick bite, rash, seasonal occurrence

litis related to entrapment of cerebral vessels in inflammatory exudate may lead to stroke syndromes. This rationale has been used for the use of corticosteroids as adjunctive therapy. Although strong evidence of improved outcome is not available, many authorities believe that corticosteroids should be given in tapering doses for 4 weeks when the diagnosis of tuberculosis is established, particularly if cranial palsies appear or stupor or coma supervenes.

Cryptococcal meningitis is the most common fungal meningitis and can occur in apparently normal, as well as immunocompromised, patients. The presentation is of insidious onset, followed by weeks to months of progressive meningoencephalitis, sometimes clinically indistinguishable from the course of tuberculous meningitis. Certain associations are useful in this differential diagnosis. The presence of immunosuppression suggests cryptococcosis, whereas chronic debilitating disease, miliary infiltrates on chest radiograph, or the syndrome of inappropriate secretion of antidiuretic hormone suggests tuberculosis. An India ink preparation of CSF reveals encapsulated yeast in 50% of patients with cryptococcal meningitis. More than 90% of patients have cryptococcal polysaccharide antigen in CSF or serum. Fungal cultures of urine, stool, sputum, and blood should be obtained; they may be positive in the absence of clinically apparent extraneural disease. Initial treatment of cryptococcal meningitis requires amphotericin B. Addition of flucytosine allows use of less amphotericin B. Fluconazole is also effective but causes less rapid sterilization of the CSF. Daily fluconazole is effective for maintenance therapy to prevent relapses in persons with acquired immunodeficiency syndrome (AIDS) and should continue until CD4 counts rise to over 200 cells/mL after initiation of HAART.

Coccidioides immitis is a major cause of granulomatous meningitis in semi-arid areas of the southwestern United States; *Histoplasma capsulatum* may cause a similar syndrome in endemic areas (Ohio and Mississippi River valleys) (see Chapter 108).

Neurosyphilis reflects the fact that the spirochete causing syphilis (*T. pallidum*) invades the CNS in most instances of systemic infection. The organism then may either be cleared by host defenses or persist to produce a more chronic infection expressed symptomatically only years later. The most common form of neurosyphilis is asymptomatic; patients harbor a few white cells in the CSF and have a positive serologic test for syphilis. Symptomatic neurosyphilis can appear

as acute or subacute meningitis (meningitic form), resembling other bacterial meningitis as discussed previously, and usually occurring during the stage of secondary syphilis when cutaneous findings are documented as well. Hydrocephalus and cranial nerve (VII and VIII) abnormalities may develop. CSF and serum serologic studies are usually strongly positive, and the disease is responsive to penicillin.

Meningovascular syphilis begins 2 to 10 years after the primary lesion. The disorder is characterized by both meningeal inflammation and a vasculitis of small arterial vessels, the latter leading to arterial occlusion. Clinically, the disorder produces few signs of meningitis but results in monofocal or multifocal cerebral or spinal infarction. The disorder may be mistaken for an autoimmune vasculitis or even arteriosclerotic cerebrovascular disease (stroke syndrome). The early and prominent spinal cord signs should lead the physician to expect syphilis, and the findings in the CSF of pleocytosis, elevated gamma globulin, and a positive serologic test for syphilis establish the diagnosis. Patients respond to antibiotic therapy, although recovery from focal abnormalities may be incomplete. Syphilis is more difficult to diagnose and may have an accelerated course in the HIV-infected individual. Meningovascular syphilis may develop within months of primary infection, despite treatment with intramuscular benzathine penicillin (see Chapter 107).

General paresis, once a common cause of admission to mental institutions, is now rare. The disorder results from syphilitic invasion of the parenchyma of the brain and begins clinically 10 to 20 years after the primary infection. Paresis is characterized by progressive dementia, sometimes with manic symptoms and megalomania and often with coarse tremors affecting facial muscles and tongue. The diagnostic clue is the presence of Argyll Robertson pupils. The CSF is always abnormal. The diagnosis is made by serologic tests. Early treatment with antibiotics usually leads to improvement but not complete recovery.

Tabes dorsalis is a chronic infective process of the dorsal nerve roots that appears 10 to 20 years after primary syphilitic infection. Lightning-like pains and a progressive sensory neuropathy affecting predominantly large fibers supplying the lower extremities characterize the disorder. A profound loss of vibration and position sense, as well as areflexia, occurs. Autonomic fibers are also affected, causing postural hypotension, trophic ulcers of the feet, traumatic arthropathy of the joints, and Argyll Robertson pupils. CSF serologic test results are usually positive. The disorder responds only partially to treatment with antibiotics.

Rare complications of syphilis include progressive optic atrophy, gumma (a mass lesion in the brain), congenital neurosyphilis, and syphilitic infection of the auditory and vestibular system.

Lyme disease, a tick-borne spirochetosis (see Chapter 95), is associated in 15% of clinically affected individuals with meningitis, encephalitis, or cranial or radicular neuropathies. Characteristically the neurologic disease begins several weeks after the typical rash of erythema chronicum migrans. Furthermore, the rash may have been so mild as to go unnoticed and usually has faded by the time neurologic manifestations appear. The diagnosis should be suggested when a patient develops subacute or chronic meningitis during late summer or early fall with CSF changes consisting of a modest mononuclear pleocytosis, protein values below 100 mg/dL,

and normal levels of glucose. The diagnosis is established serologically or by PCR analysis of CSF, which provides a sensitive approach to the diagnosis of CNS Lyme disease. Patients with early Lyme disease usually respond to oral doxycycline. Patients with late or disseminated Lyme disease respond less predictably to prolonged (14 to 21 days) courses of intravenous ceftriaxone.

Several noninfectious diseases may develop as subacute or chronic meningitis. Typical of this group is a CSF containing 10 to 100 lymphocytes, elevated protein levels, and a mildly to severely lower glucose level. Meningeal carcinomatosis represents diffuse involvement of the leptomeninges by metastatic adenocarcinoma, lymphoma, or melanoma. Cytologic analysis often identifies malignant cells. Sarcoidosis may cause basilar meningitis and asymmetrical cranial nerve involvement, as well as a low-grade pleocytosis, sometimes associated with borderline low levels of CSF glucose. Granulomatous angiitis and Behçet disease also belong in this category.

Approach to Diagnosis

Diagnosing the specific cause of subacute or chronic meningitis may be quite difficult. In patients with tuberculous or fungal meningitis, cultures may not become positive for 4 to 6 weeks or longer; moreover, meningitis caused by some fungi (e.g., *H. capsulatum*) is often associated with negative cultures of the CSF.

Because of the uncertainties involved in establishing the diagnosis of infectious diseases and even the question of whether a particular patient has an infectious or noninfectious disease, an organized approach must be taken. Routine laboratory tests (on multiple samples of CSF) should include an India ink preparation and cultures for bacteria, mycobacteria, and fungi. In addition, the patient with chronic meningitis of unknown cause should have the following: Venereal Disease Research Laboratories (VDRL) testing; cryptococcal antigens determined in blood and CSF samples; fluorescent treponemal antibody absorbed (FTA-ABS) and antinuclear antibody (and, when epidemiologically appropriate, antibody to *Borrelia burgdorferi*) in blood samples; *Histoplasma* antigen in urine and CSF samples; antibody to HIV and *H. capsulatum* in serum samples (and, when appropriate, *C. immitis*); and cytologic studies (three times) in CSF samples. A tuberculin skin test (intermediate strength, 5 TU) should be performed. Diagnosis by PCR of specific pathogens in CSF, when available, can expedite evaluation of patients with chronic meningitis.

The appropriate management is decided by the patient's clinical status and the results of these tests. If the CSF pleocytosis consists of more than 50 to 100 cells/mcL, then an infectious disease is likely. Empiric therapy for mycobacterial and/or fungal meningitis may be necessary. Repeated cytologic, microbiologic, and PCR studies of the CSF may reveal the diagnosis. If the pleocytosis is low grade (less than 50 cells/mcL), then a noninfectious cause is more likely; the condition may even be self-limited, the so-called "chronic benign lymphocytic meningitis." The approach to treating such patients must be individualized. Only rarely is brain or meningeal biopsy necessary or helpful. If all CSF studies are nondiagnostic and the patient's clinical condition is stable, then a period of careful observation is almost always preferable to an invasive diagnostic procedure.

Encephalitis

Acute viral and other infectious causes of encephalitis usually produce fever, headache, stiff neck, confusion, alterations in consciousness, focal neurologic signs, and seizures.

EPIDEMIOLOGIC FEATURES

A large number of viral and nonviral agents can cause encephalitis (see Table 97-5). Seasonal occurrence may help limit the differential diagnosis. Arthropod-borne viruses peak in the summer and fall (West Nile virus [WNV], California encephalitis [La Crosse virus], and western equine encephalitis peak in August; St Louis encephalitis peaks slightly later). The tick-borne infections (Rocky Mountain spotted fever [RMSF]) occur in early summer, enterovirus infections in late summer and fall, and mumps in the winter and spring. Geographic distribution is also helpful. Eastern equine encephalitis is confined to the coastal states. Serologic surveys indicate that infections by encephalitis viruses are most often subclinical. The reason so few among the many infected patients develop encephalitis is not clear.

HSV is the most frequent, treatable, and devastating cause of sporadic, severe focal encephalitis. Overall, it is implicated in 10% of all patients with encephalitis in North America. No age, sex, seasonal, or geographic preference exists.

PATHOGENESIS

Viruses reach the CNS via the bloodstream or peripheral nerves. HSV presumably reaches the brain by cell-to-cell spread along recurrent branches of the trigeminal nerve, which innervate the meninges of the anterior and middle fossae. Although this would explain the characteristic localization of necrotic lesions to the inferomedial portions of the temporal and frontal lobes, the reason why such spread is so rare is not clear, with one case of HSV encephalitis occurring per one million in the population per annum.

CLINICAL FEATURES

The course of HSV encephalitis is considered in this text in detail because of the importance of establishing the diagnosis of this treatable entity. Patients affected by HSV commonly describe a prodrome of 1 to 7 days of upper respiratory tract symptoms followed by the sudden onset of headache and fever. The headache and fever may be associated with acute loss of recent memory, behavioral abnormalities, delirium, difficulty with speech, and seizures (often focal). Disorders of the sensorium are not, however, always apparent at the time of presentation and are not essential for the working diagnosis of this eminently treatable but potentially lethal infection of the CNS.

LABORATORY DIAGNOSIS

In HSV encephalitis, the CSF can contain 0 to 1000 white blood cells/mcL, predominantly lymphocytes. Protein is moderately high (median 80 mg/dL). CSF glucose level is reduced in only 5% of individuals within 3 days of onset but becomes abnormal in additional patients later in the course of the disease. The CSF is normal in approximately 5% of

patients. Other laboratory findings at onset are of little help, although focal abnormalities may be present in the electroencephalogram and appear on CT or magnetic resonance imaging brain scans by the third day in most patients. Acyclovir offers such high likelihood of therapeutic benefit in HSV encephalitis with so little risk in this highly fatal and neurologically damaging disease that brain biopsy should not be performed unless an alternative, treatable diagnosis seems very likely. A low level of CSF glucose should increase the suggestion that a granulomatous infection (e.g., tuberculosis, cryptococcosis) is present. If the initial CSF shows a low glucose level, then roughly one third of individuals will have an alternatively treatable infection. If CSF studies and brain imaging remain inconclusive in such circumstances, then biopsy may be appropriate.

Cerebral spinal fluid HSV DNA detection by PCR is highly sensitive and specific in HSV encephalitis. Additional PCR-based diagnostic tests are available for other viruses and should be considered in the appropriate clinical and epidemiologic settings. Viral cultures of stool, throat, buffy coat, CSF, and brain biopsy specimens, as well as indirect immunofluorescence or immunoperoxidase staining of tissues, may provide a specific diagnosis. However, viral isolation and serologic evidence of a rise in antibody titer usually come too late to guide initial treatment. In the case of HSV encephalitis, serologic studies are particularly helpful in 30% of individuals with a primary infection. In addition, CSF titers of antibody to HSV, which reflect intrathecal production of antibody, may show a diagnostic fourfold rise.

DIFFERENTIAL DIAGNOSIS

Acute (demyelinating) encephalomyelitis, infective endocarditis producing brain embolization, meningoencephalitis caused by *Cryptococcus neoformans*, *M. tuberculosis*, or the La Crosse virus, acute bacterial abscess, acute thrombotic thrombocytopenic purpura, cerebral venous thrombosis, vascular disease, and primary and metastatic tumors may all initially simulate HSV encephalitis.

TREATMENT AND OUTCOME

The course of viral encephalitis depends on the causative agent. Untreated HSV encephalitis has a high mortality rate (70%), and survival is associated with severe neurologic residua. Acyclovir therapy improves survival and greatly lessens morbidity in patients if initiated early, before deterioration to coma. Prognosis is particularly favorable in young patients (younger than 30 years old) with a preserved mental status at the time of presentation.

West Nile Virus

WNV was first identified in 1937 and recognized as a CNS pathogen as early as 1957 during an outbreak in Israel. Infections in the United States were heralded by an outbreak that occurred in New York City in 1999. WNV infection represents an emerging mosquito-borne infectious disease in the United States. Since the outbreak of WNV meningoencephalitis in New York City, WNV has spread to most states. Similar to most cases of viral meningitis and encephalitis,

WNV occurs primarily during the summer and early fall months. Culicine mosquitoes that have bitten infected birds (primarily crows and blue jays) transmit the disease. Although direct human-to-human transmission does not occur, WNV can be transmitted through blood products and organs donated from asymptomatic donors. Additional infections in children have resulted from transplacental transmission and through breastfeeding. Although most infections are asymptomatic, symptomatic patients often exhibit (within 3 to 15 days) a range of nonspecific signs and symptoms that include fever, headache, and myalgia, and in some patients acute flaccid paralysis. Seizures have been observed in less than one third of patients. A roseolar or maculopapular rash involving the face and trunk is seen in nearly 50% of patients. CSF fluid examination typically reveals a lymphocytic pleocytosis (3 to 100 cells/mcL, mild protein elevation, and a normal glucose level. Fatal cases of meningoencephalitis have been primarily limited to patients older than 65 years of age in whom autopsy studies reveal neuronal cell death and severe cerebral edema. The diagnosis is made based on clinical grounds and identification of WNV-specific IgM or RNA. Approximately 90% of patients will have positive WNV-specific IgM within 7 to 9 days of infection, whereas detection of viral RNA is more difficult because symptoms usually begin as the viremia wanes.

Recovery is the rule, although chronic fatigue, weakness, memory loss, and depression may follow WNV infections. Specific antiviral therapy is not available, and management is supportive. Both personal protective measures (e.g., insect repellents) and environmental control measures are important in controlling exposure to mosquitoes and limiting outbreaks and disease transmission.

Rabies

Rabies encephalitis is always fatal, requiring major attention on prevention. Currently, zero to six cases of rabies occur each year in the United States, and approximately 20,000 people receive postexposure prophylaxis.

The incubation period for rabies is generally 20 to 90 days, during which the rabies virus replicates locally and then migrates along nerves to the spinal cord and brain. Rabies begins with fever, headache, fatigue, and pain or paresthesias at the site of inoculation; confusion, seizures, paralysis, and stiff neck follow. Periods of violent agitation are characteristic of rabies encephalitis. Attempts at drinking produce laryngospasm, gagging, and apprehension. Paralysis, coma, and death supervene. When rabies is suggested, protective isolation procedures should be instituted to minimize additional exposure of the hospital staff to saliva and other infected secretions. Detecting rabies-neutralizing antibody or isolating the virus from saliva, CSF, and urine sediment confirm the diagnosis. Immunofluorescent rabies antibody staining of a skin biopsy specimen taken from the posterior neck is a rapid means of establishing the diagnosis.

Indications for prophylaxis are based on two central principles. First, the patient must have been exposed. Nonbite exposure is possible if mucous membranes or open wounds are contaminated with animal saliva; exposure to bat urine in heavily contaminated caves has been followed by rabies. Second, small rodents (rats, mice, chipmunks, and squirrels) and rabbits rarely are infected and have not been associated

with human disease. Consultation with local or state health authorities is essential because certain areas of the United States are considered rabies free. In other areas, if rabies is present in wild animals, then dogs and cats have the potential to transmit rabies. Domestic dogs and cats should be quarantined for 10 days after biting someone; if they develop no signs of the illness, then no risk of transmission from their earlier bite is possible. Nondomestic animals should be destroyed and their brains examined for rabies virus by direct fluorescent antibody testing. Bites from bats, skunks, and raccoons always require treatment if the animal is not caught. Unusual behavior of animals and truly unprovoked attacks can be signs of rabies.

Currently, postexposure management consists of (1) thorough wound cleansing; (2) human rabies immune globulin, 20 IU/kg, one half infiltrated locally in the area of the bite and one half intramuscularly away from the site; and (3) human diploid cell rabies vaccine, 1.0 mL given intramuscularly four times for immunocompetent and five times for immunocompromised patients during a 1-month period. Individuals at high risk of exposure (e.g., veterinarians, spelunkers) should be vaccinated.

Spectrum of Tuberculous, Fungal, and Parasitic Infections

The spectrum of tuberculous, fungal, and parasitic infections of the CNS is briefly considered. Many, but not all, of these infections are increasing in incidence as the direct result of the increasing prevalence of HIV infection in the population (see Chapter 108).

TUBERCULOSIS

CNS tuberculosis can occur in several forms, sometimes without evidence of active infection elsewhere in the body. The most common form is *tuberculous meningitis*. This disorder is characterized by the subacute onset of headache, stiff neck, and fever. After a few days, affected patients become confused and disoriented. They often develop abnormalities of cranial nerve function, particularly hearing loss as a result of significant inflammation at the base of the brain. Most patients, if left untreated, lapse into coma and die within 3 to 4 weeks of onset. An accompanying arteritis may produce focal signs, including hemiplegia, during the course of the disorder. Tuberculous meningitis must be distinguished from other causes of acute and subacute meningeal infection, a process that is often not easy even after examination of the CSF. The pressure and cell counts are elevated with up to a few hundred cells, a mixture of leukocytes and lymphocytes. The protein level is elevated, usually above 100 mg/dL and often to very high levels, and the glucose concentration is depressed. Smears for acid-fast bacilli are positive in only 15% to 25% of CSF samples. Tuberculosis organisms grow on culture but only after several weeks. Thus, patients with subacutely developing meningitis consistent with tuberculosis should be treated with antituberculous agents before definitive diagnosis, if rapid PCR identification of mycobacterial antigens in CSF is not available. Large samples of CSF should be sent for

culture, and a careful search should be made for tuberculosis elsewhere in the body.

Tuberculomas of the brain produce symptoms and signs either of the mass lesion or of meningitis with the tuberculomas being found incidentally. One or multiple lesions are identified on a CT scan, but the scan itself does not distinguish tuberculomas from brain tumor or other brain abscesses. Without evidence of meningitis or systemic tuberculosis, biopsy is necessary for diagnosis. Patients with tuberculomas usually respond well to antituberculous therapy, but brain lesions may remain visible on the CT scan long after the patient's condition has improved clinically; the clinical course, not the scan, predicts the outcome.

Less common manifestations of CNS tuberculosis include chronic arachnoiditis, characterized by a low-grade inflammatory response in the CSF and progressive pain with signs of either cauda equina or spinal cord dysfunction. The diagnosis of arachnoiditis is suggested by a myelogram showing evidence of fibrosis and compartmentalization instead of the usually smooth subarachnoid lining. The disorder responds poorly to treatment. Tuberculous myelopathy probably results from direct invasion of the organism from the subarachnoid space. Patients exhibit a subacutely developing myelopathy, characterized by sensory loss in either the legs or all four extremities, depending on the site of the spinal cord invasion. Many patients have additional signs of meningitis, including fever, headache, and stiff neck. The CSF usually contains cells and tuberculous organisms.

FUNGAL AND PARASITIC INFECTIONS

Fungal and parasitic infections of the CNS are less common than viral and bacterial infections and often affect patients who are immunosuppressed. Similar to bacterial infections, fungal and parasitic infections may cause either meningitis or parenchymal abscesses. These meningitides exhibit clinical symptoms that, although similar, are usually less severe and abrupt than those of acute bacterial meningitis. The common fungal causes of meningitis include cryptococcosis, coccidioidomycosis, and histoplasmosis. Cryptococcal meningitis is a sporadic infection that affects both patients who are immunosuppressed (>50%) and those who are nonimmunosuppressed. Headache and sometimes fever and stiff neck characterize the disorder. The clinical symptoms may evolve for periods as long as weeks or months; diagnosis can be made only by identifying the organism or its antigen in the CSF. *Histoplasma* and coccidioidal meningitides occur in endemic areas and often affect individuals who are nonimmunosuppressed. The diagnosis is suggested by a history of residence in appropriate geographic areas and is confirmed by CSF and serologic evaluation. Antifungal treatment, particularly in the nonimmunosuppressed patient, is usually effective.

Parasitic infections of the nervous system usually produce focal abscesses rather than diffuse meningitis. The most common infection to affect the patient who is nonimmunosuppressed is cysticercosis, a disorder caused by the larval form of the *Taenia solium* tapeworm and contracted by ingesting food or water contaminated with parasite eggs (see Chapter 110). The disorder is common in many resource-restricted regions, as well as in Southern California. The brain may be invaded in as many as 60% of infected persons.

Figure 97-1 Neurocystercosis. A computed tomographic scan shows multiple confluent cysts.

Invasion of the brain leads to the formation of either single or multiple cysts, which often lie in the parenchyma but sometimes reside in the ventricles or subarachnoid space. Seizures and increased intracranial pressure are the most common clinical symptoms. A CT scan identifies small intracranial calcifications and hypodense cysts (Fig. 97-1). Serum indirect hemagglutination tests are usually positive and confirm the diagnosis. Where cysts obstruct the ventricular system to cause symptoms, shunting procedures may be necessary. The anthelmintic agent praziquantel may be effective therapy but has risks.

Toxoplasmosis of the brain, when it occurs in the adult, is a manifestation of immunosuppression. Patients with abnormal cellular immunity usually develop single or multiple abscesses, which generally appear as ring-enhancing lesions on a CT scan (Fig. 97-2). The management of CNS toxoplasmosis is discussed in Chapter 108.

Infection Risks Associated with Use of Emerging Immune Response Modifiers

Immune response modifiers have emerged as novel treatment modalities for patients with rheumatoid arthritis, psoriasis, multiple sclerosis, and Crohn disease that have been refractory to traditional disease-modifying agents (e.g., prednisone, methotrexate, cyclosporine, azathioprine). Many immune response modifiers are humanized monoclonal antibodies (e.g., infliximab [Remicade] and efalizumab [Raptiva]) or soluble receptor decoys that function as cytokine antagonists (e.g., etanercept [Enbrel]). In addition, humanized monoclonal antibodies have been used to condition donor hematopoietic cell allografts (alemtuzumab

Figure 97-2 *Toxoplasma* abscesses in a patient with acquired immunodeficiency syndrome. **A**, Computed tomography (CT) scan shows a contrast medium–enhanced mass (arrow). **B**, Magnetic resonance image reveals multiple masses (arrows) not visualized with CT scanning, leading physicians to suggest abscesses rather than tumor of mature T lymphocytes.

Table 97-6 Immune Response Modifiers Associated with Central Nervous System Infections

Immunotherapy	Mechanism of Action	Central Nervous System Infection
Infliximab	Inhibition of TNF- α	Aseptic meningitis
Adalimumab		West Nile virus encephalitis
Etanercept		<i>Aspergillus</i> brain abscess <i>Mycobacterium tuberculosis</i> meningitis
Efalizumab	Inhibition of CD11a-mediated cellular adhesion and migration	Aseptic meningitis
Anti-thymocyte globulin	Inhibition of T cell immunity	Cryptococcal meningitis
Rituximab	Binding of CD20 and depletion of premature and mature B cells	Aseptic meningitis
Natalizumab	Inhibition of α 4 β 1 integrin-mediated cellular adhesion and migration	PML (JC viral encephalitis)
Alemtuzumab	Binding of CD52 and depletion	PML (JC viral encephalitis)
		HHV-6 encephalitis

HHV, Human herpesvirus; PML, progressive multifocal leukoencephalopathy; TNF, tumor necrosis factor.

[Campath]) and treat refractory cases of multiple sclerosis (rituximab [Rituxan]). Although immune response modifiers are frequently used in conjunction with traditional immunosuppressive medications that promote engraftment (e.g., prednisone, tacrolimus, and mycophenolate), immune response modifiers have a long half-life and extend the duration of profound immunosuppression. Thus, many immune response modifiers are associated with delayed appearance or reactivation of opportunistic or latent infections of the CNS, respectively.

The spectrum of infections associated with immune response modifiers includes many of the pathogens discussed previously (see Tables 97-2, 97-4, and 97-5) but fungal and mycobacterial organisms should be especially considered in the differential diagnosis of CNS infections. Some of the more commonly used agents deserve special

emphasis and are reviewed in Table 97-6. Infliximab and efalizumab administration has been implicated in cases of noninfectious aseptic meningitis, but these agents more commonly are associated with mycobacterial and fungal infections. Anti-thymocyte globulin also has been implicated in cases of aseptic meningitis. Reactivation of latent John Cunningham (JC) virus has been associated with natalizumab (Tysabri), which has been used to treat refractory multiple sclerosis, and with rituximab, which is used in patients with B-cell lymphomas or multiple sclerosis. Although JC virus causes an untreatable progressive multifocal leukoencephalopathy, it is important to raise awareness and recognition of this CNS infection promptly and reduce immunosuppression if possible. Alemtuzumab (Campath) has been used to reduce graft-versus-host disease (GVHD) in hematopoietic cell allografts, but it has been associated

with human herpesvirus 6 (HHV-6) encephalitis. In addition, GVHD and its treatment (e.g., prednisone, tacrolimus, mycophenolate) represent independent risk factors for reactivation of HHV-6, which is treatable with ganciclovir or foscarnet.

The development and increased use of novel immune response modifiers pose additional risks for the develop-

ment of less common viral, fungal, and mycobacterial CNS infections, especially in patients who have other immunosuppressive comorbidities. Therefore a thorough knowledge of a patient's current and past treatment history with immune response modifiers is essential for prompt diagnosis of uncommon opportunistic and latent infections of the CNS.

Prospectus for the Future

The expanded availability and use of immune response modifiers (e.g., infliximab, etanercept, rituximab, and efalizumab) for the treatment of several immune-mediated diseases (e.g., rheumatoid arthritis, Crohn disease, multiple sclerosis, and psoriasis) and for the conditioning of hematopoietic cell transplants may increase further the incidence and risk of less common central nervous system (CNS) infections, such as progressive multifocal leukoencephalopathy (PML), human herpesvirus 6 (HHV-6), and *Mycobacterium tuberculosis* infection.

CNS infections may result in permanent loss of cognitive and motor neuron function. Immunization can reduce the incidence and morbidity and mortality associated with select viral and bacterial infections of the CNS. This fact has been most evident from the near worldwide eradication of poliomyelitis. Recent development and use of newer protein-conjugated vaccines against *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae* have dramatically reduced invasive CNS infections caused by these respiratory bacterial pathogens. Treatment of primary infections, prophylactic treatment of nonimmune contacts, and immunization of at-risk

patients are important in controlling and preventing outbreaks.

Environmental control (e.g., insecticides) and personal protective measures (e.g., *N,N*-Diethyl-*meta*-toluamide [DEET]) are important measures that help reduce insect reservoirs and personal exposure to insect-borne CNS infections. However, transmission of new viruses (e.g., West Nile) through organ transplantation or blood transfusion mandates heightened awareness that often new asymptomatic infections may be transmitted unwittingly to others. Medical personnel must maintain a high index of suspicion for new and old CNS infections.

Sensitive molecular diagnostic tests (e.g., polymerase chain reaction [PCR] assays) will continue to evolve and will play a critical role in identifying both old and new emerging pathogens associated with CNS infections. Rapid identification of CNS pathogens may limit collateral exposure of high-risk patients such as older adults, who represent a large proportion of the general population.

Infections of the Head and Neck

Christoph Lange and Michael M. Lederman

Infections of the Ear

Otitis externa is an infection of the external auditory canal. The process may begin as a folliculitis or pustule within the canal. Staphylococci, streptococci, and other skin flora are the most common pathogens. Some cases of otitis externa have been associated with the use of hot tubs. This infection (swimmer's ear) is usually caused by *Pseudomonas aeruginosa*.

Patients with otitis externa complain of ear pain that is often quite severe, and they may also complain of itching. Pain and discomfort should be treated with analgesics. Obstructing debris or excess cerumen should be cleared from the canal, and the tympanic membrane should be inspected. Examination shows an inflamed external canal; the tympanic membrane may be uninvolved. (Patients with otitis media, in contrast, do not have involvement of the external canal unless the tympanic membrane is perforated.) Otitis externa with cellulitis can be treated with systemic antibiotics such as dicloxacillin or a macrolide and local heat. In the absence of cellulitis or perforation of the tympanic membrane, eardrops (0.3% ofloxacin solution or polymyxin B + neomycin + hydrocortisone) are sufficient. There are no randomized controlled trials that directly compare oral with topical antimicrobial therapy in otitis externa, and few that compare ototopicals. Higher tissue concentrations may be achieved with ototopicals compared with systemic antibiotic therapy.

Patients with diabetes mellitus are at risk for an invasive external otitis (malignant otitis) caused by *P. aeruginosa*. In malignant otitis externa, pain is a presenting complaint, and infection rapidly invades the bones of the skull and may result in cranial nerve palsies, invasion of the brain, and death. Computed tomography (CT) or magnetic resonance imaging of the cranial bones can establish the extent of disease. Treatment must include débridement of as much necrotic tissue as is feasible and at least 4 to 6 weeks of treatment with two different drugs active against *Pseudomonas* (a carbapenem, piperacillin, an antipseudomonal cephalosporin plus ciprofloxacin or aminoglycoside).

Otitis media is an infection of the middle ear seen primarily among preschool children but occasionally in adults as well. Infection caused by upper respiratory tract pathogens is promoted by obstruction to drainage through edematous, congested eustachian tubes. *Streptococcus pneumoniae*, *Haemophilus influenzae* (usually nontypable strains), and *Moraxella catarrhalis* are the most common bacterial pathogens, and viral infection from respiratory syncytial virus, influenza virus, enteroviruses, and rhinovirus may predispose to acute otitis media. Fever, ear pain, diminished hearing, vertigo, or tinnitus may occur. In young children, however, localizing symptoms may not be present. The tympanic membrane may appear inflamed, but for otitis media to be diagnosed with certainty, either fluid must be seen behind the membrane or diminished mobility of the membrane must be demonstrated by tympanometry or after air insufflation into the external canal.

Treatment with amoxicillin is recommended; however β -lactamase-producing strains of *H. influenzae* and *M. catarrhalis* are found in this setting, so the addition of a β -lactamase inhibitor may be preferred. Amoxicillin should be dosed at 80 mg/kg body weight to achieve high drug concentrations in the middle ear fluid. Addition of decongestants or corticosteroids is of no proven value. Complications of otitis media are uncommon but include infection of the mastoid air cells (mastoiditis), bacterial meningitis, brain abscess, and subdural empyema.

Infections of the Nose and Sinuses

Rhinitis is a common manifestation of numerous respiratory viral infections. It is characterized by a mucopurulent or watery nasal discharge that may be profuse. When rhinitis is caused by respiratory virus infection, pharyngitis, conjunctival suffusion, and fever may be present. Rhinitis can also be caused by hypersensitivity responses to airborne allergens. Patients with allergic rhinitis often have a history of

atopy and often have a transverse skin crease on the bridge of the nose a few millimeters from the tip. The demonstration of eosinophils in a wet preparation of nasal secretions readily distinguishes allergic rhinitis from rhinitis of infectious origin (eosinophils can be identified in wet preparations by the presence of large refractile cytoplasmic granules). Occasionally, after head trauma or neurosurgery, cerebrospinal fluid (CSF) may leak through the nose. “CSF rhinorrhea” places patients at risk for bacterial meningitis. CSF is readily distinguished from nasal secretions by its low protein and relatively high glucose concentrations.

Sinusitis is an infection of the air-filled paranasal sinuses, which are thought to be sterile under normal conditions. Allergic rhinitis and structural abnormalities of the nose that interfere with sinus drainage also predispose to sinusitis. With chronic sinusitis, anaerobic bacteria play a more important role. Viral infections such as those caused by rhinovirus, influenza virus, parainfluenza virus, and adenovirus are frequently associated with sinusitis. Acute bacterial sinusitis is primarily caused by upper respiratory tract bacterial pathogens *S. pneumoniae* and *H. influenzae*, by *M. catarrhalis*, and less often by gram-negative bacteria, anaerobes, and staphylococci. Nosocomial sinusitis, to which patients are predisposed by nasal catheters, may be caused by *Staphylococcus aureus* or gram-negative bacteria.

Sinusitis may be difficult to distinguish from a viral upper respiratory tract illness, which in many instances precedes sinus infection. Patients may complain of persistent cough, headache, “stiffness,” a “toothache,” or purulent nasal discharge. Headache may be exacerbated by bending over. Sinusitis should be suspected in a person with a febrile upper respiratory tract illness that lasts more than 7 to 10 days. There may be tenderness over the involved sinus, and pus may be seen in the turbinates of the nose.

Unfortunately, clinical signs and symptoms cannot identify patients with rhinosinusitis for whom treatment is clearly justified. Failure of a sinus to light up on transillumination may suggest the diagnosis, but not all sinuses transilluminate even in health. CT is more sensitive than sinus radiographs in establishing the diagnosis of sinusitis. Patients with bacterial sinusitis confirmed radiographically should be treated with a 10-day course of amoxicillin-clavulanate, cefuroxime, or levofloxacin along with nasal decongestants. Patients with high fever, facial swelling or erythema, or severe facial pain should also be treated for bacterial sinusitis, and the involved sinus should be identified by radiographs or CT scan. Patients who appear severely ill and those who do not respond quickly to antibiotic therapy should undergo sinus puncture for drainage and lavage and further microbiologic evaluation. Sinusitis may be complicated by bacterial meningitis, brain abscess, or subdural empyema. Therefore patients with sinusitis and neurologic abnormalities must be evaluated carefully for these complications, by CT if a space-occupying lesion is suspected or by CSF examination if meningitis is suspected (see Chapter 97).

Fungi also can produce disease of the nasal sinuses. Chronic indolent fungal sinusitis is most commonly associated with *Aspergillus fumigatus* or *Aspergillus flavus*. Treatment consists of surgery and systemic antifungal therapy. Fulminant (angioinvasive) sinusitis is mostly seen in immunocompromised patients, including those with diabetes mellitus and those with prolonged neutropenia secondary to

chemotherapy. Clinical features include fever, cough, and nasal discharge and, with central nervous system (CNS) invasion, mental status changes. Causative fungi are *Aspergillus* species and organisms of the order Mucorales. Despite emergency surgery with sinus débridement and intravenous antifungal therapy, the prognosis is poor. *Aspergillus* species can cause fungus balls that typically produce nasal blockage as a symptom. Treatment in most cases is restricted to surgical débridement. Some instances of allergic sinusitis have been attributed to hypersensitivity to fungi. This syndrome occurs in immunocompetent patients with asthma; nasal polyps are found frequently. Medical therapy with topical and sometimes oral steroids is recommended. Polyps may require surgical intervention. Antifungal therapy is not used.

Infections of the Mouth and Pharynx

STOMATITIS

Stomatitis, or inflammation of the mouth, can be caused by a wide variety of processes. Patients with stomatitis may complain of diffuse or localized pain in the mouth, difficulty in swallowing, and difficulty in managing oral secretions. Various nutritional deficiencies (vitamins B₁₂ and C, folic acid, and niacin), cytotoxic chemotherapies, and viral infections can produce stomatitis.

Thrush is an infection of the oral mucosa by *Candida* species. Thrush may be seen among infants and also in patients receiving broad-spectrum antibiotics or corticosteroids (systemic or inhaled), among patients with leukopenia (e.g., acute leukemia), among diabetics, and among patients with impairments in cell-mediated immunity (e.g., acquired immunodeficiency syndrome [AIDS]). In its milder form, thrush is manifested by an asymptomatic white, “cheesy” exudate on the buccal mucosa and pharynx that when scraped leaves a raw surface. In more severe cases there may be pain and also erythema surrounding the exudate. The diagnosis is suggested by the characteristic appearance of the lesions and is confirmed by microscopic examination of a potassium hydroxide preparation of the exudate, which reveals yeast and the pseudohyphae characteristic of *Candida*. Thrush related to administration of antibiotics and corticosteroids should resolve after the drugs are withdrawn. Otherwise, thrush can be managed with clotrimazole troches. Refractory thrush or candidal infection involving the esophagus should be treated with fluconazole, or rarely, when azole resistance has developed, it may require treatment with an echinocandin.

ORAL ULCERS AND VESICLES

Herpes Simplex Virus Infection

Although most recurrences of oral herpes simplex infections occur on or near the vermilion border of the lips, the primary infection usually involves the mouth and pharynx (Table 98-1). Generalized symptoms of fever, headache, and malaise often precede the appearance of oral lesions by as much as 24 to 48 hours. The involved regions are swollen and erythematous. Small vesicles soon appear; these rupture, leaving shallow, discrete ulcers that may coalesce. Autoinoculation

Table 98-1 Oral Vesicles and Ulcers

Pemphigoid

may spread the infection; herpetic keratitis is one of the major infectious causes of blindness in the industrialized world. The diagnosis can be made by scraping the base of an ulcer. Wright or Giemsa stain of this material (Tzanck preparation) may reveal the intranuclear inclusions and multinucleated giant cells characteristic of herpes simplex infection. Viral cultures are more sensitive but more expensive. Diagnosis may also be established by immunoassay for viral antigen or by amplification of viral sequences in the scraping by polymerase chain reaction (PCR). Treatment of primary infection with acyclovir or valacyclovir will decrease the duration of symptoms but has no effect on the frequency of recurrence. Cytomegalovirus and varicella zoster virus are other herpesviruses that can cause oral ulcerations or vesicles, particularly in immunocompromised individuals.

Aphthous Stomatitis

Aphthae are discrete, shallow, painful ulcers on erythematous bases; they may be single or multiple and are usually present on the labial or buccal mucosa. Attacks of aphthous stomatitis may be recurrent and quite debilitating. The cause of the disease is uncertain, and many consider it an autoimmune disorder (see later). Symptoms may last for several days to 2 weeks. Treatment is symptomatic with saline mouthwash or topical anesthetics. Giant aphthous ulcers may occur in persons with AIDS and often respond to topical or systemic corticosteroids or to thalidomide.

Vincent Stomatitis

Vincent stomatitis is an ulcerative infection of the gingival mucosa caused by anaerobic fusobacteria and spirochetes. The patient's breath is often foul, and the ulcerations are covered with a purulent, dirty-appearing, gray exudate. Gram stain of the exudate reveals the characteristic gram-negative fusobacteria and spirochetes. Treatment with penicillin is curative. If not treated, the infection may extend to the peritonsillar space (quinsy) and even involve vascular structures in the lateral neck (see later).

Syphilis

Syphilis may produce a painless primary chancre in the mouth or a painful mucous patch that is a manifestation of secondary disease. The diagnosis should be considered in the sexually active patient with a large (>1 cm) oral ulceration and should be confirmed serologically, because darkfield

examination may be confounded by the presence of non-syphilitic oral spirochetes.

Herpangina

Herpangina is a childhood disease that causes painful, tiny, discrete ulcerations of the soft palate and is caused by infection with coxsackievirus A.

Fungal Disease

Occasionally an oral ulcer or nodule may be a manifestation of disseminated infection resulting from histoplasmosis. These ulcers are generally mildly or minimally symptomatic and are overshadowed by the constitutional symptoms of disseminated fungal illness.

Systemic Illnesses Causing Ulcerative or Vesicular Lesions of the Mouth

Recurrent aphthous oral ulcerations may be part of Behçet syndrome. Oral ulcerations have been associated with connective tissue diseases, such as systemic lupus erythematosus and Reiter syndrome, and with Crohn disease. Although isolated oral bullae and ulcerations may be seen in patients with erythema multiforme, pemphigus, and pemphigoid, almost all patients have an associated rash. The "iris" or "target" lesion of erythema multiforme is diagnostic. Otherwise, biopsy will establish the diagnosis. Corticosteroids may be life saving for patients with pemphigus. Corticosteroids are also used in the treatment of erythema multiforme major (Stevens-Johnson syndrome), although proof of their efficacy is not available.

PHARYNGITIS AND APPROACH TO THE PATIENT WITH SORE THROAT

When evaluating a patient with a sore throat, it is first important to distinguish between the relatively common and benign sore throat syndromes (viral or streptococcal pharyngitis) and the less common but more dangerous causes of sore throat. Patients with viral or streptococcal pharyngitis often give a history of exposure to persons with upper respiratory tract infections. Symptoms of cough, rhinitis, and hoarseness (indicating involvement of the larynx) suggest a viral upper respiratory tract infection, although it is important to remember that hoarseness may also be seen with more serious infections, such as epiglottitis.

Examination of the Throat

Two points regarding examination of the throat need emphasis. The first is that complete examination of the oral cavity is important. Not only will a thorough examination give clues to the cause of the complaint, but it may also provide early diagnosis of an asymptomatic malignancy at a time when cure is feasible. The second point is that the normal tonsils and mucosal rim of the anterior fauces are generally a deeper red than the rest of the pharynx in healthy subjects. This should not be mistaken for inflammation. Patients with pharyngitis often have a red, inflamed posterior pharynx. The tonsils are often enlarged and red and may be covered with a punctate or diffuse white exudate. Lymph nodes of the anterior neck are often enlarged.

If any of the seven *danger signs* listed in Table 98-2 is present, the clinician must suspect an illness other than

Table 98-2 Seven Danger Signs in Patients with Sore Throat

1. Persistence of symptoms longer than 1 week without improvement
2. Respiratory difficulty, particularly stridor
3. Difficulty in handling secretions
4. Difficulty in swallowing
5. Severe pain in the absence of erythema
6. A palpable mass
7. Blood, even in small amounts, in the pharynx or ear

*Most frequent identifiable causes of pharyngitis.

viral or streptococcal pharyngitis. Symptoms persisting longer than 1 week are rarely caused by streptococci or viruses and should prompt consideration of other processes (see later section on persistent or penicillin-unresponsive pharyngitis). Respiratory difficulty, particularly stridor, difficulty in handling oral secretions, or difficulty in swallowing should suggest the possibility of epiglottitis or soft tissue space infection. Severe pain in the absence of erythema of the pharynx may be seen with some of the “extrarespiratory” causes of sore throat, as well as in some cases of epiglottitis or retropharyngeal abscess. A palpable mass in the pharynx or neck suggests a soft tissue space infection, and blood in the ear or pharynx may be an early indication of a lateral pharyngeal space abscess eroding into the carotid artery.

A good history and careful examination will distinguish between the common and benign causes of a sore throat and the unusual but often more serious causes.

Pharyngitis

Agents that have been associated with pharyngitis are presented in Table 98-3. More than half of all cases are caused by respiratory viruses or group A streptococci. Most of the remainder are without a defined cause. Most cases occur

during the winter months. In practice, once a diagnosis of pharyngitis is established clinically, it is most important to distinguish between group A streptococcal infections, which should be treated with penicillin, and viral infections, which should be treated symptomatically (e.g., salicylates, saline gargles). Clinical criteria do not reliably predict streptococcal pharyngitis; however, the presence of fever, tonsillar exudates, and tender cervical lymphadenopathy and the absence of cough increase the likelihood of streptococcal infection. In patients with at least two of these findings, a positive rapid streptococcal antigen test will confirm the diagnosis. Some cases may be missed by this test, and for patients with three or four of these findings, clinicians may prefer to treat empirically with penicillin for 10 days.

Pharyngitis and Respiratory Virus Infections

Many patients with common colds caused by rhinovirus, coronavirus, adenovirus, or influenza virus have an associated pharyngitis. Other signs such as rhinorrhea, conjunctival suffusion, and cough suggest a cold virus; fever and myalgias suggest influenza. Symptoms generally resolve in a few days without treatment.

Infectious mononucleosis (IM) caused by Epstein-Barr virus is often associated with pharyngitis. Patients often also complain of malaise and fever. On examination, the pharynx may be inflamed and the tonsils hypertrophied and covered by a white exudate. Cervical lymph node enlargement is often prominent, and generalized lymph node enlargement and splenomegaly are common. Examination of a peripheral blood smear shows atypical lymphocytes, and the presence of heterophil antibodies (e.g., Monospot test) or a rise in antibodies to Epstein-Barr virus viral capsid antigen will confirm the diagnosis. Treatment is supportive. In instances when swelling threatens to compromise the airway, treatment with systemic corticosteroids may be considered. Patients with acute Epstein-Barr virus infection should be advised to abstain from contact sports, because traumatic rupture of the enlarged spleen may be fatal.

Primary human immunodeficiency virus (HIV) seroconversion illness is often manifested by fever, pharyngitis, and lymph node enlargement and is sometimes associated with a generalized maculopapular rash. A high index of suspicion is essential, because this diagnosis is often missed in clinical practice. Diagnosis is established by demonstration of HIV RNA in plasma (see Chapter 108).

Streptococcal Pharyngitis

Streptococcal pharyngitis may produce mild or severe symptoms. The pharynx is generally inflamed, and exudative tonsillitis is common but not universal. Fever may be present, and cervical lymph nodes may be enlarged and tender. Clinical distinction between streptococcal and non-streptococcal pharyngitis is inaccurate, and patients with pharyngitis should therefore have a swab of the posterior pharynx tested for streptococcal infection. The growth of group A β -hemolytic streptococci or detection of group A streptococcal antigen is an indication for treatment with penicillin (or erythromycin if the patient is penicillin allergic). Antibiotics may shorten the duration of symptoms caused by this infection but are administered for 10 days primarily to decrease the frequency of rheumatic fever, which may follow untreated streptococcal pharyngitis.

Pharyngitis Caused by Other Bacteria

Diphtheria, caused by *Corynebacterium diphtheriae*, is not expected in the United States; the last case was reported in 2003 in an unvaccinated person who had traveled to Haiti. The gray pseudomembrane bleeds when removed and in rare cases may cause death by means of airway obstruction. Most morbidity and mortality in diphtheria are related to the elaboration of a toxin with neurologic and cardiac effects. Treatment consists of antitoxin plus erythromycin. A self-limited pharyngitis, often associated with a diffuse scarlatiniform rash, may be caused by *Arcanobacterium* (formerly *Corynebacterium*) *haemolyticum*. This infection, when recognized, can be treated with penicillin or erythromycin.

Epiglottitis

Epiglottitis, usually an aggressive disease of young children, occurs in adults as well. Early recognition of this entity is critical, because delay in diagnosis or treatment frequently results in death, which may occur abruptly, within hours after the onset of symptoms. This diagnosis must be considered in any patient with a sore throat and any of the following key symptoms or signs: (1) difficulty in swallowing; (2) copious oral secretions; (3) severe pain in the absence of pharyngeal erythema (the pharynx of patients with epiglottitis may be normal or inflamed); and (4) respiratory difficulty, particularly stridor.

Patients with epiglottitis often display a characteristic posture; they lean forward to prevent the swollen epiglottis from completely obstructing the airway and resist any attempt at placement in the supine position. The diagnosis can be confirmed by lateral radiographs of the neck or by indirect laryngoscopy with visualization of the swollen, erythematous epiglottis. This examination should be performed with the patient in the sitting position to minimize the risk of laryngeal spasm. Furthermore, the physician must be prepared to perform emergency tracheostomy should spasm occur. Therapy has two major objectives: protecting the airway and providing appropriate antimicrobial coverage. Because the most likely pathogen is *H. influenzae*, which may produce β -lactamase, a good antibiotic choice is a second- or third-generation cephalosporin or ampicillin-sulbactam. Corticosteroids may relieve some inflammatory edema; however, the role of this therapy remains unproven. Patients with respiratory difficulty should have the airway protected by endotracheal intubation or tracheostomy. Patients without respiratory complaints may be monitored continuously in an intensive care setting and intubated at the first sign of respiratory difficulty. Young children who are close contacts of patients with invasive disease caused by *H. influenzae* are themselves at particular risk for serious infection. Children younger than 4 years of age who have not received the complete *H. influenzae* vaccine series and are close contacts of the index patient, and all family members in a household with children younger than 4 years of age who have not been completely vaccinated, should receive prophylaxis with rifampin (20 mg/kg given orally, up to 600 mg twice daily for four doses).

Soft Tissue Space Infections

Quinsy

Quinsy is a unilateral peritonsillar abscess or phlegmon that is an unusual complication of tonsillitis. The patient has

Table 98-4 Indications for Surgical Drainage: Parapharyngeal Soft Tissue Space Infections

Infection	Indications for Surgery
Quinsy	Abscess or respiratory compromise
Lateral pharyngeal space abscess	Abscess
Jugular vein septic thrombophlebitis	Febrile after 5-6 days of medical therapy
Retropharyngeal abscess	Abscess or respiratory compromise
Ludwig angina	Abscess or respiratory compromise

pain and difficulty in swallowing and often trouble in handling oral secretions. Trismus (inability to open the mouth because of muscle spasm) may be present. Examination shows swelling of the peritonsillar tissues and lateral displacement of the uvula. A mass may be felt on digital examination. In the phlegmon stage, penicillin therapy may be adequate; abscess can be identified by CT and requires surgical drainage (Table 98-4). If untreated, quinsy may result in glottic edema and respiratory compromise or lateral pharyngeal space abscess.

Septic Jugular Vein Thrombophlebitis

An uncommon complication of bacterial pharyngitis or quinsy is septic jugular vein thrombophlebitis (syndrome of postanginal sepsis). Several days after a “sore throat,” the patient (in general, a teenager or young adult) will note increasing pain and tenderness in the neck. Often there is swelling at the angle of the jaw. The patient will have a high fever; bacteremia, usually with *Fusobacterium* species; and often septic pulmonary emboli. Treatment is intravenous penicillin, 24 million U/day, plus metronidazole, 500 mg every 6 hours. Patients with persistent fevers may require surgical excision of the jugular vein.

Lateral Pharyngeal Space Abscess

Lateral pharyngeal space abscess is a rare infection associated with serious morbidity because of the proximity of the lateral pharyngeal space to vascular structures. Extension to the jugular vein may result in thrombophlebitis with septic pulmonary emboli and bacteremia (syndrome of “postanginal sepsis,” discussed earlier). Erosion of the carotid artery may also complicate this infection, with resultant exsanguination. This may be preceded by small amounts of blood in the ear or pharynx. This infection is generally associated with tenderness and a mass at the angle of the jaw. Prompt surgical intervention may be life saving.

Retropharyngeal Space Abscess

Retropharyngeal space abscess, a complication of tonsillitis, is rare in adults, because by adulthood the lymph nodes that give rise to this infection are generally atrophied. Most cases in adults are secondary to trauma (e.g., endoscopic) or to extension of a cervical osteomyelitis. The patient often has difficulty in swallowing and may complain of dyspnea, particularly when sitting upright. Diagnosis may be suspected

by the presence of a posterior pharyngeal mass and confirmed by lateral neck films.

Ludwig Angina

Ludwig angina, a cellulitis or phlegmon of the floor of the mouth, is generally secondary to an odontogenic infection. The tongue is pushed upward, and there is often firm induration of the submandibular space and neck. Laryngeal edema and respiratory compromise may also occur and necessitate protection of the airway. Surgery may be necessary to decompress the infected space. Penicillin is the antibiotic of choice; protection of the airway is crucial in this setting, and endotracheal intubation should be provided if there is any suggestion of airway compromise.

Extracranial Causes of Sore Throat

Several extracranial causes of sore throat should be kept in mind. The older patient who complains of soreness in the throat when climbing stairs or when upset may be experiencing angina pectoris with an unusual radiation. The hypertensive patient with an abrupt onset of a “tearing pain” in the throat may have a dissecting aortic aneurysm. In these patients, swallowing is generally unaffected. Patients with de Quervain subacute thyroiditis may develop fever and pain in the neck radiating to the ears. In patients with thyroiditis, the thyroid is generally tender, and the sedimentation rate is markedly increased. Patients with vitamin deficiencies may complain of soreness in the mouth and throat (see discussion of stomatitis, earlier). Examination may reveal a red “beefy” tongue with flattened papillae, resulting in a smooth appearance.

Persistent or Penicillin-Unresponsive Pharyngitis

Most cases of viral or streptococcal pharyngitis are self-limited, and symptoms generally resolve within 3 to 4 days. In addition to acute HIV infection and IM, as discussed earlier, persistent sore throat should prompt consideration of the following possibilities.

Soft Tissue Abscess or Phlegmon

In rare cases tonsillitis extends to the soft tissues of the pharynx, producing a potentially life-threatening infection (see earlier discussion).

Pharyngeal Gonorrhea

Infection with *Neisseria gonorrhoea* may affect almost any mucous membrane. In the head and neck, the most commonly affected areas include the pharynx and the conjunctiva, and the infection may occur without symptoms. This infection will not respond to doses of penicillin used for pharyngitis; moreover, the gonococcus is relatively resistant to phenoxymethyl penicillin (Pen-V). The gonococcus will not likely be identified on routine culture medium; isolation generally requires culture of a fresh throat swab on a selective medium such as Thayer-Martin (see Chapter 107).

Acute Lymphoblastic Leukemia

Persistent exudative tonsillitis may be a presentation of acute lymphoblastic leukemia (ALL). Diagnosis can be suspected after examination of the peripheral blood smear; however, some experience may be required to distinguish between the blasts of ALL and the atypical lymphocytes of IM.

Other Leukopenic States

Stomatitis or pharyngitis may be the presenting complaint of patients with *aplastic anemia* or *agranulocytosis*. Because some of these cases are drug induced (e.g., propylthiouracil, phenytoin), a complete medication history on initial presentation may suggest this possibility. Prompt discontinuation of the offending drug may be life saving.

Although sore throat is a common complaint of patients with relatively benign illness, it is sometimes the presenting complaint of a patient with a serious or life-threatening disease. Any of the key signs or symptoms shown in Table 98-2 should alert the clinician to the possibility of an extraordinary process.

Prospectus for the Future

- Simpler point of care assays for rapid diagnosis of bacterial and viral pharyngitis
- Broader use of imaging methods such as magnetic resonance imaging for accurate diagnosis of serious soft tissue infections of the neck

Infections of the Lower Respiratory Tract

Christoph Lange and Michael M. Lederman

Pneumonia is one of the most common causes of admission to adult medical services in North America and is one of the leading causes of death during the productive years of life.

Viruses, bacteria including chlamydia, rickettsia and mycoplasmas, fungi, protozoans, and parasites can all produce serious infection of the lower respiratory tract. A careful history and physical examination can provide clues to the likely cause of infection. The clinical spectra of pneumonias caused by different pathogens overlap considerably, however. Microscopic examination of respiratory secretions, although uncommonly applied now, can provide a rapid and useful step in the differential diagnosis of pneumonia.

Pathogenesis

Under normal circumstances the lower respiratory tract is generally sterile. Microbes can enter the lung to produce infection by hematogenous spread, by spread from a contiguous focus of infection, by inhalation of aerosolized particles, or, most commonly, by aspiration of oropharyngeal secretions. In the last instance, the organisms colonizing the oropharynx will determine the spectrum of microorganisms in the aspirated secretions and presumably the nature of the resultant pneumonia. Some organisms such as *Streptococcus pneumoniae* may transiently colonize the oropharynx in healthy individuals. Colonization often results in the development of protective antibodies to that strain. Aspiration of normal oropharyngeal flora may lead to necrotizing pneumonia caused by mixtures of oral anaerobic bacteria.

Inoculum size (the number of bacteria aspirated) is an important factor in the development of pneumonia. Studies using radioisotopes have shown that up to 45% of healthy men aspirate some oropharyngeal contents during sleep. In most instances, the bacteria aspirated are relatively avirulent, and backup defenses, including cough, mucociliary clearance, and other innate immune defenses, are adequate to prevent the development of pneumonia. Individuals with structural alterations of the oropharynx and lungs or patients

with impaired cough reflexes or neuromuscular disease are at particular risk for the development of pneumonia as a result of aspiration. The specialized ciliated cells of the bronchial mucosa are covered by a layer of mucus that traps foreign particles, which are propelled upward by rhythmic beating of the cilia to a point where a cough can expel the particles. Impaired mucociliary transport, as seen in persons with chronic obstructive pulmonary disease, predisposes to bacterial infection. Denuding of the respiratory epithelium by infection with the influenza virus is one mechanism by which influenza predisposes to bacterial pneumonia. Within the alveoli and smaller airways, alveolar macrophages, granulocytes, lymphocytes, and small peptides such as defensins and humoral opsonins, including antibody and complement, serve as host defenses against infection.

Infection by *Mycobacterium tuberculosis* is usually acquired through inhalation of aerosolized contaminated droplet nuclei. A primary infection is established in the parenchyma of the lungs and in the draining lymph nodes, which may result in a progressive primary infection, but in most instances it remains clinically silent or produces a mild respiratory illness. The mycobacteria may remain alive, sequestered within host macrophages, and are contained by host cell-mediated defenses in granulomas. Reactivation of infection may never occur, may occur without apparent precipitating events, or may occur at times when host cell-mediated immune responses are impaired and granulomas break down. Examples of these impairments include starvation, intercurrent viral infections, administration of immunosuppressive drugs (including corticosteroids and therapies that block the activity of tumor necrosis factor [TNF]), and illnesses associated with immunosuppression, such as Hodgkin disease and human immunodeficiency virus (HIV) infection.

Epidemiology

Common pathogens of community-acquired and nosocomial pneumonia are shown in Table 99-1. As a general rule,

Table 99-1 Important Pathogens Causing Pneumonia

Population*	Pathogens
Young, healthy adult	<i>Streptococcus pneumoniae</i> , <i>Legionella</i> species, <i>Mycoplasma pneumoniae</i> , <i>Chlamydia pneumoniae</i> , respiratory viruses
Elderly	<i>S. pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Mycobacterium tuberculosis</i> , gram-negative bacilli
Debilitated	<i>S. pneumoniae</i> , influenza virus, oral flora, <i>M. tuberculosis</i> , gram-negative bacilli
Hospitalized	Oral flora, <i>Staphylococcus aureus</i> , gram-negative bacilli, <i>Legionella</i> species

*See also Chapters 108 and 109.

Table 99-2 Specific Disorders and Associated Pneumonias

Disorder	Pneumonia
Seizures	Aspiration (mixed anaerobes)
Alcoholism	Aspiration, <i>Streptococcus pneumoniae</i> , <i>Klebsiella pneumoniae</i> and other gram-negative bacilli
Diabetes mellitus	Gram-negative bacilli, <i>Mycobacterium tuberculosis</i>
Sickle cell disease	<i>S. pneumoniae</i> , <i>Mycoplasma pneumoniae</i>
Chronic lung disease	<i>S. pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i> , <i>Pseudomonas aeruginosa</i> , <i>Burkholderia cepacia</i> and other gram-negative bacilli
Chronic renal failure	<i>S. pneumoniae</i> , <i>M. tuberculosis</i> , <i>Legionella pneumophila</i>

the pneumococcus is an important pathogen in all age groups, and influenza and tuberculosis become more frequent with increasing age. Although *Mycoplasma* occasionally produces pneumonia in the elderly, it is primarily a pathogen of the young. Certain systemic disorders appear to be associated with pneumonias caused by particular organisms (Table 99-2). The exposure history may be helpful in suggesting specific causative agents (Table 99-3). Pneumonias associated with bone marrow suppression and malignant disorders are discussed in Chapter 109.

Differential Diagnosis

A critical historical point in the differential diagnosis of pneumonia is the duration of symptoms. Pneumonia caused by pneumococci, *Mycoplasma*, or virus is usually an acute illness. Symptoms last for hours to a few days, although there may occasionally be a longer viral prodrome before bacterial superinfection. In contrast, symptoms of pneumonia lasting 10 days or more are rarely caused by the common bacterial pathogens and should raise suspicion of mycobac-

Table 99-3 Exposures Associated with Pneumonia

Source or Location	Pneumonia
Cattle, goats, sheep	Q fever, brucellosis, tularemia
Rabbits	Tularemia
Birds	Psittacosis, avian-influenza, cryptococcosis, histoplasmosis*
Rodents	Hantavirus

Developing countries	Tuberculosis

*Exposure to bird and bat droppings.

terial, fungal, or anaerobic pneumonia (anaerobes can produce acute or chronic infection) and/or the presence of an anatomic defect such as bronchiectasis or an endobronchial mass.

A history of an unusual exposure or the knowledge of the nature of an underlying immunodeficiency often provides clues to the cause of some less common pneumonias (see Table 99-3). Although these pneumonias are uncommon, they should be considered in the appropriate setting, because if improperly treated, some may be fatal.

A history of rhinitis or pharyngitis suggests respiratory virus or *Mycoplasma* or *Chlamydia* pneumonia. A persistent hacking, nonproductive cough characterizes some *Mycoplasma* infections; an abrupt onset of myalgia, arthralgia, headache, and fever is the typical clinical presentation of a patient with influenza virus infection and may also be seen with *Mycoplasma* pneumonia. A true rigor is very suggestive of a bacterial (often pneumococcal) pneumonia. Whereas small pleural effusions may be seen in nonbacterial pneumonias, severe pleuritic pain and/or empyema in a patient with pneumonia is highly suggestive of bacterial infection. Night sweats in the absence of rigors are seen in chronic pneumonias and suggest tuberculosis, fungal disease, or lung abscess.

Most patients with pneumonia have cough, fever, tachypnea, and tachycardia. Fever without a concomitant rise in pulse rate may be seen in legionellosis, *Mycoplasma* infections, and other “nonbacterial” pneumonias. Respirations may be shallow in the presence of pleurisy. Increasing tachypnea, cyanosis, and the use of accessory muscles for respiration indicate serious illness. Foul breath suggests anaerobic infection (e.g., lung abscess). Mental confusion in a patient with pneumonia should immediately raise the suspicion of meningeal involvement, which occurs most commonly in patients with pneumococcal pneumonia. Confusion may, however, be the most prominent clinical feature of pneumonia in elderly patients in the absence of associated meningitis. Nonetheless, patients with pneumonia who are confused must be evaluated by examination of cerebrospinal fluid.

Physical evidence of consolidation, dullness to percussion, bronchial breath sounds, crackles, increased fremitus, and whispered pectoriloquy suggest bacterial pneumonia. Early in the course of pneumonia, however, the physical examination findings may be normal.

RADIOGRAPHIC PATTERNS

No radiographic image is pathognomonic for a causative agent of pneumonia, but integration of radiographic and clinical findings may be useful in sorting through differential diagnostic possibilities.

As a rule of thumb, fever and malaise often help to differentiate the miliary pattern of tuberculosis from that of sarcoidosis, where patients may be without symptoms. A clinical-radiographic dissociation is a typical feature of *Mycoplasma pneumoniae* pneumonia, where the clinical suspicion of pneumonia is low but infiltrates are detected on the chest radiograph. The converse applies to patients with early *Pneumocystis jirovecii* pneumonia, in early miliary tuberculosis, or in hypersensitivity pneumonia wherein chest radiographs are often normal despite symptomatic clinical disease. Here, high-resolution computed tomography (CT) may demonstrate evidence of pathology. Likewise, early in the course of acute bacterial pneumonias, pleuritic chest pain, cough, purulent sputum, and inspiratory crackles may precede specific radiographic findings by many hours. A “negative” radiograph can never rule out the possibility of acute bacterial pneumonia when the patient’s symptoms and signs point to this diagnosis; however, infiltrates should then appear within 24 hours. Common radiologic features of pneumonias are shown in Table 99-4. A lobar consolidation suggests a bacterial pneumonia; however, patients with chronic lung disease often do not manifest clinical or radiographic evidence of consolidation during the course of bacterial pneumonia. Interstitial infiltrates suggest a nonbacterial process but may also be seen in early staphylococcal pneumonia. Enlarged hilar lymph nodes suggest a concomitant lung tumor but may also be seen in primary tuberculous,

viral, or fungal pneumonias. Large pleural effusions suggest streptococcal pneumonia or tuberculosis. Pneumatoceles are seen in patients after ventilator-mediated barotrauma but occur frequently in the evolution of staphylococcal pneumonia, particularly among children and also in patients with *P. jirovecii* pneumonia. The presence of cavitation identifies the pneumonia as necrotizing. This finding virtually excludes viruses and *Mycoplasma* and makes pneumococcal infection unlikely (see Table 99-4). Whenever possible, radiographs should be compared with older films.

OTHER LABORATORY FINDINGS

In patients with bacterial pneumonia, the white blood cell count is often (but not invariably) elevated. A left shift with immature forms is common. Patients with nonbacterial pneumonias tend to have lower white blood cell counts. The serum procalcitonin is a useful marker both for monitoring the severity of the bacterial infection as well as the treatment response. Modest elevations of serum bilirubin (conjugated) level may be noted in many bacterial infections but are particularly common in patients with pneumococcal pneumonia.

Diagnosis

When the patient exhibits abrupt onset of shaking chills, followed by cough, pleuritic chest pain, fever, rusty or yellow sputum, and shortness of breath, and the physical examination shows tachypnea and even minimal signs of alveolar inflammation (e.g., harsh breath sounds at one lung base), the presumptive diagnosis of bacterial pneumonia should be

Table 99-4 Classical Radiologic Patterns of Pneumonia

Radiologic Pattern	Clinical Situation	Predominant Microorganism
Lobar pneumonia	Community acquired Diabetes mellitus	<i>Streptococcus pneumoniae</i> <i>Mycoplasma pneumoniae</i> <i>Klebsiella pneumoniae</i> Gram-negative rods

Table 99-5 CRB-65 Score for the Risk Stratification in Community Acquired Pneumonia

Characteristics		Points
Mental confusion	Confusion regarding place and time	+1
Blood urea >19 mg/dL (>7 mmol/L)	Serum urea	+1
Respiratory rate >30/min	Respiratory rate	+1
Blood pressure: RR diastolic <60 mm Hg or systolic <90 mm Hg	Blood pressure	+1
>65	Age	+1
CRB-65 Risk Group	Fatality	Treatment Location
0	Low (1, 2%)	Outpatient
1 or 2	Moderate (8, 1%)	Consider admission
3 or 4	High (31%)	Admission, consider intensive care unit

RR, time duration between two consecutive R waves of an ECG.

made and appropriate therapy should be begun regardless of radiographic findings. The radiographic abnormalities in pneumonia may lag for several hours after the clinical onset of pneumonia, and when the clinical diagnosis of pneumonia is made, therapy should not be delayed while awaiting results of diagnostic procedures. When the diagnosis of pneumonia is made, heightened risks for mortality and hence decisions to treat as an outpatient, hospitalize, or place into an intensive care unit can be estimated according to the presence of confusion, serum urea >7 mmol/L (>19 mg/dL), respiration rate >30/min, blood pressure <90/60 mm Hg, and age >65 years (Table 99-5). Patients with one or more of these factors may benefit from hospitalization; those with three or more are often best managed in an intensive care unit. Decisions based on these scores must be made also in the context of good clinical judgment. For persons in whom outpatient treatment for pneumonia is recommended, a “second look” reevaluation should be performed 24 to 48 hours after the initial examination to ensure that good progress is being made and hospitalization is not needed.

Empirical antibiotic treatment without laboratory examination of sputum has been recommended for uncomplicated cases of community-acquired pneumonia, and in many instances a good sputum specimen is not readily provided by the patient. Nonetheless, in our view a pretreatment sputum examination helps guide management and is especially useful for review and guidance in instances of first treatment failure. Examination of respiratory secretions is especially valuable for prompt diagnosis and proper treatment of pneumonia in hospitalized patients or in outpatients with risk factors for infections with staphylococci or gram-negative rods; these risk factors include older age, recent hospitalizations, recent antibiotic therapy, underlying lung disease, or impairments of host defenses. The adequacy of a Gram-stained sputum specimen can be ascertained by

(1) the absence of squamous epithelial cells and (2) the presence of polymorphonuclear leukocytes (10 to 15 per high-power field). The presence of alveolar macrophages and bronchial epithelial cells confirms the lower respiratory tract origin of the specimen. The presence of a predominant organism, particularly if found within white blood cells in the absence of squamous cells, suggests that this is the likely pathogen. A specimen with many (>5 per high-power field) squamous epithelial cells is of no value for either culture or Gram stain, because it is contaminated with upper respiratory tract secretions.

In some cases the patient cannot produce an adequate sputum sample despite vigorous attempts at sputum induction using an aerosolized solution of 3% hypertonic saline. The sicker the patient and the greater the likelihood of a multidrug-resistant pathogen, the more important it is to get an adequate sample of sputum for examination and culture. In cases of aspiration of mouth flora, a mixture of oral streptococci, gram-positive rods, and gram-negative organisms is found. In some cases, there may be inflammatory cells and no organisms seen on Gram stain. This finding suggests a number of possibilities, many of which are “nonbacterial” pneumonias (Table 99-6). Unless the diagnosis of acute bacterial pneumonia is clear, an acid-fast stain or fluorescent auramine-rhodamine stain of sputum for mycobacteria should be performed. If legionellosis is suspected, immunofluorescence stains for *Legionella* can be used, although the yield on expectorated sputum is low. The demonstration of elastin fibers in a potassium hydroxide preparation of sputum establishes a diagnosis of necrotizing pneumonia (Table 99-7). Blood cultures should be obtained and may be positive in as many as 20% to 30% of patients with bacterial pneumonia.

Results of sputum cultures must be interpreted with caution, because pathogens causing pneumonia may fail to grow and sputum isolates may not be the pathogens responsible for infection. Careful screening of sputum specimens with Gram stain increases the accuracy of culture results. A tuberculin skin test or a blood test for interferon (IFN)- γ release in response to mycobacterial antigens should be applied in all cases of pneumonia of uncertain cause. A negative tuberculin test may occur despite active pulmonary and/or disseminated tuberculosis.

Specific Pathogenic Organisms

VIRAL AGENTS

Respiratory viral infection is usually limited to the upper respiratory tract, and only a small proportion of infected adults develop pneumonia. In children, viruses are the most common cause of pneumonia, and respiratory syncytial virus is the most frequent organism. In adults, viruses are estimated to account only for a minority of pneumonias, and the influenza virus is the most common organism. Patients at increased risk for influenzal pneumonia include the aged; patients with chronic disease of the heart, lung, or kidney; and women in the last trimester of pregnancy. Cytomegalovirus may cause severe pneumonia in immunosuppressed patients, especially in organ transplant recipients. When varicella occurs in adults, some 10% to 20% develop pneu-

Table 99-6 Sputum Gram Stain Showing Inflammatory Cells and No Organisms

Possibilities	Clinical Setting	Confirmation of Diagnosis	Treatment
Prior antibiotic treatment			
Viral pneumonia	Winter months influenza, may be mild or life threatening	Serologic studies, virus culture, antigen detection	Oseltamivir or zanamivir for influenza A or B, ribavirin for respiratory syncytial virus
<i>Mycoplasma pneumoniae</i> infection	Hacking, nonproductive cough	Cold agglutinins, serologic studies	Doxycycline or macrolide
<i>Legionella pneumophila</i> infection	Chronic lung disease, hospital acquired, summer predominance	DFA of sputum, bronchial brush biopsy, or pleural fluid, culture, serologic studies	Azithromycin or levofloxacin
<i>Chlamydomphila psittaci</i> infection	Exposure to birds (e.g., parrots, turkeys)	Serologic studies	Tetracycline or doxycycline
<i>Chlamydomphila pneumoniae</i> infection	Hacking cough, sinusitis	Serologic studies, antigen detection	Tetracycline or macrolides
Q fever	Exposure to cattle, South Africa	Serologic studies	Tetracycline or chloramphenicol

DFA, direct immunofluorescence assay.

monia, which commonly leaves a pattern of diffuse punctate calcification on chest radiographs. Measles is occasionally complicated by pneumonia. Cases of pneumonia and adult respiratory distress syndrome caused by hantavirus have been reported, primarily among persons residing in the southwestern United States. This severe, rapidly progressive, and often fatal infection occurs largely among otherwise healthy young adults who have been exposed to rodent droppings. Treatment is supportive.

Other viral pneumonias, of which influenza is the prototype in adults, typically occur in community epidemics and usually develop 1 to 2 days after the onset of flulike symptoms. Major features include a dry cough, dyspnea, generalized discomfort, unremarkable physical examination findings, and an interstitial pattern on the chest radiograph. Influenza-induced necrosis of respiratory epithelial cells predisposes to bacterial colonization. This may result in superimposed bacterial pneumonia, most often caused by *S. pneumoniae*, *Staphylococcus aureus*, or *Haemophilus influenzae*. A presumptive diagnosis may be made on the basis of the clinical presentation and the epidemiologic setting. Gram stain of sputum reveals inflammatory cells and rare bacteria. Detection of viral antigens in sputum can confirm the diagnosis rapidly. Viral isolation or serology also can establish the diagnosis, but not in time to guide management

decisions. Persons with laboratory-confirmed diagnosis of influenza B can benefit from treatment with the neuraminidase inhibitors oseltamivir or zanamivir for five days. If infection is caused by influenza A virus, zanamivir may be preferred or oseltamivir may be given together with rimantadine as influenza A viruses are increasingly resistant to oseltamivir. Treatment should be started within 48 hours of the onset of illness and is indicated for persons with influenza pneumonia or pneumonia complicated by bacterial superinfection and those who are very ill and at high risk for complications.

Recently, highly pathogenic influenza virus strains (H5N1) emerging from avian reservoirs have caused mortality in more than 65% of infected persons in some southeast Asian nations. If and when recombination with currently circulating strains occurs, avian influenza could potentially cause another devastating influenza pandemic. In the spring and summer of 2009, a new H1N1 strain of influenza caused disease worldwide. Younger patients were at most risk. The strain produced a typical flu-like syndrome. Fatalities were noted predominantly in patients with underlying conditions. Other viral agents that may cause pneumonia in adults include parainfluenza virus, respiratory syncytial virus, adenovirus, and newly described viruses such as metapneumovirus.

In 2003, pandemic spread of a newly identified coronavirus (SARS-CoV) caused morbidity in more than 8000 persons around the globe with a mortality of nearly 10%. To date, no effective antiviral treatment is available. Seasonal outbreaks of this severe acute respiratory syndrome and other emerging viral respiratory infections, such as Nipah virus and Hendra virus infections, may be anticipated.

BACTERIAL AGENTS**Streptococcus Pneumoniae**

The pneumococcus is still the most common bacterial cause of pneumonia in the community. The organism colonizes the oropharynx in up to 25% of healthy adults. An increased predisposition to pneumococcal pneumonia is seen in

persons with sickle cell disease, prior splenectomy, chronic lung disease, hematologic malignancy, alcoholism, HIV infection, and renal failure. Clinical features include fever, rigors, chills, cough, respiratory distress, signs of pulmonary consolidation, confusion, and herpes labialis. By the second or third day of illness, the chest radiograph typically shows lobar consolidation with air bronchograms, but a patchy bronchopneumonic pattern may also be found. Abscess or cavitation rarely occurs. Sterile pleural effusions occur in up to 25% of cases, and empyema occurs in 1%. Typically, a leukocytosis of 15,000 to 30,000 cells/ μ L with neutrophilia is found, but leukopenia may be observed with fulminant infection, particularly among alcoholics and persons with HIV infection. Gram-positive cocci in pairs can be seen on microscopic examination of expectorated sputum samples in >60% of cases in patients with pneumococcal pneumonia. Positive blood cultures are found in 20% to 25% of patients. In most regions of the world, penicillin G remains the treatment of choice. In regions with a higher frequency of penicillin-resistant pneumococci, or in persons who are severely ill, cephalosporins or vancomycin may be indicated, depending on regional antibiotic sensitivity patterns.

Staphylococcus Aureus

S. aureus infection accounts for 2% to 5% of community-acquired pneumonias, 11% of hospital-acquired pneumonias, and up to 26% of pneumonias after a viral infection. Persistent nasal colonization is observed in 15% to 30% of adults, and 90% of adults display intermittent colonization. Presentation is similar to that of pneumococcal pneumonia, but contrasting features include the development of parenchymal necrosis and abscess formation in up to 25% of patients and empyema in 10%. A hematogenous source of infection, such as septic thrombophlebitis, infective endocarditis, or an infected intravascular device, should be suspected in cases of staphylococcal pneumonia, particularly if the chest radiograph shows multiple or expanding nodular or wedge-shaped infiltrates. Early in staphylococcal pneumonia of hematogenous origin, sputum is rarely available. Blood cultures are usually positive, and associated skin lesions occur in 20% to 40% of cases. When sputum is available, Gram stain shows grapelike clusters of gram-positive cocci. *S. aureus* is recovered very easily from mixed culture samples, so its absence in a purulent specimen usually excludes it as a cause of the pneumonia.

An increasing proportion of community acquired *S. aureus* strains in the United States is now methicillin resistant (MRSA). In affected regions, initial treatment with vancomycin or linezolid is recommended until sensitivity studies indicate that the isolate is sensitive to semisynthetic penicillins or cephalosporins.

Haemophilus Influenzae

H. influenzae is a gram-negative coccobacillus often present in the upper respiratory tract, particularly among patients with chronic obstructive pulmonary disease. Its isolation from sputum in these patients is to be expected. Confirmation of its role in the pathogenesis of pneumonia depends on isolating the organism in the blood, pleural fluid, or lung tissue. Nevertheless, many cases of pneumonia caused by this organism will not be confirmed using these rigid criteria, and in a patient with pneumonia the demonstration

of gram-negative coccobacilli on Gram stain of sputum should prompt institution of treatment with ampicillin plus a β -lactamase inhibitor or a second- or third-generation cephalosporin.

Gram-Negative Bacilli

Gram-negative bacilli have emerged as pathogens of major importance with the introduction of potent antibiotics and the proliferation of intensive care units. They are frequently encountered in patients with structural abnormalities of the tracheobronchial tree, such as chronic obstructive pulmonary disease and cystic fibrosis in the setting of neutropenia, alcoholism, diabetes mellitus, malignancy, and chronic disease of the heart and kidney. They are ubiquitous throughout the hospital, contaminating equipment and instruments, and are the major source of nosocomial pneumonia.

Specific organisms have been associated with certain situations; for example, *Klebsiella pneumoniae* is particularly common in chronic alcoholics, *Escherichia coli* pneumonia is associated with bacteremias arising from the intestinal or urinary tract, and *Pseudomonas* species commonly infect the lungs of patients with cystic fibrosis. Precise etiologic diagnosis is confounded by the frequency with which these organisms colonize the upper airways in predisposed patients. Treatment of patients with *Pseudomonas aeruginosa* infection or seriously ill patients generally includes the use of two active agents, such as an extended spectrum penicillin, a carbapenem, or a third-generation cephalosporin plus a fluoroquinolone.

OTHER CAUSES OF ACUTE PNEUMONIA

Mycoplasma Pneumoniae

Not only is *Mycoplasma pneumoniae* a common cause of pneumonia in young adults, but it also produces a wide range of extrapulmonary features that may be the only findings. Fewer than 10% of infected patients develop symptoms of lower respiratory tract infection. Respiratory findings resemble those of viral pneumonia. Hacking, nonproductive cough is characteristic. Nonpulmonary features include myalgias, arthralgias, skin lesions (rashes, erythema nodosum and multiforme, or Stevens-Johnson syndrome), and neurologic complications (meningitis, encephalitis, transverse myelitis, cranial nerve, or peripheral neuritis). The occurrence of acute, multifocal neurologic abnormalities may be helpful in distinguishing *Mycoplasma* pneumonia from that caused by *Chlamydia* or *Legionella*. The neurologic abnormalities characteristically resolve completely as the acute illness subsides.

In some patients, cold agglutinins may be seen at the bedside by observing red blood cell clumping on the walls of a glass tube containing anticoagulated blood incubated on ice for at least 10 minutes; they are also occasionally positive in other respiratory infections. Complement fixation antibody testing can suggest the diagnosis. Treatment for 7 to 14 days with doxycycline or a macrolide decreases the duration of symptoms and hastens radiographic resolution but does not eradicate the organism from the respiratory tract.

Chlamydothila (Chlamydia) Pneumoniae

Five percent to 15% of cases of community-acquired pneumonia may be caused by *Chlamydothila pneumoniae*

(formerly called the *TWAR* agent). Infection is spread presumably through the respiratory route, from person to person, and onset of disease is generally subacute, often manifested by pharyngitis, sinusitis, bronchitis, and pneumonia. The radiographic appearance of pneumonia caused by *C. pneumoniae* resembles that of *Mycoplasma* infection. Illness is relatively mild and often prolonged. Diagnosis of this infection is difficult and requires cultivation of the organism in special cell lines or testing of acute and convalescent sera for antibody levels. Although the organism is sensitive to macrolides and tetracyclines, treatment may have little effect on the course of disease.

Legionella

Legionella are fastidious gram-negative bacilli that were responsible for respiratory infections long before the well-publicized outbreak of legionnaires' disease in 1976, which led to the recognition of this distinct disease entity and to the identification of the responsible bacillus. (The high mortality rate from this outbreak of a hitherto unrecognized disease among participants at an American Legion convention destroyed the reputation of one of Philadelphia's finest hotels.) These organisms are distributed widely in water, and outbreaks have been related to their presence in water towers, air conditioners, condensers, potable water, and even hospital showerheads. Infection may occur sporadically or in outbreaks. Although healthy subjects can be affected, there is an increased risk in patients with chronic diseases of the heart, lungs, or kidneys; malignancy; and impairment of cell-mediated immunity. After an incubation period of 2 to 10 days, the illness usually begins gradually with a dry cough, respiratory distress, fever, rigors, malaise, weakness, headache, confusion, and gastrointestinal disturbance. The chest radiograph shows alveolar shadowing that may have a lobar or patchy distribution, with or without pleural effusions. Approximately half of patients have a mild disease course; in those with a more severe clinical course, the diagnosis is suggested clinically by the combination of a rapidly progressive pneumonia, dry cough, and multiorgan involvement. Microhematuria and a low serum sodium concentration are often present. Gram stain of sputum shows neutrophils and no organisms.

Diagnosis can be made by the following four methods:

- Indirect fluorescent antibody testing of serum is positive in 75% of patients, but up to 8 weeks is required for seroconversion.
- Direct fluorescence antibody testing of respiratory secretions is technically demanding and has a specificity of 95%. Sensitivity of this method is low when using expectorated sputum but greater in specimens obtained from bronchoscopy or transtracheal aspirate.
- *Legionella* antigen can be detected in urine with a sensitivity of 80% to 95% for *Legionella pneumophila* type 1.
- The organism can be cultured on charcoal yeast extract medium (the laboratory must be informed), but up to 10 days is required for growth.

Levofloxacin for 10 to 14 days or alternatively azithromycin for 7 to 10 days is effective therapy. Rifampin may be added in the gravely ill patient, but its value is unproven. Prompt treatment results in fourfold to fivefold reduction in

mortality. Patients usually respond within 12 to 48 hours, and it is very unusual for fever, leukocytosis, and confusion to persist beyond 4 days of therapy.

COMMUNITY-ACQUIRED PNEUMONIA OF UNCERTAIN CAUSE

Although it is important to make the best effort to obtain specimens, there are many instances in which, because of difficulty in obtaining adequate sputum specimens or lack of laboratory facilities, empirical treatment of acute community-acquired pneumonia may be necessary. In such instances, initial therapy should be guided by the patient risk factors, comorbidities, and the severity of illness (Table 99-8).

TUBERCULOSIS

Approximately 25,000 new cases of tuberculosis occur in the United States each year, with a worldwide incidence of 7 to 10 million. In North America, a disproportionately high number of cases occurs among the foreign born, racial and ethnic minorities, and the poor. *M. tuberculosis* is transmitted by the respiratory route from an infected patient with pulmonary tuberculosis to a susceptible host. Primary infection may be documented by the development of a positive tuberculin skin test result or a positive blood test for IFN- γ release in response to mycobacterial antigens. Occasionally the patient develops sufficient symptoms of fever and non-productive cough to visit a physician, and a chest radiograph is taken; patchy or lobular infiltrates are noted in the anterior segment of the upper lobes or in the middle or lower lobes, often with associated hilar adenopathy. Pleurisy with effusion is a less common manifestation of primary tuberculosis. Primary infection usually is self-limited, but hematogenous dissemination seeds multiple organs, and latent foci are established and become niduses for delayed reactivation. Overall, 5% to 10% of individuals with a positive tuberculin skin test result develop disease over their lifetime. Factors associated with progression to clinical disease are age (the periods of greatest biologic vulnerability to tuberculosis being infancy and old age); underlying diseases that depress the cellular immune response (see Chapter 109); diabetes mellitus, gastrectomy, silicosis, and sarcoidosis; and the interval since primary infection, with disease progression most likely in the first few years after infection. Anti-TNF- α therapy can lead to activation of latent tuberculosis infection. Early progression of infection to disease is known as *progressive primary tuberculosis* and may manifest as miliary tuberculosis, sometimes with meningitis, or as pulmonary disease of the apical and posterior segments of the upper lobes or lower lobe disease.

Most commonly, tuberculosis represents delayed reactivation. Symptoms begin insidiously with night sweats or chills and fatigue; fever is noted by fewer than 50% of patients, and hemoptysis by fewer than 25%. Physical examination findings may be unremarkable, or dullness and crackles may be present in the upper lung fields, occasionally with amphoric breath sounds. The chest radiograph may show cavitary disease with infiltrates in the posterior segment of the upper lobes or apical segments of the lower lobes; however, the radiographic findings in pulmonary tuberculosis can be quite variable.

Table 99-8 Empirical Therapy for Treatment of Community-Acquired Pneumonia

Outpatient Treatment	
Previously healthy, no recent antibiotics	Azithromycin, doxycycline
Underlying comorbidities or recent (within 3 months) antibiotics or regions where macrolide-resistant <i>Pneumococcus</i> is prevalent	Levofloxacin, moxifloxacin, or gemifloxacin, 750 mg bid
Inpatient Treatment (Non-ICU)	
	Levofloxacin, moxifloxacin, or gemifloxacin (750 mg bid) <i>Or</i> A β -lactam (e.g., penicillin, ampicillin) plus azithromycin or azithromycin
Inpatient Treatment (ICU)	
	Cefotaxime, ceftriaxone, or ampicillin-sulbactam plus either azithromycin or (levofloxacin, moxifloxacin, or gemifloxacin)
Special Considerations	
If <i>Pseudomonas</i> is a concern	Piperacillin-tazobactam, cefepime, imipenem, or meropenem Plus ciprofloxacin or levofloxacin, 15 mg/kg every 12 hrs
If cMRSA is a concern	Add vancomycin or linezolid, 600 mg IV or PO every 12 hrs Azithromycin, 500 mg daily (IV, PO) Doxycycline, 100 mg bid PO Ciprofloxacin, 750 mg bid PO, 400 mg bid IV; levofloxacin, 750 mg daily (IV, PO); moxifloxacin, 400 mg daily (IV, PO); gemifloxacin, 320 mg daily PO Ampicillin-sulbactam, 500 mg q8h IV Piperacillin-tazobactam, 3.375 g IV q6h Ceftazidime, 2 g IV q8h; cefepime, 2 gm IV q12h Meropenem, 1 g IV q8h, imipenem, 1 g IV q8h

Data from Mandell LA, Wunderink RG, Anzueto A, et al: Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. *Clin Infect Dis* 44(Suppl):S27-S72, 2007.
cMRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; IV, intravenously; PO, orally.

Extrapulmonary tuberculosis also reflects reactivation of latent foci and accounts for approximately 15% of cases. Miliary tuberculosis is discussed in Chapter 95, meningeal tuberculosis in Chapter 97, and tuberculosis of bones and joints in Chapter 104.

The elderly and patients with diabetes mellitus are more likely to have lower lobe tuberculosis. Because of the growing proportion of elderly individuals in our society and the growing prevalence of HIV infection, “atypical” presentations of tuberculosis are increasingly common. In HIV-infected patients, involvement of the lower lobes is frequent and extrapulmonary tuberculosis, frequently involving lymph nodes, is almost as common as pulmonary involvement. Tuberculin skin tests are likely to be negative in patients with CD4⁺ T-cell counts <200 cells/ μ L. The index of suspicion must be high in these settings.

Before antituberculosis drug treatment is started, two or three sputum samples should be obtained for cultures; bronchoscopy and bronchial washing are indicated only if sputum smears are negative for acid-fast bacilli. Amplification of bacterial sequences by polymerase chain reaction (PCR) can distinguish between *M. tuberculosis* and nontuberculous mycobacteria. It is important to obtain baseline evaluation of liver function for individuals who are to receive potentially hepatotoxic drugs (isoniazid, rifampin, or pyrazinamide); color vision, visual fields, and acuity when ethambutol will be used; and audiometry for patients who are to receive streptomycin.

The main principle of chemotherapy for tuberculosis is to avoid resistance by treating with at least two drugs to which the organism is likely to be sensitive. Pulmonary tuberculosis should be treated with daily isoniazid (5 mg/kg, up to 300 mg), rifampin (10 mg/kg, up to 600 mg), ethambutol (15 to 25 mg/kg, up to 2.5 g), and pyrazinamide (15 to 30 mg/kg, up to 2.0 g) for 2 months, followed by isoniazid

and rifampin for 4 more months. A longer treatment duration (a total of 9 months) is suggested when cultures are still positive after 2 months of therapy. When *M. tuberculosis* is resistant to one or more antimycobacterial drugs, expert advice should be sought to design an alternative treatment regimen. Close monitoring during treatment is mandatory to maximize compliance and minimize side effects. Directly observed therapy is recommended by the World Health Organization (WHO) for all patients with tuberculosis.

Contact tracing is critical, because recent infection or additional cases of tuberculosis are likely in some household contacts. Preventive therapy should be considered for all young children and all adults with TST or IFN- γ release assay conversion or those with positive results of these studies who will receive immunosuppressive therapies (e.g., anti-TNF).

Treatment and Outcome

BACTERIAL PNEUMONIA

If the pathogen is readily identified on Gram stain, the antibiotic choices are straightforward (Table 99-9). Otherwise, empiric therapies are indicated (see Table 99-8). The decision as to whether a patient with pneumonia should be hospitalized can be aided by the results of the CRB-65/CURB scores (see Table 99-5). Patients who are treated at home must be able to take their medicines by mouth, should have others at home to attend to their needs, and should be seen again within 24 to 48 hours to ensure that there is an adequate clinical response.

Hospitalized patients should receive supplemental oxygen if hypoxemic. Patients at risk for the development of respiratory failure should be monitored in a critical care setting. Mechanical ventilation should be strongly considered in

Table 99-9 Targeted Initial Therapy for Pneumonia

Pathogen	Treatment
<i>Streptococcus pneumoniae</i>	Ceftriaxone, 2 g IV daily*
<i>Mycoplasma pneumoniae</i>	Azithromycin, 500 mg PO day 1, 250-500 mg PO days 2-7
<i>Chlamydomphila pneumoniae</i>	Azithromycin, 500 mg PO day 1, 250-500 mg PO days 2-7
<i>Haemophilus influenzae</i>	Ampicillin-sulbactam, 500 mg q8h IV, or cefuroxime, 1 g q8h IV
<i>Staphylococcus aureus</i>	Vancomycin, 1 g IV q12h [†] or linezolid, 600 mg q12h IV
<i>Legionella pneumophila</i>	Levofloxacin, 500 mg IV or PO bid Azithromycin, 500 mg PO day 1, 250-500 mg PO days 2-7
<i>Ehrlichia chaffeensis</i>	Doxycycline, 100 mg PO bid
Mixed oral flora (anaerobes)	Ampicillin-sulbactam, 500 mg IV q8h, or clindamycin, 600 mg IV or PO q8h
Gram-negative rods Double coverage against <i>Pseudomonas aeruginosa</i>	Extended-spectrum penicillin (e.g., piperacillin-tazobactam, 3.375 g IV q6h) or third-generation cephalosporin (e.g., ceftazidime, 2 g IV q8h) [‡] or carbapenem (e.g., meropenem, 1 g IV q8h plus fluoroquinolone (e.g., ciprofloxacin, 400 mg IV or 750 mg PO bid)
Tuberculosis	Isoniazid/vitamin B ₆ , 300/50 mg PO qd, plus rifampin, 600 mg PO qd, ethambutol, 15-25 mg/kg PO qd, and pyrazinamide, 30 mg/kg PO qd

*Levofloxacin, 500 mg daily, for penicillin-allergic patients. Vancomycin, 1 g IV twice daily, for penicillin-resistant isolates.

[†]Vancomycin or linezolid is preferred if methicillin-resistant *Staphylococcus aureus* (MRSA) is at all prevalent, and regimen can modified if the organism is found sensitive to nafcillin or cephalosporins.

[‡]Antibiotics can be adjusted when sensitivity data are available.
IV, intravenously; PO, orally.

those with a blood pH <7.25. Patients should be placed in a 45-degree sitting position to avoid aspiration. Meticulous attention must be paid to suctioning of oral secretions. Patients with suspected pulmonary tuberculosis should be placed in isolation rooms with negative pressure, frequent air exchange, and germicidal lamps to prevent nosocomial transmission of infection.

Patients treated for pneumococcal pneumonia should begin to improve within 48 hours after institution of antibiotics. Patients with pneumonia caused by gram-negative bacilli, staphylococci, *P. jirovecii*, and oral anaerobes may remain ill for longer periods after initiation of treatment. Several possibilities should be considered among patients who fail to improve or whose condition deteriorates during treatment.

ENDOBRONCHIAL OBSTRUCTION

Physical examination may fail to show sounds of consolidation, and radiographs may show evidence of lobar collapse. Bronchoscopy can establish the diagnosis.

UNDRAINED EMPYEMA

Radiographs may not always distinguish between fluid and consolidation; ultrasonography and CT can identify the fluid and provide direction for its drainage.

INCORRECT DIAGNOSIS OR TREATMENT

In cases in which clinical response is poor, the patient's hospital course and admission sputum stains should be reviewed by a clinician with expertise in the diagnosis and treatment of pneumonia. Pulmonary embolism with infarction, a treatable disease, can prove fatal if misdiagnosed as bacterial pneumonia. Misinterpretation of sputum gram-stained preparations with either failure to recognize an important pathogen or a treatment decision based on examination of an inadequate specimen is an avoidable pitfall of

medical practice. Bronchoscopy should be considered, both to obtain better specimens for diagnosis and to exclude underlying endobronchial obstruction.

THE PATIENT WITH PLEURAL EFFUSION AND FEVER

The approach to patients with pleural effusion and fever is quite straightforward: the fluid must be examined. If a bacterium other than *S. pneumoniae* is seen on Gram stain of pleural fluid or grown in culture, chest tube drainage is required. A pleural effusion infected with pneumococci can often be treated with simple needle aspiration and antibiotics. Among patients with pneumonia, fluids that have a pH of less than 7.2 and/or a glucose concentration below 40 mg/dL may require chest tube drainage for satisfactory resolution. Patients with empyema complicating an aggressive bacterial pneumonia such as that caused by group A streptococci may benefit from early surgical débridement of the pleural space (decortication).

Pleurisy caused by *M. tuberculosis* is often an acute illness. In most cases, pneumonia is not present or readily appreciated. Inflammatory cells—polymorphonuclear leukocytes, mononuclear leukocytes, or both—are present in the pleural fluid. Mesothelial cells are usually sparse (<0.5% of the total cell count). Pleural fluid glucose levels are often low but may be normal. Mycobacteria are rarely seen on stains of pleural fluid. As many as one third of these patients do not have positive tuberculin skin test results. Detection of M Tb antigen-specific IFN- γ -secreting T-cells in pleural fluid may help to establish a diagnosis of tuberculous pleuritis. Other causes of pleural effusion in this setting may be pulmonary infarction (fewer than half of patients produce a hemorrhagic exudate), malignancy (most do not have fever), and connective tissue diseases such as systemic lupus erythematosus and rheumatoid arthritis (the latter is typically associated with very low pleural fluid glucose levels). If the cause of the effusion is not evident, a biopsy of the pleura is needed.

Table 99-10 Prevention of Pneumonia: Candidates for Pneumococcal and Influenza Vaccines

Factor	Pneumococcal Vaccine (may be repeated after 5-7 yr)
Patient ≥ 65 years	Yes
Chronic lung or heart disease	Yes
Sickle cell disease	Yes
Asplenic patients	Yes
Hodgkin disease	Yes
Multiple myeloma	Yes
Cirrhosis	Yes
Chronic alcoholism	Yes
Chronic renal failure	Yes
Cerebrospinal fluid leaks	Yes
Residents of chronic care facilities	Consider
Diabetes mellitus	Yes
Human immunodeficiency virus infection	Yes
Children receiving long-term aspirin therapy	No
Pregnant women in the second or third trimester during influenza season	No
Health care workers	No

Note that annual influenza immunization is now recommended for all persons over the age of 6 months. Trivalent inactivated vaccine (TIV) can be given to all persons who are not hypersensitive to its components. Live inactivated influenza vaccine can be given to healthy persons from 2 to 49 years of age. It should not be given to young children (<5 years old) with hyperactive airway disease or persons with underlying medical conditions placing them at higher risk for complications of influenza. TIV should be given to these persons instead.

Prevention

Pneumococcal pneumonia may be preventable by immunizing patients at high risk with polyvalent pneumococcal polysaccharide vaccine. The current polyvalent vaccine is 60% to 80% effective for a 5-year period in individuals with normal immune responses. Yearly immunization with influenza vaccine is also advised for many of these patients; by decreasing the attack rate of influenza, immunization also decreases

morbidity and mortality resulting from secondary bacterial pneumonia (Table 99-10).

Patients without active tuberculosis but with skin test reactivity to purified protein derivative or a positive IFN- γ release assay in response to mycobacterial antigens are at risk for reactivation of infection. The development of active tuberculosis can be prevented in most instances by treatment for 9 to 12 months with isoniazid, 300 mg/day. Indications for prophylaxis are shown in Table 99-9.

Prospectus for the Future

- Preservation of clinical skills for diagnosis and treatment of pneumonia:
 - Development of better techniques for rapid etiologic diagnosis of pneumonia
 - Development of techniques for rapid evaluation of antimicrobial susceptibility
- An increasing incidence of drug resistance in bacteria causing pneumonia, including pneumococci, staphylococci, and gram-negative bacteria
- Preparation for outbreaks of life-threatening pneumonias such as those caused by organisms such as avian influenza

Infections of the Heart and Blood Vessels

Benigno Rodríguez and Michael M. Lederman

Infective Endocarditis

Infective endocarditis (IE) ranges from an indolent illness with few systemic manifestations, readily responsive to antibiotic therapy, to a fulminant septicemic disease with malignant destruction of heart valves and life-threatening systemic embolization. The varied features of endocarditis relate in large measure to the different infecting organisms. Viridans group streptococci are prototypic bacteria that originate in the oral flora, infect previously abnormal heart valves, and may initially cause minimal symptoms despite progressive valvular damage. *Staphylococcus aureus*, in contrast, can invade previously normal valves and destroy them rapidly. Universally fatal in the preantibiotic era, endocarditis remains a life-threatening but potentially curable disorder.

EPIDEMIOLOGY

The average age of patients with endocarditis has increased in the antibiotic era to the current median of 58 years. This change can be attributed to the decreasing prevalence of rheumatic heart disease, the increasing prevalence of underlying degenerative heart disease, and the increasing frequency of procedures and practices predisposing older patients to bacteremia (genitourinary instrumentation, intravenous catheters, hemodialysis shunts). Rheumatic heart disease is now a predisposing factor in fewer than 25% of patients with IE in industrialized countries. Up to 24% of patients have congenital heart disease (exclusive of mitral valve prolapse). The propensity to develop endocarditis varies with the congenital lesion. For example, infection of a bicuspid aortic valve accounts for one fifth of cases of IE occurring in persons over the age of 60; a secundum atrial septal defect, however, rarely becomes infected. Mitral valve prolapse with valvular regurgitation also can predispose to endocarditis. Intravenous drug users have a unique propensity to develop IE of the tricuspid valve. On long-term follow-up, patients with prosthetic heart valves have a 4% to 17% lifetime risk of IE.

PATHOGENESIS

Endocarditis ensues when bacteria entering the bloodstream from an oral or other source lodge on heart valves, particularly those bearing platelet-fibrin thrombi as a consequence of prior valvular damage or turbulent blood flow. Bacteremia occurs frequently after dental extraction (18% to 85%) or periodontal surgery (32% to 88%), but also after everyday activities such as tooth brushing (0% to 26%) and chewing candy (17% to 51%). These episodes rarely result in endocarditis. The ability of certain organisms to adhere to platelet-fibrin thrombi, such as through production of extracellular dextran by some streptococcal strains, promotes occurrence of endocarditis after bacteremia caused by these organisms. The localization of infection is partly determined by the production of turbulent flow; therefore left-sided infection is much more common than right-sided infection, except among intravenous drug users. Vegetations usually are found on the valve surface facing the lower pressure chamber (e.g., atrial surface of the mitral valve), a relative haven for deposition of bacteria from the swift bloodstream. Occasionally, “jet lesions” develop in foci in which the regurgitant stream strikes the heart wall or the chordae tendineae. Once infection begins, bacteria proliferate freely within the interstices of the enlarging vegetation; in this relatively avascular site, they are protected from serum bactericidal factors and leukocytes.

The infection may cause rupture of the valve tissue itself or of its chordal structures, leading to either gradual or acute valvular regurgitation, with resultant congestive heart failure. Some virulent bacterial (e.g., *S. aureus*, *Haemophilus* species) or fungal vegetations may become large enough to obstruct the valve orifice or create a large embolus. Aneurysms of the sinus of Valsalva may occur and can rupture into the pericardial space. The conducting system may be affected by valve ring or myocardial abscesses. The infection may invade the interventricular septum, causing intramyocardial abscesses or septal rupture that can also damage the conduction system of the heart. Systemic septic emboli may

occur with left-sided endocarditis, and septic pulmonary emboli may occur with right-sided endocarditis.

CLINICAL FEATURES

Some cases of endocarditis caused by oral streptococci become clinically manifest within 2 weeks of a precipitating event, such as dental extraction, but the diagnosis may be delayed an additional 4 to 5 weeks or more because of the paucity of symptoms. If the causative organism is slow growing and produces an indolent syndrome, symptoms may be extremely protracted (6 months or longer) before definitive diagnosis is made. The symptoms and signs of IE relate to systemic infection, emboli (bland or septic), metastatic infective foci, congestive heart failure, or immune complex-associated lesions. The most common complaints in patients with IE are fever, chills, weakness, shortness of breath, night sweats, loss of appetite, and weight loss. Musculoskeletal symptoms, particularly back pain, develop in nearly one half of patients and may dominate the presentation. Fever is present in 90% of patients. Fever is more often absent in elderly or debilitated patients or in the setting of underlying congestive heart failure, liver or renal dysfunction, or previous antibiotic treatment. Heart murmurs are frequent (85%); changing murmurs (5% to 10%) and new cardiac murmurs, when observed, suggest the diagnosis of IE. All too often, however, a soft new murmur heard during hospitalization is not new but rather newly noticed. With endocarditis involving the aortic or the mitral valve, congestive heart failure occurs in up to two thirds of patients; it may occur precipitously with perforation of a valve or rupture of chordae tendineae. The classical peripheral manifestations of endocarditis (Table 100-1) have become less common in recent years. Splenomegaly (25% to 60%) and clubbing (10% to 15%) are more likely when symptoms have been prolonged.

The clinical syndrome of IE differs in intravenous drug users. Fever remains the most common manifestation in this group, but the majority do not have an underlying cardiac lesion, and only one third of proven cases have audible murmurs on admission. Tricuspid valve infection is most common, probably because of scarring of the tricuspid valve by injected particulate matter. Some patients have pleuritic chest pain caused by septic pulmonary emboli, and round, cavitating infiltrates may be found on the chest radiograph. The infective foci are initially centered in blood vessels; only after they erode into the bronchial system does cough develop, which may be productive of bloody or purulent sputum.

Serious systemic emboli, associated with infection of the aortic or mitral valve, may cause dramatic findings, at times masking the systemic nature of IE. Stroke may be the initial manifestation of IE. Embolism to the splenic artery may lead to left upper quadrant pain, sometimes radiating to the left shoulder, a friction rub, and/or left pleural effusion. Renal, cerebral, coronary, and mesenteric arteries are frequent sites of clinically important emboli.

Neurologic manifestations occur in one third of patients with IE and may be the predominant clinical features in 10% of cases, sometimes delaying the diagnosis. Central nervous system (CNS) embolization is one of the most serious complications of IE, and acute neurologic deterioration is an ominous sign during IE, being associated with a twofold to fourfold increase in mortality. IE must always be considered in the differential diagnosis of stroke in young adults, as well as in all patients with valvular heart disease. Patients with IE may complain of headache or may develop seizures. The pathophysiologic explanation for these symptoms is not always apparent. In addition to stroke caused by vascular occlusion by an infected embolus, toxic encephalopathy, which may mimic psychosis, and meningoencephalitis also occur. The aseptic meningitis or meningoencephalitis seen in patients with IE is not always readily distinguished from viral causes of a similar syndrome.

The consequences of CNS embolization depend on the site of lodging and the bacterial pathogen, and clinical syndromes caused by CNS emboli may be distinctive. Organisms such as *Streptococcus viridans* initially produce a syndrome entirely attributable to the vascular occlusion; however, unnoticed damage to the blood vessel can result in formation of a mycotic aneurysm that may leak or rupture at a later date. Resolution of aneurysms may occur after antimicrobial therapy. In many patients, however, surgical clipping is necessary to prevent recurrent hemorrhage. Single aneurysms in accessible areas should be considered for prompt surgical clipping. *S. aureus*, in contrast, produces progressive infection extending from the site of embolization; brain abscess and purulent meningitis are common sequelae.

The kidney can be the site of abscess formation, multiple infarcts, or immune complex glomerulonephritis. When renal dysfunction develops during antibiotic therapy, drug toxicity is an additional consideration.

LABORATORY FINDINGS

Nonspecific laboratory abnormalities occur in IE and reflect chronic infection. These include anemia (typically normo-

Table 100-1 Peripheral Manifestations of Infective Endocarditis

Physical Finding (Frequency)	Pathogenesis	Most Common Organisms
Petechiae (20%-40%) (red, nonblanching lesions in crops on conjunctivae, buccal mucosa, palate, extremities)	Vasculitis or emboli	<i>Streptococcus</i> , <i>Staphylococcus</i>
Splinter hemorrhages (15%) (linear, red-brown streaks most suggestive of infective endocarditis when proximal in nail beds)	Vasculitis or emboli	<i>Staphylococcus</i> , <i>Streptococcus</i>
Osler nodes (10%-25%) (2- to 5-mm painful nodules on pads of fingers or toes)	Vasculitis	<i>Streptococcus</i>
Janeway lesions (<10%) (macular, red or hemorrhagic, painless patches on palms or soles)	Emboli	<i>Staphylococcus</i>
Roth spots (<5%) (oval, pale retinal lesions surrounded by hemorrhage)	Vasculitis	<i>Streptococcus</i>

cytic, normochromic in subacute cases), reticulocytopenia, increased erythrocyte sedimentation rate, hypergammaglobulinemia, circulating immune complexes, false-positive serologic test results for syphilis, and rheumatoid factor. The presence of rheumatoid factor may be a helpful clue to diagnosis in patients with culture-negative endocarditis. Urinalysis frequently shows proteinuria (50% to 60%) and microscopic hematuria (30% to 50%). The presence of red blood cell casts is indicative of immune complex-mediated glomerulonephritis. The finding of gram-positive cocci in the urine of a febrile patient with microscopic hematuria should prompt consideration of the possibility of IE.

The bacteremia of IE is continuous, but often low grade (often 1 to 100 bacteria per milliliter in subacute cases). Therefore, in most instances, all blood cultures are positive, and persistent bacteremia on multiple blood cultures may have diagnostic value in distinguishing IE from other causes of bacteremia. Three blood culture sets should be obtained 1 hour apart before the initiation of antibiotic therapy if possible; and two or three additional sets should be drawn if the patient has received antibiotic therapy in the preceding 1 to 2 weeks or if initial blood cultures are negative at 48 to 72 hours. Up to 14% of patients with IE may have negative blood cultures; half of these are patients who have received previous antibiotic therapy. Fastidious organisms, including *Legionella*, *Coxiella*, *Bartonella*, and *Chlamydia* and fungi account for the majority of the remaining cases. Cultures may be negative in as many as 50% of cases of fungal endocarditis. Although modern automated blood culture systems have improved detection of the HACEK group and nutritionally deficient streptococci that were previously difficult to cultivate, the fastidious organisms noted previously remain difficult to recover with conventional microbiologic techniques. Serologic tests and, more recently, nucleic acid target or signal amplification are necessary to diagnose infections from these pathogens.

Echocardiography is recommended in all cases of suspected IE. Although transthoracic echocardiography (TTE) may be sufficient when suspicion is low and the patient's body habitus and clinical condition allow for optimal imaging quality, transesophageal echocardiography (TEE) is considerably more sensitive, especially for small (<10 mm) vegetations, and is capable of identifying such complications of IE as ring abscesses and valvular perforation more readily than TTE. Valvular vegetations can be demonstrated in most (75% to 95%) cases of IE by TEE, but the enhanced detail provided by TEE also mandates caution in interpreting the findings in the presence of other structural abnormalities, such as prosthetic valves, which may produce nonspecific echoes that are easily mistaken for vegetations.

The clinical, microbiologic, and echocardiographic features discussed earlier, known as the Duke criteria, have been shown to be highly predictive of the likelihood of IE in various groups of patients, and recently proposed modifications have increased their diagnostic performance. The currently proposed Duke criteria are summarized in Table 100-2.

DIFFERENTIAL DIAGNOSIS

The diagnosis of IE usually is established on the basis of the clinical findings and the results of blood cultures. In some

instances, the distinction between IE and nonendocarditis bacteremia may be difficult. Because the bacteremia is usually continuous in IE and intermittent in other bacteremias, the fraction of blood cultures that are positive may be helpful in distinguishing between these entities. The more frequent causative agents of IE are shown in Table 100-3. With increasing numbers of patients acquiring IE after invasive procedures or intravenous drug abuse, the relative importance of staphylococci has increased in recent years. In streptococcal infection, the speciation of the blood culture isolate may provide circumstantial evidence for or against infection of the heart valves (Table 100-4). The identity of the causative organism may be helpful for other bacteria as well; the ratio of IE to non-IE bacteremias is approximately 1:1 for *S. aureus*, 1:7 for group B streptococci, and 1:200 for *Escherichia coli*. *Streptococcus bovis* bacteremia and endocarditis are often (>50%) associated with colonic carcinomas or polyps. Hence, isolation of this organism warrants thorough evaluation of the lower gastrointestinal tract.

The initial presentation of IE can be misleading; the young adult may have a stroke, pneumonia, or meningitis; the elderly patient may have confusion or simply fatigue or malaise without fever. The index of suspicion for IE, therefore, must be high, and blood cultures should be obtained in these varied settings, particularly if antibiotic use is contemplated.

Major problems in diagnosis arise if antibiotics have been administered before blood is cultured or if blood cultures are negative. Attempts to culture slow-growing organisms, including those with particular nutritional requirements, should be done in consultation with a clinical microbiologist. The differential diagnosis of culture-negative endocarditis includes acute rheumatic fever, multiple pulmonary emboli, atrial myxoma, systemic vasculitis, and nonbacterial thrombotic endocarditis. Nonbacterial thrombotic endocarditis (sometimes called *marantic endocarditis*) occurs in patients with severe wasting, whether caused by malignancy or other conditions. Also, patients with systemic lupus erythematosus may develop sterile valvular vegetations, termed *Libman-Sacks lesions*, on the undersurfaces of the valve leaflets. These diagnoses should be considered and excluded, if possible, before a prolonged course of therapy for presumed culture-negative IE is begun. As noted earlier, the absence of vegetations on TEE makes a diagnosis of endocarditis unlikely.

MANAGEMENT AND OUTCOME

The outcome of endocarditis is determined by the extent of valvular destruction, the size and friability of vegetations, the presence and location of emboli, and the choice of antibiotics. These factors, in turn, are influenced by the nature of the causative organism and delays in diagnosis. The goal of antibiotic therapy is to halt further valvular damage and to cure the infection. Surgery may be necessary for hemodynamic stabilization, prevention of embolization, or control of drug-resistant infection.

Antibiotics should be selected on the basis of the clinical setting (Tables 100-5 and 100-6) and started as soon as blood cultures are obtained if the diagnosis of IE appears highly likely and the course is suggestive of active valvular destruction or systemic embolization. The antibiotics

Table 100-2 Modified Duke Criteria for the Diagnosis of Infective Endocarditis

Major Criteria

Blood culture positive for IE, defined as follows:

- Typical microorganisms consistent with infective endocarditis (IE) from two separate blood cultures—viridans streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus* or community-acquired enterococci in the absence of a primary focus *or*
- Microorganisms consistent with IE from persistently positive blood cultures defined as follows: at least two positive cultures of blood samples drawn >12 hr apart; or all of three or a majority of four or more separate cultures of blood (with first and last sample drawn at least 1 hr apart) *or*
- Single positive blood culture for *Coxiella burnetii* or anti-phase 1 IgG antibody titer >1:800

Evidence of endocardial involvement:

Echocardiogram positive for IE defined as follows: oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; or abscess; or new partial dehiscence of prosthetic valve; new valvular regurgitation (worsening or changing or preexisting murmur not sufficient)

Minor Criteria

Predisposing heart condition or intravenous drug use

Fever, temperature >38° C

Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions

Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor

Microbiologic evidence: positive blood culture but does not meet a major criterion as noted above (excluding single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis) or serologic evidence of active infection with organism consistent with IE

Interpretation**Definite Infective Endocarditis****Pathologic Criteria**

Microorganisms demonstrated by culture or histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen; *or*

Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis

Clinical Criteria

Two major criteria *or*

One major criterion and three minor criteria *or*

Five minor criteria

Possible Infective Endocarditis

One major criterion and one minor criterion *or*

Three minor criteria

Infective Endocarditis Rejected

Firm alternative diagnosis explaining evidence of infective endocarditis *or*

Resolution of clinical syndrome with antibiotic therapy for <4 days *or*

No pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for <4 days *or*

Does not meet criteria for possible infective endocarditis as above

Data from Li JS, Sexton DJ, Mick N, et al: Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. Clin Infect Dis 30:633-638, 2000.

Fastidious gram-negative rods

Aggressive Course (Acute)

Staphylococcus aureus
Streptococcus pneumoniae
Streptococcus pyogenes
Neisseria gonorrhoeae

Intravenous Drug Users

S. aureus and coagulase-negative staphylococci
Pseudomonas aeruginosa
E. faecalis
Candida species
Bacillus species

Intravenous Catheters

S. aureus and coagulase-negative staphylococci
Candida species
Aerobic gram-negative bacilli

Animal Contact

Bartonella species
Pasteurella species
Capnocytophaga species
Brucella species
Coxiella burnetii

Frequent Major Emboli

Haemophilus species
Bacteroides species

can be adjusted later on the basis of culture and sensitivity data.

Antibiotics

A number of different regimens have been advocated for the treatment of IE resulting from each of the causative organisms. Few, however, have been subjected to comparative trials. Both animal models and clinical data indicate that bactericidal regimens directed against the causative pathogen are associated with much greater rates of therapeutic success and are therefore the standard of therapy. The duration of treatment should be sufficient to sterilize the affected heart valves, usually 4 to 6 weeks in left-sided endocarditis.

Table 100-6 Treatment of Endocarditis*

<i>Staphylococcus aureus</i>	Nafcillin or ceftazolin or vancomycin ± gentamicin
<i>Streptococcus pneumoniae</i>	PCN G or ampicillin
Viridans group streptococci, <i>Streptococcus bovis</i>	PCN G or ampicillin or ceftriaxone + gentamicin
<i>Enterococcus</i>	Ampicillin or PCN G or vancomycin + gentamicin
<i>Enterococcus</i> , vancomycin-resistant	Linezolid or quinupristin-dalfopristin or imipenem ± ampicillin
HACEK organisms	Ceftriaxone or ampicillin-sulbactam or ciprofloxacin
Fungal	Amphotericin B + surgery
<i>Pseudomonas</i>	Antipseudomonal penicillin (e.g., piperacillin) or ceftazidime or cefepime + tobramycin

*See text for details. The choice among the various alternatives presented should be guided by sensitivity results. Therapy for prosthetic valve endocarditis may differ.

HACEK = *Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, *Kingella*; PCN G, penicillin G.

Many but not all strains of viridans group streptococci and group D streptococci, such as *S. bovis*, are exquisitely sensitive to penicillin. The penicillin concentration inhibiting growth of such organisms is less than 0.1 mcg/mL, and they are killed by similar concentrations of penicillin. A variety of antibiotic regimens have been advocated to treat these forms of IE, and several appear to be equally effective. Aqueous penicillin G, 12 to 18 million U/day given intravenously (IV) for 4 weeks, is curative in almost all patients, as is a 2-week course of penicillin G plus gentamicin in younger patients with uncomplicated disease. In the stable patient at low risk for complications, some of the antibiotic course can be administered on an outpatient basis.

Treatment of enterococcal endocarditis and IE caused by other penicillin-resistant streptococci is much less satisfactory because of frequent relapses and high mortality. The recommended regimen for these strains is intravenous aqueous penicillin G, 18 to 30 million U/day, plus intravenous gentamicin, 3 mg/kg/day. This relatively low dose of aminoglycoside is associated with a lower incidence of nephrotoxicity. The aminoglycoside dose should be adjusted according to measured serum levels. In view of the high frequency of relapses, regimens to treat enterococcal infection should be continued for 6 weeks. Culture-negative endocarditis should be treated with the combination of a β-lactam and an aminoglycoside, with or without an agent active against intracellular pathogens (a tetracycline or a quinolone), depending on the level of suspicion for such organisms.

Determination of the minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) is important in the management of IE, as therapeutic success is largely dependent on the ability to achieve a bactericidal effect in the relative sanctuary of the vegetation. Serum bactericidal titers have been used in an attempt to translate these values to activity in vivo, but these assays have a limited role in current antimicrobial therapy of IE.

S. aureus endocarditis should be treated with intravenous nafcillin, 12 g/day, unless the isolate is penicillin sensitive, in which case penicillin, 12 million U/day, is the treatment of choice. Infection with a methicillin-resistant species of *Staphylococcus* necessitates the use of vancomycin. The lipopeptide daptomycin may be an alternative in certain patients, particularly those with right-sided endocarditis. The addition of an aminoglycoside hastens clearance of bacteremia and is indicated during the initial phases of therapy in very ill patients. The duration of antibiotic therapy for staphylococcal endocarditis of the mitral or aortic valve is a minimum of 6 weeks.

In the patient with streptococcal or staphylococcal IE and a history of serious penicillin allergy, vancomycin can be substituted for penicillin. Among patients at risk for complicated disease, consideration should be given to penicillin desensitization.

Pseudomonas endocarditis is a particular problem in intravenous drug users. Therapy should be initiated with tobramycin, 8 mg/kg/day IV, plus an extended-spectrum penicillin such as piperacillin, given IV every 4 hours, or a third- or fourth-generation cephalosporin with antipseudomonal activity. The unusually high doses of aminoglycosides have improved the outcome of medical therapy of *Pseudomonas* infection of the tricuspid valve in younger patients with surprisingly little nephrotoxicity. Left-sided *Pseudomonas aeruginosa* infections, however, most often require surgery for cure. It is particularly important to measure serum drug levels and adjust dosages as appropriate when aminoglycosides are used. Quinolones may be of value in combined antibiotic treatment of *Pseudomonas* endocarditis, but experience with these agents is largely anecdotal.

Fungal endocarditis is refractory to antibiotics and almost always requires surgery for management. Amphotericin B generally is administered to such patients but is not in itself curative.

Surgery

The indications for early surgery in IE need to be individualized and forged by discussions with the cardiac surgeon. Refractory infection is a clear indication for surgery; as noted, the requirement for surgery is predictable in IE caused by certain organisms. Persistence of bacteremia for longer than 7 to 10 days, despite the administration of appropriate antibiotics, frequently reflects paravalvular extension of infection with development of valve ring abscess or myocardial abscesses. Medical cure is not likely in this setting. Intravenous drug users are more likely to have IE caused by organisms refractory to medical therapy (e.g., *Pseudomonas* species, fungi). Refractory tricuspid endocarditis may be amenable to valve débridement or excision without immediate placement of a prosthetic valve. Tricuspid valvectomy may, however, be associated with the eventual onset of right-sided congestive heart failure.

Protracted fever is not unusual in patients undergoing treatment of endocarditis and should not automatically be equated with refractory infection. In fact, 10% of patients remain febrile for more than 2 weeks, and persistent fever is not an independent indication for surgery, particularly when tricuspid endocarditis is complicated by multiple septic pulmonary emboli with necrotizing pneumonia. Delayed defervescence also is common, despite appropriate

antimicrobial therapy, with endocarditis caused by *S. aureus* and enteric bacteria.

Congestive heart failure refractory to medical therapy is the most frequent indication for early cardiac surgery. The extent of valvular dysfunction may be difficult to gauge clinically, particularly in patients with acute aortic regurgitation; in the absence of compensatory ventricular dilation, classic physical signs associated with aortic regurgitation, such as wide pulse pressure, may not be present. Echocardiography, fluoroscopy, and cardiac catheterization may be necessary to evaluate the extent of aortic regurgitation in some instances. However, when congestive heart failure develops in the patient with *S. aureus* IE, aortic valvular destruction usually is extensive, necessitating early surgery. Delaying surgery to prolong the course of antibiotic therapy is never appropriate if the patient is hemodynamically unstable or fulfills other criteria for surgical intervention. Prosthetic valve endocarditis (PVE) seldom occurs after cardiac valve replacement for IE, and its incidence is not influenced by duration of preoperative antibiotics.

Recurrent major systemic embolization is another indication for surgery. If valvular function is preserved, vegetations sometimes can be removed without valve replacement. Septal abscess, although often difficult to recognize clinically, and aneurysms of the sinus of Valsalva are absolute indications for surgery.

Prosthetic Valve Endocarditis

PVE complicates 3% to 6% of cardiac valve replacements within 5 years after surgery. Two separate clinical syndromes have been identified. Early PVE occurs within 60 days of surgery and most often is caused by *Staphylococcus epidermidis*, gram-negative enteric bacilli, *S. aureus*, or diphtheroids. The prosthesis may be contaminated at the time of surgery or seeded by bacteremia from extracardiac sites (e.g., intravenous cannula, indwelling urinary bladder catheter, wound infection, pneumonia). In addition to forming vegetations, which may be quite bulky and cause obstruction, particularly of mitral valve prostheses, circumferential spread of infection often causes dehiscence and paravalvular leak at the site of an aortic prosthesis. The combination of intravenous vancomycin, 2 g/day, and intravenous gentamicin, 3 mg/kg/day, plus oral rifampin, 900 mg/day, is indicated to treat *S. epidermidis* infection. Other infections should be treated with synergistic bactericidal combinations of antibiotics based on in vitro sensitivity testing. Surgery is mandatory in the presence of moderate to severe congestive heart failure. The rate of mortality from early PVE remains high.

Late PVE is most frequently caused by bacteremia from viridans group streptococci from an oral site that seeds a reendothelialized valve surface. Treatment with intravenous aqueous penicillin G, 12 to 20 million U/day, or ceftriaxone, 2 g/day, plus intravenous gentamicin, 3 mg/kg/day, is appropriate. The prognosis for cure with antibiotic therapy alone is better in patients infected with penicillin-sensitive streptococci. Moderate to severe congestive heart failure is the main indication for surgery. The rate of mortality from late PVE remains approximately 40%.

Table 100-7 Prophylaxis of Infective Endocarditis**Prophylaxis for Specific Procedures Recommended***

Prosthetic heart valves
 Prior endocarditis
 Cyanotic congenital heart disease (CHD), unrepaired;
 repaired CHD with prosthetic material or device (initial 6 months after the procedure only); partially repaired CHD with residual defects
 Cardiac transplantation with ensuing cardiac valvulopathy

Prophylaxis Not Routinely Recommended

Most other congenital cardiac malformations
 Acquired valvular dysfunction (e.g., rheumatic heart disease)
 Hypertrophic cardiomyopathy
 Mitral valve prolapse
 Physiologic murmurs
 Isolated secundum atrial septal defect
 Surgically repaired atrial septal defect, ventricular septal defect, patent ductus arteriosus (after 6 mo)
 Cardiac pacemakers, coronary artery stents, and defibrillators
 History of rheumatic fever or Kawasaki disease without valvular dysfunction
 Previous coronary artery bypass surgery

*For procedures that involve an area of established infection, the antimicrobial regimen used for treatment in high-risk patients should include the organisms likely to arise from that anatomic area that are commonly associated with endocarditis.

Prophylaxis of Infective Endocarditis

Patients with prosthetic heart valves, patients with prior endocarditis, and persons with certain kinds of congenital heart lesions have an increased risk of IE. Other abnormalities of the aortic and mitral valve are also associated with an increased lifetime risk of IE, yet neither the value of nor the optimal regimens for antibiotic prophylaxis in this setting have been established definitively. Moreover, it is not clear that the overall risk of endocarditis as a result of dental procedures exceeds the risk of endocarditis as a result of other unrecognized bacteremias from oral sources. Thus only a small number of IE cases would be prevented with antibiotics for dental procedures, even if such prophylaxis were 100% effective. Revised recommendations by the American Heart Association indicate that prophylaxis may be reasonable for those patients at the highest risk for severe adverse outcomes only, and only for some specific procedures. Conditions that place patients at risk for endocarditis are presented in Table 100-7. Procedures for which prophylaxis is recommended are listed in Table 100-8, and appropriate prophylactic antibiotic regimens are presented in Table 100-9.

Administration of antibiotics has become an accepted practice for patients undergoing open heart surgery, including valve replacement. Intravenous cefazolin, 2 g at induction of anesthesia, repeated 8 and 16 hours later, or intravenous vancomycin, 1 g at induction and 0.5 g 8 and 16 hours later, is an appropriate regimen. Cardiac diagnostic procedures (catheterization), pacemaker placement, and coronary artery bypass do not pose sufficient risk to warrant the use of prophylactic antibiotics for IE or PVE.

Table 100-8 Procedures for Which Antimicrobial Prophylaxis Against Infective Endocarditis Is Recommended**Dental Procedures**

All procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa

Respiratory Tract Procedures

Tonsillectomy or adenoidectomy
 Other invasive procedures involving incision or biopsy of the respiratory mucosa

Gastrointestinal and Genitourinary Tract Procedures

Prophylaxis no longer routinely recommended

Table 100-9 Prophylactic Regimens Recommended for Dental, Oral, or Respiratory Tract Procedures in High-Risk Patients

Amoxicillin, 2.0 g PO, 30 to 60 minutes before the procedure.

Allergic to penicillin: clindamycin, 600 mg PO, or cephalexin, 2.0 g PO, or azithromycin or clarithromycin, 500 mg PO, all given 30 to 60 minutes before the procedure

Unable to receive oral medication: ampicillin, 2.0 g, or cefazolin or ceftriaxone, 1.0 g, all given intramuscularly or intravenously 30 to 60 minutes before the procedure

Devices that are associated with high rates of infection and bacteremia (e.g., intravenous cannulas, indwelling urinary bladder catheters) should be avoided in hospitalized patients at risk for IE if at all possible; established local infections should be treated promptly and vigorously.

Bacterial Endarteritis and Suppurative Phlebitis

Bacterial endarteritis usually develops by one of three mechanisms: (1) arteries, particularly those with intimal abnormalities, may become infected as a consequence of transient bacteremia; (2) during the course of IE, septic emboli to vasa vasorum may lead to mycotic aneurysms; or (3) blood vessels also may be infected by direct extension from contiguous foci and trauma.

A septic presentation is characteristic of endarteritis caused by organisms such as *S. aureus*. Besides sepsis, the major problem caused by endarteritis is hemorrhage. Three percent to 4% of patients with IE develop intracranial mycotic aneurysms. Mycotic aneurysms in IE typically are situated peripherally and in the distribution of the middle cerebral artery. Focal seizures, focal neurologic signs, or aseptic meningitis may herald catastrophic rupture of such aneurysms. These premonitory findings therefore indicate the need for evaluation with arteriography; neurosurgical intervention should be contemplated if accessible lesions are demonstrated.

Infection of an atherosclerotic plaque can occur as a complication of bacteremia, particularly in elderly patients with bacteremia caused by *Salmonella* species. Traumatic endarteritis with pseudoaneurysm often complicates arterial injection of illicit drugs and rarely complicates arterial catheterizations. Treatment often requires combined medical and surgical management; antibiotic selection should be based on the results of in vitro sensitivity testing.

Suppurative thrombophlebitis usually is a complication of the use of intravenous plastic cannulas. Burn patients, especially those with lower extremity catheterization, are at particular risk. Typically, intravenous cannulas have been left in

place 5 days or more. Often, the vein is sclerosed and tender, and the surrounding skin is erythematous. The vein should be milked to identify pus. If pus is present or if bacteremia and fever persist despite antibiotic therapy, involved segments of vein must be excised. Initial therapy should be selected to ensure coverage of the most common pathogens, *Staphylococcus* species (vancomycin, 15 mg/kg every 12 hours IV) and Enterobacteriaceae (e.g., piperacillin-tazobactam, 3.375 g every 6 hours IV).

Suppurative phlebitis is preventable. Peripheral intravenous cannulas should be inserted aseptically and replaced at least every 72 hours by well-trained personnel.

Prospectus for the Future

- Refinement in imaging techniques for the diagnosis and management of infective endocarditis (IE) and its complications
- Increased use of molecular microbiology techniques for the diagnosis of culture-negative IE
- New biomaterials with increased resistance to microbial colonization

Skin and Soft Tissue Infections

Christoph Lange and Michael M. Lederman

Innate immune defense mechanisms render the normal skin remarkably resistant to infection. Most common infections of the skin are initiated by breaks in the epithelium. Hematogenous seeding of the skin by pathogens is less frequent.

Some superficial infections, such as folliculitis and furuncles, may be treated with local measures alone (e.g., incision and drainage). Other superficial infections (e.g., impetigo, cellulitis) necessitate systemic antibiotics. Deeper soft tissue infections, such as fasciitis and myonecrosis, necessitate emergency surgical débridement. As a general rule, infections of the face and hands should be treated particularly aggressively because of the risks of intracranial spread in the former and the potential loss of function as a result of closed-space infection in the latter.

Superficial Infections of the Skin

CIRCUMSCRIBED INFECTIONS OF THE SKIN

Vesicles, papules, pustules, nodules, and ulcerations are the lesions in the category of circumscribed infections of the skin (Table 101-1).

Folliculitis is a superficial infection of hair follicles. The lesions are crops of red papules or pustules that are often pruritic; careful examination using a hand lens shows hair in the center of most papules. Staphylococci, yeast, and, occasionally, *Pseudomonas* species are the most common pathogens. Local treatment with cleansing and hot compresses is usually sufficient. Topical antibacterial or antifungal agents also may be useful. The skin lesions of disseminated candidiasis seen in neutropenic patients may resemble folliculitis. In these ill patients, skin biopsy readily distinguishes the two processes; in disseminated disease, yeast is found within blood vessels and not simply surrounding the hair follicle.

Furuncles and carbuncles are subcutaneous abscesses caused by *Staphylococcus aureus*. Recently, community-associated methicillin-resistant *S. aureus* (cMRSA) has caused severe infections including those of skin and soft tissues such as cellulitis, necrotizing fasciitis, and myositis. Furuncles and carbuncles are red, tender nodules that may have a surrounding cellulitis and occur most prominently on the face and back of the neck. They often drain spontaneously. Furuncles may be treated with moist hot compresses. If fluctuant, the larger carbuncles necessitate incision and drainage. β -lactam antibiotics can no longer be considered to be reliable as empirical therapy for community-acquired skin and soft tissue infections. Antistaphylococcal antibiotics covering for MRSA (e.g., trimethoprim and sulfamethoxazole [TMP/SMX] or linezolid) should be given if the patient has systemic symptoms such as fever or malaise, if there is accompanying cellulitis, or if the lesions are on the head.

Impetigo is a superficial infection of the skin caused by group A streptococci, although *S. aureus* may also be found in the lesions. Impetigo is seen primarily among children, who initially develop a vesicle on the skin surface; this rapidly becomes pustular and breaks down, leaving the characteristic dry, golden crust. This pruritic lesion is highly contagious and spreads by the child's hands to other sites on the body or to other children. Gram stain shows gram-positive cocci in chains (streptococci); occasionally, clusters of staphylococci are also seen. Certain strains of streptococci causing impetigo have been associated with the later development of poststreptococcal glomerulonephritis. The differential diagnosis of impetigo includes herpes simplex infection and varicella. These viral lesions may become pustular; Gram stain of an unruptured viral vesicle or pustule should not, however, contain bacteria. A scraping of the pustule assayed for viral antigens can establish the diagnosis of herpes simplex or varicella if the differential diagnosis is uncertain. Topical mupirocin can be used to treat localized impetigo, but systemic antibiotics are recommended if the infection is extensive. Penicillin remains generally effective for treatment of impetigo; however, some authorities prefer penicillinase-resistant penicillins (e.g., dicloxacillin) because

Table 101-1 Circumscribed Cutaneous Infections (Predominant Organism)

Folliculitis (<i>Staphylococcus aureus</i> , <i>Candida</i> species)

Rickettsialpox
Ulcerative lesions of the skin
Pressure sores
Stasis ulcerations
Diabetic ulcerations
Sickle cell ulcers
Mycobacterial infection
Fungal infection
Ecthyma gangrenosum
Syphilis
Chancroid

penicillinase-producing staphylococci may also be present in these lesions. Large bullous lesions, particularly in children, suggest bullous impetigo caused by *S. aureus*. This should be treated initially with an antibiotic such as TMP/SMX or linezolid that is effective against MRSA. Antibiotics do not appear to affect the development of poststreptococcal glomerulonephritis but will prevent the spread of infection to others.

Ecthyma gangrenosum is a cutaneous manifestation of disseminated gram-negative rod infection, usually caused by *Pseudomonas aeruginosa* in neutropenic patients. The initial lesion is a vesicle or papule with an erythematous halo. Although generally small (<2 cm), the initial lesion may exceed 20 cm in diameter. In a short time the vesicle ulcerates, leaving a necrotic ulcer with surrounding erythema or a violaceous rim. Gram stain of an aspirate may show gram-negative rods; cultures of the aspirate are generally positive. Biopsy of the lesion shows venous thrombosis, often with bacteria demonstrable within the blood vessel walls. Because these lesions are manifestations of gram-negative rod bacteremia, treatment should be instituted immediately with ciprofloxacin or an aminoglycoside plus a third-generation cephalosporin, piperacillin, or a carbapenem to cover against *P. aeruginosa* until the results of culture and sensitivity studies are known (see also Chapter 96).

Herpes Simplex Virus

Oral infections caused by herpes simplex virus are discussed in Chapter 98, and genital infections are discussed in Chapter 107. On occasion, infection with this virus occurs on extra-oral or extragenital sites, usually on the hands. This is most often the case in health care workers but also may result from sexual contact or from autoinoculation. The virus may produce a painful erythema, usually at the junction of the nail bed and skin (whitlow). This progresses to a vesiculopustular lesion. At both stages of infection, herpetic whitlow

can resemble a bacterial infection (paronychia). When more than one digit is involved, herpes is much more likely. It is important to distinguish between herpetic and bacterial infections, because incision and drainage of a herpetic whitlow are contraindicated. Puncture of the purulent center of a paronychia and Gram stain of the exudate allow prompt and accurate diagnosis. In the case of herpetic whitlow, bacteria are not present unless the lesion has already drained and become superinfected. In the case of a bacterial paronychia, bacteria are readily seen. Recurrences of herpetic whitlow may be seen but are generally less severe than the primary infection. Treatment with oral acyclovir, famciclovir, or valacyclovir may shorten the duration of symptoms.

Varicella-Zoster Virus

Primary infection with varicella-zoster virus (chickenpox) is thought to occur through the respiratory route but may also occur through contact with infected skin lesions. Viremia results in crops of papules that progress to vesicles and then to pustules, followed by crusting. The lesions are most prominent on the trunk. This is almost always a disease of childhood. Systemic symptoms may precede development of the characteristic rash by 1 or 2 days but are mild except in the case of an immunocompromised patient or primary infection in the adult. In the immunocompromised patient, chickenpox can produce a fatal systemic illness. In otherwise healthy adults, chickenpox can be a serious illness with life-threatening pneumonia. Clinical diagnosis is based on the characteristic appearance of the rash. Impetigo and folliculitis are readily distinguished clinically by Gram stain of the pustule contents. Disseminated herpes simplex virus infection is seen only in the immunocompromised host or in patients with eczema. Viral culture or viral antigen detection will distinguish herpes simplex from herpes zoster in these settings. Most patients with rickettsialpox, which in rare cases is confused with chickenpox, also have an ulcer or eschar that precedes the generalized rash by 3 to 7 days and represents the bite of the infected mouse mite, which transmits the disease. Although officially eradicated, smallpox must be included in the differential diagnosis of chickenpox, when bioterrorism could be an issue. Lesions of smallpox are characteristically larger than those of varicella, are sometimes umbilicated, and tend to be more concentrated peripherally than the central lesions of varicella, and all tend to be at the same stage of development.

Immunocompromised children exposed to varicella should receive prophylaxis with zoster immune globulin. Immunocompromised persons and seriously ill patients with varicella should be treated with acyclovir. Prophylaxis within 96 hours of exposure with varicella-zoster immune globulin is recommended for adults at risk for complications (immunodeficiencies, malignancies, pregnancy). Active immunization against varicella-zoster virus is recommended for all children and susceptible adults in the United States.

After primary infection, the varicella-zoster virus persists in a latent state within sensory neurons of the dorsal root ganglia. The infection may reactivate, producing the syndrome of zoster (shingles). Pain in the distribution of the affected nerve root precedes the rash by a few days. Depending on the dermatome, the pain may mimic pleurisy, myocardial infarction, or gallbladder disease. A clue to

the presence of early zoster infection is the finding of dysesthesia, an unpleasant sensation when the involved dermatome is gently stroked by the examiner's hand. The appearance of papules and vesicles in a unilateral dermatomal distribution confirms the diagnosis. Herpes zoster infections of certain dermatomes merit special attention. The Ramsay Hunt syndrome can be caused by infection involving the geniculate ganglia and causes painful eruption of the ear canal and tympanic membrane, often associated with an ipsilateral seventh cranial nerve (facial nerve) palsy. Infection involving the second branch of the fifth cranial nerve (trigeminal nerve) often produces lesions of the cornea. This infection should be treated promptly with systemic acyclovir to prevent loss of visual acuity. A clue to possible ophthalmic involvement is the presence of vesicles on the tip of the nose.

In most instances, dermatomal zoster is a disease of the otherwise healthy adult. However, immunocompromised patients (e.g., persons with human immunodeficiency virus [HIV] infection) and the elderly are at greater risk for reactivation of this virus. Patients with zoster should undergo a careful history taking and physical evaluation; in the absence of specific suggestive findings or recurrent episodes of zoster, these patients do not require an exhaustive evaluation for a malignancy or immunodeficiency.

In older, nonimmunocompromised patients, postherpetic neuralgia (severe, prolonged burning pain, with occasional lightning-like stabs in the involved dermatomes) may persist for 1 to 2 years and become disabling. A brief course of corticosteroids (40 to 60 mg of prednisone, tapered over 3 to 4 weeks) during the acute episode of zoster shortens the duration of acute neuritic pain but does not prevent postherpetic neuralgia. Initiation of treatment during the first 72 hours with antiviral drugs (e.g., valacyclovir, famciclovir) accelerates the healing of lesions and may decrease the occurrence of postherpetic neuralgia. Immunization with a high-titer attenuated virus vaccine (Zostavax) can protect against the occurrence of zoster and postherpetic neuralgia and is recommended for immunocompetent adults over the age of 60.

Cutaneous Mycobacterial and Fungal Diseases

Mycobacteria and fungi can produce cutaneous infection, manifesting generally as papules, nodules, ulcers, crusting lesions, or lesions with a combination of these features. *Mycobacterium marinum*, for example, can produce inflammatory nodules that ascend through lymphatic channels of the arm in individuals who keep or are exposed to fish; similar lesions caused by *Sporothrix schenckii* may be seen among gardeners. *Blastomyces dermatitidis* and *Coccidioides immitis* are other fungi that produce skin nodules or ulcerations.

As a general rule, a biopsy should be done on a chronic inflammatory nodule, crusted lesion, or nonhealing ulceration that is not readily attributable to pressure, vascular insufficiency, or venous stasis. Mycobacteria and fungi should be carefully sought, using acid-fast and silver stains and appropriate cultures. It is essential that biopsy samples for culture are not placed in formalin or other fixatives, as these will make cultivation for pathogens impossible. In specialized laboratories, gene amplification by polymerase chain reaction (PCR) may rapidly identify the causative microbe.

Ulcerative Lesions of the Skin

A common factor in the pathogenesis of many skin ulcers is the presence of vascular insufficiency. Microbial infection of these lesions is secondary but often extends into soft tissue and bone.

Pressure sores occur at weight-bearing sites in individuals incapable of moving. Patients with stroke, quadriplegia, or paraplegia, or patients in coma who remain supine, rapidly develop skin necrosis at the sacrum, spine, and heels, because pressures at these weight-bearing sites can exceed local perfusion pressure. Patients kept immobile on their sides will ulcerate over the greater trochanter of the femur. As the skin sloughs, bacteria colonize the necrotic tissues; abetted by further pressure-induced necrosis, the infection extends to deeper structures. Infected pressure sores are common causes of fever and occasional causes of bacteremia in debilitated patients. Not infrequently, a necrotic membrane hides a deep infection. The physician should probe the extent of a pressure sore with a sterile glove; potential sites of deeper infection should be probed with a sterile needle. Necrotic material must be débrided, and the ulceration may be treated with topical antiseptics and relief of pressure. Systemic antibiotics are indicated when bacteremia, osteomyelitis, or significant cellulitis is present. Anaerobes and gram-negative rods are the most frequent isolates. Skin grafting can be used to repair extensive ulceration in patients who can eventually be mobilized. Prevention of pressure sores by frequent turning and by inspection of pressure sites in immobilized patients is far more effective than treatment. The use of specialized beds that distribute pressure more evenly may be of particular value among immobilized patients.

Stasis Ulceration

Patients with lower extremity edema are at risk for skin breakdown and formation of stasis ulcers. These may become secondarily infected, but unless cellulitis is present, systemic antibiotics are not necessary and treatment is aimed at reducing the edema.

Diabetic Ulcers

Patients with diabetes mellitus often develop foot ulcers. Peripheral neuropathy may result in the distribution of stress to sites on the foot not suited to weight bearing and may also result in failure to sense foreign objects stepped on or caught within the shoe. The resulting ulceration heals poorly. This is related to microangiopathy, macroangiopathy, and poor metabolic control. Secondary infection with *S. aureus*, anaerobes, and gram-negative bacilli progresses rapidly to involve bone and soft tissue. Prevention of these events requires meticulous foot care, avoidance of walking barefoot, the use of properly fitting shoes, and checking the inside of the shoe before use. Once an ulcer develops, the physician should evaluate the patient promptly. Bed rest and topical antiseptics are always indicated. Systemic antibiotics active against anaerobes and gram-negative bacilli should be employed for all but the most superficial and clean wounds. In most instances, this treatment requires admission to the hospital. Aggressive management including optimization of the vascular supply, control of hyperglycemia, appropriate antibiotic treatment, immobilization, and state-of-the-art wound care (which may be enhanced by vacuum wound

Table 101-2 Diffuse Cutaneous and Subcutaneous Bacterial Infections

Description	Predominant Organisms
Erysipelas	Group A streptococci
Cellulitis	Group A (B, C, and G) streptococci, <i>Staphylococcus aureus</i> , <i>Haemophilus influenzae</i> , <i>Clostridium perfringens</i> , other anaerobic organisms, gram-negative bacilli
Erythema migrans (expanding circular erythema after tick bite)	<i>Borrelia burgdorferi</i>
Fasciitis	Group A streptococci, <i>C. perfringens</i> , other anaerobic organisms, gram-negative bacilli
Myonecrosis	<i>C. perfringens</i> , streptococci, mixed anaerobes, gram-negative bacilli

drainage) is indicated, because if the ulcer is left untreated or is improperly treated, the proximate bones and soft tissues of the entire foot may become involved. Once this involvement occurs, eradication of infection without amputation may be difficult.

Other Ulcerative Lesions of the Skin

Ulcerative lesions of the skin, particularly in the genital region, may be caused by *Treponema pallidum*, the agent of syphilis, or by *Haemophilus ducreyi*, the agent of chancroid (see Chapter 107).

DIFFUSE LESIONS OF SKIN

Erysipelas

Erysipelas is an infection of the superficial layers of the skin (Table 101-2); it is usually caused by group A streptococci. This infection, seen primarily among children and the elderly, most commonly occurs on the face. Erysipelas is a bright red to violaceous raised lesion with sharply demarcated edges. This sharp demarcation distinguishes erysipelas from the deeper tissue infection, cellulitis, the margins of which are not raised and merge more smoothly with uninvolved areas of skin. Fever is generally present in erysipelas, but bacteremia is uncommon; in rare cases, the pathogen can be isolated by aspiration or biopsy of the leading edge of the erythema (clysis culture). Penicillin, 2 to 6 million U/day, can be used if the diagnosis of streptococcal erysipelas can be made with confidence; defervescence is gradual. If distinction between erysipelas and cellulitis is not clear, treatment for staphylococcal infection with dicloxacillin is reasonable. If MRSA is common in the community, treatment with TMP/SMX or linezolid is indicated.

Cellulitis

Cellulitis is an infection of the deeper layers of the skin. Cellulitis has a particular predilection for the lower extremities, where venous stasis predisposes to infection. It predisposes to recurrent infection, perhaps by impairing lymphatic drainage. A breakdown in normal skin barriers almost

Table 101-3 Processes That May Resemble Cellulitis

Process	Diagnosis
Thrombophlebitis	Tender cord, no lymphangitis, ultrasound
Arthritis	Pain on passive joint movement, joint effusion, joint aspiration
Ruptured Baker cyst	History of arthritis, joint effusion, arthrogram, MRI
Brown recluse spider bite	Exposure history
Fasciitis	MRI, surgical exploration
Myositis	Muscle tenderness, less prominent skin involvement, MRI, surgical exploration

MRI, magnetic resonance imaging.

always precedes this infection. Lacerations, small abscesses, tick bites (in the instance of erythema migrans caused by *Borrelia burgdorferi*), or particularly tiny fissures between the toes caused by minor fungal infection antedate the onset of pain, swelling, and fever. Although shaking chills often occur, bacteremia is infrequently documented. Linear streaks of erythema and tenderness indicate lymphatic spread. Regional lymph node enlargement and tenderness are common. Patches of erythema and tenderness may occur a few centimeters proximal to the edge of infection; they are probably caused by spread through subcutaneous lymphatics. Cellulitis of the calf is often difficult to distinguish from thrombophlebitis. Rupture of a Baker cyst or inflammatory arthritis may also mimic cellulitis (Table 101-3). Pain within the joint on passive motion suggests arthritis, whereas after a Baker cyst rupture, examination of the joint may yield relatively benign findings. Lymph node enlargement and lymphatic streaking virtually confirm the diagnosis of cellulitis. Most cases of lower extremity cellulitis are caused by group A β -hemolytic streptococci (less frequently group B, C, or G streptococci), but on occasion *S. aureus* is responsible. Purulence suggests that staphylococci and especially MRSA are likely present as MRSA often produces the Panton-Valentine leukocidin that is toxic to white blood cells. Gram-negative bacilli often cause cellulitis in neutropenic and other immunosuppressed patients. In patients with diabetes mellitus, streptococci and staphylococci are the predominant pathogens of cellulitis. However, if the cellulitis is associated with an infected ulceration of the skin, there is a good chance that anaerobic bacteria and gram-negative rods are also involved. After a cat or dog bite, cellulitis caused by *Pasteurella multocida* or other facultative anaerobes may develop.

Occupational exposures are often associated with painful cellulitis of the hands. Erysipeloid cellulitis (caused by *Erysipelothrix rhusiopathiae*) most often occurs in fish or meat handlers and responds to high doses of penicillin (12 to 20 million U/day). Freshwater exposures are associated with cellulitis caused by *Aeromonas* species, and saltwater exposures may result in aggressive cellulitis caused by *Vibrio* species; third-generation cephalosporins are usually effective in the treatment of these potentially lethal infections.

As in the case of erysipelas, cultures of blood and clysis cultures of the leading edge of infection rarely yield the

pathogen. Patients with cellulitis whose condition appears toxic or who have underlying diseases causing impaired immune response should be hospitalized. Suitable oral agents for the treatment of cellulitis include dicloxacillin, clindamycin, or erythromycin, unless streptococci or staphylococci resistant to these agents are common in the community, in which instance TMP/SMX or linezolid is useful.

If *Haemophilus* infection is suspected, ampicillin-sulbactam is usually effective. Erythema migrans is treated with doxycycline, amoxicillin, or ceftriaxone.

Diabetics with foot ulcers complicated by cellulitis should be treated with agents active against anaerobes and enteric gram-negative rods. Only for the mildest of infections are oral antibiotics indicated (e.g., ampicillin-sulbactam; clindamycin plus levofloxacin). For more serious infections, hospitalization and parenteral therapy are warranted.

The control of diabetes should be optimized. Radiologic studies should be performed on patients with ulcers to determine if osteomyelitis is present (see Chapter 104). The affected limb should be elevated to enhance venous drainage. Prevention of cellulitis can be achieved by institution of measures aimed at reducing venous stasis and edema. Patients with recurrent cellulitis may benefit from antibiotic prophylaxis and resolution of venous stasis, if present.

Soft Tissue Gas

Crepitus on palpation of the skin indicates the presence of gas in the soft tissues. Although this often reflects anaerobic bacterial metabolism, subcutaneous gas can also be found after ventilator-induced barotrauma or after application of hydrogen peroxide to open wounds.

In the setting of soft tissue infection, crepitus suggests the presence of gas-forming anaerobes that may include clostridia or facultative bacteria such as streptococci or gram-negative rods. Roentgenograms will occasionally demonstrate gas before crepitus is detected (Fig. 101-1). Magnetic resonance imaging is more sensitive than other techniques in detecting soft tissue gas. The presence of gas in the setting of infection necessitates emergency surgery to determine the extent of necrosis and requirements for débridement. Involvement of the muscle establishes the diagnosis of myonecrosis (see later discussion) and mandates extensive débridement. Despite the often extensive crepitus seen in clostridial cellulitis, exploration shows the muscles to be

Figure 101-1 Radiograph of patient with clostridial myonecrosis shows gas within tissues. (Courtesy Dr. J. W. Tomford.)

uninvolved, and proper treatment is limited to débridement of necrotic tissue, open drainage, and antibiotics, usually penicillin G, 10 to 20 million U/day, and clindamycin, 900 mg every 8 hours. The principles of treatment for necrotizing soft tissue infections are (1) removal of necrotic tissue, (2) drainage, and (3) appropriate antibiotics. These apply to superficial necrotizing infections (clostridial cellulitis), deeper anaerobic infections (necrotizing fasciitis [see later discussion]), and deepest infections (necrotizing myonecrosis [see later discussion]).

Deeper Infections of the Skin and Soft Tissue

NECROTIZING FASCIITIS

Necrotizing fasciitis is a deep infection of the subcutaneous tissues that generally occurs after trauma (sometimes minor) or surgery but may occur spontaneously in previously healthy persons. Most cases are caused by β -hemolytic streptococci with or without staphylococci; some cases, especially in diabetics, are caused by mixtures of anaerobic organisms and gram-negative bacilli. Because fasciitis involves subcutaneous tissues, the skin may appear normal or may have a red or dusky hue. The clues to this diagnosis are pain and the presence of subcutaneous swelling, particularly in the absence of overlying cellulitis. In some instances, crepitus is present. In time, skin necrosis and dark bullae may develop. The patient's condition appears more toxic than one would expect from the superficial appearance of the skin. Radiographs may show gas within tissues; its absence does not exclude the diagnosis. Men with diabetes mellitus, urethral trauma, or obstruction may develop an aggressive fasciitis of the perineum called Fournier gangrene. Perineal pain and swelling may antedate the characteristic discoloration of the scrotum and perineum. Prompt débridement of all necrotic tissue is critical to the cure of these infections. Once the diagnosis is suspected, the patient must be taken immediately to the operating room, where incision and exploration will determine if fasciitis is present. Gram stain of necrotic material will guide antibiotic choice. Broad and repeated dissection with removal of infected tissue is required for cure.

INFECTIONS OF MUSCLE

Pyomyositis

Pyomyositis is a deep infection of muscle usually caused by *S. aureus* and occasionally by group A β -hemolytic streptococci or enteric bacilli. Most cases occur in warm or tropical regions, and most occur among children. Nonpenetrating trauma may antedate the onset of symptoms, suggesting that infection of a minor hematoma during incidental bacteremia may be causative. Patients have fever and tender swelling of the muscle; the skin is uninvolved or minimally involved. In older patients, myositis may mimic phlebitis. Diagnosis can be readily made, if suspected, by needle aspiration, ultrasonography, or computed tomography. Early aggressive débridement and appropriate antibiotics are usually curative.

Myonecrosis

Myonecrosis generally occurs after a contaminated injury to muscle. Within 1 or 2 days of injury, the involved extremity becomes painful and begins to swell. The patient's condition appears toxic, and he or she is often delirious. The skin may appear uninvolved at first but eventually may develop a bronzed-blue discoloration. Crepitus may be present but is not as prominent as in patients with necrotizing cellulitis (a less aggressive lesion). Most of these infections are caused by clostridial species (gas gangrene), but some are caused by streptococci, mixtures of anaerobes, or gram-negative rods. In rare cases, clostridial myonecrosis occurs spontaneously in the absence of trauma; most of these patients have an underlying malignancy, usually involving the bowel. Regardless of cause, this illness progresses rapidly, producing extensive necrosis of muscle. Hypotension, hemolytic anemia caused by clostridial lecithinase, and renal failure can complicate this illness. Gram stain of the thin and watery wound exudate reveals large gram-positive rods and very few inflammatory cells. Emergency surgery with wide débridement is essential. Large doses of penicillin (10 to 20 million U/day) plus clindamycin, 900 mg every 8 hours, may prevent further spread of the bacilli. Chloramphenicol may be used in patients with hypersensitivity to penicillin. If gram-negative rods are seen in the exudate, treatment with an extended-spectrum penicillin that also has excellent anaerobic activity (e.g., piperacillin-tazobactam) is indicated. Hyperbaric oxygen therapy is of uncertain value.

APPROACH TO THE PATIENT WITH "RED LEG"

Cellulitis of the leg is a common infection that is generally responsive to antibiotic therapy as discussed earlier. A willingness to accept this common diagnosis uncritically

can result in missed diagnoses of other treatable diseases, which in some instances are life threatening (see Table 101-3).

The first key issue is to determine if the process is infectious. The presence of fever does not exclude inflammatory mimics of cellulitis that also may cause a red leg. The presence of ulcers or other wounds that provide entry to bacteria suggests infection; streaks of lymphangitis, tender lymph nodes, and skip areas of skin inflammation are highly suggestive of cellulitis. Thrombophlebitis may occasionally be distinguished by palpation of a tender, inflamed, and clotted vein; this diagnosis may be suggested by elevated fibrin degradation products in plasma (e.g., D-dimers) and confirmed by ultrasound. Septic or crystal-induced arthritis has findings most prominent around the affected joint, and even minimal passive joint motion is painful; aspiration of joint fluid is diagnostic.

For each patient in whom a diagnosis of cellulitis is presumed, the careful clinician must ask: Does this patient also have deeper infection, such as necrotizing fasciitis? Although this disorder is uncommon, it progresses at life-threatening speed, and clues to its presence are often subtle. To miss this diagnosis even for a few hours can place patients at risk for loss of limb or life. Clues to this diagnosis include pain and swelling out of proportion to degree of inflammation, particularly at sites where there is no erythema (alternatively, some patients may experience topical anesthesia as a sign of skin necrosis); a dusky or bluish appearance of the skin with development of hemorrhagic vesicles or bullae; clinical "toxicity" out of proportion to degree of fever; and history of rapid clinical progression. Magnetic resonance imaging sometimes will show gas in tissues. If the diagnosis of necrotizing fasciitis or of myonecrosis is suspected, emergent surgical exploration is required with repeated broad dissection to remove necrotic tissues. Antibiotic therapy plays a supplementary role.

Prospectus for the Future

- Improved methods of wound care management including use of recombinant growth factors
- Increased prevalence of drug-resistant bacteria in hospitals, extended care facilities, and the community
- Emphasis on better patient recognition of early signs of diabetic foot infections
- Improved treatment strategies for patients with recurring soft tissue infections

Intra-Abdominal Abscess and Peritonitis

Christoph Lange and Michael M. Lederman

Intra-Abdominal Abscess

There are two general categories of intra-abdominal abscess. The first is an infection of an intra-abdominal organ, generally arising as a consequence of hematogenous, lymphatic, or enteral spread. The second consists of extravisceral abscesses, which are localized collections of pus within the peritoneal or retroperitoneal space. These abscesses usually follow peritonitis or contamination by rupture or leakage from the bowel. Most patients with an intra-abdominal abscess are febrile; however, some patients (e.g., those with tuberculous abscesses) may not be. The fever may be recurrent and may be associated with rigors, suggesting intermittent bacteremia. Nausea, vomiting, and paralytic ileus are common with extravisceral abscesses. Clues to the presence of intra-abdominal abscess may be subtle and may include extravisceral gas or air-fluid levels on plain radiographs. Abdominal ultrasound, computed tomography (CT) and magnetic resonance imaging (MRI) have simplified both the diagnosis and the management of these potentially life-threatening infections.

With the exception of tuberculous and amebic abscess or multiple microabscesses of the liver, antibiotic therapy alone is rarely curative. Failure of the antibiotic to penetrate the abscess cavities, binding and inactivation of antibiotics within the abscess by proteins and bacterial enzymes, low pH, and low redox potential all contribute to the failure of medical management. Drainage is essential; antibiotics are important primarily to prevent bacteremia and seeding of other organs.

ABSCESSES OF SOLID ORGANS

Hepatic Abscess

Pyogenic liver abscess is a disease that occurs predominantly among individuals with other underlying disorders, most commonly biliary tract disease. Obstruction to biliary drainage allows infected bile to produce ascending infection of the liver. Inflammatory diseases of the bowel, such as appendicitis and diverticulitis, may also lead to hepatic abscess through spread of infection through portal veins

(Table 102-1). Hepatic abscesses are also recognized complications of liver transplantation. Penetrating or nonpenetrating trauma may also result in pyogenic liver abscess.

Clinical findings in patients with pyogenic hepatic abscess are often nonspecific. Most patients are febrile, but only about half have abdominal pain and tenderness. Two thirds have palpable hepatomegaly, but fewer than one in four is clinically jaundiced.

The chest roentgenogram may show an elevated right hemidiaphragm and atelectasis or effusion at the right lung base. The diagnosis is best achieved by contrast-enhanced CT of the abdomen or ultrasonography of the right upper quadrant. Pyogenic abscesses may be single or multiple; multiple abscesses often arise from a biliary source of infection.

Anaerobic bacilli, microaerophilic streptococci, and gram-negative bacilli are the predominant microorganisms in pyogenic liver abscess. Occasionally, *Staphylococcus aureus* causes hepatic abscesses during the course of bacteremic seeding of multiple organs. Positive blood cultures are obtained from about half the patients with pyogenic liver abscess.

Clinical laboratory studies generally show a moderate elevation of the alkaline phosphatase level, which is disproportionate to the modest elevation in bilirubin level that occurs in roughly half of patients. In contrast, patients with the nonspecific jaundice that occasionally accompanies bacterial infection at other sites generally have elevated bilirubin levels of as much as 5 to 10 mg/dL or more and only slightly elevated alkaline phosphatase levels. In patients with leukemia, multiple hepatic abscesses caused by *Candida* species may cause fever and poorly localized abdominal pain, and an elevated serum alkaline phosphatase level may be the only abnormality pointing to the hepatic origin. MRI is the most sensitive imaging technique for diagnosis.

Hepatic abscess caused by *Entamoeba histolytica* is rare in North America, although it should be suspected in a patient with fever and right upper quadrant pain who has traveled to or emigrated from the developing world. Amebic abscesses are generally single and are usually located in the right lobe of the liver. Only a minority of patients with amebic liver

Table 102-1 Intra-Abdominal Abscesses

Site	Predisposing Factors	Likely Pathogens	Diagnosis	Empirical Treatment*
Solid Organs				
Hepatic	Gastrointestinal or biliary sepsis, trauma	Gram-negative bacilli, anaerobes, streptococci, amebae	CT, MRI, ultrasonography	Drainage Vancomycin plus piperacillin-tazobactam or ampicillin-sulbactam
Splenic	Trauma, hemoglobinopathy, endocarditis, injection drug use	Staphylococci, streptococci, gram-negative bacilli	CT, MRI, ultrasonography	Vancomycin plus piperacillin-tazobactam or ampicillin-sulbactam Drainage and/or splenectomy
Pancreatic	Pancreatitis, pseudocyst	Gram-negative bacilli, streptococci	CT, MRI, ultrasonography	Drainage Piperacillin-tazobactam or ampicillin-sulbactam
Extravisceral				
Subphrenic	Abdominal surgery, peritonitis	Gram-negative bacilli, streptococci, anaerobes	CT	Piperacillin-tazobactam or ampicillin-sulbactam Drainage
Pelvic	Abdominal surgery, peritonitis, pelvic or gastrointestinal inflammatory disease	Gram-negative bacilli, streptococci, anaerobes	CT	Piperacillin-tazobactam or ampicillin-sulbactam Drainage
Perinephric	Renal infection or obstruction, hematogenous	Gram-negative bacilli, staphylococci	CT	Piperacillin-tazobactam or ampicillin-sulbactam plus vancomycin Drainage
Psoas	Vertebral osteomyelitis, hematogenous	Staphylococci, gram-negative bacilli, mycobacteria	CT	Piperacillin-tazobactam or ampicillin-sulbactam plus vancomycin (antituberculous therapy if indicated by histology or culture results) Drainage

*Dosages: ampicillin-sulbactam, 3 g IV every 6 hours; piperacillin-tazobactam, 3.375 g q6h IV. CT, computed tomography; MRI, magnetic resonance imaging.

abscess have concurrent intestinal amebiasis. Antibody titers against *E. histolytica* are nearly always positive.

The Fitz-Hugh-Curtis syndrome, or gonococcal perihepatitis, may share some clinical manifestations suggestive of hepatic abscess and should be suspected in young, sexually active women with fever and right upper quadrant tenderness. Tumors involving the liver may produce fever and a clinical and radiologic picture that may mimic hepatic abscess. This is complicated by the occasional concurrence of malignancy and abscess. Patients with hepatic abscesses generally have a less acute illness than patients with cholecystitis or cholangitis. Ultrasonography, CT, and MRI are all useful in defining liver abscesses; MRI is most effective when the abscesses are less than 1 cm in diameter.

If pyogenic abscess is suggested, needle aspiration is indicated. With the guidance of ultrasonography or CT, a percutaneous catheter can be inserted into the abscess cavity for both diagnostic and therapeutic purposes. The pus should be Gram-stained and cultured aerobically and anaerobically. Unless the Gram stain indicates otherwise, initial therapy for pyogenic liver abscess should include drugs active against enteric aerobic and anaerobic bacteria (see Table 102-1). Antibiotics should be continued for at least 4 to 6 weeks. Surgery is required to relieve biliary tract obstruction and to drain abscesses that do not respond to percutaneous drainage and antibiotics. Patients with pyogenic liver abscess should be evaluated for a primary intra-abdominal source of infection.

Patients with hepatic abscesses caused by *Candida glabrata* require long-term therapy with an echinocandin, amphotericin B, or fluconazole, as determined by the microbiology of the fungus.

If epidemiologic features strongly suggest an amebic abscess, metronidazole is the drug of choice. Needle aspiration is necessary only to exclude pyogenic infection or, if the abscess is large or close to other viscera, to prevent rupture. In the case of amebic abscess, the “anchovy paste” material obtained by needle drainage is not pus but necrotic liver tissue. Trophozoites of *E. histolytica* are infrequently seen on aspiration of abscesses but are often seen on biopsy of the abscess capsule. Large numbers of white cells suggest pyogenic abscess or bacterial superinfection.

Splenic Abscess

Splenic abscesses are generally the result of hematogenous seeding of the spleen. In the preantibiotic era, splenic infarction and abscess were common complications of infective endocarditis. Now the most common predisposing factors are trauma and (in children) sickle cell disease. Patients with splenic abscess most often have left upper quadrant abdominal pain, which may be pleuritic. The left hemidiaphragm may be elevated, and there may be an associated pleural rub or effusion. The diagnostic approach, most likely causative agents, and initial antimicrobial therapy are outlined in Table 102-1. Splenectomy is usually the definitive treatment, but ultrasound- or CT-guided percutaneous

drainage of large, solitary abscesses may also be successful in selected cases.

Pancreatic Abscess

Pancreatic abscess is an uncommon complication of pancreatitis. The symptoms of pancreatic abscess (fever, nausea, vomiting, and abdominal pain radiating to the back) resemble those of pancreatitis. Thus abscess should be suspected in cases of persistent or recurrent fever after pancreatitis. The inflamed organ becomes colonized and infected with microbes inhabiting the upper gastrointestinal tract. Enterobacteriaceae, anaerobes, and streptococci (including the pneumococci) are likely pathogens. The diagnosis may be made by abdominal ultrasound, CT, or MRI; however, radiographic definition of the pancreatic bed is often difficult. Initial antibiotic therapy (see Table 102-1) should be followed by drainage of the abscess as soon as the patient's condition is stable.

EXTRAVISCERAL ABSCESSSES

Extravisceral abscesses most often arise after peritonitis, after intra-abdominal surgery, as a consequence of rupture of the bowel, or after extension of infection of a viscus, such as diverticulitis or appendicitis. Abscesses may occur in the subphrenic, pelvic, or retroperitoneal spaces. Fever, nausea, vomiting, and paralytic ileus are common. Although fever is almost always present, localizing symptoms may be very subtle, making the bedside diagnosis difficult. Predisposing factors, most likely causative pathogens, and appropriate initial antimicrobial therapy are outlined in Table 102-1.

When an abscess is suspected, CT, MRI, or ultrasound scans should be obtained. CT can identify abscesses in the retroperitoneal and abdominal spaces and guide percutaneous drainage. Ultrasonography may be more helpful in the identification of pelvic fluid collections. Fluid-filled abscesses may be difficult to distinguish from loops of viscera on CT or ultrasonography; review of such studies by an experienced radiologist is essential before they are considered negative. Radionuclide imaging using gallium-67- or indium-111-labeled leukocytes may be useful in localizing collections of pus when other studies are not diagnostic. Drainage of an abscess either by radiologic guidance or by surgery in conjunction with antibiotics is the mainstay of treatment.

Peritonitis

Peritonitis may occur spontaneously (primary peritonitis) or as a consequence of trauma, surgery, peritoneal dialysis, or peritoneal soilage by bowel contents (secondary peritonitis). Peritonitis also may be caused by chemical irritation. Patients with peritonitis generally complain of diffuse abdominal pain. They may have nausea and vomiting; some have diarrhea, and others have paralytic ileus. Patients are usually febrile and uncomfortable and prefer to lie quietly in the supine position. Physical examination may reveal diffuse tenderness, diminished bowel sounds, and evidence of peritoneal inflammation, including rebound tenderness and involuntary guarding. In patients with underlying ascites, the signs and symptoms of peritonitis may be more subtle, with fever as the only manifestation of infection.

PRIMARY PERITONITIS

Primary or spontaneous peritonitis occurs principally among persons with ascites associated with chronic liver disease or the nephrotic syndrome. Bacteria may infect ascitic fluid by means of bacteremic spread or transmural migration through the bowel or through the fallopian tubes. In cirrhotic patients, clearance of portal bacteremia by hepatic reticuloendothelial cells may be impaired by intrahepatic portosystemic shunting. Not surprisingly, therefore, gram-negative rods, especially *Escherichia coli*, are the predominant pathogens in spontaneous bacterial peritonitis; enteric streptococci are isolated in approximately one third of cases. Staphylococci, *Streptococcus pneumoniae*, or anaerobic bacilli are isolated in a smaller proportion of cases (Table 102-2).

In patients with ascites, the presenting symptoms may be nonspecific abdominal pain, nausea, vomiting, diarrhea, or altered mental status. Thus febrile patients with ascites should undergo paracentesis unless there is another certain explanation for fever. Inoculation of ascites fluid into blood culture bottles should be performed at the bedside. A leukocyte reagent strip (dipstick) is useful for a rapid diagnosis. A white blood cell count in the fluid that exceeds 250/ μ L is suggestive of infection. Gram stain may reveal the responsible pathogen. Antibiotic penetration into the peritoneum is excellent, and medical therapy is the treatment of choice (see Table 102-2) unless a mixture of bacterial isolates suggests soilage by bowel contents. Bacteria may be cultured from ascitic fluid in the absence of clinical findings of peritonitis (bacterascites), and as many as one third of patients with clinical and laboratory findings consistent with peritonitis have sterile ascitic fluid cultures. Treatment is indicated in these settings. Among patients with cirrhosis and ascites, or with a single episode of spontaneous bacterial peritonitis, prophylactic administration of norfloxacin or trimethoprim-sulfamethoxazole decreases the risk of spontaneous peritonitis.

SECONDARY PERITONITIS

If Gram stain or culture reveals a mixed flora or if anaerobes are suspected on stain or are cultured, secondary peritonitis caused by leakage of bowel contents should be suspected. Secondary peritonitis may follow penetrating abdominal trauma or surgery or may result from contamination of the peritoneum with bowel contents. This syndrome may be heralded by the sudden presentation of visceral rupture (e.g., perforated duodenal ulcer or appendix) or visceral infarction. In the postoperative setting, secondary peritonitis should be suspected in the patient whose abdominal discomfort and fever do not resolve, or even worsen, after the first few postoperative days. If peritonitis is secondary to the leakage of bowel contents, immediate surgical intervention is mandatory. Despite the use of appropriate antibiotics (see Table 102-2) and intensive support systems, mortality from generalized peritonitis in this setting approaches 50%.

Peritonitis is also a common complication of peritoneal dialysis. Most infections are caused by staphylococci, followed by gram-negative bacilli and yeast. Intraperitoneal antibiotics, administered via the dialysis catheter, are generally effective and may be preferred over intravenous

Table 102-2 Causes, Diagnosis, and Treatment of Peritonitis

Site	Predisposing Factors	Causative Agent	Clues to Diagnosis	Empirical Treatment*
Primary				
Spontaneous	Cirrhosis, nephrotic syndrome	Gram-negative bacilli, streptococci	>250 neutrophils/ μ L of ascites	Cefotaxime or piperacillin-tazobactam or ampicillin-sulbactam or if resistant <i>Escherichia coli</i> or <i>Klebsiella</i> : carbapenem or fluoroquinolone
Secondary				
Postoperative	Hemorrhage, visceral rupture	Gram-negative bacilli, streptococci, staphylococci, anaerobes	Postoperative fever, pain, prolonged ileus	Piperacillin-tazobactam or ampicillin-sulbactam or carbapenem
Chemical	Abdominal surgery	Bile, starch, talc	Postoperative fever, pain	Biliary drainage when indicated
Visceral rupture	Perforating ulcer, ruptured appendix, bowel infarction	Gram-negative bacilli, anaerobes, streptococci	Polymicrobial Gram stain or culture	Piperacillin-tazobactam or ampicillin-sulbactam or carbapenem Surgery
Peritoneal dialysis		Staphylococci, gram-negative bacilli	Pain, fever, neutrophilic pleocytosis	Vancomycin [†] + third-generation cephalosporin or piperacillin-tazobactam Consider catheter removal
Periodic peritonitis	Familial		Recurrent, familial	Colchicine prophylaxis, 0.6 mg two or three times daily
Tuberculosis	Infection of fallopian tubes or ileum	<i>Mycobacterium tuberculosis</i>	Lymphocytic pleocytosis, high protein level (>3g/dL) in ascitic fluid	Isoniazid, rifampin, pyrazinamide, ethambutol

*Dosages: ampicillin-sulbactam, 3 g IV every 6 hours; piperacillin-tazobactam, 3.375 g q6h IV; imipenem, 0.5 g q6h IV; metronidazole, 500 mg q6h IV; vancomycin, 1 g IV q12h; isoniazid, 300 mg/day; rifampin, 600 mg/day; ethambutol, 15-25 mg/kg/day; pyrazinamide, 25 mg/kg/day (maximum, 2.5 mg/kg/day); ceftazidime, 2 g q8h IV; moxifloxacin, 400 mg qd IV.
[†]Intraperitoneal vancomycin, initially 1 g/L dialysate, followed by 25 mg/L dialysate.

antibiotics. Refractory or recurrent peritonitis may necessitate dialysis catheter removal.

TUBERCULOUS PERITONITIS

Tuberculous peritonitis may occur as a result of hematogenous, lymphatic or local extension of tuberculous infection

into the peritoneal cavity. Fever, abdominal pain, and weight loss are common. In patients with underlying ascites, a lymphocytic pleocytosis in the peritoneal fluid should suggest the diagnosis. Laparoscopy, with biopsy of the granulomatous peritoneal nodules, is the most effective approach to diagnosis. Standard antituberculous therapy over 6 months is generally curative (see Table 102-2).

Prospectus for the Future

- Increasing complexity of diagnostic and therapeutic challenges as more intra-abdominal infections are seen in the compromised, hospitalized patient
- Development of better imaging tools for the diagnosis of intra-abdominal infections

Infectious Diarrhea

Christoph Lange and Michael M. Lederman

Acute infectious diarrhea typically consists of an increased frequency of bowel movements of three or more times daily and at least 200 g of stool per day and lasting less than 14 days. Acute infectious diarrhea accounts for more than 2 million worldwide deaths annually. With the best techniques available, a specific causative agent can be identified in 70% to 80% of cases.

Pathogenesis and Pathophysiology: General Concepts

In general, pathogens or microbial toxins that produce acute diarrhea must be ingested. Therefore socioeconomic conditions that result in crowding, poor sanitation, and contaminated water sources lead to increased risk of diarrheal illnesses. Normally the low pH of the stomach, the rapid transit time of the small bowel, and antibody and innate host defense molecules produced by cells in the lamina propria of the small bowel are adequate to keep the jejunum and proximal ileum free of pathogenic microorganisms (although not sterile). Furthermore, the ileocecal valve inhibits retrograde migration of the huge numbers of bacteria that reside in the large bowel.

Pathogenic microorganisms can pass through the hostile environment of the stomach if (1) they are acid resistant (e.g., *Shigella*) or (2) they are ingested with food and are therefore partially protected in the neutralized environment. People with decreased gastric acidity are at increased risk for acute diarrheal disease.

In the small bowel, either the organisms colonize (e.g., *Vibrio cholerae*, *Escherichia coli*) or invade (e.g., rotavirus, noroviruses) the local mucosa, or they pass through to colonize and invade the mucosa of the terminal ileum (*V. cholerae*, *E. coli*) or colon (*Shigella*). Small bowel peristalsis deters colonization of most organisms. Special colonization factors such as fimbria (hairlike projections from the cell wall) or lectins (proteins that attach to mucosal cell surface carbohydrates) facilitate adherence of successful colonists to mucosal cell surfaces.

Organisms that do not have special colonization properties pass into the terminal ileum and colon, where they may compete with the naturally residing microorganisms. These resident intestinal bacteria produce substances that prevent intraluminal proliferation of most newly introduced bacterial species (*Bacteroides* produces inhibitory fatty acids; other enteric bacteria produce inhibitory colicins). The ability of the colonic enteropathogens (e.g., *Shigella dysenteriae*) to invade intestinal mucosa allows these microorganisms to multiply preferentially.

Types of Microbial Diarrheal Diseases

Microbes can cause diarrhea either directly by invasion of the gut mucosa or indirectly through elaboration of one of three classes of microbial toxins: secretory enterotoxins, cytotoxins, or neurotoxins. Toxins may be elaborated after microbial replication in the gut or, in some instances, are preformed and ingested directly.

SECRETORY TOXIN-INDUCED DIARRHEAS

Patients infected with secretory toxin-producing pathogens seldom have fever or other major systemic symptoms, and there is little or no inflammatory response. Characteristically, large numbers of bacteria (10^5 to 10^8) must be ingested with grossly contaminated food or water (although a small inoculum may produce disease in individuals with achlorhydria). The enterotoxin-producing bacteria then colonize, but do not invade, the small bowel. After multiplying to large numbers (10^8 to 10^9 organisms per milliliter of fluid), the bacteria produce enterotoxins that bind to mucosal cells, causing hypersecretion of isotonic fluid at a rate that overwhelms the reabsorptive capacity of the colon. The diarrhea is watery, with a low protein concentration and an electrolyte content that reflects its source. Rapid loss of this diarrheal fluid results in predictable saline depletion, base-deficit acidosis, and potassium deficiency. The amount and rate of fluid loss determine the severity of the illness. Certain of the secretory diarrheas, such as those caused by

V. cholerae or *E. coli* enterotoxins, can result in massive intestinal fluid losses, exceeding 1 L/hr in adults. The *V. cholerae* enterotoxin rapidly binds to monosialogangliosides of the gut mucosa and causes sustained stimulation of cell-bound adenylate cyclase. This results, through both increased secretion and decreased absorption of electrolytes, in net movement of large quantities of isotonic fluid into the gut lumen. The disease runs its course in 2 to 7 days, during which time continued fluid and electrolyte repletion is of critical importance.

Enterotoxigenic *E. coli* (ETEC), probably the major cause of traveler's diarrhea worldwide, produces two major types of plasmid-encoded bacterial enterotoxins. The labile toxin (LT) of *E. coli* is nearly identical in mode of action to cholera enterotoxin. The *E. coli* stable toxin (ST) causes gut fluid secretion through activation of guanylate cyclase. Secretory enterotoxins may also be produced by other enteropathogenic bacteria that cause diarrhea primarily through direct invasion (e.g., *Salmonella typhimurium*, *S. dysenteriae*).

CYTOTOXIN-INDUCED DIARRHEAS

Cytotoxins are soluble factors that directly destroy mucosal epithelial cells. *S. dysenteriae* elaborates a toxin (Shiga toxin) that causes the destructive colitis seen in patients with shigellosis. A closely related cytotoxin is produced by enterohemorrhagic *E. coli* strains that are associated with hemorrhagic colitis and hemolytic uremic syndrome. Other bacteria that can produce cytotoxins include *Clostridium perfringens* and *Vibrio parahaemolyticus*. *C. perfringens*, often ingested in contaminated meat or poultry, replicates within the small bowel and produces a secretory enterotoxin that also has cytotoxin activity. Toxin-induced diarrhea caused by *C. perfringens*, like that caused by *Staphylococcus aureus* and *Bacillus cereus*, has a short incubation period and brief (<36 hours) duration. *Clostridium difficile* can colonize the large bowel and, in the presence of antibiotic therapy that limits the growth of naturally occurring bacteria, can produce cytotoxins that can cause severe mucosal damage, producing a colitis that may have a pseudomembranous appearance or may resemble the diffuse colitis seen in shigellosis.

FOOD POISONING (CAUSED BY CYTOTOXINS, SECRETORY ENTEROTOXINS, AND/OR NEUROTOXINS)

Some toxins are ingested directly in food, as with *S. aureus* and *B. cereus* food poisoning. These organisms grow to a high concentration in the food, and ingestion of the toxins they produce causes the symptoms of food poisoning. Distinctive features of acute food poisoning include a short incubation period (2 to 6 hours), high attack rates (up to 75% of the population at risk), and prominent vomiting (probably caused by the effect of absorbed neurotoxins on the central nervous system).

Food poisoning syndromes of somewhat longer incubation (8 to 16 hours) can be caused by organisms ingested in food that produce toxins during replication in the bowel. In this setting, *B. cereus* produces a cytotoxin similar to *E. coli* LT. The longer-incubation food poisoning syndrome caused by some strains of *B. cereus* (often associated with ingestion of contaminated rice) may resemble the diar-

rhea caused by ETEC. *C. perfringens* can produce both secretory and cytotoxic enterotoxins after ingestion and replication in the bowel, also producing a longer-incubation food poisoning. Nausea and vomiting are less prominent than diarrhea in these food poisoning syndromes with longer incubation times.

DIARRHEAS CAUSED BY INVASIVE PATHOGENS

Diarrheas caused by invasive pathogens are usually accompanied by fever and other systemic symptoms, including headache and myalgia. Cramping abdominal pain may be prominent, and small amounts of stool are passed at frequent intervals, often associated with tenesmus. The invasive microorganisms often induce a marked inflammatory response, so that the stool contains pus cells, large amounts of protein, and often gross blood. Significant dehydration rarely results from this kind of diarrhea in adults, because the diarrheal fluid volume is small, seldom exceeding 750 mL/day, although critical dehydration may occur in children. Although certain clinical features are statistically more frequent in invasive diarrheas caused by specific enteropathogens (e.g., more severe myalgias with shigellosis, higher temperature spikes with salmonellosis), epidemiologic characteristics are more helpful than signs or symptoms in determining the causative agent in invasive diarrheal illnesses (Table 103-1).

Acute Shigellosis

Acute shigellosis occurs when susceptible individuals ingest fecally contaminated water or food. The bacteria are relatively resistant to killing by gastric acid; shigellosis can therefore occur after ingestion of only 10 to 100 microorganisms. Largely for this reason, direct person-to-person transmission (e.g., in day-care centers) is more common with shigellosis than with other bacterial enteric infections. The organism initially multiplies in the small intestine, producing watery, noninflammatory diarrhea. Later the organisms invade the colonic epithelium, causing the characteristic bloody stool. Unlike *Salmonella*, *Shigella* rarely causes bacteremia. The disease usually resolves spontaneously after 3 to 6 days, but the clinical course can be shortened by antimicrobial agents (see Table 103-1).

Acute Salmonellosis

Acute salmonellosis usually results from ingestion of contaminated meat, dairy, or poultry products. In the industrialized world, nontyphoidal *Salmonella* is often transmitted by means of commercially prepared dried and processed foodstuffs (e.g., spices). Unlike *Shigella*, *Salmonella* is remarkably resistant to desiccation. The nontyphoidal salmonellae invade primarily the distal ileum. The organism typically causes a short-lived (2 to 3 days) illness characterized by fever, nausea, vomiting, and diarrhea (This is in marked contrast to typhoid fever, a 3- to 4-week febrile illness, usually not associated with diarrhea, that is caused by *Salmonella typhi*).

Campylobacter jejuni Infection

C. jejuni may be responsible for up to a third of acute febrile diarrheal illnesses in North America. This organism may

Table 103-1 Epidemiologic Characteristics of Common Invasive Enteric Pathogens

Microorganisms	Epidemiologic Features	Recommended Treatment
<i>Shigella</i> species	Outbreaks in child care centers or custodial institutions; person-to-person transmission	Fluoroquinolones (e.g., ciprofloxacin 500 mg bid) for 3 days Alt: TMP/SMZ
Nontyphoidal <i>Salmonella</i> species	Zoonosis; survives desiccation in processed foodstuff	Only when patient is severely ill, immunocompromised, >50 years old, has prosthesis, valvular heart disease, atherosclerosis, cancer, uremia: • Fluoroquinolones (e.g., ciprofloxacin 500 mg bid) for 5-7 days Alt: TMP/SMZ or ceftriaxone
<i>Escherichia coli</i>	Outbreaks caused by foodborne transmissions	None
<i>E. coli</i> (toxin producing)	Traveler's diarrhea	Levofloxacin 500 mg PO \times 1, or azithromycin 1 g PO \times 1 dose, or other fluoroquinolones for 3 days
<i>Yersinia enterocolitica</i>	Zoonosis; occasionally transmitted in dairy products	Only for severe infections: • Doxycycline and an aminoglycoside Alt: TMP/SMZ, a fluoroquinolone
<i>Vibrio cholerae</i>	Ingestion of seafood	O1 or O139: • Hydration plus azithromycin 1 g or doxycycline 300 mg Alt: single dose fluoroquinolone
<i>Clostridium difficile</i>	Follows antimicrobial therapy; nosocomial spread	Discontinuation of offending antimicrobial therapy Treatment with metronidazole (e.g., 500 mg tid for 10 days or vancomycin 500 mg to 1 g q 12 hrs)
Rotavirus	Outbreaks among children; worldwide distribution; unusual and mild in adults	No
Norovirus	Winter outbreaks; vomiting and diarrhea in families, nursing homes, schools, etc	No
<i>Giardia lamblia</i>	Day-care centers; waterborne transmission; IgA deficiency	Tinidazole 2 g \times 1, or nitazoxanide 500 mg PO bid \times 3 days, or metronidazole 500-750 mg tid for 7-10 days
<i>Campylobacter jejuni</i>	Consumption of undercooked poultry	Only if high fevers, bloody stools, and illness >1 wk: • Erythromycin 500 mg bid for 5 days Alt: fluoroquinolone
<i>Cyclospora cayentanensis</i>	Foodborne transmission; travel	TMP/SMZ 160/800 mg for 7-10 days
<i>Cryptosporidium parvum</i>	Waterborne transmission; travel; immunocompromised hosts	In HIV and AIDS: • Effective antiretroviral therapy plus nitazoxanide 500 mg PO bid for 14 days
<i>Entamoeba histolytica</i>	Person-to-person transmission; travel to or recent emigration from tropical regions	Metronidazole 750 mg tid for 5-10 days followed by either iodoquinol 650 mg tid for 20 days or paromomycin 500 mg tid for 7 days

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; IgA, immunoglobulin A; TMP/SMZ, trimethoprim-sulfamethoxazole.

invade both the small intestine and the colon. Thus the range of symptoms is broad, ranging from an acute *Shigella*-type syndrome to a milder, but more protracted, diarrheal illness.

Other Invasive Enteropathogens

Three other organisms—*Yersinia enterocolitica*, *V. parahemolyticus*, and enteroinvasive *E. coli*—also cause tissue invasion and acute diarrheal illnesses that may be clinically indistinguishable from those caused by the more commonly recognized invasive bacterial enteropathogens (see Table 103-1).

Another distinct *E. coli* strain—0157; H7 enterohemorrhagic *E. coli* (EHEC)—produces bloody diarrhea without evidence of mucosal inflammation (grossly bloody stool with few or no leukocytes), usually with little or no fever. The intestinal mucosal damage is caused by a Shiga-like toxin, which is also thought to be responsible for the hemolytic uremic syndrome, which develops in 2% to 5% of patients. In the past decade, EHEC has been responsible for several multistate outbreaks of acute diarrheal illness,

most often associated with ingestion of inadequately cooked hamburger meat.

Although most diarrhea-causing pathogens produce either invasive or enterotoxic diarrhea, both processes contribute to the illness in some situations. Certain strains of *Shigella*, nontyphoidal *Salmonella*, *Y. enterocolitica*, and *C. jejuni* both invade and produce secretory enterotoxins in vitro. Such enterotoxins may play a contributory role in the acute disease process. The invasive capacity of these organisms is, however, of paramount importance in their ability to produce disease.

Viral Causes of Diarrhea

Both rotavirus and norovirus invade and damage villous epithelial cells, with the degree of injury ranging from modest distortion of epithelial cells to sloughing of villi. Presumably, both rotavirus and norovirus cause diarrhea by interfering with the absorption of normal intestinal secretions. This may occur through selective destruction of absorptive villous tip cells with sparing of secretory crypt

cells. Affected patients may have low-grade fever and mild to moderate cramping abdominal pain. The stool is usually watery, and its contents resemble those of a noninvasive process, with few inflammatory cells, probably because of lack of damage to the colon. Other viruses that can cause outbreaks of diarrhea include sapoviruses, astroviruses, and certain adenoviruses.

Protozoan Causes of Diarrhea

In North America, Rocky Mountain water sources are frequent origins of *Giardia lamblia* microepidemics. As is the case in shigellosis, ingestion of only a few organisms is required to establish infection. The organisms multiply in the small bowel, attach to and occasionally invade the mucosa, but do not cause gross damage to the mucosal cells. Clinical manifestations span the spectrum from an acute, febrile diarrheal illness to chronic diarrhea with associated malabsorption and weight loss. Diagnosis may be made by identification of the organism in either the stool or the duodenal mucus or by small bowel biopsy. *Entamoeba histolytica* may cause intestinal syndromes ranging from mild diarrhea to fulminant amebic colitis with multiple bloody stools, fever, and severe abdominal pain. Although *E. histolytica* has a worldwide distribution, it is an uncommon cause of diarrhea in the United States. Three other protozoa, *Cryptosporidium parvum*, *Isoospora belli*, and *Cyclospora cayentanensis*, occasionally cause self-limited acute diarrheal illness in otherwise healthy individuals and may cause voluminous, life-threatening diarrheal disease in patients with immunodeficiencies. Stool examination will often distinguish *Giardia*, *Entamoeba*, *Isoospora*, *Cryptosporidium*, *Microsporidia*, and *Cyclospora*; occasionally biopsy may be needed for diagnosis.

General Epidemiologic Considerations

In developing countries where sanitation is inadequate, young children (up to 2 years of age) contract multiple episodes of diarrhea, a process that engenders intestinal immunity to the majority of enteropathogens in their environment. Most of these diarrheal episodes are mild, but some are life threatening. In these areas, ETEC and rotavirus together cause the large majority of diarrheal illnesses. *Shigella* infections are far less common during this period.

Infants and small children in industrialized countries have fewer episodes of diarrhea than do those in developing countries, and the most common causative agent is the rotavirus. Most episodes are mild. ETEC and *Shigella* infections are infrequent except in a few defined population groups (e.g., individuals in custodial institutions).

Throughout the world, clinically significant diarrhea is relatively unusual in adults except in specific defined epidemics or common-source outbreaks caused by contaminated food or water. However, diarrhea is the most common illness to affect travelers. More than 20% of travelers to Latin America, Africa, South Asia, and the Middle East develop traveler's diarrhea. When immunologically inexperienced adults from the developed world visit developing countries, the organisms responsible are the same ones as those causing most childhood diarrhea in the country visited.

In addition to the pathogens listed earlier, certain sexually transmissible pathogens that may cause acute diarrheal illnesses among sexually active homosexual men (see Chapter 107) differ from those that most commonly occur in the general population.

Nosocomially acquired *C. difficile*-associated diarrhea, related to the use of broad-spectrum antibiotics such as fluoroquinolones and cephalosporins, has been increasingly observed in North America and Europe in the past decade, involving a more severe course, higher mortality, increased risk of relapse, and more complications than appreciated previously. This increased virulence is thought to be a result of greater toxin production by these emerging strains. Outbreaks of diarrhea with these strains are often difficult to control. Health care workers caring for persons with *C. difficile*-associated diarrhea should wash their hands with chlorhexidine solutions between all patient contacts, as spores of *C. difficile* are resistant to alcohol-based hand washing solutions.

Diagnosis

In managing life-threatening diarrheal illnesses, determining the specific causative agent is not as important as prompt repletion of lost electrolytes. Fluid losses represent the chief cause of serious morbidity and mortality in diarrheal illness. Moreover, antimicrobial therapy has proven of value in only a minority of cases (see Table 103-1). Discerning the epidemiology of the illness is often more helpful than are laboratory techniques in identifying cases in which antimicrobial therapy is likely to be helpful. Figure 103-1 provides a schematic approach to diagnosis and management.

The examination of a methylene blue-stained stool preparation for erythrocytes and white blood cells may be helpful in distinguishing between acute diarrheal illnesses caused by invasive pathogens and those caused by noninvasive pathogens. This is easily accomplished by adding one drop of methylene blue dye to one drop of liquid stool or mucus, allowing the preparation to air dry, and examining the specimen under the high dry microscope lens. Few, if any, leukocytes or erythrocytes are seen in the stools of patients with diarrhea caused by noninvasive organisms (e.g., ETEC). Variable numbers of leukocytes and erythrocytes are present in diarrheas secondary to invasive bacteria (e.g., *Shigella*) or cytopathic toxins (*C. difficile* toxin).

The precise diagnosis of any diarrheal illness lasting longer than 4 to 5 days is important because these illnesses (e.g., giardiasis) may be responsive to specific antimicrobial therapy. Furthermore, in patients with negative stool examinations and cultures, endoscopy may yield a diagnosis of a noninfectious disease (e.g., ulcerative colitis or Crohn disease).

Management: General Principles of Electrolyte Repletion Therapy

INTRAVENOUS FLUIDS

All acute diarrheal diseases respond to a similar fluid repletion regimen because voluminous infectious diarrhea in adults consistently produces the same pattern of electrolyte

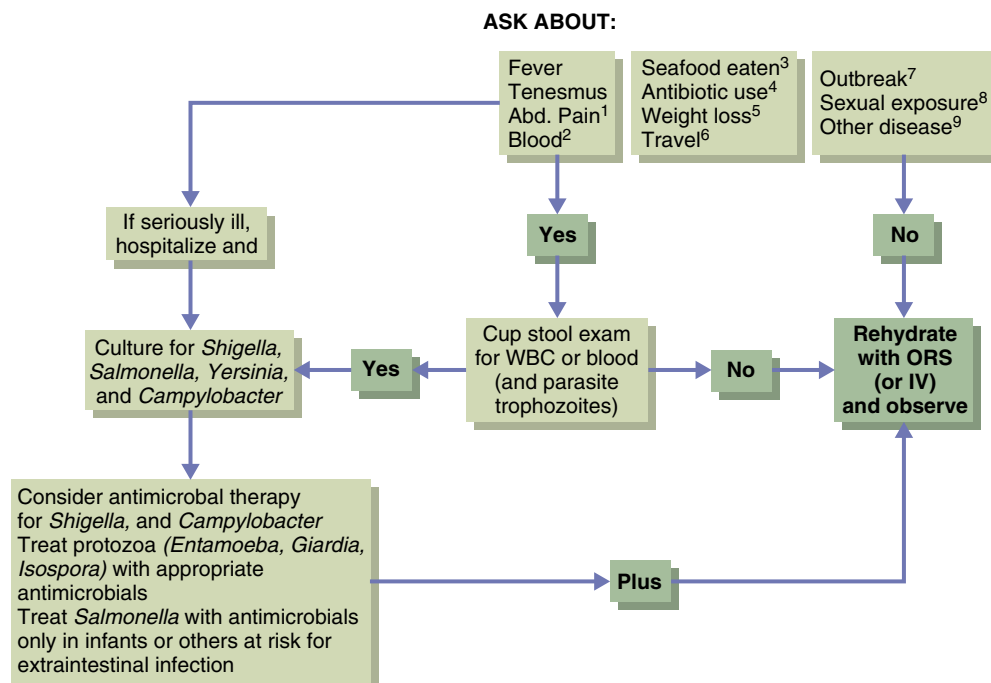

Figure 103-1 Approach to the diagnosis and management of acute infectious diarrhea.

1. If unexplained abdominal pain and fever suggest an appendicitis-like syndrome, culture for *Yersinia enterocolitica*.
 2. Bloody diarrhea, in the absence of fecal leukocytes, suggests enterohemorrhagic *Escherichia coli* or amebiasis (where leukocytes are destroyed by the parasite).
 3. Ingestion of inadequately cooked seafood prompts consideration of *Vibrio* infections or noroviruses.
 4. Associated antibiotics should be stopped and *Clostridium difficile* considered.
 5. Persistence of diarrhea (>10 days) with weight loss prompts consideration of giardiasis, cryptosporidiosis, or inflammatory bowel disease.
 6. Travel to tropical areas increases the chance of enterotoxigenic *E. coli* (ETEC) as well as viral, protozoal (*Giardia*, *Entamoeba*, *Cryptosporidium*), and, if fecal leukocytes are present, invasive bacterial pathogens.
 7. Outbreaks should prompt consideration of *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium perfringens*, ETEC, *Vibrio*, *Salmonella*, *Campylobacter*, or *Shigella* infection.
 8. Sigmoidoscopy in symptomatic homosexual males should distinguish proctitis in the distal 15 cm (caused by herpesvirus, gonococcal, chlamydial, or syphilitic infection) from colitis (*Campylobacter*, *Shigella*, or *C. difficile* infection).
 9. Immunocompromised hosts should have a wide range of viral (e.g., cytomegalovirus, herpes simplex virus, rotavirus), bacterial (e.g., *Salmonella*, *Mycobacterium avium* complex, *C. difficile*), protozoal (e.g., *Cryptosporidium*, *Isospora*, *Microsporidia*, *Entamoeba*, *Giardia*) and parasitic (*Strongyloides* hyperinfection syndrome) agents considered.
- IV, intravenous; ORS, oral rehydration solution; WBC, white blood cell. (Adapted from Guerrant RL, Shields DS, Thorson SM, et al: Evaluation and diagnosis of acute infectious diarrhea. *Am J Med* 78:91-98, 1985.)

loss. The fluid losses of massive diarrhea can rapidly be corrected by infusing fluids intravenously that approximate those that have been lost. Lactated Ringer's solution is readily available and provides uniformly good results. With patients who are hypotensive, the intravenous fluids should initially be infused rapidly. Subsequent maintenance fluid administration can be guided by the patient's clinical appearance, including the vital signs, the appearance of neck veins, and skin turgor. Clinical evaluation alone provides an adequate guide to fluid replacement in most acute diarrheal illnesses. If intravenous fluids are administered in adequate quantities throughout the diarrheal illness, virtually every patient with diarrhea caused by toxigenic bacteria should be restored to health. Complications (e.g., acute renal failure secondary to hypotension) are exceedingly rare if these principles are followed.

ORAL FLUIDS

In most patients with acute diarrheal illness, fluid repletion can also be achieved through the oral route, using isotonic

glucose-containing electrolyte solutions. A uniformly effective solution can easily be prepared by the addition of 2 tablespoons of sugar, a quarter teaspoon of salt (NaCl), and a quarter teaspoon of baking soda (NaHCO₃) into 1 L of boiled drinking water (Table 103-2). These fluids should be administered initially in large quantities, 250 mL every 15 minutes in adults, until clinical observations indicate that fluid balance has been restored. Thereafter, sufficient fluids are given to maintain normal balance; if stool output is measured, approximately 1.5 L of glucose-electrolyte solution should be given orally for each liter of stool. The oral glucose-electrolyte fluid does not decrease the volume of fluid lost through the intestinal tract but rather facilitates absorption of adequate fluid to counterbalance the toxin-induced fluid secretion.

Patients with fluid depletion caused by invasive microbial agents (e.g., rotavirus, *Salmonella*) also respond well to oral glucose-electrolyte therapy, although the pathogenesis of diarrheal disease caused by invasive microbes is quite different from that caused by enterotoxigenic bacteria.

Table 103-2 Rehydration and Eating in Cases of Diarrhea**Rehydration**

1 L boiled (drinking) water
 2 tablespoons sugar (or honey)
 ¼ teaspoon salt (NaCl)
 ¼ teaspoon baking soda (NaHCO₃)

"BRAT" Diet

Banana, rice, applesauce, toast

ANTIMICROBIAL THERAPY

Most acute infectious diarrheas do not require antibiotic therapy (see Table 103-1). In the noninvasive bacterial diarrheas, antibiotics dramatically decrease the volume of diarrhea only in cholera. Doxycycline, 300 mg in a single dose, is the drug of choice.

In the invasive bacterial diarrheas, short-term antimicrobial treatment significantly decreases the duration and severity of shigellosis. A quinolone such as ciprofloxacin, 500 mg twice daily for 5 days, is effective; trimethoprim-sulfamethoxazole, one double-strength tablet given twice daily, may be used if the organism is sensitive.

Antimicrobial therapy may also be helpful in decreasing the duration and severity of enteritis caused by *Yersinia* and *Campylobacter*. Ciprofloxacin, 500 mg twice daily for 5 days, is useful against these pathogens as well. Antimicrobial agents are of no known value in *V. parahaemolyticus* infections. In uncomplicated nontyphoidal *Salmonella* enteritis, antibiotics may prolong the fecal shedding of salmonellae. Treatment of nontyphoidal salmonella gastroenteritis is, however, indicated in certain settings to prevent bacteremia and its complications (e.g., meningitis, endovascular infection, or infections of joint or vascular prostheses). Treatment until defervescence with a third-generation cephalosporin or a quinolone is therefore indicated for patients with sepsis, those ill enough to be hospitalized, immunocompromised patients, patients with recognized atherosclerotic disease, patients with sickle cell disease, and patients with bone or vascular prostheses.

Antimicrobial therapy is indicated, paradoxically, for treatment of antibiotic-associated diarrhea. Antibiotic-associated diarrhea develops in 1% to 15% of patients who receive broad-spectrum antimicrobial agents and is caused by cytotoxins produced by *C. difficile*, which proliferate in the colonic mucosa when the colonization of bacteria that naturally live in the gut is disturbed. Peripheral leukocytosis

is common. Although generally characterized by mild diarrhea, antibiotic-associated diarrhea may result in a potentially lethal pseudomembranous colitis. In all cases, the responsible antibiotic should be stopped. In moderately ill patients (fever, mucosal ulceration, and/or pseudomembranes), oral vancomycin (500 mg-1 g every 12 hours) or metronidazole (500 mg every 8 hours) should be started and continued for 10 days on the basis of strong clinical suspicion, before the diagnosis is confirmed by stool assay for *C. difficile* toxins. Empirical treatment with these agents should be avoided in patients with mild diarrhea that resolves with cessation of antibiotics because this may result in the emergence of antibiotic-resistant bacteria, such as vancomycin-resistant enterococci.

Antimicrobial agents decrease the duration and severity of giardiasis. In adults, metronidazole, 250 mg every 8 hours for 3 days, and quinacrine, 300 mg/day for 7 days, appear to be equally effective in adults. Acute intestinal amebiasis demands antimicrobial therapy. Metronidazole, 750 mg every 8 hours for 5 days, is the drug of choice in adults. The duration of diarrhea caused by *I. belli* is significantly shortened by administration of trimethoprim-sulfamethoxazole twice daily for 5 days.

ANTIMICROBIAL PROPHYLAXIS

Prophylactic antimicrobial agents are effective in preventing traveler's diarrhea, which is caused most often by ETEC. Doxycycline, trimethoprim-sulfamethoxazole, and a quinolone such as ciprofloxacin are each effective when taken once daily for up to 3 weeks. However, because of the rapid response of most patients to early treatment with any of these three agents, the advantages of prophylactic drugs are generally outweighed by their potential risks (adverse reactions).

SYMPTOMATIC THERAPY

Adjuvant symptomatic therapy is not essential but may provide modest symptomatic relief in acute infectious diarrheas associated with cramping abdominal pain. Bismuth subsalicylate, 0.6 g every 6 hours, may ameliorate symptoms of traveler's diarrhea. Agents that decrease intestinal motility (e.g., codeine, diphenoxylate, loperamide) also relieve the cramping abdominal pain associated with many acute diarrheal illnesses but are potentially hazardous because they may enhance the severity of illness in shigellosis, the prototype of invasive bacterial diarrheas.

Prospectus for the Future

- Continuing increase in the occurrence of diarrheal illness as populations migrate to urban areas in the developing world with inadequate clean water supply and waste disposal
- Increasing development of antibiotic resistance among pathogens causing acute diarrhea
- Development of better strategies to limit the nosocomial spread of *Clostridium difficile*

Infections Involving Bones and Joints

Christoph Lange and Michael M. Lederman

Arthritis

In adults, almost all cases of infective arthritis of natural joints occur through hematogenous seeding. Joint replacement surgery accounts for another significant proportion of septic arthritis cases. Causative agents for infective arthritis include bacteria (including mycobacteria), viruses, and fungi. In addition, certain viruses such as human parvovirus B19, rubella, and hepatitis B and C viruses can produce a polyarthritis by means of direct infection of joint synovial tissue or immune complex deposition. Immune mechanisms also underlie arthritis syndromes seen after diarrhea caused by *Salmonella*, *Shigella*, *Yersinia*, and *Clostridium difficile* infections; the majority of individuals with postdysentery arthritis syndrome share the human leukocyte antigen B27 (see Chapter 80).

ACUTE ARTHRITIS

Underlying joint disease, particularly rheumatoid arthritis, predisposes to septic arthritis. Many patients with septic arthritis give a history of joint trauma antedating symptoms of infection. Conceivably, disruption of capillaries during an unrecognized and transient bacteremia allows bacteria to spill into hemorrhagic and traumatized synovium or joint fluid, resulting in the initiation of infection. Joint replacement has a very low, although definite, incidence of septic arthritis.

Microbiology

Staphylococcus aureus is the most common cause of septic arthritis (Table 104-1). Patients with underlying joint disease and injection drug users are at particular risk for infection with this organism. *Pseudomonas aeruginosa* is another important cause of septic arthritis among injection drug users. Surgical cases are usually caused by staphylococcal species, both coagulase positive and coagulase negative.

Other gram-negative bacilli are infrequent causes of septic arthritis and are found primarily among elderly debilitated patients with chronic arthritis. In adults younger than age

30, *Neisseria gonorrhoeae* is the most likely pathogen. Isolates causing disseminated gonococcal infection with arthritis are generally resistant to killing by normal serum.

Clinical Presentation

Symptoms of septic arthritis are generally present for only a few days before the patient seeks medical attention. Fever is usual; shaking chills may occur. The knee is the most commonly affected joint and is generally painful and swollen. Fluid can be found in most infected joints, and limitation of motion is marked. In some cases, however, particularly among patients with underlying rheumatoid arthritis who are receiving corticosteroids, physical findings indicating infection may be subtle. In these individuals, who are at particular risk for septic arthritis, superimposed infection may be difficult to distinguish from a flare-up of underlying disease. Symmetrical symptoms in multiple joints are more indicative of a rheumatoid flare-up. Approximately 10% of cases of septic arthritis, however, involve more than one joint.

Differential Diagnosis of Acute Monoarticular or Oligoarticular Arthritis

Infections, crystal deposition (uric acid gout or calcium pyrophosphate pseudogout), trauma, osteoarthritis, ischemic necrosis, foreign bodies, tumors, and systemic diseases such as systemic lupus erythematosus can produce an acute monoarticular arthritis. Radiographs may show evidence of osteoarthritis, gouty tophi, or the linear densities of chondrocalcinosis, which are characteristic of pseudogout. All red, warm, tender joints must be aspirated. The synovial fluid should be cultured anaerobically and aerobically. A Gram-stained preparation should be examined, and a wet mount of fluid should be examined using a polarized microscope to look for crystals. Synovial fluid leukocyte counts and chemistries are of limited value in the differential diagnosis of a suspected septic joint. As a general rule, however, synovial fluid white blood cell counts in excess of 100,000/ μL suggest either infection or crystal-induced disease (see Table 78-3). Blood cultures should be obtained in all cases of suspected septic arthritis.

Table 104-1 Infective Arthritis—Acute

	Causative Agent	Characteristics
Bacterial	<i>Staphylococcus aureus</i>	Most common overall; usually monarticular, large joint involvement
	<i>Streptococcus</i> species	Second most common overall Groups B, F, and G Associated with diabetes mellitus, malignancy, and genitourinary tract abnormalities
	<i>Neisseria gonorrhoeae</i>	Most common in young, sexually active adults; commonly polyarticular in onset; often associated with skin lesions
	<i>Pseudomonas aeruginosa</i>	Largely restricted to injection drug users; often involves sternoclavicular joint
Viral	Hepatitis B, rubella, mumps, parvovirus	Usually polyarticular, with minimal joint effusions, normal peripheral white blood cell count

Treatment

The two major modalities for treatment of acute septic arthritis are drainage and antibiotics. The first needle aspiration of a septic joint should remove as much fluid as possible. Initial antibiotic choice should be based on the clinical presentation and the results of the Gram stain. Staphylococcal infection should be treated with vancomycin, linezolid, or daptomycin until the results of in vitro antimicrobial resistance tests are available. A penicillinase-resistant penicillin may still be the best treatment option for drug-sensitive strains of staphylococci. Gonococcal infections should be treated with ceftriaxone, 1 g every 24 hours for 10 days. Arthritis caused by gram-negative rods should initially be treated with an aminoglycoside or a quinolone, such as ciprofloxacin, plus another drug active against *P. aeruginosa*, such as a third-generation cephalosporin or piperacillin. Arthritis caused by *S. aureus* or gram-negative bacilli should be treated with antibiotics for 4 to 6 weeks. Otherwise, 2 to 3 weeks of antibiotic treatment are usually sufficient to eradicate infection. The treatment for infected prosthetic joints is removal of the prosthesis plus antibodies.

Septic joints (with the notable exception of joints infected with gonococci) generally reaccumulate fluid after treatment is initiated. These reaccumulations must be removed by repeated needle aspirations as often as necessary. Indications for open surgical drainage of the joint include failure of the synovial fluid white blood cell count to fall after 5 days of antibiotic treatment and repeated needle aspirations, and the presence of loculated fluid within the joint. Septic arthritis of the hip is generally drained surgically because of the difficulty and potential hazard of repeated needle aspirations of this joint. Early surgical drainage also should be considered for joint infections with gram-negative rods or with *S. aureus*. Untreated or inadequately treated septic arthritis may be complicated by osteomyelitis. In instances in which the diagnosis and treatment have been delayed, radiographs of the involved joint should be obtained at the beginning and termination of treatment.

POLYARTICULAR ARTHRITIS

Arthritis involving multiple joints is generally a consequence of bacteremic seeding and is infrequently attributable to direct microbial invasion. In many instances, a polyarticular arthritis represents an immunologically mediated process. Acute rheumatic fever, a delayed immune-mediated response to group A streptococcal infection, may manifest as a migratory, asymmetrical arthritis of the knees, ankles, elbows, and wrists. Heart involvement, subcutaneous nodules, or erythema marginatum is present in a minority of cases. Most patients have serologic evidence of recent streptococcal infection. Anti-streptolysin O, anti-DNAse, and antihyaluronidase antibodies are usually present. The importance of making this diagnosis lies primarily in the requirement for long-term prophylaxis against streptococcal infection and the clinical response of this process to salicylates.

Viral infections including hepatitis B and C, rubella, parvovirus B19 infection, and mumps may be associated with polyarthritis. In mumps and rubella, the arthritis results from direct infection of articular tissue; with hepatitis viruses, the joint inflammation is a secondary result of the host immune response. Serum sickness, polyarticular gout, sarcoidosis, rheumatoid arthritis, and other connective tissue disorders must be considered in the differential diagnosis. Chronic essential mixed cryoglobulinemia induced by hepatitis B or C virus can cause arthralgias, although severe arthritis is rare. Because 10% of cases of septic arthritis involve more than one joint, acutely inflamed joints containing fluid should be tapped to exclude bacterial infection.

Disseminated gonococcal infection (see Chapter 107) may manifest with fever, tenosynovitis, or arthritis involving several joints and a characteristic rash. The rash may be petechial but usually consists of a few to a few dozen pustules on an erythematous base. Cultures of the joint fluid are usually negative at this stage, but blood cultures are often positive; Gram stain of a pustule may reveal the pathogen. Ceftriaxone, 1 g/day for 10 days, is curative.

CHRONIC ARTHRITIS

Mycobacteria and fungi may produce an indolent, slowly progressive arthritis, usually involving only one joint or contiguous joints, such as those of the wrist and hand (Table 104-2). Fever may be low grade or absent. Cultures of joint fluid may be negative. Some patients with tuberculous arthritis have no evidence of active disease in the lungs. As a general rule, patients with inflammatory chronic monoarticular arthritis should undergo synovial biopsy for mycobacterial and fungal cultures and histology. Granulomas indicate the likelihood of fungal or mycobacterial infection. Cultures should confirm the diagnosis.

Fungal osteoarticular infections are unusual and are typically a consequence of contiguous spread of local infection.

Table 104-2 Causes of Infective Arthritis—Chronic

Nontuberculous mycobacteria
Tuberculosis
Fungi
Lyme disease (oligoarticular)

Osteoarthritis caused by *Candida* species is relatively rare. Fungal arthritis should be treated surgically by arthroscopic débridement and drainage together with antifungal agents. Mycobacterial arthritis should be treated for 9 months with at least two drugs active against the isolate.

A spirochete, *Borrelia burgdorferi*, is the pathogen responsible for Lyme disease. Several months to years (mean 6 months) after the bite of the *Ixodes* tick and the characteristic expanding rash of erythema chronicum migrans, some patients develop an intermittent arthritis with large effusions involving one or more joints, usually including the knees. This chronic arthritis may result in joint destruction, but fever is unusual. Treatment with intravenous ceftriaxone, 4 g/day for 14 to 21 days, will halt the progression of disease in the majority of cases (see Chapter 95), but treatment during the rash stage with amoxicillin or doxycycline will prevent the later development of arthritis.

Septic Bursitis

In more than 80% of cases, septic bursitis is caused by *S. aureus* and involves predominantly the olecranon or the prepatellar bursa. In most instances there is a history of antecedent infection or irritation of the skin overlying the bursa. On examination, the skin over the bursa is red and often peeling. The bursa has a doughy consistency, and fluid may be found to be present on careful examination. Daily needle aspiration until sterile fluid is obtained and antibiotics that are selected according to the Gram-stain, culture, and sensitivity findings are generally curative. Occasionally, long courses of antibiotics (>2 to 3 weeks) may be required for cure.

Osteomyelitis

Infections of the bone occur either as a result of hematogenous spread or through extension of local infection.

HEMATOGENOUS OSTEOMYELITIS

This infection occurs most commonly in the long bones or vertebral bodies (Table 104-3). The peak age distributions are in childhood and old age. Individuals predisposed to hematogenous osteomyelitis include injection drug users, who are at risk for infections with *S. aureus* and *P. aeruginosa*, and patients with hemoglobinopathy, in whom nontyphoidal salmonellae often infect infarcted regions of bone. *Staphylococcus epidermidis* has emerged as an important nosocomial pathogen in patients with infected intravenous catheters. Like patients with septic arthritis, patients

with hematogenous osteomyelitis often give a history of trauma antedating symptoms of infection, suggesting that transient, unrecognized bacteremia might result in infection of traumatized tissue.

Patients with acute hematogenous osteomyelitis generally manifest acute onset of pain, tenderness, and fever; there may also be soft tissue swelling over the affected bone. In most instances, physical examination distinguishes acute osteomyelitis from septic arthritis, because range of joint motion is preserved in osteomyelitis. In the first 2 weeks of illness, roentgenograms may be negative or show only soft tissue swelling; technetium scans or gallium scans are almost always positive, but technetium scans may also be positive in the setting of increased vascularity or increased bone formation of any cause. Magnetic resonance imaging (MRI) is the imaging technique of choice for diagnosis of osteomyelitis. Bone erosion, with decreased signal intensity on T1-weighted images and increased signal intensity on T2-weighted images, are seen on MRI before plain films are abnormal. After 2 weeks of infection, plain radiographs generally show some abnormality, and untreated osteomyelitis may produce areas of periosteal elevation or erosion followed by increased bone formation (sclerosis). The erythrocyte sedimentation rate is generally elevated, as is the white blood cell count.

A patient with back pain and fever must be considered to have a serious infection until proven otherwise. Spasm of the paravertebral muscles is common in patients with vertebral osteomyelitis but nonspecific. Point tenderness over bone suggests the presence of local infection. A good history should be obtained and a careful neurologic examination performed. Abnormalities of bowel or bladder or of strength or sensation in the lower extremities suggest the possibility of spinal cord involvement by means of spinal epidural abscess with or without osteomyelitis. Acute spinal epidural abscess is a surgical emergency. The challenge is to make the diagnosis before neurologic signs appear (see Chapter 128). MRI provides excellent definition of epidural or paravertebral abscess and is the diagnostic procedure of choice. Demonstration of an epidural abscess mandates immediate intervention, either by surgery or, in selected cases, by computed tomography-guided drainage. Although most cases of hematogenous osteomyelitis have an acute presentation, some cases may have an indolent course. These patients may have an illness of more than 1 year's duration characterized by pain and low-grade fever. Radiographs are abnormal but may show only collapse of a vertebral body. This most often occurs in infections with *P. aeruginosa*, but *Candida* species and *S. aureus* infections may also occasionally manifest in this manner.

Blood cultures are positive in about half of acute cases of osteomyelitis. Patients with acute osteomyelitis should have a needle biopsy and culture of the involved bone unless blood culture results are known beforehand. Antibiotic treatment directed against the causative pathogen for 4 to 6 weeks is usually sufficient for native bone and joint infections (in prosthetic joint infections rifampin is often added). In instances when a causative agent has not been identified after appropriate specimens have been cultivated for routine pathogens, a diagnosis of mycobacterial infection should be considered; if ordinary bacterial infection still remains the most likely diagnosis, treatment should include vancomycin for methicillin-resistant *S. aureus*.

Table 104-3 Factors Predisposing to Hematogenous Osteomyelitis

Setting	Likely Pathogens
Injection drug use	<i>Staphylococcus aureus</i> <i>Pseudomonas aeruginosa</i>
Intravenous catheters	<i>S. aureus</i> <i>Staphylococcus epidermidis</i> <i>Candida</i> species
Urinary tract infection	Enterobacteriaceae

Table 104-4 Osteomyelitis Secondary to Contiguous Spread

Setting	Likely Microorganisms
Surgery, trauma	<i>Staphylococcus aureus</i> Aerobic gram-negative bacilli
Cat or dog bites	<i>Pasteurella multocida</i>
Human bites	Mixed anaerobic infections
Periodontal infections	Mixed anaerobic infections
Cutaneous ulcers	Mixed aerobic and anaerobic organisms

OSTEOMYELITIS SECONDARY TO EXTENSION OF LOCAL INFECTION

Local infection predisposes to osteomyelitis in several major settings (Table 104-4). The first is after penetrating trauma or surgery where local infection gains access to traumatized bone. In postsurgical infections, staphylococci and gram-negative bacilli predominate. Generally there is evidence of wound infection, with erythema, swelling, increased post-operative tenderness, and drainage. A traumatic incident often associated with osteomyelitis is either a human or an animal bite. Human bites, if deep enough, may result in osteomyelitis caused by anaerobic mouth bacteria. Cat bites notoriously result in the development of osteomyelitis because the cat's thin, sharp, long teeth often penetrate the periosteum. *Pasteurella multocida* is a frequent pathogen in this setting. A 4- to 6-week course of ampicillin-sulbactam 3 g q8h is recommended.

The intimate relationship of the teeth and periodontal tissues to the bones of the maxilla and mandible may predispose to osteomyelitis after local infection. Débridement of necrotic tissue and ampicillin-sulbactam 3 g q6h comprise an effective treatment, because mixed-anaerobic infections are usually present.

The third setting in which local infection predisposes to osteomyelitis is that of an infected sore or ulcer. Pressure sores of the sacrum or femoral region may erode into contiguous bone and produce an osteomyelitis (see Chapter 101) caused by several bacterial species including anaerobic organisms. Patients with diabetes mellitus often develop traumatic vascular ulcerations of their toes and feet, with eventual development of osteomyelitis. Anaerobes, streptococci, staphylococci, and gram-negative bacilli are often involved in these infections (see Chapter 101).

An ulcer area larger than 2 cm², probe patency through the ulcer to bone, an erythrocyte sedimentation rate of more

than 70 mm/hr, and an abnormal plain radiograph are helpful in diagnosing the presence of lower extremity osteomyelitis in patients with diabetes. A negative MRI result makes the diagnosis much less likely when all of these findings are absent. Treatment involves débridement (often amputation in the case of diabetics) and antibiotics active against the pathogens involved for at least 6 weeks. Optimizing metabolic control and correction of macrovasculopathy if possible (e.g., by angioplasty) may improve wound healing; the benefits of vacuum-assisted drainage are controversial.

CHRONIC OSTEOMYELITIS

Untreated or inadequately treated osteomyelitis results in avascular necrosis of bone and the formation of islands of nonvascularized and infected bone called *sequestra*. Patients with chronic osteomyelitis may tolerate their infection reasonably well, with intermittent episodes of disease activity manifested by increased local pain and the drainage of infected material through a sinus tract. Some patients have tolerated chronic osteomyelitis for decades. A normochromic, normocytic anemia of chronic disease is common in this setting, and occasionally amyloidosis and, in rare cases, osteogenic sarcoma complicate this disorder. Fluorodeoxyglucose positron emission tomography may have the highest diagnostic accuracy for the diagnosis of chronic osteomyelitis.

S. aureus is responsible for the great majority of cases of chronic osteomyelitis; the major exception is among patients with sickle cell anemia, in whom nontyphoidal salmonellae may cause chronic infection of the long bones.

Cultures of sinus tract drainage do not reliably reflect the pathogens involved in the infection. Diagnosis and cure are best effected by surgical débridement of necrotic material followed by long-term administration of antibiotics active against the organism found in the surgical specimens.

Mycobacteria, most often *Mycobacterium tuberculosis*, can produce a chronic osteomyelitis. The anterior portions of vertebral bodies are the most common sites of infection. Hematogenous dissemination and lymphatic spread are the most likely routes of infection. Paravertebral abscess (often termed *cold abscess* because of lack of signs of acute inflammation) may complicate this infection. Diagnosis is usually confirmed by histologic examination and culture of biopsy material. Treatment against skeletal tuberculosis involves at least 9 months of standard therapy and often surgical débridement.

Prospectus for the Future

- Better limb sparing treatment modalities for diabetic osteomyelitis
- Improvement of multidisciplinary approaches in the treatment of chronic osteomyelitis

Infections of the Urinary Tract

Christoph Lange and Michael M. Lederman

The urethra, bladder, kidneys, and prostate are all susceptible to infection. Most urinary tract infections (UTIs) cause local symptoms, yet clinical manifestations do not always pinpoint the site of infection. The purpose of this chapter is to simplify the clinical and laboratory approach to diagnosis and treatment of UTIs. Infections associated with indwelling urinary catheters are discussed in Chapter 106.

Urethritis

Urethritis is predominantly an infection of sexually active individuals, usually men. The symptoms are pain and burning of the urethra during urination, and there is generally some discharge at the urethral meatus. Urethritis may be gonococcal in origin. However, nongonococcal urethritis is now more frequent in North America. Nongonococcal urethritis may be caused by *Chlamydia trachomatis* or *Ureaplasma urealyticum* and less commonly by *Trichomonas vaginalis* or herpesviruses. Diagnosis and management of urethritis are considered in Chapter 107.

Cystitis and Pyelonephritis

EPIDEMIOLOGY

Bacterial infection of the bladder (cystitis) and kidney (pyelonephritis) is more frequent in women, and the incidence of infection increases with age. Factors that predispose to UTI include instrumentation (e.g., catheterization, cystoscopy), pregnancy, anatomic abnormalities of the genitourinary tract, and diabetes mellitus.

PATHOGENESIS

Although some infections of the kidney may arise as the result of hematogenous dissemination, most UTIs ascend through a portal of entry in the urethra. Most pathogens

responsible for community-acquired UTIs are bacterial species that naturally live in the human bowel. *Escherichia coli* is the most common isolate; in women, colonization of the vaginal and periurethral mucosa may antedate infection of the urinary tract. Bacteria with fimbriae capable of adherence to epithelial cells are more likely to cause UTIs, and persons whose epithelial cells bind these fimbriae may be at greater risk for infection. The longer and protected male urethra may account for the lower incidence of UTI in men. Motile bacteria may swim upstream, and reflux of urine from the bladder into the ureters may predispose to the development of kidney infection.

CLINICAL FEATURES

Suprapubic pain, discomfort, a burning sensation on urination, and frequency of urination are common symptoms of infection of the urinary tract. Back or flank pain or the occurrence of fever suggests that infection is not limited to the bladder (cystitis) but involves the kidney (pyelonephritis) or prostate as well. Clinical presentation, however, often fails to distinguish between simple cystitis and pyelonephritis. Approximately one half of infections that appear clinically to involve the bladder can be shown by instrumentation and other specialized techniques to affect the kidneys. Elderly or debilitated patients with infection of the urinary tract may have no symptoms referable to the urinary tract and may have only fever, altered mental status, or hypotension as a presenting sign.

LABORATORY DIAGNOSIS

Analysis of a midstream urine sample obtained from patients with infection of the bladder or kidney shows white blood cells (WBCs) and may also reveal red blood cells and slightly increased amounts of protein. The presence of at least 10 WBCs/mm³ of midstream urine by counting chamber is defined as pyuria. The vast majority of patients with symptomatic or asymptomatic bacteriuria have pyuria. The presence of WBC casts in an infected urine sample indicates the

presence of pyelonephritis. Bacteria may be seen in sedimented urine and can be readily identified by Gram stain. For asymptomatic women, bacteriuria is defined as two consecutive voided urine specimens with isolation of the same bacterial strain at levels of at least 10⁵ colony-forming units (CFUs) per milliliter. In men a single, clean-catch, voided urine specimen with one bacterial species at concentrations >10⁵ CFU/mL identifies bacteriuria. The diagnosis of bacteriuria is also established in both women and men from a single catheterized urine specimen (not from an indwelling catheter) with one bacterial species isolated at concentrations >10² CFU/mL.

A hazard in interpreting results of urine culture is that if the sample is allowed to stand at room temperature for a few hours before being cultured, bacteria can multiply. This results in spuriously high bacterial counts. For this reason, urine for culture should not be obtained from a catheter bag. Specimens that are not plated immediately should be refrigerated. Biochemical tests to detect bacteriuria are not reliable when numbers of bacteria are low.

TREATMENT AND OUTCOME

Asymptomatic bacteriuria has not been shown to be harmful in most adult populations. Antimicrobial treatment for asymptomatic bacteriuria is indicated only for pregnant women and for patients undergoing urologic instrumentation. These patients should be screened for asymptomatic bacteriuria and treated if test results are positive.

Pyuria accompanying asymptomatic bacteriuria is not an indication for antimicrobial treatment. On the other hand, all symptomatic patients with UTI should be treated with antimicrobials. Although most women with lower UTIs are cured by a single dose of antibiotic, such as a double-strength trimethoprim-sulfamethoxazole (TMP/SMZ 160/800 mg) tablet, a 3-day (“short course”) treatment with ciprofloxacin 250 mg bid or TMP/SMZ 160/800 mg bid provides higher cure rates and is now generally recommended. (Note that in some regions, more than 20% of *E. coli* are resistant to TMP/SMZ.) β -lactams are not recommended for short-course therapy because of suboptimal clinical and bacteriologic results compared with those of other agents. Short-course therapy is not recommended for women with a history of UTI caused by a resistant bacterium, when the duration of symptoms is >1 week, or for men. In these patients 7 to 10 days of treatment are recommended. Cultures and results of sensitivity testing confirm the diagnosis and ascertain if the antibiotic is active against the pathogen, but these tests are not advocated in persons with uncomplicated cystitis unless treatment fails. Because of the difficulty in clinical distinction between cystitis and upper urinary tract disease, some patients treated for cystitis may experience relapse because of unrecognized upper tract disease. Recurrent UTIs in males should always raise the suspicion for an anatomic alteration of the urinary tract.

Occasionally, urine cultures obtained from a patient with symptoms of UTI and pyuria are reported as exhibiting “no growth” or “insignificant growth.” This situation has been labeled the “urethral syndrome.” Low numbers of bacteria (as few as 100/mL of urine) may produce such infections of the urinary tract. In other instances, the urethral syndrome may be caused by *Chlamydia* or *Ureaplasma*, which will not

grow on routine culture media. Thus, if a patient with the urethral syndrome has responded to antibiotics, the course should be completed; otherwise, if symptoms and pyuria persist, the patient should receive a 7- to 10-day course of tetracycline, which is active against *Chlamydia* and *Ureaplasma*. Other considerations for patients with lower urinary tract symptoms and no or “insignificant” growth on cultures of urine include vaginitis, herpes simplex infection, and gonococcal infection (*Neisseria gonorrhoeae* will not grow on routine media used for urine culture). A pelvic examination and culture for gonococci may be indicated in this setting if the patient is sexually active. Men with urethral discomfort and discharge should be evaluated for urethritis (see Chapter 107). Men with suprapubic pain, frequency, and urgency should be evaluated for cystitis, as discussed earlier.

The presence of fever suggests that infection involves more than just the bladder. Young, otherwise healthy, febrile patients with UTI may be treated on an ambulatory basis with a fluoroquinolone for 2 weeks, provided that (1) their condition does not appear toxic, (2) they are able to take oral fluids and medications, (3) they have friends or family at home, (4) they have good provisions for follow-up, and (5) they have no potentially complicating features such as diabetes mellitus, history of renal stones, obstructive disease of the urinary tract, or sickle cell disease. In this setting, urine specimens should be sent for culture and antimicrobial susceptibility testing. Gram stain of urine in patients hospitalized for pyelonephritis will guide initial therapy. Initial therapy with TMP/SMZ for pyelonephritis can no longer be recommended in the United States because of high levels of resistance in *E. coli* and in other organisms that can cause urosepsis.

In ill patients with community-acquired pyelonephritis, parenteral treatment of a Gram-negative rod infection should be initiated with either a fluoroquinolone, piperacillin-tazobactam, or a third-generation cephalosporin. An aminoglycoside may be added if drug resistance is suspected or if the patient is very ill. The aminoglycoside should be promptly discontinued if antibiotic sensitivity studies indicate that it is not essential. The finding of gram-positive cocci in chains suggests that enterococci are the pathogens. This infection should be treated, at least initially, with vancomycin plus an aminoglycoside, until antimicrobial drug susceptibility of the enterococci is known. Gram-positive cocci in clusters may indicate staphylococci. *Staphylococcus saprophyticus* is a likely agent in otherwise healthy women and is sensitive to most antibiotics used in the treatment of UTI. In the older patient, *Staphylococcus aureus* should be considered, and this infection should initially be treated with vancomycin or linezolid, as methicillin-resistant *S. aureus* is increasingly prevalent even in the community. When antimicrobial resistance testing indicates susceptibility to a penicillinase-resistant penicillin, such as nafcillin or a cephalosporin, the regimen should be adjusted. Gram-positive cocci in the urine may represent endocarditis with septic embolization to the kidney.

Therapy should be simplified when reports of antimicrobial susceptibility are available. A repeat urine culture after 2 days of effective treatment should show sterilization or a marked decrease in the urinary bacterial count. If the patient fails to demonstrate some clinical improvement after 2 to 3 days of treatment, or if the clinical picture indicates sepsis

and the patient has been febrile for more than 1 week, a complicating feature should be suspected. Intranephric or perinephric abscess or obstruction caused by a stone or an enlarged prostate may underlie this presentation. Ultrasonography is a good first diagnostic procedure in this setting. This will generally detect obstruction and collections of pus and will also detect stones greater than 3 mm in diameter. If ultrasonography is negative in this setting, computed tomography is indicated. Obstruction must be relieved and abscesses drained to result in cure. Computed tomography–guided percutaneous drainage is the procedure of choice whenever possible.

All patients with complicated UTI should have repeat urine cultures 1 to 2 weeks after treatment is completed to check for relapse. If relapse occurs, the patient may have pyelonephritis, prostatitis, or neuropathic or structural disease of the urinary tract. If a 6-week course of antibiotics active against the bacterial isolate is not effective in eradicating infection, the possibility of structural abnormalities or prostatic infection should be investigated. Urologic evaluation should be performed for all men with UTI (except urethritis) because of the high frequency of correctable anatomic lesions in this population.

Long-term antibiotic prophylaxis may benefit some persons who experience frequent UTI such as persons with obstructive uropathy or children with vesiculoureteral reflux. A single daily dose of nitrofurantoin 50 mg, TMP/SMZ 40/200, or ciprofloxacin 100 mg may suffice to prevent recurrence. Some women have frequent reinfections related to sexual activity. Prompt voiding and a single dose of an active antibiotic, such as 100 mg nitrofurantoin, 80/400 mg TMP/SMZ, or 100 mg ciprofloxacin just after sexual contact can decrease the reinfection rate in these women.

The occurrence of pyuria in the absence of bacterial growth on culture of urine ($<10^2$ colonies/mL) may be termed *sterile pyuria*. If this occurs in the patient with lower urinary tract symptoms, then chlamydial or gonococcal infection, vaginitis, or herpes simplex infection should be considered. In the absence of lower urinary tract symptoms, sterile pyuria may be seen in patients with interstitial nephritis of numerous causes or with tuberculosis of the urinary

tract. Patients with renal tuberculosis often have nocturia, polyuria, and hematuria; more than half of male patients also have involvement of the genital tract, most commonly the epididymis. The diagnostic approach to urogenital tuberculosis includes the collection of three specimens of concentrated morning urine; the patient should avoid drinking for >12 hours, and the first-void portion of the urine is collected for mycobacterial cultures. Genital masses, when present, should be biopsied for microbiologic and histopathologic examination.

Prostatitis

Although prostatic fluid has antibacterial properties, the prostate can become infected, usually by direct invasion through the urethra. Symptoms of back or perineal pain and fever are common. Some patients have pain with ejaculation. Rectal examination usually shows a tender prostate. Patients with acute prostatitis generally have an abnormal urinary sediment and pathogenic bacteria in cultures of urine.

Acute prostatitis may be caused by the gonococcus but is most often caused by gram-negative bacilli. Treatment is directed against the pathogen observed on Gram stain of urine and is generally effective. Therapy should be continued for a minimum of 4 weeks. Parenteral therapy is required rarely. Prostatic abscesses can be drained with ultrasound guidance. Chronic prostatitis may be asymptomatic and should be suspected in men with recurrent UTIs. The urine sediment may be relatively benign in patients with chronic bacterial prostatitis. In this instance, comparison of the first part of the urine sample, midstream urine, excretions expressed by massage of the prostate, and postmassage urine should reveal bacterial counts more than 10-fold greater in the prostatic secretions and postmassage urine samples than in first-void and midstream samples. Treatment of chronic bacterial prostatitis is hampered by poor penetration of the prostate by most antimicrobial agents. Long-term (6 to 12 weeks) treatment with a fluoroquinolone or TMP/SMZ is indicated and is effective in 60% to 70% of cases.

Prospectus for the Future

- Better directed therapies to limit the spread of drug resistance
- Better assays to identify low level bacterial infection in symptomatic patients
- Better treatment for chronic infection of the prostate

Health Care–Associated Infections

Amy J. Ray, Michelle V. Lisgaris, and Robert A. Salata

A health care–associated or nosocomial infection is an infection that was not present or incubating at the time of admission to a health care facility. Although traditionally these infections have been described in the acute care setting, the proportion of such infections that occurs in long-term care and rehabilitation settings is increasing. Indeed, the risk of health care–associated infection (HAI) for such patient populations approaches that in the acute care setting. In most patients, infections appearing after 48 to 72 hours of hospitalization are considered to be nosocomially acquired.

In the United States a patient admitted to a health care facility has a 5% to 10% chance of developing an HAI. These infections result in significant morbidity and mortality, with 2 million infections and nearly 100,000 deaths annually. The medical costs of HAIs in the United States are estimated to be approximately \$10 billion per year.

HAIs are unintended consequences of medical care. As with any infection, necessary elements for acquisition of infection are an infectious agent, a susceptible host, and a means of transmission. Pathogens in health care settings frequently include multidrug-resistant organisms such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus*, highly resistant gram-negative bacilli, and *Clostridium difficile*. The increasing drug resistance of many of these pathogens makes treatment challenging. With regard to the host, some factors associated with increased risk are not avoidable, such as advancing age, immunosuppression, and severity of illness. Contributing factors that can be minimized by thoughtful patient management include prolonged duration of hospitalization, the inappropriate use of antibiotics, the prolonged use of indwelling urinary and bloodstream catheters, and the failure of health care personnel to wash their hands. It is important to note that the most common means of transmission of health care–associated pathogens is via the hands of health care workers.

Infection Control

Surveillance of HAIs and the implementation of practices to prevent and control them are the responsibility of infection-control personnel. Practices used to limit the spread of infection include isolating patients with potentially transmissible diseases (e.g., tuberculosis, influenza, MRSA infection), isolating patients at increased risk for acquiring infections (e.g., patients with neutropenia and cancer), and instituting mandatory hand washing and standard precautions with all patient contact. Standard precautions consider all blood and body fluids (e.g., cerebrospinal, amniotic, peritoneal, seminal, vaginal, blood-contaminated fluids) as potentially infectious. Gloves must be worn when exposure to these fluids is possible, especially with nonintact skin or mucosal surfaces. In addition, masks and gowns are worn when splashes are expected. Standard precautions are designed to reduce the risk of transmission of microorganism from both recognized and unrecognized sources of infection in hospitals and therefore must be used for every patient and every encounter.

Approach to the Hospitalized Patient with Possible Health Care–Associated Infection

The development of an HAI is often heralded by a rise in temperature. The only sign of infection, particularly in the older or demented patient, may be a change in mental status (Table 106-1). Confusion or alterations in vital signs may be the only sign of serious underlying infection. Respiratory alkalosis or metabolic acidosis (caused by lactate accumulation), either with or without hypoxia, may be present.

Table 106-1 Signs of Infection in the Hospitalized Patient

Fever or hypothermia
Change in mental status
Tachypnea and respiratory alkalosis
Hypotension
Oliguria
Leukocytosis

When evaluating a patient with a new fever or possible infection, the physician should first assess the stability of the patient's condition; hypotension, tachypnea, or new obtundation mandates rapid evaluation and treatment. The patient's comorbidities, medications, recent procedures, and hospital course must be reviewed. The physician should elicit a history directed at possible causes of the fever, given that the patient often has a specific complaint that helps identify the source. Possible causes for nosocomial infections by anatomic site are listed in **Web Table 106-1**. Special attention should be given to examination of the skin for rash (e.g., drug eruption, ecthyma gangrenosum, disseminated candidiasis), wounds, or pressure sores; in addition, the physician must examine the sinuses (especially with nasogastric or nasotracheal tubes in place), mouth (for candidiasis or herpes infections), lungs (for pneumonia or thromboembolism), abdomen (e.g., for *C. difficile*-associated colitis, post-operative abscess, biliary sepsis), catheters, joints (for septic arthritis, gout, and pseudogout), and extremities (for deep-venous thrombosis). The patient's medications should also be reviewed carefully for agents likely to produce fever (antibiotics and anticonvulsants especially). With drug fever, associated eosinophilia and/or rash is present in fewer than 25% of patients. Occasionally, a source of fever cannot be identified despite extensive evaluation. The classic definition of fever of unknown origin has recently been adapted to include the diagnosis of fever of unknown origin acquired nosocomially (see Chapter 95).

Catheter-Associated Urinary Tract Infections

Urinary tract infections are the most common HAI and result in 900,000 additional hospitalization days at a cost well over \$615 million annually. Approximately 80% of nosocomial urinary tract infections are associated with the use of indwelling urinary catheters, and up to 16% of all patients in a health care setting will have a urinary catheter during their stay. Fifteen percent of nosocomial bacteremias originate from the catheterized urinary tract, and some studies have shown increased mortality in patients with a catheter-associated urinary tract infection (CAUTI).

Placement of an indwelling catheter into the urethra of a hospitalized patient facilitates access of pathogens to an ordinarily sterile site. Factors that predispose the patient to infection are shown in Table 106-2. The most common pathogens are enteric gram-negative rods; however, *Candida* and *Enterococcus* species are also important causes of infec-

Table 106-2 Factors That Contribute to Nosocomial Urinary Tract Infection

Indwelling catheters
Extended duration of catheterization
Open drainage (versus closed-bag drainage)
Interruption of closed drainage system
Use of broad-spectrum antibiotics (<i>Candida</i>)

tion. Prophylactic antibiotics, irrigation, urinary acidification, and use of antiseptics are of no value in preventing infection in this setting. Using indwelling catheters only when necessary can reduce CAUTI; studies have observed that 21% to 50% of all urinary catheters placed were for inappropriate indications. Urinary incontinence and routine fluid balance monitoring are not sufficient indications. Examples of situations in which catheterization is unavoidable may include the management of acute urinary retention or pressure wound healing in an incontinent patient. Thrice-daily straight (*in-and-out*) catheterization, with the use of aseptic technique, is less likely to produce infection than use of indwelling catheters, and many patients with dysfunctional bladders have used this technique for years without developing significant urinary tract infections.

If the use of an indwelling catheter is unavoidable, then the catheter drainage system should remain closed and unobstructed and kept securely fastened, with the collection bag remaining below the level of the bladder. The catheter should not be disconnected from the bag because specimens can be collected aseptically by inserting a needle through the distal catheter wall. Most important, the catheter should be removed as soon as possible. Additional strategies to reduce the incidence of urinary catheter-related infections have been the use of silver-coated or antibiotic-impregnated catheters; several studies have been performed and show either conflicting results or benefit only in select populations, respectively. Therefore implementation of their use as routine practice has not been widely recommended.

The clinical presentation of CAUTI is most commonly heralded by fever; localizing symptoms and signs may be absent in the catheterized patient. Microbiologic diagnosis usually requires the growth of at least 10^5 colony-forming units (CFU) of an organism per milliliter of a urine specimen collected aseptically from the catheter.

Asymptomatic bacterial colonization of the catheterized bladder is highly prevalent and need not be treated. *Candida* infection of the bladder often resolves once broad-spectrum antibiotics are discontinued and the indwelling catheter has been removed. If *Candida* infection persists, then oral fluconazole or single-dose intravenous amphotericin B will often eradicate the organism, although recurrence rates are high and the long-term benefit of this approach has not been demonstrated.

The best way to prevent CAUTI is to avoid catheterization unless absolutely necessary. For patients with indwelling urinary catheters, the most important risk factor of CAUTI is extended duration of catheterization; hence assessment for removal on a daily basis is encouraged.

Nosocomial Pneumonia

Pneumonia comprises 15% to 20% of all nosocomial infections, making it the second most frequent hospital-acquired infection. The vast majority of instances arise from aspiration of oropharyngeal contents. Aerobic gram-negative bacilli and often staphylococci, typically after the first 5 days of hospitalization, rapidly replace the normal oropharyngeal flora of the patient admitted to the hospital. The administration of broad-spectrum antibiotics, severe underlying illness (e.g., chronic lung disease), respiratory intubation, surgery, advanced age, and prolonged duration of hospitalization predispose individuals to colonization with these organisms.

Sedation, loss of consciousness, and factors that depress gag and cough reflexes place the colonized patient at increased risk for aspiration and the development of pneumonia. The development of a new pulmonary infiltrate in a hospitalized patient may represent pneumonia, atelectasis, aspiration of gastric contents, drug reaction, or pulmonary infarction. If pneumonia is suggested, then prompt identification of the pathogen and appropriate treatment are critical because nosocomial pneumonia carries a 20% to 50% risk of mortality. If the patient cannot produce a sputum specimen adequate for interpretation (<10 epithelial cells, >25 neutrophils per low-power [$\times 100$] field), then nasotracheal aspiration or bronchoscopic evaluation should be performed (see Chapter 99). Ventilator-associated pneumonia (VAP) accounts for up to 80% of nosocomially acquired respiratory infections; therefore the intubated patient in the intensive care unit should be monitored carefully for signs of pneumonia. Many patients are paralyzed to facilitate ventilator-dependent respiration. These patients have ineffective gag reflexes and often depressed cough as well and are therefore entirely dependent on suctioning to prevent aspiration. Patients whose airways are simply colonized but whose lower respiratory tracts are not infected should not be treated with antibiotics, despite positive sputum cultures. Premature treatment of colonization results in replacement of the initial colonists by more-resistant organisms, whereas delay in treatment of nosocomial pneumonia can result in death from overwhelming infection. The physician must therefore be able to accurately distinguish colonization from infection. The development of new fever, leukocytosis, pulmonary infiltrates, or deterioration of oxygenation suggests pneumonia rather than colonization. A Gram stain of sputum should be performed to identify the predominant organism or organisms, but initial antimicrobial therapy in these critically ill patients should include all likely pathogens because the high frequency of colonization makes interpretation of Gram stain results difficult. The use of clinical tools to assist in the distinction between colonization and infection, primarily in ventilated patients, is helpful in determining when antimicrobial treatment is needed (Fig. 106-1). The clinical pulmonary infection score (CPIS) assigns a numeric value to readily available clinical variables and assists in the determination of the presence of VAP. A CPIS of 6 has greater than 90% sensitivity in detecting pulmonary infection. Epidemics of nosocomial pneumonia are most often caused by transmission of pathogenic bacteria from the hands of medical personnel.

The results of Gram stain and culture of the sputum and aspirate or the results of bronchoscopy specimens guide

Diagnostic Criterion	Results	Points
Temperature ($^{\circ}\text{C}$)	≥ 36.5 and ≤ 38.4	0
	≥ 38.5 and ≤ 38.9	1
	≤ 36.0 and ≤ 39.0	2
Leukocyte count ($/\mu\text{L}$)	≥ 4000 and $\leq 11,000$	0
	< 4000 or $> 11,000$	1
	≥ 500 band forms	1
Tracheal secretions	Absent	0
	Nonpurulent	1
	Purulent	2
PaO ₂ /FiO ₂ (mm/Hg)	> 240 or ARDS	0
	≤ 240 and no evidence of ARDs	2
Pulmonary radiographic findings	No infiltrate	0
	Diffuse or patchy infiltrate	1
	Localized infiltrate	2
Progression of pulmonary infiltrate	No radiographic progression	0
	Radiographic progression after excluding CHF/ARDS	2
Tracheal aspirate Gram stain and culture	No pathologic bacteria cultured	0
	Pathologic bacteria cultured	1
	Some pathologic bacteria on Gram stain	1

Figure 106-1 With use of these diagnostic criteria, a clinical pulmonary infection score of 6 or greater has better than 90% sensitivity in detecting pulmonary infection.

antibiotic therapy. Gram-negative rods have been the predominant pathogens in this setting over the past three decades; these infections should be treated with a fluoroquinolone or aminoglycoside plus an extended-spectrum penicillin or cephalosporin until results of culture and sensitivity testing are known. Recent data from the National Nosocomial Infection Surveillance System indicate that *S. aureus* is the most common cause of nosocomial pneumonia in critically ill patients in the United States and that the prevalence of methicillin resistance is on the rise among these organisms. Therefore if gram-positive cocci in clusters are seen, then vancomycin or linezolid should be administered until sensitivities are known. A mixed flora suggestive of aspiration of oral anaerobes should prompt treatment with clindamycin or a penicillin- β -lactamase inhibitor combination. In certain hospitals, nosocomial pneumonia caused by *Legionella* species is a consideration, and if suggested, then a fluoroquinolone or macrolide should be included in the initial treatment regimen until specific testing can be performed. Selection of an appropriate antimicrobial agent is critical because initial treatment with an antibiotic to which the causative organism is not sensitive is associated with a greater than twofold increase in mortality. Patients with nosocomial pneumonia should also receive aggressive respiratory therapy to promote coughing and expectoration of secretions.

Nosocomial pneumonias are best prevented in ventilated and nonventilated patients by (1) avoiding excessive sedation, (2) providing frequent suctioning and respiratory therapy, (3) positioning the patient in the semirecumbent

position, (4) weaning the patient from mechanical respiratory support as soon as possible, (5) initiating early enteral nutrition with avoidance of gastric overdistention, (6) encouraging frequent hand washing by all health care personnel, and (7) avoiding injudicious use of broad-spectrum or high-dose antibiotics. In addition, for ventilated patients orotracheal intubation is preferred because of increased risk of sinusitis and possibly VAP when nasogastric intubation is performed. The use of a cuffed endotracheal tube with in-line or subglottic suctioning is encouraged to manage secretions and prevent aspiration.

Intravascular Catheter–Related Bloodstream Infections

More than 200,000 health care–associated bloodstream infections occur annually in the United States, the vast majority of which can be attributed to the presence of an intravascular catheter (catheter-related bloodstream infection [CRBSI]). Infections related to intravascular catheters may occur by means of bacteremic seeding or through infusion of contaminated material, but the vast majority of these infections occur through bacterial invasion at the site of catheter insertion. Catheters in frequent use today differ in their indications for use and their risk for CRBSI; therefore familiarization with appropriate selection may go a long way toward preventing CRBSI (Table 106-3; **Web Fig. 106-1**).

Bacteria migrating through the catheter insertion site may colonize the catheter and then produce a septic phlebitis or bacteremia without evidence of local infection. Factors associated with a greater risk of intravenous CRBSI are shown in Table 106-4. Coagulase-negative staphylococci are the predominant pathogen in this setting, followed in equal frequency by *S. aureus* and enterococci. *Candida* species have now surpassed individual gram-negative rods as the third leading cause of CRBSI. The rising incidence of candidemia and enterococcal bacteremia is a reflection of the increasing proportion of immunocompromised and severely ill patients being admitted to acute care facilities. As a group, gram-negative enteric bacilli are the fourth most common cause of nosocomial bacteremia. Patients receiving parenteral nutrition are at particular risk for systemic infection with *Candida* species and gram-negative bacilli.

If nosocomial bacteremia is suggested, then at least two sets of blood cultures should be obtained, one of which should be drawn from a peripheral vein and the other or others through the catheter of concern. Management of CRBSI varies according to the type of catheter involved and whether bacteremia-associated complications (e.g., septic thrombophlebitis, septic embolization, tunnel-site infection, endocarditis, osteomyelitis, metastatic seeding of bacteria) are present (see Table 106-3 and **Web Fig. 106-1**).

A peripheral catheter (and all readily removable foreign bodies) should be replaced if bacteremia develops and no other primary site of infection is found. The catheter should also be removed if fever without an obvious source or if local phlebitis develops. Once the catheter has been removed, the site should be compressed in an attempt to express pus from

the catheter entry site. If septic thrombophlebitis is documented, then surgical exploration may be required. The value of culturing a peripheral catheter tip is limited unless semiquantitative techniques are used (e.g., isolation of >15 CFU of bacteria by the roll plate method). Routine replacement of peripheral indwelling intravascular catheters every 72 hours decreases the risk of CRBSI.

Central venous catheters are of the nontunneled, tunneled, or implanted device variety (**Web Fig. 106-1**). These catheters may be kept in place for prolonged periods with a lower infection risk than peripheral catheters. However, because they typically remain in place for prolonged periods of time, central venous catheters are associated with a greater overall rate of infection. Special microbiologic techniques can be employed to assist in the diagnosis of catheter-related bacteremia. When the diagnosis is confirmed, assessment for infection-related complications (e.g., port abscess, tunnel infection, endocarditis, septic thrombosis) should be performed to devise an appropriate management strategy. Consideration of catheter removal should be given with any nontunneled, central venous catheter–related bacteremia and is generally recommended. Removal of tunneled catheters or implanted devices is generally required when infectious complications occur. In situations in which the infected tunneled catheter or port cannot be removed, an *antibiotic lock* technique may be employed as an attempt to salvage the catheter. In cases of central venous catheter infections involving *Candida* species, other fungi, and *S. aureus*, attempts at catheter salvage have been largely unsuccessful.

Prevention of central line–related bloodstream infection (CLBSI) can be accomplished by practicing an evidence-based approach that includes avoidance of the femoral site for catheterization, hand hygiene before insertion, and maximum sterile barriers including full drape and cap, sterile gown, and gloves for the inserter. In addition, chlorhexidine gluconate (concentration $\geq 0.5\%$) is the preferred antiseptic for skin preparation for patients at least 2 months of age as it broadly inhibits microbial growth with a prolonged residual effect. Antiseptic-coated catheters such as those coated with silver sulfadiazine may also reduce infection rates in the adult patient population. A simple checklist of these insertion interventions combined with catheter removal as soon as possible has been shown to significantly reduce rates of CLBSI.

Clostridium difficile Infection

C. difficile infection (CDI) is the most clinically significant cause of hospital-acquired diarrheal disease and is often accompanied by fever and leukocytosis. It is a cause of significant morbidity and mortality and becoming increasingly difficult to control and eradicate. An epidemic strain of *C. difficile* associated with more severe disease, mortality, and frequent relapses has emerged in the United States, Canada, and Europe since 2003. *C. difficile* now rivals MRSA as the most common organism to cause HAIs in the United States. For full description of this important clinical condition, the reader is referred to Chapter 103.

Table 106-3 Catheters Used for Vascular Access

Catheter Type	Entry Location	Size	Replacement	Comments
Peripheral Catheters				
Venous catheter (IV)	Peripheral veins, usually of the forearm or the hand	<3 in	72 hr is recommended; 96 hr is safe if IV site is not indicative for thrombosis or phlebitis. Indicative for thrombosis or phlebitis.	The most commonly used short-term intravascular device Risk of phlebitis exists with prolonged use; CRBSI is rare.
Arterial catheter	Primarily used in radial artery	<3 in	Routine replacement is not supported unless malfunction or signs and symptoms of systemic complications exist.	For short-term use; commonly used to monitor hemodynamic status and to determine blood-gas levels of critically ill patients; risk of bloodstream infection may approach that of CVCs.
Midline catheter	Distal tip lies in proximal basilica or cephalic veins; does not enter central veins	3-8 in	Same as for arterial catheters.	Phlebitis occurs less often with midline catheters than with standard IV catheters; associated with lower rates of infection compared with CVCs.
Central Catheters (See Web Fig. 106-1 for images)				
Nontunneled or short-term central venous catheter (Web Fig. 106-1A and C)	Subclavian, internal jugular, or femoral vein	≥8 cm*	Routine replacement is not supported unless malfunction or signs and symptoms of systemic complications are exhibited.	Accounts for the majority of all catheter-related bloodstream infections; placement in upper torso is preferred. Replacement of catheter over a guidewire is <i>only</i> acceptable in cases of catheter malfunction.
Peripherally inserted central venous catheter (PICC) (Web Fig. 106-1B)	Basilic, cephalic, or brachial vein into the SVC; provides an alternative to subclavian or jugular vein catheterization	≥20 cm*	Same as nontunneled venous catheters	Similar risk of infection as CVCs in patients hospitalized in intensive care units
Tunneled venous catheter (Broviac, Hickman) (Web Fig. 106-1D)	Subclavian, internal jugular, or femoral vein	≥8 cm*	Is the same as nontunneled venous catheters.	Lower rates of infection with tunneled venous catheters than with nontunneled catheters; cuff inhibits the migration of bacteria into the catheter tract or <i>tunnel</i> .
Implanted venous catheter (Mediport) (Web Fig. 106-1E)	Tunneled beneath skin into internal jugular or subclavian vein; accessed with needle placement into a subcutaneous port; needle may remain in place for up to 6 months, barring infection	≥8 cm*	Is the same as nontunneled venous catheters.	Carries lowest risk for CRBSI; no local care is required for maintenance; is a cosmetically appealing option for patients; requires surgery for removal.
Pulmonary artery catheter (Web Fig. 106-1F)	Enters central circulation through a Teflon-coated introducer placed in subclavian, internal jugular, or femoral vein	≥30 cm*	No recommendations for replacement of catheters that are required for >7 days.	Typically heparin bonded; carries same risk for CRBSI as central venous catheters; subclavian vein is insertion site of choice to reduce risk of CRBSI. Typically remains in place for an average duration of 3 days.

*Length depends on patient size.

CRBSI, catheter-related bloodstream infection; IV, intravenous; SVC, superior vena cava; CVC, central venous catheter.

Table 106-4 Factors Associated with Greater Risk of Intravenous Catheter–Related Infection

Failure of staff to wash hands
Duration of catheterization >72 hr for peripheral intravenous catheters
Lower extremities and groin are at greater risk than upper extremities
Cutdown presents a greater risk than percutaneous insertion
Emergency insertion results in a greater risk than elective insertion
Breakdown in skin integrity (e.g., burns)
Insertion by physician is a greater risk than insertion by intravenous therapy teams

Surgical Site Infections

Surgical site infections (SSIs) occur in up to 5% of the inpatient surgical population in the United States. These infec-

tions increase length of hospital stay, are costly, and are associated with increased mortality. Infection at the surgical site usually occurs within the first 30 days postoperatively; however, in patients undergoing surgical placement of indwelling devices, surveillance for SSI continues up to 1 year postoperatively. The pathogenesis of these infections involves inoculation of skin bacteria at the time of the surgical incision. These infections can be classified as superficial, involving the skin and subcutaneous tissue; deep incisional, involving the fascia and muscles; or deep organ space. Prevention measures, such as minimizing preoperative length of stay, using nonirritative hair removal techniques, performing tight blood glucose control perioperatively, and using appropriate preoperative skin cleansing, are of great importance. If possible, preexisting infections must be treated before surgery to decrease the risk of bacterial seeding of the surgical site. Antibiotic therapy directed at staphylococci and streptococci, administered no later than 2 hours before the time of incision, markedly reduces but does not eliminate the risk of infection for select surgical procedures. Treatment of SSI should be directed by culture and may require débridement for cure.

Prospectus for the Future

Antimicrobial-resistant bacteria (methicillin-resistant *Staphylococcus aureus* [MRSA], vancomycin-resistant enterococci, extended-spectrum β -lactamase [ESBL]–producing gram-negative bacilli), produced by injudicious use of broad-spectrum antimicrobial agents, will continue to offer greater challenges in the treatment of nosocomially acquired infections. With continued medical advances, such as organ and bone marrow transplantations, the emergence of additional opportunistic nosocomial pathogens will undoubtedly occur. In addition,

monitoring and controlling infections in chronic care facilities will be increasingly important because of the emergence and transmission of antibiotic-resistant bacteria in this patient population and the risk of introducing these strains into the hospital environment. As medical professionals, we must share with infection-control practitioners the burden of recognizing individuals who are at risk for developing HAIs and instituting appropriate measures to prevent these infections.

Sexually Transmitted Infections

Corrilynn O. Hileman, Keith B. Armitage, and Robert A. Salata

Sexually transmitted infections (STIs) comprise a diverse group of infections caused by multiple microbial pathogens. These infections have common epidemiologic and clinical features. Since the mid 1980s, the field of STIs has evolved from one emphasizing the traditional venereal diseases of gonorrhea and syphilis to one concerned also with infections associated with *Chlamydia trachomatis*, herpes simplex virus (HSV), human papillomavirus (HPV), and human immunodeficiency virus (HIV).

Changes in sexual attitudes and practices have contributed to a resurgence of some, but not all, venereal infections. For example, after a decline in primary and secondary syphilis in the 1990s, between 2000 and 2006 the incidence of syphilis increased. Concurrently, rates of syphilis infection in men who have sex with men (MSM) also increased, suggesting that this at-risk group may in part be reason for the trend. Indeed, 64% of primary and secondary syphilis cases in 2006 occurred in MSM. Chlamydia, the most commonly reported STI in the United States, with over a million cases reported in 2006, has been increasing in prevalence as well. Rates in women are increasing more than men and most in women aged 15 to 19. This likely represents increased screening efforts; however, it may also reflect the trend toward earlier sexual debut.

At the outset, two common errors in approaching a patient with an STI should be avoided. The first error is failing to consider that an individual is at risk for an STI. All sexually active persons are at risk, not only because of their own sexual behavior, but because of their sexual partner's behavior as well. Failure to consider risk factors often results in mistakes in diagnosis, inappropriate treatment, poor follow-up of infected sexual contacts, and, ultimately, recurrent or persistent infection. A second error with STIs is failing to recognize and diagnose co-infection. The most serious co-infection is with HIV. The worldwide epidemic of STIs fuels the global spread of HIV. STIs, most of which can be readily diagnosed and treated, may greatly enhance

the transmission of HIV infection. HIV, in turn, may alter the natural history of other STIs.

This chapter divides STIs into broad groups according to whether major initial manifestations are (1) genital ulcers; (2) urethritis, cervicitis, and pelvic inflammatory disease (PID); (3) vaginitis; or (4) warts. All patients with an STI should be strongly encouraged to undergo screening for HIV infection and other concurrent STIs (see Chapter 108). Updated information on STIs can be found on the Centers for Disease Control and Prevention website at www.cdc.gov/std.

Genital Ulcer Disease

Six infectious agents cause most genital ulcers (Table 107-1). The appearance of the lesions, natural history, and laboratory findings allow a clear-cut distinction among the possible causes in most instances. The two most common and significant infections in the United States are HSV-2 infection and syphilis.

HERPES SIMPLEX VIRUS INFECTION

Genital herpes infection has reached epidemic proportions, causing a corresponding increase in public awareness and concern. Genital herpes differs from other STIs in its tendency for spontaneous recurrence. Its importance stems from the morbidity, both physical and psychological, of the recurrent genital lesions; the danger of transmission of a fulminant, often fatal, disease to newborns; and an association with transmission of HIV-1 infection.

Epidemiologic Factors

HSV has a worldwide distribution. Humans are the only known reservoir of infection, which is spread by direct contact with infected secretions. Of the two types of HSV,

Table 107-1 Differentiation of Diseases Causing Genital Sores

Disease	Primary Lesion	Adenopathy	Systemic Features	Diagnosis and Treatment
Herpes genitalis (at least 50 million people have herpes genitalis in the United States; most caused by HSV-2) Primary	Incubation 2-7 days; multiple painful vesicles on erythematous base; persists 7-14 days	Tender, soft; often bilateral	Fever	Tzanck smear positive; tissue culture isolation, HSV-2 antigen; fourfold rise in antibodies to HSV-2 Rx: acyclovir, valacyclovir, or famciclovir for 7-10 days
Recurrent	Grouped vesicles on erythematous base; painful; lasts 3-10 days	None	None	Tzanck smear positive; tissue culture positive; HSV-2 antigen; titers not helpful Rx: same as above, except shorter duration required
Primary syphilis (90,000 cases in United States per year; caused by <i>Treponema pallidum</i>)	Incubation 10-90 days (mean, 21) Chancere: painless papule that ulcerates with firm, raised border and smooth base; usually single; may be genital or almost anywhere; persists 3-6 wk, leaving thin, atrophic scar	1 wk after chancre appears; bilateral or unilateral; firm, discrete, movable, no overlying skin changes, painless, nonsuppurative; may persist for months	Later stages	Cannot be cultured; positive darkfield; VDRL test positive, 77%; FTA-abs positive, 86% (see Table 107-2) Rx: see Table 107-3
Chancroid (2000 cases in United States per year; caused by <i>Haemophilus ducreyi</i>)	Incubation 3-5 days; vesicle or papule to pustule to ulcer; soft, not indurated; very painful	1 wk after primary in 50%; painful, unilateral in two thirds; suppurative	None	Organism in Gram stain of pus; can be cultured on special media (75%); direct yields highest from lymph node Rx: azithromycin, 1 g PO once, ceftriaxone, 250 mg IM once, ciprofloxacin, 500 mg PO twice daily for 3 days, or erythromycin base, 500 mg PO 3 times daily for 7 days; sexual partners should be treated
Lymphogranuloma venereum (600-1000 cases per year in United States; caused by <i>Chlamydia trachomatis</i> serovars L1, L2, L3)	Incubation 5-21 days; self-limited, painless papule, vesicle, or ulcer; lasts 2-3 days; noted in only 10%-40%	5-21 days after primary; one third bilateral, tender, matted iliac or femoral groove sign; multiple abscesses; coalescent, caseating, suppurative; thick yellow pus; sinus tracts; fistulas; strictures; genital ulcerations	Fever, arthritis, pericarditis, proctitis, meningoencephalitis, keratoconjunctivitis, preauricular adenopathy, edema of eyelids, erythema nodosum	Test genital or lymph node specimens for <i>C. trachomatis</i> by culture, direct immunofluorescence, or nucleic acid detection; LGV CF positive 85%-90% (1-3 wk); must have high titer (>1:16), cross-reacts with other <i>Chlamydia</i> ; also positive STS, rheumatoid factor, cryoglobulins Rx: surgical drainage may be required; doxycycline, 100 mg PO twice daily for 21 days
Granuloma inguinale, or donovanosis (rare in United States; caused by <i>Klebsiella granulomatis</i>)	Incubation 9-50 days; at least one painless papule that gradually ulcerates; ulcers are large (1-4 cm), irregular, nontender, with thickened, rolled margins and beefy red tissue at base; older portions of ulcer show depigmented scarring, white; advancing edge contains new papules	No true adenopathy; in one fifth, subcutaneous spread through lymphatics leads to indurated swelling or abscesses of groin (<i>pseudobuboes</i>)	Metastatic infection of bones, joints, liver	Scraping or deep curetting at actively extending border; Wright or Giemsa stain reveals short, plump, bipolar staining; dark-staining Donovan bodies in macrophage vacuoles Rx: doxycycline, 100 mg PO twice daily for at least 21 days and until all lesions healed; may recur
Condyloma acuminatum (genital warts; caused by human papillomavirus)	Characteristic large, soft, fleshy, cauliflower-like excrescences around vulva, glans, urethral orifice, anus, perineum	None	None per se; association with cervical dysplasia or neoplasia	Chief importance is distinction from syphilis and chancroid Rx: topical podophyllin ± cryosurgery, laser resection

CF, complement fixation; FTA-abs, fluorescent treponemal antibody absorption; HSV, herpes simplex virus; IM, intramuscular; LGV, lymphogranuloma venereum; PO, orally; Rx, prescription; STS, serologic test for syphilis; VDRL, Venereal Disease Research Laboratory.

HSV-2 is the more frequent cause of genital infection. The major risk of infection is in the 14- to 29-year-old cohort and varies with sexual activity. Seroprevalence rates for HSV-2 infection are 22% in the general population and are as high as 40% to 50% in some North American populations. Many patients with serologic evidence of infection remain asymptomatic, and most transmission is thought to occur during periods of asymptomatic shedding of the virus.

Pathogenesis

After exposure, HSV replicates within epithelial cells and lyses them, producing a thin-walled vesicle. Multinucleated cells are formed with characteristic intranuclear inclusions. Regional lymph nodes become enlarged and tender. HSV also migrates along sensory neurons to sensory ganglia, where it assumes a latent state. Exactly how viral reactivation occurs is uncertain. During reactivation, the virus appears to migrate back to skin along sensory nerves.

Clinical Presentation

Genital lesions that develop 2 to 7 days after contact with infected secretions are the manifestation of the clinical illness. In men, painful vesicles usually appear on the glans or penile shaft; in women, they occur on the vulva, perineum, buttocks, cervix, or vagina. A vaginal discharge is frequently present. Primary infection is usually accompanied by inguinal adenopathy, fever, and malaise. Sacroradiculomyelitis or aseptic meningitis can complicate primary infection. Perianal and anal HSV-2 infections are especially common in MSM; tenesmus and rectal discharge often are the main complaints.

The precipitating events associated with genital relapse of HSV infection are poorly understood. In individual cases, stress or menstruation may be implicated. Overall, genital recurrences develop in approximately 60% of patients infected with HSV. However, the frequency of asymptomatic cervical recurrence in women is not known. Many patients describe a characteristic prodrome of tingling or burning for 18 to 36 hours before the appearance of lesions. Recurrent HSV genital lesions are decreased in number, are usually stereotyped in location, are often restricted to the genital region, heal more quickly, and are associated with fewer systemic complaints. Recurrences are much higher and disease is more severe and prolonged in HIV co-infected patients; particularly those with advanced acquired immunodeficiency syndrome (AIDS).

Laboratory Diagnosis

Although clinical features of HSV infection are suggestive diagnostically, these features are insensitive and not specific. Also, knowing the infection is caused by HSV-1 or -2 is helpful prognostically, as HSV-1 infections are less likely to recur and viral shedding is less. Diagnosis should be confirmed by laboratory testing. Isolation of HSV in cell culture is the gold standard for diagnosis, but sensitivity is low. Additional testing that may be performed includes Tzanck smear (66% sensitive) (see Chapter 93), Papanicolaou smear, immunofluorescent assay for viral antigen, and serologic testing. Direct antigen detection by means of an enzyme immunoassay test shows greater sensitivity than culture for later-stage HSV lesions and is equivalent to culture for early-stage infection. This is generally the diagnostic test of choice.

Serologic studies for HSV are generally useful only in the diagnosis of primary infection. Polymerase chain reaction (PCR) assays are available for the detection of HSV but are not currently approved by the U.S. Food and Drug Administration (FDA) for use on genital specimens.

Treatment

Antiviral therapy for herpes genitalis has been shown to be beneficial and is the mainstay of management. Oral acyclovir, valacyclovir, and famciclovir have all been shown to be effective in treatment of symptomatic HSV infection. Treatment of both primary and recurrent episodes can partially control signs and symptoms of the infection if initiated early in the course. After primary infection, treatment can follow one of two strategies (i.e., episodic or chronic daily suppressive treatment). Chronic daily suppressive therapy has been shown to decrease the number of recurrences by 70% to 80% in those with six or more episodes per year. This strategy has also been shown to decrease transmission of HSV from those infected, although viral shedding may still occur. Despite the benefits of chronic daily therapy, acquired resistance to acyclovir has been seen occasionally in HIV-infected persons and in other immunocompromised hosts (e.g., after bone marrow transplantation). HSV most commonly becomes acyclovir resistant through a mutation in the thymidine kinase gene. Acyclovir-resistant HSV infection is commonly characterized by chronic, progressive mucocutaneous ulcers.

In general, oral therapy is sufficient. It should be noted, however, that antiviral agents do not eradicate the latent stage of virus and do not affect the risk, frequency, or severity of recurrences once the medication is stopped. Hospitalization and administration of intravenous acyclovir are recommended for severe cases with fever, systemic symptoms, or extensive local or disseminated disease (e.g., pneumonia, meningitis, or hepatitis).

The greatest risk of neonatal HSV infection occurs in pregnant women who acquire herpes genitalis near term. This risk is as high as 30% to 50%. However, in those women with a history of recurrent HSV or if primary HSV infection occurs during the first half of pregnancy, the risk of neonatal acquisition is low (i.e., <1%). Regardless, if a woman has active cervical or vulvar lesions late in pregnancy, delivery by cesarean section should be considered. It should be noted, however, that even without active lesions, neonates exposed to asymptomatic shedding of HSV during parturition may also rarely acquire neonatal HSV. If HSV is acquired late in pregnancy or active lesions are present near term, some experts recommend administration of acyclovir. Consultation with an infectious diseases specialist also should be strongly considered.

SYPHILIS

Syphilis is of unique importance among the venereal diseases because early lesions heal without specific therapy; however, serious systemic sequelae of untreated syphilis pose a major risk to the patient, and transplacental infections can occur.

Epidemiologic Factors

Primary syphilis occurs mostly in sexually active 15- to 30-year-old individuals. The incidence of primary syphilis

increased sharply in North America during the early 1990s but decreased in most risk groups in the early 2000s, with the exception of MSM. Approximately 50% of the sexual contacts of a patient with primary syphilis become infected. The long incubation period of syphilis becomes a key factor in designing strategies for contact tracing and management. Unless successful follow-up seems certain, contacts of proven cases must be treated with penicillin, the antibiotic of choice. HIV co-infection is increasing, which poses a serious problem because the mucosal lesions of primary syphilis facilitate transmission of HIV infection (see Chapter 108). Also, HIV appears to accelerate the course of syphilis, with more rapid and frequent involvement of the neurologic system.

Pathogenesis

Treponema pallidum penetrates intact mucous membranes or abraded skin, reaches the bloodstream by means of the lymphatics, and disseminates. The incubation period for the primary lesion depends on inoculum size, with a range of 3 to 90 days.

Natural History and Clinical Presentation

Primary syphilis is considered in Table 107-1. If the primary chancre is not treated, secondary syphilis may develop 6 to 8 weeks later. This time period can be accelerated in persons infected with HIV. With secondary syphilis, skin, mucous membranes, and lymph nodes are involved. A variety of skin manifestations may occur, including macular, papular, papulosquamous, pustular, follicular, or nodular lesions. Discrete, erythematous, macular lesions over the thorax or hyperpigmented macules on the palms and soles occur most commonly. In moist intertriginous areas, large, pale, flat-topped papules coalesce to form highly infectious plaques or condylomata lata; darkfield microscopy reveals that these lesions are teeming with spirochetes. Mucosal lesions are painless, dull, erythematous patches or grayish-white erosions. These lesions are infectious and darkfield positive as well.

Systemic manifestations of secondary syphilis include malaise, anorexia, weight loss, fever, sore throat, arthralgias, and generalized, nontender, discrete adenopathy. Specific organ involvement may develop and includes gastritis (superficial, erosive), hepatitis, renal involvement manifesting as nephritis or nephrotic syndrome (immune complex mediated), and symptomatic or asymptomatic meningitis. If secondary syphilis is not treated, one fourth of patients have relapses of the mucocutaneous syndrome within 2 years of onset. Thereafter, infected patients become asymptomatic and noninfectious except through blood transfusions or transplacental spread.

Latent syphilis, now relatively rare in the United States, develops after 1 to 10 years in 15% of untreated patients. Latent syphilis occurs when patients are asymptomatic but have a positive serologic test for syphilis. Early latent syphilis is when latent syphilis has been acquired within the last year. Late latent syphilis occurs after this. Tertiary infection may develop out of latent syphilis. Manifestations of tertiary infection include but are not limited to gummas and cardiac, ophthalmologic, and auditory abnormalities. Gummas are nonspecific, granulomatous lesions once common in late syphilis but rarely seen today. The skin gumma is a superfi-

cial nodule or deep granulomatous lesion that may develop punched-out ulcers. Superficial gummas respond dramatically to therapy. Gummas also may involve bone, liver, and the cardiovascular or central nervous system. Deep-seated gummas may have serious pathophysiologic consequences, and treatment often does not reverse organ dysfunction. Gradually progressive cardiovascular syphilis begins within 10 years in more than 10% of untreated patients and occurs most frequently in men. Patients develop aortitis with medial necrosis secondary to an obliterative endarteritis of the vasa vasorum. Central nervous system syphilis develops in 8% of untreated patients 5 to 35 years after primary infection and includes the following: meningovascular syphilis, tabes dorsalis, and general paresis (see Chapter 97). Late central nervous system syphilis may be asymptomatic despite cerebrospinal fluid (CSF) abnormalities indicating active inflammation.

The natural history of syphilis may be altered by co-infection with HIV; such patients may develop signs and symptoms of secondary syphilis more rapidly, sometimes even before healing of the primary chancre (see Chapter 108).

Diagnosis

Serologic studies are the primary method for diagnosis of syphilis, but the diagnosis may also be made by darkfield examination or direct fluorescent antibody tests of clinical specimens. Spirochetes can be seen in darkfield preparations of chancres or moist lesions of secondary syphilis. Serologic diagnosis is considered in Table 107-2. The differential diagnosis of a primary chancre includes herpes simplex and three conditions that are relatively rare in the United States: chancroid, lymphogranuloma venereum (LGV), and granuloma inguinale. The characteristics of these diseases are presented in Table 107-1.

Treatment

The treatment of syphilis is considered in Table 107-3. In general, all stages and manifestations of syphilis can be treated with intramuscular benzathine penicillin; however, the presence of neurosyphilis requires modification of this standard therapy. For this reason, a lumbar puncture should be considered in all patients with latent syphilis or latent syphilis of unknown duration especially if HIV co-infected. An elevated CSF white blood cell count, elevated protein, and a positive result of a Venereal Disease Research Laboratory (VDRL) test on diluted samples of CSF establish the diagnosis of neurosyphilis. In absence of other CSF abnormalities, a patient with a persistently positive blood VDRL test result and a positive CSF VDRL test result should be considered to have neurosyphilis and treated accordingly. It should be noted, however, that the sensitivity of the CSF VDRL test in proven cases of neurosyphilis is only 40% to 50%. Therefore, in the absence of a positive CSF VDRL test result, treatment of neurosyphilis is still indicated in patients with a consistent neurologic syndrome, characteristic CSF changes, and a positive serum VDRL test result. Furthermore, because the VDRL test result may be negative in late syphilis, the presence of a positive serum fluorescent treponemal antibody absorption (FTA-abs) test in a patient with a neurologic syndrome consistent with syphilis is also a sufficient indication for treatment. Some experts recommend

Table 107-2 Serologic Studies in Syphilis

	VDRL	FTA-abs
Technique	Standard nontreponemal test; antibody to cardiolipin-lecithin	Standard treponemal test; antibody to Nichol strain of <i>Treponema pallidum</i> after absorption on nontreponemal spirochetes
Indications	Screening and assessing response to therapy; should be quantified by diluting serum	Confirmation of specificity of positive VDRL test; remains reactive longer than VDRL test; useful for late syphilis, particularly neurosyphilis
Percent Positive in Syphilis		
Primary	77%	86%
Secondary	98%	100%
Early latent	95%	99%
Late latent and late	73%	96%
False positives	Weakly reactive VDRL test is common (~30% of normals); if result of VDRL test is positive, test should be repeated; if positive result confirmed, FTA-abs performed; relative frequency of false positives determined by prevalence of syphilis in the population	Borderline positive is frequent (80%) in pregnancy; test should be repeated

FTA-abs, fluorescent treponemal antibody absorption; VDRL, Venereal Disease Research Laboratory.

Table 107-3 Treatment for Syphilis in the Nonimmunocompromised Patient

Clinical Category	Regimen of Choice	History of Penicillin Allergy
Primary Secondary Early latent Healthy contact*	Benzathine penicillin, 2.4 MU IM once	Penicillin desensitization or doxycycline, 100 mg PO twice daily, or tetracycline, 500 mg PO 4 times daily, both for 14 days; some experts recommend ceftriaxone or azithromycin
Late latent or latent syphilis of unknown duration	Benzathine penicillin, 2.4 MU IM per week for 3 wk	Penicillin desensitization, no regimen adequately evaluated; doxycycline, 100 mg PO twice daily, or tetracycline, 500 mg 4 times daily, both for 28 days
Neurosyphilis	Aqueous penicillin G, 20 MU IV daily for 10-14 days	Penicillin desensitization or ceftriaxone, 2g IV or IM daily for 10-14 days

*Contact of patient with active skin or mucous membrane lesions.
IM, intramuscularly; IV, intravenously; MU, million units; PO, orally.

performing an FTA-abs test on CSF to improve diagnostic accuracy in neurosyphilis. This test does, however, have a high false-positive rate in the CSF.

After initiation of treatment for syphilis, some patients may develop an acute febrile reaction called a *Jarisch-Herxheimer reaction*. This reaction is thought to represent a systemic response to penicillin-induced lysis of spirochetes, and manifestations include fever, myalgias, and headache within 24 hours of treatment. Antipyretics may be used. This reaction is especially important in neurosyphilis, as patients may display an acute worsening of original presenting symptoms and signs. Corticosteroid therapy may be administered for severe reactions.

Serologic studies for syphilis must be followed after treatment. With the recommended treatment schedules, 1% to 5% of patients with primary syphilis will develop relapse or be reinfected. In successfully treated primary syphilis, the VDRL test result should become negative by 2 years after therapy (usually by 6 to 12 months). The FTA-abs test result, however, often remains positive for life. In secondary syphilis, 75% of adequately treated patients will have a negative serum VDRL test result by 2 years. If the VDRL test result does not become negative or if a low fixed titer is not achieved, lumbar puncture should be performed to evaluate

the possibility of asymptomatic neurosyphilis, and the patient should be re-treated with penicillin. Of patients with central nervous system syphilis, 2% to 10% will experience relapse after treatment. However, asymptomatic patients rarely develop symptomatic disease after penicillin therapy. The only major exception is the patient infected with HIV, in whom meningovascular syphilis can develop within months of the standard treatment for primary syphilis. All patients who are treated for syphilis should become seronegative or *serofast* with a low fixed titer before cessation of follow-up. If this does not occur, therapy should be repeated.

Because of the documented progression to neurosyphilis in some individuals infected with HIV who have received treatment for primary syphilis, the following approach is suggested. All patients with syphilis should be tested for HIV infection. All individuals infected with HIV should be tested for syphilis. If dual infection is likely or documented, a lumbar puncture should be performed regardless of the stage or activity of the syphilis unless it is primary syphilis. Any CSF abnormality warrants a 10- to 14-day course of intravenous penicillin to treat neurosyphilis. If the CSF is unremarkable, treatment as described in Table 107-3 is appropriate. In any event, careful clinical and laboratory follow-up is essential.

Urethritis, Cervicitis, and Pelvic Inflammatory Disease

These syndromes can be considered broadly as gonococcal and nongonococcal in origin.

GONORRHEA

Neisseria gonorrhoeae is second only to *C. trachomatis* as the most common STI in the United States.

Epidemiologic Factors

It is estimated that 600,000 new infections with *N. gonorrhoeae* occur each year. Particular risk factors are urban location, low socioeconomic status, unmarried status, and large numbers of unprotected sexual contacts. Fifty percent of women having intercourse with a man with gonococcal urethritis will develop symptomatic infection. The risk for men is 20% after a single sexual contact with an infected woman. Orogenital contact and anal intercourse also transmit infection. Both men and women can have this infection and not have symptoms. In fact, asymptomatic infection of men is an important factor in transmission. Indeed, untreated patients may remain culture positive and capable of transmitting infection for periods of up to 6 months. Coinfection with *C. trachomatis* is observed in up to 30% to 40% of patients with gonorrhea. Higher rates of gonorrhea are being observed in MSM.

Pathogenesis

N. gonorrhoeae is a gram-negative, kidney bean-shaped diplococcus. Specialized projections from the organism, called *pili*, aid in attachment to mucosal surfaces, contribute to resistance to killing by neutrophils, and constitute an important virulence factor. In women, several factors alter susceptibility to infection. Group B blood type increases susceptibility, whereas vaginal colonization with normal flora, high immunoglobulin (Ig) A content of vaginal secretions, and high progesterone levels may be protective. Spread from the cervix to the upper genital tract is associated with menstruation as well as intrauterine contraceptive devices, and binding of gonococci to spermatozoa.

Clinical Presentation

Men with gonorrhea generally develop symptoms of urethritis including purulent discharge and severe dysuria. These symptoms develop 2 to 7 days after sexual contact with an infected partner. Prompt treatment usually follows, so more extensive genital involvement is uncommon.

In women, asymptomatic infection is common and is why screening of women is advocated so highly during routine gynecologic examination. For symptomatic infections, cervicitis is the most frequent manifestation and results in copious, yellow, vaginal discharge. Overall, 20% of women with gonococcal cervicitis develop PID, usually beginning at a time close to the onset of menstruation. PID manifests as endometritis (abnormal menses and midline abdominal pain), salpingitis (bilateral lower abdominal pain and tenderness), or pelvic peritonitis. Salpingitis can cause tubal

occlusion and sterility. Gonococcal perihepatitis or Fitz-Hugh-Curtis syndrome may complicate PID. Women also may develop urethritis with dysuria and urinary frequency. In certain populations of sexually active women, 25% of those with urinary tract symptoms and 60% of those with symptoms but no bacteriuria have urethral cultures positive for *N. gonorrhoeae*.

Gonorrhea can infect sites other than the genitourinary tract. Anorectal gonorrhea occurs in both MSM and heterosexual women. In men, the resultant rectal pain, tenesmus, mucopurulent discharge, and bleeding may represent the only signs of infection. In women, however, asymptomatic anorectal involvement is a frequent complication of symptomatic genitourinary disease, occurring in up to 44%. This is possible even in the absence of anal intercourse. Isolated anorectal infection and acute or chronic proctitis are rare. Treatment failure is common and occurs in 7% to 35%. Pharyngeal gonorrhea may occur in MSM or heterosexual women after oral sex and is less frequent in heterosexual men. The pharynx is rarely the lone site of gonococcal infection, occurring in 5% to 8%. Because of the frequency of asymptomatic infection in each of the potential sites, patients with symptoms suggestive of gonococcal infection should have cultures from the urethra, cervix, anus, and, where applicable, pharynx.

Extragenital dissemination occurs in approximately 1% of men and 3% of women with gonorrhea. Strains of *N. gonorrhoeae* causing dissemination are generally more penicillin sensitive but resist the normal bactericidal activity of antibody and complement. This may result from binding of a naturally occurring blocking antibody by the gonococci. Complement deficiency states can predispose patients to disseminated gonorrhea. Dissemination of gonococcal infection may take several forms. First, it may manifest as an arthritis-dermatitis syndrome with 3 to 20 papular, petechial, pustular, necrotic, or hemorrhagic skin lesions, usually found on the extensor surfaces of the distal extremities. An associated finding is an asymmetrical polytenosynovitis, with or without arthritis, predominantly involving the wrists, fingers, knees, and ankles. Joint fluid cultures usually are negative in the arthritis-dermatitis syndrome, leading to speculation that circulating immune complexes, demonstrable in most patients, are important in its pathogenesis. However, synovial biopsies may yield positive cultures. Biopsy of skin lesions reveals gonococcal antigens by immunofluorescent antibody staining in two thirds of patients. Blood cultures are positive in 50% of patients. Septic arthritis is another manifestation of dissemination. Indeed, *N. gonorrhoeae* is the most frequent cause of septic arthritis in sexually active 16- to 50-year-old persons. The joint fluid cultures are positive in less than 50% of cases and generally not unless the leukocyte count in the joint fluid exceeds 80,000/ μ L. Blood cultures are positive in less than 25%. The diagnosis is most often confirmed by extra-articular cultures, usually at genital sites. Finally, gonococcemia may lead to endocarditis, meningitis, myopericarditis, or toxic hepatitis in rare cases.

Diagnosis

Gram stain and culture, nucleic acid hybridization tests, and nucleic acid amplification tests are available for the diagnosis of *N. gonorrhoeae* (and *C. trachomatis*). Culture and

hybridization tests require a swab of the urethra or other potentially infected site. The amplification test can be performed on swabs or urine specimens. In men with symptomatic infection, Gram stain of the urethral discharge is sufficient to make the diagnosis of gonorrhea because typical intracellular diplococci are diagnostic (**Web Fig. 107-1**). Furthermore, the absence of gonococci on a smear of urethral discharge from a man virtually excludes the diagnosis. If, however, gram-negative diplococci are only seen extracellularly, this test is equivocal. In women, Gram staining of cervical exudates is insensitive (<60%) but relatively specific. Therefore further diagnostic modalities are necessary for women. Culture for *N. gonorrhoeae* is possible with a modified Thayer-Martin medium containing antibiotics that inhibit the growth of other organisms. This medium increases the yield of gonococci from samples likely to be contaminated. Thayer-Martin culture of normally sterile fluids, such as joint fluid, blood, and CSF, is not necessary; specimens from these sites should be cultured on chocolate agar. Other important considerations for isolating gonococci in culture include the following: (1) a synthetic swab must be used for specimen collection, as unsaturated fatty acids in cotton may be inhibitory; (2) a calcium alginate swab or a loop must be inserted 2 cm into the male urethra for adequate specimen sampling; (3) vaginal douching should be avoided for 12 hours and urination for 2 hours before specimen collection; and (4) vaginal speculum lubricants should not be used when cervical specimens are obtained. In all suggested cases of gonorrhea, the urethra, cervix, anus, and pharynx should be cultured. In women, 20% of cases in which initial cervical cultures were negative yield *N. gonorrhoeae* when cultures are repeated. Although hybridization and amplification tests are very attractive options for diagnosis of gonorrhea, the importance of culture should not be underestimated. Growing the organism in culture is currently the only means by which susceptibility testing can be performed, and with resistance to many antibiotic classes developing in *N. gonorrhoeae*, this becomes important.

Treatment

Gonococcal resistance to penicillin is increasing worldwide. The current recommendation for the treatment of uncomplicated gonorrhea is ceftriaxone, 125 mg given intramuscularly once, or cefixime, 400 mg orally once. Currently, the Centers for Disease Control and Prevention recommends this single class of antimicrobials for gonorrhea infection, given the high rate of resistance to other classes. Fluoroquinolones are no longer recommended for treatment of gonorrhea in the United States and in many other geographic areas. Treatment of gonorrhea should always be followed by a course of doxycycline, 100 mg orally twice daily for 7 days, or azithromycin, 1 g orally as a single dose, to treat possible concurrent chlamydial infection. In patients with severe β -lactam allergy, spectinomycin, 2 g intramuscularly once, can be used; however, this therapy is inadequate for pharyngeal infection. PID should be treated with cefoxitin, 2 g given intramuscularly once, with probenecid, 1 g orally once, followed by doxycycline, 100 mg orally twice daily for 14 days. Ceftriaxone, 250 mg intramuscularly once, may be substituted for cefoxitin plus probenecid. Metronidazole, 500 mg orally twice daily for 14 days, may be added as well. Seriously ill women with PID should be hospitalized.

Therapy with cefoxitin, 2 g intravenously every 8 hours, or cefotetan, 2 g intravenously every 12 hours, should be administered with doxycycline, 100 mg orally twice a day. Evaluation by ultrasonography for the presence of a pelvic abscess or peritonitis is warranted in this setting. Surgery or percutaneous drainage may be indicated if a tubo-ovarian or pelvic abscess is found.

Disseminated gonococcal infection should be treated with ceftriaxone, 1 g every 24 hours, until clinical symptoms and signs improve, generally in 24 to 48 hours. The treatment course can then be complete with cefixime, 400 mg twice a day orally to complete at least a week of therapy. In patients with severe β -lactam allergy, spectinomycin, 2 g intramuscularly twice a day for 7 to 10 days, is recommended.

Other considerations regarding the management and treatment of a patient with gonorrhea follow. A VDRL test should be performed in all patients with gonorrhea. If the result is negative, no further follow-up is necessary because ceftriaxone in the dosage used is probably effective in treating incubating syphilis. If alternative drugs are used, the VDRL test should be repeated after 4 weeks. Next, anal cultures for *N. gonorrhoeae* should be part of the routine follow-up of women because persistent anorectal carriage may be a source of relapse. Finally, postgonococcal urethritis occurs in 30% to 50% of men 2 to 3 weeks after treatment if doxycycline is not prescribed concomitantly. It usually is caused by *C. trachomatis* or *Ureaplasma urealyticum*.

NONGONOCOCCAL URETHRITIS, CERVICITIS, AND PELVIC INFLAMMATORY DISEASE

The diagnosis of nongonococcal urethritis (NGU) requires the exclusion of gonorrhea because considerable overlap exists in the clinical syndromes. In addition, infections frequently occur concurrently.

Epidemiologic Factors

Chlamydia is the most commonly reported infectious disease in the United States, and *C. trachomatis* is implicated in NGU 15% to 50% of the time. Other causative agents in NGU include: *U. urealyticum*, *Mycoplasma genitalium*, *Trichomonas vaginalis*, HSV, and adenovirus. Typically, NGU predominates in higher socioeconomic groups. NGU is less contagious than gonococcal infection, and the incubation period is 7 to 14 days.

Clinical Presentation

Men and women with chlamydial infections may be asymptomatic. However, in symptomatic infection, men generally report urethral discharge, itching, and dysuria, which are characteristic complaints indicating urethritis. It is important to note that the discharge is not spontaneous but becomes apparent after milking the urethra in the morning. The mucopurulent discharge consists of thin, cloudy fluid with purulent specks. These characteristics do not always allow clear distinction from gonococcal disease. *C. trachomatis* also is a common cause of epididymitis and prostaticitis in men younger than 35 years of age and proctitis in men (or women) who practice receptive anal intercourse.

Symptomatic women most commonly report vaginal discharge. Two thirds of women with mucopurulent cervicitis

have chlamydial infection. Similarly, many women with the acute onset of dysuria, urinary frequency, and pyuria, but sterile urine, have *C. trachomatis* infection. Untreated chlamydial infection in women may lead to PID, ectopic pregnancy, and infertility.

Diagnosis

Culture, direct immunofluorescence, enzyme immunoassay, and nucleic acid hybridization and amplification tests are available for identification of *C. trachomatis*. For diagnosis of cervicitis, nucleic acid amplification is the preferred method, as it is the most sensitive and specific test for *Chlamydia*. In addition, this test may be performed on cervical swabs or urine specimens, making it a convenient option in clinics. The exclusion of gonorrhea relies mainly on Gram-stained preparations of exudates and ultimately culture. However, a nucleic acid amplification test may be performed for this purpose as well. Screening for chlamydia at routine gynecologic examinations is now recommended for all women 25 years of age or younger.

Treatment

The patient and all sexual contacts should be treated with azithromycin, 1 g orally as a single dose, or doxycycline, 100 mg orally twice daily for 7 days. Recurrence may occur and requires longer duration of treatment (i.e., 2 to 3 weeks). In pregnancy, erythromycin base, 500 mg orally four times daily for 7 days, is an alternative regimen. Patients who fail to respond to doxycycline may be infected with *U. urealyticum*, given that 30% of strains are doxycycline resistant. Furthermore, patients who fail to respond to doxycycline

and azithromycin may have a syndrome of NGU caused by *T. vaginalis*, and consideration should be given to therapy with metronidazole.

Vaginitis

Table 107-4 considers salient features in the diagnosis and management of patients with vaginitis. The vaginal milieu is normally maintained by an intricate balance of microorganisms. This balance may be upset by a number of factors including administration of antibiotics, vaginal douching, or a new sexual partner. Disruption of the usual vaginal flora may lead to vaginitis. In this setting vulvovaginal candidiasis and bacterial vaginosis are two common conditions that contribute to the development of vaginitis. A third cause of vaginitis is trichomoniasis, which is sexually transmitted. Characteristic signs and symptoms of any vaginitis are vulvar irritation, pruritus, odor, and vaginal discharge. Diagnosis can now be made with rapid tests; however, the standard method for diagnosis remains evaluation of the vaginal pH, the whiff test, and microscopic examination of discharge collected during speculum examination. Treatment of vaginitis depends on the causative infection and may involve intravaginal application or oral administration of antimicrobials. See Table 107-4 for specific diagnostic and treatment modalities for the vulvovaginal candidiasis, bacterial vaginosis, and trichomoniasis. Of note, any woman with recurrent or refractory candidiasis should be tested for diabetes mellitus and HIV infection, as these conditions promote this infection.

Table 107-4 Vaginitis

Disease	Epidemiology and Pathogenesis	Clinical Findings	Diagnosis	Treatment
Candidiasis (generally, <i>Candida albicans</i>)	Yeast is part of normal flora; overgrowth favored by broad-spectrum antibiotics, high estrogen levels (pregnancy, before menses, oral contraceptives), diabetes mellitus; may be early clue to HIV infection	Itching, occasional dysuria; little or no urethral discharge; labia pale or erythematous with satellite lesions; vaginal discharge thick, adherent, with white curds; balanitis in 10% of male contacts	Vaginal pH = 4.5 (normal); negative whiff test; yeast seen on wet mount in 50%; culture positive; rapid tests available	Miconazole, butoconazole, terconazole, clotrimazole, nystatin or tioconazole cream or suppository for 3-7 days; fluconazole, 150 mg PO once
<i>Trichomonas vaginalis</i> infection	STI; incubation 5-28 days; symptoms begin or exacerbate with menses	Soreness, irritation, mild dysuria, dyspareunia; copious loose discharge, one fifth yellow-green, one third bubbly	Elevated pH; wet mount shows large numbers of WBCs, trichomonads; positive whiff test (10% KOH causes fishy odor); rapid tests available	Metronidazole, 2 g PO once; tinidazole, 2 g PO once; treat sexual contacts
Bacterial vaginosis	Replacement of <i>Lactobacillus</i> species with <i>Gardnerella vaginalis</i> , <i>Mycoplasma hominis</i> , and anaerobes (<i>Mobiluncus</i> and <i>Prevotella</i> species); associated with multiple or new partners, douching	Vaginal odor, little inflammation; mild discharge, grayish, thin, homogeneous with small bubbles	Elevated pH; positive whiff test; wet prep contains clue cells (vaginal epithelial cells with intracellular coccobacilli), few WBCs; rapid tests available	Metronidazole, 500 mg PO twice daily for 7 days; metronidazole gel (0.75%), 5 g intravaginally once daily for 5 days, or clindamycin cream (2%), 5 g intravaginally daily at night for 7 days; do not treat contacts unless recurrent vaginitis

HIV, human immunodeficiency virus; KOH, potassium hydroxide; PO, orally; STI, sexually transmitted infection; WBCs, white blood cells.

Genital Warts and Other Human Papilloma Virus–Associated Diseases

HPV is the most important cause of genital warts as well as cervical dysplasia and cancer in women and anorectal dysplasia and cancer in MSM. Of importance, there is now a quadrivalent vaccine that protects against infection with HPV types 6, 11, 16, and 18, types most commonly implicated in genital warts and cervical cancer. Currently the three-vaccine series is recommended for 11- and 12-year-old girls, with catch-up vaccination offered to female patients aged 13 to 26 years.

EPIDEMIOLOGIC FACTORS

More than 100 types of HPV have been identified, and more than 30 can cause genital infection. Important types include HPV types 6 and 11, which cause the majority of genital warts, and HPV types 16, 18, 31, 33, and 35, which can lead to cervical, vaginal, or anal cancer. Patients infected with HPV can have more than one type of the HPV virus present simultaneously.

CLINICAL PRESENTATION

Genital warts are flat, papular, or pedunculated and are asymptomatic, in general. However, depending on size and location, warts can be painful, pruritic, and friable. The natural history of genital warts is benign, but recurrence is common. Immunocompromised patients such as those with HIV may have warts that are larger in size and number.

DIAGNOSIS

HPV infection may be diagnosed by detection of HPV DNA, RNA, or capsid proteins in cells. Identification of HPV infection is recommended as part of cervical cancer screening and is used in triage of women with atypical squamous cells of undetermined significance (ASC-US). Outside of cervical cancer screening, however, routine testing for HPV infection is not recommended. The diagnosis of genital warts is made by visual inspection and may be confirmed by biopsy. Biopsy should be performed in any case where the diagnosis is in question, if the warts do not respond or worsen during therapy, if the patient is immunocompromised, or if the warts have any red flag signs such as pigmentation, induration, friability, or ulceration. Specialized testing for HPV infection is generally unnecessary.

TREATMENT

Treatment for HPV is not indicated unless a patient has a cervical squamous intraepithelial lesion (SIL) or warts, as subclinical HPV infection frequently resolves spontaneously. Furthermore, untreated genital warts may also spontaneously resolve. Therefore the decision to initiate treatment for genital warts needs to be individualized. Consideration of the following should enter into the decision regarding whether to treat and what modality should

be used: number, size, morphology, and location of the warts, patient preference, cost of therapy, convenience, adverse effects, and provider experience. If treatment is initiated, the goal is to remove visible warts. Removal of warts may induce a wart-free period but does not guarantee that the HPV virus has been eradicated or that HPV cannot continue to be transmitted. Response to therapy will depend on the immune status of the patient as well as adherence.

For external warts, treatment may be patient or provider applied. Patient-applied modalities include podofilox 0.5% solution or gel or imiquimod 5% cream. Podofilox is an antimitotic agent that destroys warts. Imiquimod stimulates an immune reaction to increase the production of interferon and cytokines, which in turn leads to destruction of the warts. These agents are applied once or twice daily for a defined period, and then several days of no therapy is allowed. This cycle may be repeated for several weeks. Mild to moderate irritation and inflammation occur with the application of these medications. Provider-applied modalities include cryotherapy, podophyllin resin 10% to 25%, trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80% to 90%. Cryotherapy with liquid nitrogen destroys warts by thermal-induced cytolysis. Pain and blistering are common after treatments. Podophyllin resin contains several compounds including antimitotic agents. Local irritation may occur if the agent spreads to areas surrounding the warts. TCA and BCA are caustic and destroy warts by chemical coagulation of proteins. Damage to adjacent areas of tissue may be encountered if the product is allowed to spread. A final treatment for external warts is surgical removal. Warts may be removed by scissor or shave excision, curettage, electrosurgery, or laser surgery. Surgery offers the advantage of treatment of warts in one visit and is most beneficial for those with a large number of genital warts or warts that cover a large area.

The presence of genital warts is not an indication to increase the frequency of cervical cancer screening or to perform cervical colposcopy. However, for cervical warts, underlying cervical dysplasia needs to be ruled out. Management should occur in conjunction with a specialist.

For vaginal or anal warts, cryotherapy or TCA or BCA is the recommended treatment modality. Surgery is also an option. For those with anal warts, a digital rectal examination and anoscopy should be performed to rule out the presence of warts on the rectal mucosa. Management of warts on the rectal mucosa should occur in conjunction with a specialist. Lastly, warts in the urethral meatus may be treated with cryotherapy or podophyllin. Surgical management may be required.

Proctocolitis in Men Who Have Sex with Men

Men who practice receptive anal intercourse may have proctitis or proctocolitis, causing anorectal pain, mucoid or bloody discharge, tenesmus, diarrhea, or abdominal pain. Sigmoidoscopy should be performed, with culture and Gram stain of the discharge. The potential causative organisms are diverse (**Web Table 107-1**), and 10% of patients harbor two

or more pathogens. That being said, proctitis may occur without a definable pathogen in up to 42% of cases. LGV has been recognized as an important causative agent in this population. If not treated early, LGV may lead to chronic

colorectal fistulas and strictures. Diarrheal syndromes are considered in Chapter 103, and diarrhea in the HIV-infected patient has an entirely different set of implications (see Chapter 108).

Prospectus for the Future

Effective treatment of sexually transmitted infections (STIs) will be increasingly important in worldwide efforts to counter the human immunodeficiency virus (HIV) epidemic. However, more extensive treatment of STIs may lead to increasing resistance of gonococci and other genital pathogens to currently

available antimicrobial agents. Molecular-based diagnostic testing continues to be developed and will aid in rapid identification of pathogens. Treatment guidelines will necessarily evolve in response to the changing patterns of antimicrobial resistance.

Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

Curt G. Beckwith, Edward J. Wing, Benigno Rodríguez, and Michael M. Lederman

Almost three decades after the acquired immunodeficiency syndrome (AIDS) was recognized as a new disease entity in 1981, more than 65 million individuals worldwide have been infected with the human immunodeficiency virus (HIV), the causative agent. The World Health Organization (WHO) estimates that by the end of 2007 there were 33 million persons living with HIV or AIDS in the world, and 2.7 million acquired HIV in the previous year alone. Of these, more than 90% live in the developing world, and the vast majority acquired the infection through heterosexual intercourse.

HIV type 1 (HIV-1) is responsible for the majority of infections worldwide. A second type of HIV (HIV-2) was identified in West Africa in the mid 1980s. HIV-2 infection also results in AIDS, but HIV-2 infection has a considerably longer clinically latent period than HIV-1. Although HIV-2 shares many biologic and genetic characteristics with HIV-1, each of the two viruses has regulatory and structural genes that are unique. Whereas HIV-1 is closely related to the simian immunodeficiency virus (SIV) isolated from a subspecies of chimpanzee (SIV_{cpz}), HIV-2 is more closely related to an SIV that is commonly found in the sooty mangabey (SIV_{sm}). The rare HIV-2 infections in the United States, Europe, and Asia to date have been of West African origin. Throughout the remainder of this chapter, the abbreviation *HIV* refers to HIV-1.

Epidemiology

Available data suggest that humans first became infected with HIV in the 1930s or 1940s, in the process of slaughtering chimpanzees for human consumption in the African bushmeat market. In retrospect, HIV infection had spread extensively in Central Africa by the early 1970s; the significant wasting of advanced HIV disease was then reflected by the descriptive eponym *slim disease*, which was applied to the unexplained illness that was occurring in large numbers of young adults in Uganda at that time.

AIDS was first recognized as a clinical entity in previously healthy men who had sex with men (MSM) who had serious infections caused by unusual opportunistic pathogens, most frequently *Pneumocystis jirovecii* pneumonia (PCP), an illness previously found only among patients with severe cellular immunodeficiency. Studies confirmed profound immunodeficiency in these individuals, leading to the name *acquired immunodeficiency syndrome*, or AIDS.

When similar opportunistic infections (OIs) were subsequently observed in injection drug users and in men with hemophilia and their female sexual partners, it became clear that this syndrome was caused by an agent transmitted either through sexual contact or through infusion of blood or blood products. HIV was identified in 1983 and confirmed in 1984 as the causative agent of AIDS.

Table 108-1 Opportunistic Infections Indicative of a Defect in Cellular Immune Function Associated with AIDS

Protozoan Infection

Toxoplasma gondii encephalitis
Cryptosporidium parvum enteritis (>1 mo)
Isospora belli enteritis (>1 mo)

Fungal Infection

Candida esophagitis
Cryptococcus neoformans meningitis
 Disseminated histoplasmosis
 Disseminated coccidioidomycosis
Pneumocystis jirovecii pneumonia (PCP)

Bacterial Infection

Disseminated *Mycobacterium avium-intracellulare*
 Active *Mycobacterium tuberculosis* infection
 Recurrent *Salmonella* septicemia
 Recurrent bacterial pneumonia

Viral Infection

Chronic (>1 mo) mucocutaneous or esophageal herpes simplex virus infection
 Cytomegalovirus retinitis, esophagitis, or colitis
 Progressive multifocal leukoencephalopathy (JC virus)

Table 108-2 Other Conditions Fulfilling Clinical Criteria for AIDS

Neoplasms

Kaposi sarcoma
 High-grade, B-cell non-Hodgkin lymphoma
 Immunoblastic sarcoma
 Primary brain lymphoma
 Invasive carcinoma of the cervix

Systemic Illness

Human immunodeficiency virus (HIV) wasting syndrome (unintentional, unexplained loss of >10% of body weight)

Although the average lag period between initial infection by HIV and the clinical manifestations of severe immunodeficiency (AIDS) suggests that the introduction of the virus into North America may have occurred in the early 1970s, preserved specimens suggest that cases may have occurred in this part of the world as early as the 1960s.

The Centers for Disease Control and Prevention (CDC) surveillance criteria for the diagnosis of AIDS, as modified in 1987, included a large number of OIs (Table 108-1) indicative of defects in cellular and/or humoral immunity, as well as certain neoplasms and other conditions associated with severe immunodeficiency (Table 108-2). The occurrence of any one of these conditions in an HIV-infected individual with no other cause of immunosuppression constituted the diagnosis of AIDS. In 1992 the CDC broadened the surveillance definition of AIDS to include all HIV-infected persons with severely depressed levels of cell-mediated immunity as indicated by CD4⁺ T-lymphocyte counts (CD4 counts) less than 200 cells/mm³.

By 1993, AIDS had become the leading cause of death of American adults ages 25 to 44, a trend dramatically reversed by the introduction of highly active antiretroviral therapy (HAART) at the end of 1995 (Fig. 108-1). By the end of 2006, approximately 1.1 million persons in the United States were

living with HIV and AIDS, and an estimated 56,300 persons became infected that year.

Retrospective analysis of stored serum has revealed that HIV infection had been present in parts of Central Africa for decades before recognition of the clinical syndrome of AIDS. Since the early 1980s, HIV infection has become a major worldwide pandemic. HIV infection continues to spread, albeit at strikingly different rates, throughout all continents. Since the late 1990s, exceptionally rapid transmission has occurred throughout India, Southeast Asia, Southern Africa, the former Soviet Union, and some parts of Eastern Europe.

Because of latency between HIV infection and the development of AIDS-associated illnesses, the clinically recognized epidemic of AIDS has lagged 6 to 8 years behind the spread of the virus into new populations. Although initially observed most frequently among homosexual men and intravenous drug users in the United States, heterosexual intercourse has been the dominant mode of HIV transmission throughout most of the world. The virus is present in semen and cervicovaginal secretions of infected individuals and can be transmitted by either partner during vaginal or anal intercourse. The concurrent presence of other sexually transmitted diseases (STDs), especially those associated with genital ulcerations, strongly facilitates sexual transmission of HIV-1 (see Chapter 107). In the United States, HIV infection has increased rapidly in women in the last decade; in several rural areas in the Southeast, women accounted for over one half of new cases in 2005. Over the past several years, there has also been a resurgence of HIV infection among young MSM.

A disproportionate number of North American men and women infected by HIV are African American or Hispanic. Transmission by injection drug use (IDU) has been a major factor in this imbalance, given that IDU transmission has occurred most commonly in impoverished inner-city areas, where intravenous drug abuse is most prevalent. Differences in regional patterns of IDU have been a major factor in the greater than 100-fold regional variation in prevalence of AIDS cases in the United States. Since 2003, IDU transmission has significantly declined in the United States, whereas heterosexual transmission has continued to increase (Fig. 108-2).

Vertical transmission of HIV from infected mother to child may occur in utero, during labor, or through breastfeeding. In the absence of antiretroviral treatment, HIV infects 25% to 30% of infants born to HIV-infected mothers. The rate of vertical transmission can be reduced to less than 2% by prenatal and perinatal treatment of the mother and postnatal treatment of the infant with effective antiretroviral drugs.

HIV is almost always detectable in the blood of infected persons in the absence of effective antiretroviral therapy (ART). Before the nationwide implementation of a blood screening test in late 1985, infection by means of transfused blood or blood products accounted for nearly 3% of AIDS cases in the United States. Since 1985, all blood products in North America have been screened for HIV antigens and antibodies to HIV. The risk of transfusion-acquired HIV infection in North America and Western Europe is now exceedingly small, but not absent.

HIV infection may occur after accidental parenteral exposures among health care workers. After injury by an

Figure 108-1 Trends in annual death rates in persons ages 25 to 44, United States, 1987–2004. In 1993, AIDS became the leading cause of death of Americans in this age group. Since the widespread adoption of effective combination antiretroviral therapy in 1996, AIDS-related death rates have fallen sharply. By 1998, AIDS ranked fifth among the causes of death in this age group. (Data courtesy of Centers for Disease Control and Prevention.)

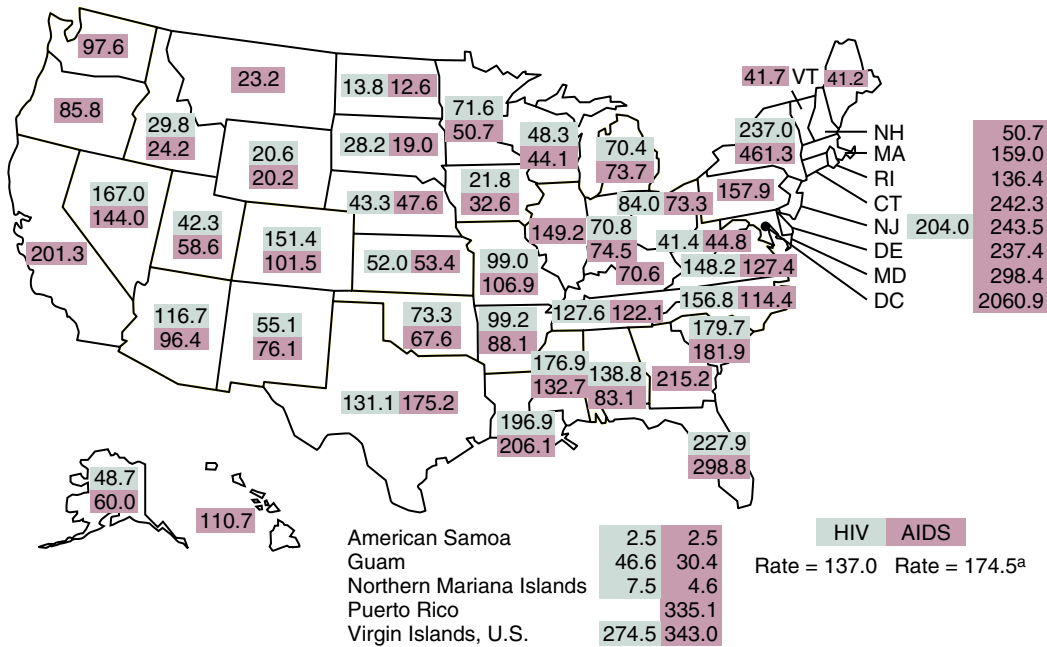

Figure 108-2 Estimated rates (per 100,000 population) for adults and adolescents living with HIV infection (not AIDS; 37 states and territories require confidential name-based HIV infection reporting) or with AIDS, United States and dependent areas (revised June 2007). AIDS rates show tremendous regional variation, from 2060 in the District of Columbia to 12 in Montana. (From Centers for Disease Control and Prevention: HIV/AIDS Surveillance Report, 2005. Vol 17, Rev ed. 2007.)

HIV-contaminated hollow needle, the risk of infection is approximately 0.3%. Observational data suggest that this risk can be reduced at least 10-fold by prompt postexposure prophylaxis.

Pathophysiology

HIV is a member of the lentivirus family of retroviruses, which includes the agents of visna, equine infectious anemia

virus, and the SIVs. The core of HIV contains two single-stranded copies of the viral RNA genome, together with the virus-encoded enzymes reverse transcriptase, protease, and integrase (Fig. 108-3). Surrounding the structural (p24 and p18) proteins is a lipid bilayer derived from the host cell, through which protrude the transmembrane (gp41) and surface (gp120) envelope glycoproteins.

The HIV envelope glycoproteins have a high affinity for the CD4 molecule on the surface of T-helper lymphocytes and other cells of monocyte-macrophage lineage. After HIV

Figure 108-3 Essential steps in the life cycle of human immunodeficiency virus-1 (HIV-1). The first step is the attachment of the virus particle to the CD4 and chemokine (CCR5 or CXCR4) receptors on the surface of the lymphocyte (site of action of viral entry inhibitors; see text). The HIV-1 RNA genome then enters the cytoplasm as part of a nucleoprotein complex. The viral RNA genome is reverse-transcribed into a DNA duplex (site of action of reverse transcriptase inhibitors; see text). Once the viral DNA has been synthesized, the linear viral DNA molecule is incorporated into a preintegration complex that enters the nucleus. In the nucleus, unintegrated viral DNA is found in both linear and circular forms. The viral integrase (target for integrase inhibitors) catalyzes integration of the linear viral DNA into the host genome, where it remains for the life of the cell and serves as a template of viral transcription. Transcription of the integrated DNA template and alternative messenger RNA (mRNA) splicing creates spliced viral mRNA species encoding the viral accessory proteins, including Tat, Rev, and Nef, and the unspliced viral mRNA encoding the viral structural proteins, including the Gag-Pol precursor protein (cleaving of the precursor proteins is prevented by protease inhibitors; see text). A shift in the transcriptional pattern from the expression of predominantly multiply spliced viral mRNA to predominantly unspliced viral mRNA is indicative of active viral replication. All the viral transcripts are exported into the cytoplasm, where translation, assembly, and processing of the retroviral particle take place. The cycle is completed by the release of infectious retroviral particles from the cell. (Modified from Furtado MR, Callaway DS, Phair JP, et al: Persistence of HIV-1 transcription in patients receiving potent antiretroviral therapy. *N Engl J Med* 340:1614-1622, 1999, with permission.)

binds to CD4, the envelope undergoes a conformational change that facilitates binding to another cellular co-receptor (the most important of these are the chemokine receptors CCR5 and CXCR4). This second binding event promotes a major conformational change that causes approximation of the viral and cellular membranes; fusion of these membranes is mediated by insertion of the newly exposed fusion domain of the envelope gp41 into the host cell membrane. As a result, the HIV nucleoprotein complex enters the cytoplasm, where the RNA viral genome undergoes reverse transcription by the virally encoded reverse transcriptase. The resulting double-stranded viral DNA enters the nucleus, where proper localization of the viral preintegration complex is mediated by host proteins, and integration of the DNA provirus into the host chromosome is catalyzed by the retroviral integrase (see Fig. 108-3). In some cells, after integration within the host genome the provirus may remain in a latent state for years, without detectable transcription of RNA or synthesis of viral protein. Latently infected resting memory CD4 lymphocytes serve as reservoirs of persistent infection for the life of infected patients even in the presence of effective ART (see later discussion). The bulk of viral replication takes place, however, in activated T cells, which are both more susceptible to HIV infection and more capable of supporting productive HIV replication.

When a CD4 lymphocyte is activated (e.g., by recognition of antigenic peptides or by binding of proinflammatory cytokines), the viral promoter-enhancer region (the long terminal repeat) is activated to increase expression of HIV messenger RNA (mRNA). Virus-encoded regulatory proteins Tat and Rev facilitate mRNA expression and cytoplasmic transport, respectively. Core proteins, viral enzymes, and envelope proteins are encoded by the *gag*, *pol*, and *env* genes of HIV, respectively. *Gag*- and *pol*-encoded polyproteins are cleaved by viral proteases (see Fig. 108-3), whereas the envelope protein is cleaved and glycosylated by host proteases and glycosylases. Recent data indicate that more than 100 host proteins, in addition to the viral proteins, may be important for viral replication. Viral particles are assembled at the cell membrane, each containing two copies of unspliced mRNA within the core as the viral genome, and virions then are released from the cell by budding. Productive viral replication is lytic to infected T cells. A number of other host cells, including macrophages and certain dendritic cells, are also infected by HIV, but viral replication does not appear to be lytic to these cells.

IMMUNE DEFICIENCY IN HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Following HIV infection, high-level viral multiplication occurs in mucosal lymphoid tissues of the gut and in other lymphatic sites, and plasma HIV RNA levels (plasma viral load [PVL]) often exceed 1 million copies per milliliter during the second to fourth weeks after infection. Almost all instances of acute HIV infection are caused by R5 tropic viruses, viruses that use the chemokine receptor CCR5 for cellular entry. CD4⁺ T cells that express CCR5 are typically memory cells that are concentrated in mucosal tissues. In the first few weeks of infection, the memory CD4⁺ T-cell

Figure 108-4 Natural history of HIV-1 infection in the untreated adult. Note the long period of clinical latency between the acute retroviral syndrome and AIDS-related disease. Note also the relative stability of the plasma HIV RNA level for several years after recovery from the initial burst of viremia, followed by an increase before the onset of AIDS-related symptoms. (Modified from Shaw GW: *Biology of human immunodeficiency viruses*. Modified from Goldman L, Bennett JC [eds]: *Cecil Textbook of Medicine*, 21st ed. Philadelphia, WB Saunders, 2000, p 1896.)

population in the gut-associated lymphoid tissue (GALT) is profoundly depleted by the high-level cytopathic infection in these tissues. During subsequent weeks the PVL decreases, often rapidly. The decrease in viremia results largely from a partially effective, but incomplete, immune response. After 6 to 12 months, the PVL generally stabilizes at a level often called the viral “set point,” and may remain roughly at this level for several years (Fig. 108-4). The PVL at 6 to 12 months after infection is a significant predictor of the subsequent rate of progression of HIV disease but accounts for only half of the population variability in disease progression rates. Thus other factors likely contribute to the pace of disease progression.

During the initial burst of viral replication shortly after infection, the majority of patients develop an acute retroviral syndrome (see discussion of sequential clinical manifestations of HIV-1 infection, later). After spontaneous recovery from the acute retroviral syndrome, the patient may feel entirely well for several years. During this period of clinical latency, however, high-level viral multiplication continues in multiple tissues. In the asymptomatic infected individual, over 100 billion new virions may be produced daily, while an equal number are removed from circulation. Rapid production and turnover of circulating CD4⁺ T-helper cells (CD4 cells) also occurs throughout the course of HIV infection. Although a highly dynamic and complex equilibrium between HIV and CD4 cells may be maintained for several years, a progressive decline in circulating CD4 cells occurs in the great majority of individuals; as disease progresses, a more dramatic CD4 cell decline is observed, following a sharp rise in PVL (see Fig. 108-4). HIV replication, with its attendant cell lysis, accounts only partially for this progres-

sive loss of CD4 cells. An ongoing state of cellular immune activation, not all of which can be attributed directly to HIV itself, appears to play a central role in this progressive immune deficiency.

An HIV-specific immune response contributes to the decrease in the rate of viral replication during the initial weeks after acute HIV infection. During the years of clinical latency, virions are present in large numbers in the follicular dendritic processes of the germinal centers of the lymph nodes, which undergo both hyperplasia and progressive fibrosis. As HIV disease progresses over several years, the lymphatic tissue atrophies, and plasma viremia intensifies. In later-stage HIV disease, there is often persistent high-level viremia (see Fig. 108-4).

The decline in the number of CD4 cells is accompanied by profound functional impairment of the remaining lymphocyte populations. Anergy may develop early in HIV infection and eventually occurs in virtually all persons with AIDS. With development of anergy, T-helper lymphocyte proliferation in response to antigenic stimuli is dramatically impaired. T-cell cytotoxic responses are diminished, and natural killer cell activity against virus-infected cells is greatly impaired, despite normal or increased numbers of these cells. Decrease in function as well as number of CD4 cells is central to the immune dysfunction, and this impairment partly underlies the failure of B-lymphocyte function, as measured by impaired capacity to synthesize antibody in response to new antigens. Profound impairment of multiple arms of the immune system underlies the enhanced risk of acquiring the OIs that are characteristic of AIDS.

INADEQUATE HOST DEFENSE MECHANISMS

HIV continues to replicate despite brisk antibody responses to many components of the virus and demonstrable cell-mediated immune responses to several HIV-derived proteins. There are several possible explanations for the inability of host responses to control HIV infection. The viral replication cycle allows integrated provirus to persist in the host genome in a transcriptionally latent state, in which it is not recognized by either humoral or cellular immune mechanisms (see Fig. 108-3). Conserved domains of the HIV envelope that are potential targets for neutralizing antibody are relatively inaccessible for generation of antibody responses, and extensive glycosylation of the viral envelope also hinders antibody formation and binding. Other conserved potential targets for antibody neutralization are typically unstable and manifest briefly only during the binding and fusion process. Envelope regions vary among different isolates, and although neutralizing antibody responses can be detected early after infection in most persons, mutational escape is readily and reproducibly demonstrable; errors in retroviral reverse transcription underlie this rapid escape from selection pressures and the resultant high degree of genetic variability among HIV isolates. Likewise, while CD8⁺ T-cell responses are key to control of retroviral replication in established infection, there is evidence of both CD8⁺ T-cell dysfunction and the emergence of escape mutations in sequences targeted by these cells. Preferential infection and deletion of

HIV-specific CD4 T helper cells additionally hamper development of an effective anti-HIV immune response.

Diagnosis and Testing for Human Immunodeficiency Virus Infection

Because HIV transmission is preventable, ART is effective, and prophylaxis against the major OIs can prevent these life-threatening events, it is important that routine testing for HIV infection be applied effectively. Testing should *not* be confined only to individuals at recognized high risk. Although not fully implemented nationwide yet, the current recommendation from the CDC is that HIV testing be considered a part of routine medical care, and that it be offered to all patients at the time of contact with the health care system without requirements for written consent or formal pretest and posttest counseling. Confidential pretest discussion is important to ensure that persons appreciate the importance and consequences of the test results. All individuals, regardless of the reason for their interaction with the health care system, should be counseled regarding safer sexual practices. Injection drug users should strongly be advised not to share needles. Positive test results should be given in a face-to-face meeting, during which the patient is given assurance that with adherence to current therapy he or she may live asymptotically with HIV infection for decades. Arrangements for continuing medical care should be made at this time. All patients should be encouraged to notify their sexual partners and persons with whom they have shared needles. This is often difficult; regional health authorities may be of great assistance in confidential notification of persons at risk. All pregnant women should routinely be offered HIV testing, because ART will dramatically reduce mother-to-child transmission.

Diagnosis of HIV infection is established by detection of antibodies to HIV in serum or in oral fluid and is confirmed by Western blot. These techniques are very sensitive in detecting HIV antibody, but individuals who have been infected recently may be antibody negative. During this “window period,” typically 1 to 2 weeks, infected persons have detectable HIV RNA and core p24 antigen in plasma. For recently exposed persons whose initial enzyme-linked immunosorbent assay (ELISA) result is negative, repeat ELISAs at 6 weeks and 3 months are indicated. False-positive ELISA results do occur because the HIV ELISA has been calibrated to achieve maximum sensitivity; all positive ELISA results must therefore be confirmed by Western blot reactivity with at least two different HIV proteins. In a person at high risk for HIV exposure, an indeterminate Western blot reaction pattern often represents early seroconversion; in such cases a positive plasma HIV RNA (>10,000 copies/mL) is indicative of acute HIV infection.

Rapid and accessible testing methods play an increasingly important role in the diagnosis and confirmation of HIV infection. Oral fluid and/or urine testing are noninvasive approaches, and rapid test kits can provide tentative results within 30 minutes.

Table 108-3 Acute HIV Retroviral Syndrome: Common Signs and Symptoms

Sign or Symptom	Frequency (%)
Fever	98
Lymph node enlargement	75
Sore throat	70
Myalgia or arthralgia	60
Rash	50
Headache	35

Sequential Clinical Manifestations of Human Immunodeficiency Virus Type 1 Infection

ACUTE HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND THE ACUTE RETROVIRAL SYNDROME

Over 50% of HIV-infected persons experience a mononucleosis-like syndrome (acute retroviral syndrome) 2 to 6 weeks after initial infection (see Fig. 108-4). Acute symptoms may include fever, sore throat, lymph node enlargement, rash, arthralgias, and headache and usually persist for several days to 3 weeks (Table 108-3). A maculopapular rash is common, is short-lived, and usually affects the trunk or face. Acute, self-limited aseptic meningitis, documented by cerebrospinal fluid (CSF) pleocytosis and isolation of HIV from CSF, is the most common clinical neurologic presentation and occurs in up to 10% of patients.

The acute retroviral syndrome is sufficiently severe that a large proportion of patients seek medical attention. In the absence of a high index of suspicion, these symptoms are often mislabeled as an “acute viral syndrome.” This is especially unfortunate, because a very high plasma HIV RNA level during this period indicates a high likelihood of HIV transmission to sexual or needle-sharing partners, or from mother to infant.

During the acute retroviral syndrome, HIV antibody is often not detectable, but HIV infection can be demonstrated by detection of HIV RNA or the HIV core p24 antigen in plasma. Within 4 to 12 weeks after HIV infection, specific antibodies develop that are directed against the three main gene products of HIV: *gag*, *pol*, and *env*.

ASYMPTOMATIC PHASE

Untreated HIV infection usually results in a slow, nonlinear progression to severe immunodeficiency. Approximately 50% of untreated individuals develop AIDS within 10 years after HIV infection (see Fig. 108-4); an additional 30% have milder symptoms related to immunodeficiency, and less than 20% are entirely asymptomatic 10 years after infection. Progression of disease varies greatly among individuals. Adolescents with HIV progress to AIDS at a slower rate than older persons, and fewer than 30% develop AIDS within 10 years after HIV infection. The rate of progression of immunodeficiency is not influenced by the route of HIV transmission and, in the long term, does not appear to differ

by gender, although typically women with HIV infection tend to experience more rapid disease progression with lower levels of HIV in plasma.

The majority of HIV-infected individuals are not diagnosed during the acute retroviral syndrome, are unaware of their infection, and are asymptomatic, often until their CD4 counts fall below 200 cells/mm³. Clinically recognized lymph node enlargement occurs in 35% to 40% of asymptomatic HIV-infected persons but is not significantly associated with either rate of progression of immunodeficiency or subsequent development of lymphoma. During early HIV infection, thrombocytopenia, probably caused by autoimmune platelet destruction, is common.

EARLY SYMPTOMATIC PHASE

Mucocutaneous lesions may be the first manifestations of immune dysfunction, especially polydermatomal varicella-zoster infection (shingles), recurrent genital herpes simplex virus (HSV) infections, oral or vaginal candidiasis, or oral hairy leukoplakia (OHL). Patients with only moderate immunodeficiency (CD4 counts between 200 and 500 cells/mm³) exhibit diminished antibody response to protein and polysaccharide antigens, as well as decreased cell-mediated immune function. These functional impairments are manifested clinically by a threefold to fourfold increase in incidence of bacteremic pneumonias caused by common pulmonary pathogens (especially *Streptococcus pneumoniae* and *Haemophilus influenzae*), as well as a marked increase in incidence of active pulmonary tuberculosis in endemic areas.

ADVANCED SYMPTOMATIC PHASE: OPPORTUNISTIC INFECTIONS

With advanced immunodeficiency, indicated by CD4 counts below 200 cells/mm³, patients are at high risk for developing OIs (Table 108-4). For example, in the late 1980s, in the absence of specific prophylaxis and before the availability of effective antiretroviral drugs, 60% of HIV-infected North American men developed PCP.

CD4 counts less than 50 cells/mm³ indicate profound immunosuppression and, in the absence of effective ART, are associated with a high mortality within the subsequent 12 to 24 months. Cytomegalovirus (CMV) retinitis, which can lead rapidly to blindness, and disseminated *Mycobacterium avium-intracellulare* (MAI) infections occur frequently. They respond adequately to specific therapy only when it is accompanied by effective control of viral replication.

SEX-SPECIFIC MANIFESTATIONS

Several sex-specific manifestations are relevant to the management of HIV infection in women. Recognition of these manifestations is especially important because they are responsive to specific therapy; each manifestation may serve as the signal for HIV testing in a person with no prior clinical manifestations of immunodeficiency.

- The earliest clinical manifestation of HIV infection in women may be frequent recurrence of *Candida* vaginitis in the absence of predisposing factors. Because recurrent

Table 108-4 Relation of CD4 Lymphocyte Counts to the Onset of Certain HIV-Associated Infections and Neoplasms in North America

CD4 Count (cells/mm ³)*	Opportunistic Infection or Neoplasm
>500	Herpes zoster, polydermatomal
200-500	<i>Mycobacterium tuberculosis</i> infection Oral hairy leukoplakia <i>Candida</i> pharyngitis (thrush) Kaposi sarcoma, mucocutaneous (M) Bacterial pneumonia, recurrent Cervical neoplasia (F)
100-200	<i>Pneumocystis jirovecii</i> pneumonia <i>Histoplasmosis capsulatum</i> infection, disseminated Kaposi sarcoma, visceral (M) Progressive multifocal leukoencephalopathy Lymphoma, non-Hodgkin
<100	<i>Candida</i> esophagitis Cytomegalovirus retinitis <i>Mycobacterium avium-intracellulare</i> , disseminated <i>Toxoplasma gondii</i> encephalitis <i>Cryptosporidium parvum</i> enteritis <i>Cryptococcus neoformans</i> meningitis Herpes simplex virus, chronic, ulcerative Cytomegalovirus esophagitis or colitis Lymphoma, central nervous system

*CD4 count at which specific infections or neoplasms generally begin to appear. Each infection may recur or progress during the subsequent course of HIV disease.

F, exclusively in women; M, usually in men.

Candida vaginitis may develop at a time of only moderate immunodeficiency (CD4 count above 200 cells/mm³), it may serve as a trigger to discuss HIV testing and lead to earlier diagnosis in otherwise asymptomatic women.

- Recurrent large painful genital, perianal, or perineal ulcers, caused by HSV-2, are more frequent in women than in men. Occurring at a time of more advanced immunodeficiency, such lesions should always prompt HIV testing, as well as specific antiviral therapy (see Chapter 107).
- A rare but potentially life-threatening complication may be development of cervical dysplasia or neoplasia. HIV-infected women show an increased prevalence of high-grade squamous intraepithelial lesions on Papanicolaou (Pap) smear. HIV-infected women should therefore undergo two Pap smears at a 6-month interval; if the initial two Pap smears are both normal, smears should be repeated once a year. Conversely, all women with high-grade squamous intraepithelial lesions on Pap smear should be encouraged to undergo testing for HIV infection.

Management of Human Immunodeficiency Virus Infection

Because patients are asymptomatic during most of the course of HIV-1 infection (see Fig. 107-4), and even seri-

Table 108-5 Management of Early HIV Disease

Monitoring

Confirm positive HIV test result
Complete baseline history and physical examination:
HIV-specific interval interview and examination every 3-4 mo

Laboratory Evaluation

Baseline plasma HIV RNA level and CD4 cell count with repeat every 3-4 mo
Baseline purified protein derivative (PPD)
Baseline *Toxoplasma* antibody, syphilis serology, hepatitis B and C antibodies, liver function tests, and chest radiograph*
Baseline genotypic resistance testing

Health Care Maintenance

Assessment for ongoing counseling needs and referral for significant psychiatric or social problems
Discussions regarding safer sex and avoidance of needle sharing
Pneumococcal vaccine, hepatitis A and B vaccine (if HAV, HBV seronegative)
Yearly influenza vaccine

*Many experts order a chest X-ray film only when clinically indicated.

HAV, hepatitis A virus; HBV, hepatitis B virus.

ously immunocompromised individuals can function productively between bouts of OIs, the ambulatory management of persons with HIV infection deserves major emphasis.

INITIAL AMBULATORY EVALUATION

Once HIV infection is recognized, the physician should discuss, in an unhurried manner, the clinical course and treatment of HIV infection and the use of immunologic and virologic studies (e.g., CD4 counts, PVL assays) to guide therapy. The physician should emphasize that most patients, even without antiviral therapy, live for 10 to 12 years after acquiring HIV infection and are asymptomatic during most of that time. The physician should then emphasize that, with effective currently available ART, HIV disease progression can be prevented indefinitely.

Prevention of further transmission through unprotected sex or sharing of needles must be discussed not only at the first visit but also periodically thereafter. It is important to emphasize that these high-risk activities place both the “contact” and the patient at risk, as they may lead to transmission of new HIV strains to the patient, some of which may be resistant to current or future medications used in his or her treatment.

Initial evaluation should include both an HIV-oriented review of systems and a complete physical examination (Table 108-5). In particular, the skin must be examined for HIV-associated rashes and Kaposi sarcoma. Examination of the oral cavity may reveal thrush, gingivitis, hairy leukoplakia, superficial ulcers caused by HSV, aphthous ulcers, or lesions characteristic of Kaposi sarcoma. In persons with very advanced disease, the optic fundi may have hemorrhagic lesions characteristic of CMV retinitis. Lymph node enlargement, hepatomegaly, splenomegaly, and any genital lesions should all be carefully noted. Neurologic

examination for both peripheral neuropathy and decreased global cognition deserves close attention. Pelvic examination with Pap smear should be routine for women.

Purified protein derivative (PPD) testing should be performed early in the course of HIV infection. Induration of 5 mm or more should be considered positive. Any patient with a positive PPD test result should be evaluated for the presence of active tuberculosis; if no active disease is present, the patient should receive 9 months of prophylaxis with isoniazid or combination drug therapy for a shorter time period (see Chapter 99). If active tuberculosis is identified, multidrug therapy should be initiated after careful consideration of possible interactions with antiretroviral medications.

Serologic testing for *Toxoplasma gondii* infection is important in the event that a person subsequently develops an intracerebral lesion (see later discussion). Serologic testing for syphilis should be followed by prompt treatment if patient is confirmed to be positive (see Chapter 107). Antibody responses to pneumococcal polysaccharides are better among patients with higher CD4 counts. The optimal timing of immunization is uncertain; however, if ART is indicated, some authorities will delay immunization for at least 3 to 4 months until HIV replication is better controlled and CD4 counts are increased.

The CD4 count and the PVL should be obtained at the first visit and repeated at intervals of 3 to 4 months. The patient should understand that the CD4 count and the PVL are rough guides to the degree of immunodeficiency and the rate of viral replication, respectively, and that modest fluctuations in these measurements may not indicate a change in clinical course. It is helpful for the physician to use graphic illustrations of the interaction between PVL and CD4 count as predictors of the course of illness in the absence of treatment, as well as a guide to the initiation and monitoring of ART (Table 108-6). Resistance testing should be performed on all patients at entry into clinical care and before initiation of ART (see later) if a considerable amount of time has elapsed between initial contact and therapy start. Transmitted resistance in some antiretroviral-naïve populations is greater than 10%.

GOALS OF ANTIRETROVIRAL THERAPY

The goal of ART is to ensure that persons living with HIV infection lead symptom-free, productive lives. Currently

available therapy makes achieving this goal possible in almost all individuals with early, asymptomatic HIV infection who have not acquired major resistance mutations as the result of earlier suboptimal ART. This circumstance is in stark contrast to the situation only 15 years ago, when progression to marked immunodeficiency was almost inevitable, and such devastating health consequences as blindness caused by CMV retinitis and crippling neurologic deficits as the result of *Toxoplasma* encephalitis were common preterminal events.

PRINCIPLES OF ANTIRETROVIRAL THERAPY

Treatment of HIV infection is exceptional among infectious diseases because specific therapy is not initiated as soon as the diagnosis has been established. Principles underlying this approach include the following:

- Antiretroviral treatment is not curative but suppressive; because HIV infection cannot be eradicated, treatment may be lifelong with currently available drugs.
- All effective treatment regimens may be associated with toxicities, some of which can be life threatening.
- There is a risk for the development of resistance to therapy that increases with the degree of nonadherence to therapy.
- Although damage to the host immune system occurs throughout the course of HIV infection, loss of protective immune response to the most serious OIs occurs only with advanced HIV disease.

ART should therefore be initiated at a time when the benefit of halting replication of the virus exceeds the risks and toxicities of prolonged treatment with available drugs.

WHEN TO INITIATE THERAPY

It is critical that initiation of therapy be based on a joint decision by the informed patient and the physician. Initiation of ART in an asymptomatic patient is seldom an urgent issue, and the physician should spend whatever time is necessary (e.g., three patient visits over a 12-week period) for the patient to understand both the potential benefits and the risks of the specific regimen that is to be undertaken. Graphs such as that shown in Figure 108-5 can be very effective in helping the patient to understand the importance of the CD4

Table 108-6 Guidelines for the Initiation of Antiretroviral Therapy in the Chronically HIV-Infected Patient*

Clinical Category	CD4 ⁺ T-Cell Count and HIV RNA	Recommendation
Symptomatic (e.g., AIDS, thrush)	Any value	Treat
Asymptomatic	CD4 ⁺ T cells <350/mm ³	Treat
Asymptomatic	CD4 ⁺ T cells >350/mm ³	Treatment may be considered in some cases, although benefit may be limited in this group of patients.
Asymptomatic with concomitant (a) pregnancy; (b) hepatitis B with an indication for treatment; or (c) HIV-associated nephropathy	Any value	Treat

*These general guidelines should be used only in conjunction with the text. There are no absolute laboratory thresholds on which the initiation of therapy can be based. This decision must always be made jointly by the informed patient and the physician.

Figure 108-5 Likelihood of developing symptomatic AIDS-related illness or death within 3 years in the absence of treatment. Values in the yellow and red zones are considered indication for initiation of antiretroviral therapy. Values in the yellow zone indicate a 6% to 24% likelihood of progression in 3 years. Values in the purple zone suggest initiation of patient-physician discussion of antiretroviral therapy (see text). Values in the green zone indicate small likelihood of 3-year progression. (Data from Mellors JW, Muñoz A, Giorgi JV, et al: Plasma viral load and CD4⁺ lymphocytes as prognostic markers of HIV-1 infection. *Ann Intern Med* 126:946-954, 1997.)

count in providing the information essential to determining when to initiate therapy. Therapy should be individualized to the extent possible (e.g., a woman of reproductive age who uses contraceptive measures unreliably may be a poor candidate for a medication that is contraindicated during pregnancy). Because the patient may anticipate lifelong ART, and because inadequate adherence to any antiretroviral regimen will result, over time, in resistance to the antiretroviral drugs, it is essential that the patient have as full an understanding of the regimen as possible before initiating ART. The physician must emphasize to the patient the critical importance of consistent adherence with the treatment regimen once started because suboptimal drug levels both provide a selection pressure and permit viral replication. This selects for emergence of viruses with drug-resistant escape mutations that will remain with the patient for the rest of his or her life.

Symptomatic Patients

All patients with symptomatic AIDS (with active or past OIs) should receive ART. Without effective ART, patients with symptomatic AIDS have a high risk of death within 6 to 18 months.

Some experts recommend treatment of patients in whom the acute retroviral syndrome is recognized. There is suggestive evidence that initiation of effective ART at this early stage may lead to more effective restoration of immune function and less rapid subsequent progression of HIV disease, but the data are insufficient to support a definitive recommendation for treatment at this stage of infection.

Asymptomatic Patients

Treatment should be initiated before the patient becomes symptomatic. The CD4 count is the major determinant of when to start antiviral treatment. Although the optimal time to initiate therapy in a given asymptomatic patient cannot be precisely defined, it is currently recommended that all

patients should receive effective ART once the CD4 count falls below 350 cells/mm³ (see Table 108-6). For persons with CD4 counts greater than 350 cells/mm³, decisions about initiating treatment should be individualized by balancing the potential disadvantages of initiating ART (short- and long-term toxicities and development of antiretroviral resistance) against the potential benefits (prevention of progressive immunologic damage and resultant risk for comorbidities) in the context of what the patient is prepared and able to do. No uniform recommendation on treatment initiation can be made for this subset of patients.

In addition to CD4 count, certain clinical circumstances can modify the timing of initiation of ART. Pregnant women, patients with hepatitis B co-infection who require treatment for hepatitis B, and patients with HIV-associated nephropathy should all receive antiretroviral treatment regardless of CD4 count. Current guidelines for treatment initiation are summarized in Table 108-6.

ANTIRETROVIRAL DRUG REGIMENS

Clarification of the mechanisms of HIV replication has identified several potential sites at which retroviral replication might be limited or blocked (see Fig. 108-3). Drugs approved by the U.S. Food and Drug Administration for treatment of HIV infection include seven nucleoside analogues (NRTIs) and one nucleotide analogue that inhibit HIV reverse transcriptase; four non-nucleoside reverse transcriptase inhibitors (NNRTIs); nine HIV protease inhibitors (PIs); and one agent each belonging to the viral fusion inhibitor, chemokine coreceptor inhibitor, and integrase inhibitor classes (Table 108-7). Additional agents in each of these categories are currently in clinical trials; several will likely be approved soon.

The goal of ART is to ensure that the patient has the highest possible quality of life for as long as possible. In general, this requires therapy that durably suppresses the PVL below levels that are detectable by the most sensitive

Table 108-7 Antiretroviral Drugs Approved for Use in Highly Active Antiretroviral Therapy Regimens for Treatment of HIV Infection

Nucleoside or Nucleotide Reverse Transcriptase Inhibitors (RTIs)	Non-nucleoside Reverse Transcriptase Inhibitors (non-RTIs)	Viral Fusion Inhibitor	Protease Inhibitors (PIs)	Chemokine Receptor Inhibitor	Integrase Inhibitor
Abacavir	Efavirenz	Enfuvirtide	Atazanavir	Maraviroc	Raltegravir
Didanosine	Nevirapine		Amprenavir		
Emtricitabine	Etravirine		Indinavir		
Lamivudine			Lopinavir		
Stavudine			Nelfinavir		
Zidovudine			Ritonavir		
Zalcitabine			Saquinavir		
Tenofovir*			Tipranavir		
			Fosamprenavir		
			Darunavir		

*Nucleotide RTI; other agents in the column are nucleoside RTIs.

available assays (<50 copies of HIV RNA per milliliter). Achievement of this objective currently demands that the patient take combination ART with a minimum of three antiretroviral drugs.

Currently recommended initial regimens that predictably provide profound and durable suppression of viral replication include a potent NNRTI plus two NRTIs or a potent PI plus two NRTIs (often in addition to a low dose of the PI ritonavir, which tends to inhibit the hepatic metabolism of other drugs in this group). In addition, combinations that include the newer classes of antiretrovirals (fusion inhibitors, integrase inhibitors, and chemokine receptor inhibitors) have been effective in highly experienced patients with viruses that have substantial levels of resistance to reverse transcriptase inhibitors and PIs. Each of these regimens can result in durable suppression of PVL, usually associated with gradual recovery of immunologic competence. Each regimen has specific advantages and potential toxicities of which the patient must be aware. For example, an efavirenz-based regimen has the advantage of simplicity of administration (once a day) but the disadvantage of a low genetic barrier to the acquisition of mutations that confer high-grade resistance to several NNRTIs if adherence is poor. Because the long-term effectiveness of any regimen is largely determined by the patient's ability to adhere closely to it, the choice of regimen should always be made jointly by the physician and the informed patient. Ease of administration and lack of adverse effects are critical to adherence, so each regimen must be tailored, as much as possible, to the individual patients. As more agents that can be given once a day are becoming available, once-a-day regimens may become regimens of choice, especially for patients with rigorous occupational schedules, or for patients receiving directly observed therapy. Most available regimens can be taken at twice-daily intervals (see Department of Health and Human Services HIV Treatment Guidelines at www.aidsinfo.nih.gov/guidelines for regularly updated treatment information). The recent development of a coformulation of efavirenz, tenofovir, and emtricitabine in a single tablet, taken once daily, represents a major step forward in providing an effective regimen that does not interfere with normal activities of daily living.

WHEN TO CHANGE THERAPY

When an effective antiretroviral regimen is initiated in an asymptomatic patient with no previous ART, the PVL should decrease sharply, generally by 10-fold in 4 weeks and to an undetectable level (<50 copies/mL) within 16 to 24 weeks. If reduction of this magnitude is not achieved, the physician should, with the patient, assess whether adherence has been adequate. If adherence has been nearly complete (>95%), the physician and patient should consider testing for resistance mutations and changing to another effective regimen. Whereas all patients should undergo resistance testing at the time of initial entry into care, minority viral subpopulations carrying resistance mutations may have been too infrequent to be detected at baseline, before exposure to antiretrovirals, but may rapidly overtake the sensitive virus once the selective pressure exerted by the medications is applied. Combination therapies permit suppression of viruses resistant to one drug. Incomplete adherence to treatment that permits drug levels to fall below those needed for complete suppression of viral replication permits the development of additional resistance mutations as viral replication is needed for new mutations to emerge; thus resistance mutations are promoted by a drug-induced selection pressure that is incompletely suppressive. Therefore, if an antiretroviral drug must be stopped for reasons of intolerance or toxicity, it is important to stop temporarily all antiretroviral drugs or alternatively to revise the regimen to sustain complete virologic suppression in order to prevent induction of resistance by an incompletely suppressive regimen. If a given regimen achieves a reduction of PVL below detectable limits and continuing adherence is achieved, the patient can anticipate effective viral suppression for many years and perhaps indefinitely. The PVL should be monitored at 3- to 4-month intervals throughout the course of therapy. If, after months or years of adequate viral suppression, the viral load again becomes detectable on two consecutive determinations, re-testing for resistance mutations and consideration of a change in therapy is indicated. Small viral load elevations on a single determination, however, are usually not significant. See regularly updated International AIDS Society–USA resistance guidelines at www.iasusa.org/guidelines/index.html.

Table 108-8 Prophylaxis Against Certain Opportunistic Infections (OIs) in HIV-Infected Adults*

Pathogen	Indication	First Choice	Alternatives
<i>Pneumocystis jirovecii</i> [†]	CD4 count <200, or history of thrush	TMP-SMZ, 1 tablet qd	Dapsone, 100 mg qd Atovaquone, 1500 mg qd Pentamidine, aerosolized, 300 mg q mo
<i>Mycobacterium tuberculosis</i> [†]			
Isoniazid-sensitive	TST reaction >5 mm, or prior positive TST result without treatment, or contact with case of active tuberculosis	Isoniazid, 300 mg PO, plus pyridoxine, 50 mg qd × 9 mo	Rifampin, 600 mg qd × 4 mo
Isoniazid-resistant	Same as above	Rifampin, 600 mg qd × 4 mo	Rifabutin, 300 mg qd × 4 mo
<i>Toxoplasma gondii</i> [†]	IgG antibody to <i>Toxoplasma</i> and CD4 count <100	TMP-SMZ, 1 double-strength tablet qd	Dapsone, 50 mg PO qd, plus pyrimethimine, 50 mg PO q wk
<i>Mycobacterium avium-intracellulare</i> [†]	CD4 count <50	Azithromycin, 1200 mg q wk	Clarithromycin, 500 mg PO bid

*Department of Health and Human Services recommendations for prophylaxis against OIs are updated regularly and are available at www.aidsinfo.nih.gov/guidelines.

[†]Strongly recommended as standard of care in all patients.

IgG, immunoglobulin G; PO, orally; TMP-SMZ, trimethoprim-sulfamethoxazole; TST, tuberculosis skin test.

Available data do not precisely define the threshold at which a change in therapy is indicated. Some experts recommend change as soon as the PVL is above detectable limits on two determinations. Others would not change until the viral load exceeds an arbitrary figure of 3000 to 5000 copies/mL. At this point, results of resistance testing should be used to define a second effective regimen. The most durable second regimen usually requires a change in at least two antiretroviral drugs.

After failure of a second antiretroviral regimen, change becomes more difficult because the remaining options are reduced. Antiviral resistance testing is even more critical in this setting because viral isolates will commonly demonstrate a significant number of resistance mutations, making the choice of the next regimen considerably more challenging. Many treated patients continue to do well clinically, with stable CD4 counts, for months to years after viral “escape” indicated by increasing PVL. In such patients, stopping ART generally results in clinical deterioration. The basis for continued clinical well-being, despite increasing PVL, during long-term ART is uncertain but may reflect diminished “pathogenicity” of viruses with antiretroviral drug resistance mutations and/or ongoing low-level antigenic stimulation in the setting of partially controlled viremia, potentially resulting in improved immunologic control of viral replication. Thus, many patients continue to receive clinical and immunologic benefit from continued ART despite loss of complete viral control. Continued administration of the ART maintains selection pressure, which results in drug-resistant viruses that tend to be less *fit* in terms of replicative capacity and possibly also less pathogenic. How long the clinical benefit will be sustained in such patients is unknown, but it is clear that these patients do not maintain CD4 cell numbers as well as do patients with more complete suppression of HIV replication. Moreover, HIV tends to accumulate further resistance mutations during periods of incomplete virologic suppression that could potentially compromise future options for salvage therapy;

hence, continuation of a partially suppressive regimen is reasonable only when no other options exist.

PROPHYLAXIS AGAINST OPPORTUNISTIC INFECTIONS

During the first 15 years of the HIV pandemic, the most effective medical interventions for HIV infection were prophylactic measures against OIs. The greatest success was the prevention of PCP in individuals with CD4 counts less than 200 cells/mm³; routine use of prophylaxis resulted in a greater than fourfold (from 60% to <15%) decrease in the frequency of PCP as the initial OI in North American men with HIV infection. Specific antimicrobial prophylaxis (Table 108-8) is also effective for prevention of *T. gondii* encephalitis in patients with anti-*Toxoplasma* antibodies with CD4 counts less than 100 cells/mm³, and for prevention of active tuberculosis in patients with positive tuberculin skin test results at any CD4 level (see Table 108-8). Prophylaxis against disseminated MAI infection is recommended at lower CD4 counts (<50 cells/mm³). Prophylaxis against CMV retinitis is moderately effective in patients with CD4 counts less than 50 cells/mm³, but prompt initiation of effective ART and early treatment of active disease are the currently preferred strategy. Prophylaxis is very effective against recurrent HSV-2 infection (acyclovir, famciclovir, or valacyclovir) and against recurrent *Candida* esophagitis (fluconazole) but should generally be reserved for those patients with recurrent symptomatic disease.

Management of Specific Clinical Manifestations of Immunodeficiency

In the course of HIV infection, OIs vary considerably in time of onset (see Table 108-4). For example, some patients may

Table 108-9 Dermatologic Conditions Common in HIV Infection

Condition	Description	Treatment
Herpes simplex	Clear or crusted vesicles with an erythematous base; ulceration common when chronic; location: oral or genital mucous membranes, face, and hands	Acyclovir, 200 mg 5 times/day, or famciclovir, 250 mg tid, or valacyclovir, 1000 mg bid, each for 7-10 days
Herpes zoster (shingles)	Cluster of vesicles in a dermatomal distribution; may involve adjacent dermatomes or may disseminate	Acyclovir, 800 mg 5 times/day, or famciclovir, 500 mg tid, or valacyclovir, 1000 mg bid, each for 7 days; if disseminated or involvement of ophthalmic branch of trigeminal nerve, IV acyclovir, 10 mg/kg q8h
Staphylococcal folliculitis	Erythematous pustules on face, trunk, and groin, often pruritic	Dicloxacillin, 500 mg qid, or erythromycin, 500 mg qid for 1 wk
Bacillary angiomatosis	Friable vascular papules or subcutaneous nodules on skin; may involve liver, spleen, and lymph nodes	Clarithromycin, 500 mg bid, or doxycycline, 200 mg qd for 1 wk
Molluscum contagiosum	Chronic, flesh-colored papules, often umbilicated, on face or anogenital area	Cryotherapy and curettage
Seborrheic dermatitis	White scaling or erythematous patches on scalp, eyebrows, face, trunk, axilla, and groin	Hydrocortisone cream 2.5% and ketoconazole cream
Psoriasis	Scaling, marginated patches on elbows, knees, and lumbosacral areas	Triamcinolone acetonide cream 0.1%
Eosinophilic folliculitis	Recurrent pruritic follicular papules and rare pustules	Immune restoration with antiretroviral therapy, topical steroids
Candidal dermatitis	Urticarial scaling or erythematous patches on face, trunk, axilla, and groin	Hydrocortisone cream 1% and ketoconazole cream

IV, intravenous.

develop multidermatomal herpes zoster with CD4 counts greater than 500 cells/mm³ and then have no other OIs until they develop PCP with CD4 counts less than 200 cells/mm³. Conversely, some patients may remain entirely asymptomatic until their CD4 counts are below 50 cells/mm³, at which time they may develop major life-threatening OIs, such as *T. gondii* encephalitis (see Table 108-4).

In general, OIs that occur with higher CD4 counts respond to routine therapy for the specific infection (e.g., appropriate β -lactam antibiotic for pneumococcal pneumonia, standard multidrug therapy for pulmonary tuberculosis), whereas OIs occurring with CD4 counts less than 200 cells/mm³ require chronic suppressive therapy after treatment of acute infection (e.g., PCP pneumonia, CMV retinitis, or *Cryptococcus neoformans* meningitis).

Effective ART has had a dramatic impact on the incidence of OIs. Although the impact on specific OIs has varied, with decreases greater than 75% in CMV retinitis and PCP pneumonia, all recognized OIs have decreased dramatically in frequency in North America and Western Europe since 1996. Furthermore, after partial restoration of immunologic function in response to effective therapy, withdrawal of prophylaxis against specific OIs is reasonable. After initiation of effective ART and two consecutive CD4 counts at least 3 months apart that exceed 100 cells/mm³ or 200 cells/mm³, prophylaxis against CMV and MAI or PCP and *T. gondii*, respectively, may be withdrawn safely.

Because of the great reduction in OIs associated with effective ART, rates of hospitalization and mortality for AIDS-related illnesses have dropped sharply since 1996, with decreases of as much as 80% in major North American and Western European cities.

CONSTITUTIONAL SYMPTOMS

Nonspecific symptoms may be the initial clinical manifestations of severe immunodeficiency. Patients may develop unexplained fever, night sweats, anorexia, weight loss, or diarrhea. These symptoms may last for weeks or months before the development of identifiable OIs in patients who do not receive effective ART. These constitutional symptoms may represent manifestations of specific, but unidentified, OIs.

CUTANEOUS DISEASE

Cutaneous infections ultimately occur in most patients with untreated HIV disease. Most respond to specific therapy as outlined in Table 108-9.

MUCOSAL DISEASE

Oral *Candida* stomatitis, or thrush, is often the earliest recognized OI. Early thrush may be entirely asymptomatic; as infection becomes more extensive, it causes pain on eating. The characteristic cheesy white exudate on the mucous membranes can easily be scraped off, and the underlying mucosa may be normal or inflamed.

OHL is a white, lichenified, plaquelike lesion most commonly seen on the lateral surfaces of the tongue that is likely caused by Epstein-Barr virus (EBV). Unlike thrush, the lesions of OHL cannot be scraped off with a tongue depressor. OHL may also be an early manifestation of moderately severe immunodeficiency. OHL is painless, may remit and relapse spontaneously, and almost always responds to effective ART.

Patients may develop painful ulcers in the mouth. These may be caused by HSV but often represent aphthous lesions of uncertain cause. Small oral aphthous ulcers may respond to topical corticosteroids, whereas giant oral or esophageal ulcers require oral administration of thalidomide or corticosteroids. It is important to obtain cultures for HSV and CMV to exclude a viral origin before initiating corticosteroid or thalidomide therapy. Thalidomide should be used, if at all, only when birth control can be ensured in women with childbearing potential because of its well-documented adverse effects on fetal development.

Kaposi sarcoma has a predilection for the oral cavity and skin. Oral lesions may be purple, red, or blue and may be raised or flat. Usually painless, these lesions cause symptoms when they enlarge, bleed, or ulcerate. The incidence of Kaposi sarcoma has decreased dramatically in the United States, but the condition continues to be a major problem in Africa.

ESOPHAGEAL DISEASE

Symptomatic esophageal disease seldom occurs with CD4 counts greater than 100 cells/mm³. Pain on swallowing and substernal burning are common and most often indicate *Candida* esophagitis, particularly when oral thrush is present. Diagnostic esophagoscopy with biopsy, cytology, and culture should be performed if symptoms do not rapidly respond (within 3 to 5 days) to antifungal therapy. If esophagoscopy shows ulcerative lesions, they are usually caused by CMV (50%), aphthae (45%), or HSV (5%). Because each of these lesions is responsive to appropriate therapy, definitive etiologic diagnosis is essential (Table 108-10). CMV esophageal ulcers respond well to intravenous ganciclovir or foscarnet therapy for 2 to 3 weeks or until resolution is confirmed endoscopically. Esophageal ulcerations caused by HSV usually respond well to intravenous acyclovir (see Table 108-10).

GENITAL DISEASE

Recurrent genital ulcers are most often caused by HSV. Viral culture or specific immunofluorescence of ulcer scrapings confirms the diagnosis. Primary syphilis also occurs with

increased frequency (see Chapter 107). Chancroid is unusual in North America.

Many genital inflammatory diseases increase the risk for acquisition of HIV infection; some, such as HSV infection, increase genital shedding of HIV, and persons with genital ulcer disease are at greater risk for transmitting HIV to their uninfected partners. These considerations make it imperative that genital mucosal infections be treated promptly and definitively.

Candida species, most often *Candida albicans*, can cause an irritating vulvovaginitis in women with HIV infection as well as in healthy HIV-seronegative women. A potassium hydroxide preparation of the cheesy white exudate will reveal budding yeast or pseudohyphae.

Bacterial vaginosis and trichomoniasis are common, and although both typically respond to specific treatment (e.g., metronidazole), bacterial vaginosis often recurs.

Infection with HPV is associated not only with development of genital warts in both men and women, but also with a greater frequency of cervical dysplasia in HIV-infected women and anal carcinoma in men. Pap smears indicative of cervical dysplasia should be followed by prompt colposcopy, biopsy when indicated, and appropriate treatment of any dysplastic lesions. With this approach, progression of cervical dysplasia to invasive cervical cancer is exceedingly rare. Some clinicians also recommend anal Pap testing for MSM with HIV infection, but the utility of routine screening in this setting has not been established.

NERVOUS SYSTEM DISEASES

Nervous system complications ultimately occur in the majority of untreated HIV-infected persons. They range from mild cognitive disturbances or peripheral neuropathy to severe dementia and life-threatening central nervous system (CNS) infections. As with other lentiviruses, HIV enters microglial cells of the CNS early in the course of HIV infection. This process may be associated with neuronal vacuolization, cell loss, and occasional lymphocytic infiltration. Both direct neuronal destruction and effects of viral proteins on neuronal cell function may contribute to nervous system disease in AIDS.

Cognitive Dysfunction

Intellectual impairment rarely occurs early in HIV infection, but subtle changes (decreased learning accuracy and learning speed) may be present in patients with only moderate immunodeficiency, and more striking changes often occur with advanced immunodeficiency. AIDS dementia complex (ADC) often begins insidiously and usually progresses over months to years (Table 108-11). ADC is characterized by poor concentration, diminished memory, slowing of thought processes, motor dysfunction, and occasionally behavioral abnormalities characterized by social withdrawal and apathy. Symptoms of clinical depression overlap with many of the characteristics of early ADC and must be considered carefully in differential diagnosis and therapy. Computed tomography (CT) of the head in ADC reveals only atrophy, with enlarged sulci and ventricles, but these findings do not reliably predict cognitive deficits. CSF is most often normal on examination.

Table 108-10 HIV-Associated Esophagitis

Condition	Characteristics	Treatment
<i>Candida</i> infection	Thrush usual, esophageal plaques	Fluconazole, 400 mg/day
CMV infection	Large, shallow esophageal ulcers on endoscopy	Ganciclovir, 5 mg/kg IV bid
Herpes simplex	Deep ulceration on endoscopy	Acyclovir, 800 mg 5 times/day
Aphthae	Giant ulcers on endoscopy; no virus on biopsy	Prednisone, 40-60 mg/day, or thalidomide, 200 mg/day*

*Thalidomide must never be given during pregnancy or when pregnancy is possible.
CMV, cytomegalovirus.

Table 108-11 Major Clinical Manifestations of AIDS Dementia Complex

	Early	Late
Cognition	Inattention, reduced concentration, forgetfulness, impaired memory	Global dementia
Motor performance	Slowed movements, clumsiness, ataxia	Paraplegia
Behavior	Apathy, altered personality, agitation	Mutism

Motor abnormalities may include a progressive gait ataxia. As the disease progresses, patients may develop focal neurologic complications characterized by spastic weakness of the lower extremities and incontinence secondary to vacuolar myelopathy.

Focal Lesions of the Central Nervous System

A large variety of neurologic problems may complicate the later stages of HIV infection. A neuroanatomic classification of these manifestations is presented in Table 108-12. Several of the more frequent or treatable problems are discussed here and in the next section.

Several opportunistic complications of HIV infection produce focal CNS lesions. Patients with focal neurologic signs, seizures of new onset, or recent onset of rapidly progressive cognitive impairment should undergo magnetic resonance imaging (MRI) and/or CT of the brain. Toxoplasmosis, CNS lymphoma, and progressive multifocal leukoencephalopathy (PML) are the most common causes of CNS focal lesions in this setting (Table 108-13).

In the absence of ART, *T. gondii* encephalitis occurs in up to one third of HIV-infected patients who have serologic evidence of *T. gondii* infection but is rare in individuals who have no such antibodies. Patients often have progressive headache and focal neurologic abnormalities, usually associated with fever. CT with contrast dye usually shows multiple ring-enhancing lesions. MRI is a more sensitive technique and often shows multiple small lesions not apparent on CT. Management of symptomatic, ring-enhancing brain lesions in persons with AIDS includes initiation of empirical therapy with pyrimethamine, sulfadiazine, and folinic acid. Brain biopsy should be reserved for patients with atypical presentations, those with no serum antibodies to *T. gondii*, or those whose lesions do not respond after 10 to 14 days of antiprotozoal treatment. After the initial response, patients must remain on chronic suppressive therapy until a sustained rise in CD4 count above 200 cells/mm³ is achieved with effective ART.

Primary CNS lymphoma complicates advanced HIV infection in 3% to 6% of cases and is almost invariably associated with detectable EBV DNA in the CSF (see Table 108-13). Lesions may be single or multiple and are often weakly ring enhancing. Irradiation often provides remission, which may be sustained as immune function is restored by effective ART.

PML is a demyelinating disease caused by a papovavirus (JC virus). Presenting signs and symptoms may include progressive dementia, visual impairment, seizures, and/or

Table 108-12 Neuroanatomic Classification of the Common Complications of HIV Infection

Meningitis and Headache

Toxic neuropathies (zalcitabine, didanosine, stavudine)
Autonomic neuropathy
Cytomegalovirus polyradiculopathy

Myopathies

Noninflammatory myopathy
Zidovudine myopathy

hemiparesis. MRI usually shows multiple lesions predominantly involving the white matter. These lesions are usually less visible on CT than on MRI and are not ring enhancing, which helps to distinguish PML from other mass lesions of the CNS. There is no effective specific treatment for PML; the disease often, but not always, regresses in response to effective ART.

Central Nervous System Diseases without Prominent Focal Signs

Evaluation of the HIV-infected patient with fever and headache is difficult because of the often subtle manifestations of serious CNS lesions in immunocompromised patients. Patients with bacterial meningitis (see Chapter 97) are managed as are noncompromised patients. Meningeal diseases in HIV-infected patients often, however, fall into the broad categories of aseptic meningitis, chronic meningitis, and meningoencephalitis.

Aseptic Meningitis

Patients with aseptic meningitis, which may be a manifestation of the acute retroviral syndrome, complain most often of headache; their sensorium is generally intact, and findings on neurologic examination are normal (see Chapter 97). In the person with established HIV infection, aseptic meningitis may result from several potentially treatable causes (see Chapters 97 and 107).

Chronic Meningitis

Patients with chronic meningitis characteristically have headache, fever, difficulty in concentrating, and/or changes

Table 108-13 Comparative Clinical and Radiologic Features of Cerebral Toxoplasmosis, Primary Central Nervous System Lymphoma, and Progressive Multifocal Leukoencephalopathy

Condition	Clinical Onset			Neuroradiologic Features		
	Temporal Profile	Level of Alertness	Fever	Number of Lesions	Characteristics of Lesions	Location of Lesions
Cerebral toxoplasmosis	Days	Reduced	Common	Usually multiple	Spheric, ring-enhancing on CT	Basal ganglia, cortex
Primary CNS lymphoma	Days to weeks	Variable	Absent	One or few	Irregular, weakly enhancing on CT	Periventricular
Progressive multifocal leukoencephalopathy	Weeks to months	Variable	Absent	Often multiple	Multiple lesions, visible on MRI	White matter

CNS, central nervous system; CT, computed tomography; MRI, magnetic resonance imaging.

in sensorium. CSF examination shows low glucose concentration, elevated protein level, and mild to modest lymphocytic pleocytosis. Cryptococcal meningitis is the most common type. The presence of cryptococcal antigen in serum or CSF or a positive CSF India ink preparation establishes the diagnosis (see Chapter 97). Treatment with amphotericin B for at least 2 weeks followed by high-dose fluconazole is usually effective. Serial lumbar punctures, with removal of CSF to decrease intracranial pressure, may be necessary in the early management of cryptococcal meningitis.

Mycobacterium tuberculosis is an eminently treatable cause of subacute or chronic meningitis in the HIV-infected patient, although rare in North America. Antituberculosis therapy should be considered in the setting of chronic meningitis if the cryptococcal antigen test is negative (see Chapter 97).

Coccidioides immitis or *Histoplasma capsulatum* may cause subacute or chronic meningitis in patients residing in, or with a travel history to, endemic regions (desert Southwest or Ohio and Mississippi River drainage areas, respectively) (see Chapter 97).

Meningoencephalitis

Patients with meningoencephalitis manifest alterations in sensorium varying from mild lethargy to coma. Patients are usually febrile, and neurologic examination often shows evidence of diffuse CNS involvement. CT or MRI may show only nonspecific abnormalities, whereas electroencephalography often is consistent with diffuse disease of the brain.

CMV encephalitis is rare and difficult to diagnose. Patients may demonstrate confusion, cranial nerve abnormalities, or long tract signs. CSF findings may resemble those of bacterial meningitis, with a modest polymorphonuclear leukocyte pleocytosis and depressed CSF glucose levels. CT scan or MRI may reveal periventricular abnormalities. Many patients have associated CMV retinitis. PCR detection of CMV DNA in CSF appears to be a sensitive and specific method for diagnosis of CMV encephalitis and polyradiculopathy.

Meningoencephalitis caused by HSV is unusual in HIV infection (see Chapter 97).

PULMONARY DISEASES

Pulmonary infections are common in persons living with HIV and range from nonspecific interstitial pneumonitis to life-threatening pneumonias (Table 108-14).

HIV-infected patients have a threefold to fourfold increased risk of bacterial pneumonia, generally caused by encapsulated bacteria, including *S. pneumoniae* and *H. influenzae*. The increased risk begins with modest degrees of immunodeficiency (CD4 counts of 200 to 500 cells/mm³). The onset is often abrupt, and the response to prompt initiation of therapy is usually good; however, delay in appropriate antimicrobial therapy may result in a fulminant downhill course. Initial therapy is guided by the results of Gram stain of sputum (see Chapter 99).

Pneumonia caused by PCP remains a common life-threatening infection in North American persons with AIDS. Patients frequently complain of gradual onset of nonproductive cough, fever, and shortness of breath with exertion; a productive cough suggests another process. A substernal “catch” with inspiration is common and suggestive of PCP. In contrast to the acute onset of PCP in other immunocompromised patients, AIDS patients with PCP may have pulmonary symptoms for weeks before presentation to a physician. Arterial hypoxemia is usual and rapidly worsens with slight exertion, and oxygen desaturation with exercise as measured by pulse oximetry can be used to suggest the diagnosis. The chest radiograph often shows a subtle interstitial pattern but may be entirely normal. The patient often appears more sick than the radiograph would suggest. The presence of pleural effusions is suggestive of a cause other than PCP.

If PCP is suspected clinically, therapy should be started immediately; treatment for several days does not interfere with the ability to make a specific diagnosis. Confirmation of PCP is essential; delay in establishing a correct diagnosis of another treatable condition may be lethal. Some experienced centers, by Giemsa or direct fluorescent-antibody stain of induced sputum, may confirm the diagnosis, although many patients are unable to produce a specimen. Alternatively, bronchoalveolar lavage with silver or immunofluorescence staining is adequate to diagnose PCP in more than 95% of patients.

Treatment with high-dose trimethoprim-sulfamethoxazole for 3 weeks is effective therapy (see Table 108-14). Patients with advanced PCP and arterial hypoxemia (oxygen tension 75 mm on breathing of room air) benefit from administration of corticosteroids (40 mg of prednisone twice daily), with tapering of the drug over a 3-week period.

As with acute bacterial pneumonia, active pulmonary tuberculosis may develop at a time when the CD4 count

Table 108-14 Pulmonary Disease Associated with HIV Infection

Condition	Characteristic	Chest Radiograph	Diagnosis	Treatment
<i>Pneumocystis jirovecii</i> pneumonia	Subacute onset, dry cough, dyspnea	Interstitial infiltrate most common	Sputum or bronchoalveolar lavage for organism by stain	Trimethoprim-sulfamethoxazole, pentamidine, or atovaquone or primaquine + clindamycin
Bacterial (pneumococcus, <i>Haemophilus</i> most common)	Acute onset, productive cough, fever, chest pain	Lobar or localized infiltrate	Sputum Gram stain and culture, blood culture	Cefuroxime or alternative antibiotics
Mycobacterial (<i>Mycobacterium tuberculosis</i> or <i>Mycobacterium kansasii</i>)	Chronic cough, weight loss, fever	Localized infiltrate, lymphadenopathy	Sputum acid-fast stain and mycobacterial culture	Isoniazid, rifampin, pyrazinamide, ethambutol
Kaposi sarcoma	Asymptomatic or mild cough	Pulmonary nodules, pleural effusion	Open lung biopsy	Chemotherapy

remains well above 200 cells/mm³ (see Table 108-4). Chest radiographs in HIV-infected patients may show features of primary tuberculosis, including hilar adenopathy, lower or middle lobe infiltrates, miliary pattern, or pleural effusions, as well as classic patterns of reactivation. Extrapulmonary *M. tuberculosis* infection also occurs with increased frequency with advanced immunodeficiency.

Both pulmonary and extrapulmonary tuberculosis generally respond promptly to standard antituberculosis therapy. Treatment therefore should begin with four antituberculosis drugs (see Chapter 99).

Disseminated histoplasmosis and coccidioidomycosis occur with much greater frequency in persons with HIV infection. Either fungal infection may cause nodular infiltrates or a miliary pattern on chest radiograph. Histoplasmosis usually involves bone marrow as well as skin; bone marrow examination often shows the organism. Standard treatment of disseminated mycoses in AIDS patients is high-dose amphotericin. Because relapse is common, oral azole therapy (fluconazole for coccidioidomycosis, itraconazole for histoplasmosis) must be continued after resolution of signs and symptoms. In patients treated for histoplasmosis receiving suppressive ART for at least 6 months, this secondary prophylaxis may be discontinued after 1 year of therapy, provided that the CD4 count is 150 cells/ μ L, blood cultures are negative, and the serum *Histoplasma* antigen titers are low. Patients treated for systemic, meningeal, or diffuse pulmonary coccidioidomycosis have a greater risk of relapse and should likely continue indefinite suppressive therapy. In patients with localized pneumonia receiving successful ART and with sustained CD4 counts of 250 cells/ μ L, on the other hand, cautious interruption of secondary prophylaxis after 1 year of treatment is a reasonable option.

GASTROINTESTINAL DISEASES

HIV affects the gastrointestinal tract early in infection, with profound depletion of memory CD4 T cells in GALT within the first few weeks of infection. Symptomatic disease of the gut is, however, unusual in the early stage of infection.

With advanced immunodeficiency (CD4 count <50 cells/mm³), gastrointestinal disease manifesting as dysphagia (see Table 108-10), diarrhea, or colitis is common. Each process may contribute to inadequate nutrition, compounding the weight loss associated with advanced HIV disease. Nausea and vomiting are often related to medications; these must be reviewed, and the likely offending drug (or drugs) withheld as a therapeutic trial. If symptoms of nausea and vomiting do not respond to empirical therapy with histamine-2 (H₂) antagonists or antiemetics, more extensive gastrointestinal evaluation is indicated.

Abnormalities of liver function tests are common in HIV disease and often are nonspecific. Elevations of serum alanine aminotransferase and aspartate aminotransferase often represent chronic active hepatitis B or C but may reflect hepatic inflammation caused by medications, including trimethoprim-sulfamethoxazole and/or antiretroviral agents. Marked elevations in serum alkaline phosphatase levels may reflect infiltrative disease of the liver (e.g., MAI or CMV) but also may occur in patients with acalculous cholecystitis, cryptosporidiosis, or AIDS-associated sclerosing cholangitis.

DIARRHEA

Diarrhea occurs, at least intermittently, in many persons with advanced immunodeficiency and may be caused by a variety of microorganisms (Table 108-15) as well as by certain antiretroviral therapies. In many instances, no clear cause is found. Stool specimens should be cultured for the common bacterial pathogens. *Salmonella*, *Campylobacter*, and *Yersinia* species are frequent causes; patients usually respond to standard antimicrobial therapy (see Chapter 103). Patients may also have recurrent episodes of diarrhea associated with *Clostridium difficile* toxin; this probably reflects the frequent use of broad-spectrum antibiotics.

In cases of persistent diarrhea, a fresh stool specimen should be examined for parasites, using a modified acid-fast stain for *Cryptosporidium parvum*, microsporidia, and *Isospora belli*, the most common enteric protozoal infections in

Table 108-15 Diarrhea in Advanced HIV Infection

Cause	Characteristics	Diagnosis	Treatment
Frequent			
<i>Cryptosporidium parvum</i>	Varies from increased frequency to large-volume diarrhea	Acid-fast stain of stool	Nitazoxanide, 100 mg bid; antiretroviral therapy
<i>Clostridium difficile</i>	Abdominal pain, fever common	<i>C. difficile</i> toxin in stool or endoscopy	Metronidazole or vancomycin
Cytomegalovirus	Small bowel movements with blood or mucus (colitis)	Colonoscopy and biopsy	Ganciclovir
<i>Mycobacterium avium-intracellulare</i>	Abdominal pain, fever, retroperitoneal lymphadenopathy	Blood culture or endoscopy with biopsy	Multidrug regimen, including clarithromycin; ethambutol
Less Frequent			
<i>Salmonella</i> or <i>Campylobacter</i>	Sometimes with blood or mucus in bowel movements (colitis)	Stool culture	A fluoroquinolone (check sensitivities)
<i>Microsporidia</i>	Watery diarrhea	Calcofluor white or trichrome staining of stool; electron microscopy of biopsy material	Albendazole, antiretroviral therapy
<i>Isospora belli</i>	Watery diarrhea	Acid-fast stain of stool	Trimethoprim-sulfamethoxazole

AIDS patients. Microsporidium infection often requires biopsy with electron microscopy for diagnosis. Although cryptosporidiosis may be self-limited, massive diarrhea (up to 10 L/day) may occur. Isosporiasis responds to oral trimethoprim-sulfamethoxazole, and several microsporidial species to albendazole. Symptoms of both cryptosporidiosis and isosporiasis resolve in response to effective ART.

If stool diagnostic studies are negative and diarrhea persists, patients should undergo endoscopy (see Chapter 34). Biopsy of the duodenum or small bowel may show histologic evidence of cryptosporidial, microsporidial, MAI, or CMV infection. Biopsy of the colon may be indicative of HSV proctitis, CMV colitis, or MAI infection. For patients with refractory diarrhea, symptomatic treatment may improve the quality of life.

VIRAL HEPATITIS

Because of common routes of transmission, HIV-infected persons have a much greater prevalence of hepatitis B and hepatitis C infection than the general population. With improved survival as a result of effective ART, the consequences of liver disease from these viruses have become increasingly apparent. HIV co-infection alters the natural history of viral hepatitis, leading to more rapid progression to end-stage liver disease, greater infectiousness, and diminished response to specific treatments. Conversely, co-infection with hepatitis viruses may have deleterious consequences on the natural history of HIV disease and may compromise the effectiveness of ART. Thus, all HIV-infected patients should be screened for viral hepatitis co-infection, and immunized against those that are preventable by vaccination. Treatment of viral hepatitis and HIV co-infection is best done in consultation with an expert, as management of the combinations of drugs required in these circumstances is complex. It is especially important to screen for active hepatitis B co-infection before initiating antiretroviral therapies, as some agents (e.g., lamivudine,

emtricitabine, tenofovir) are also active against hepatitis B virus and may select for resistance mutations when used in judiciously.

UNEXPLAINED FEVER

Most persistent fevers late in the course of HIV infection reflect a definable OI.

The most common cause of unexplained fever and anemia in patients with CD4 counts less than 50 cells/mm³ is disseminated MAI infection. This may be diagnosed by bone marrow biopsy, but blood cultures in *Mycobacterium*-selective media are usually positive. Treatment (see Table 108-8) usually results in resolution of fever and weight gain.

Aggressive non-Hodgkin lymphoma may cause unexplained fever and weight loss. A rapidly enlarging spleen or asymmetrical lymph node enlargement may suggest the diagnosis. CT-guided biopsy of enlarged intra-abdominal nodes may provide the diagnosis.

WASTING

Cachexia may be prominent in advanced HIV disease. In some instances the wasting is caused by an intercurrent infectious process. Heightened production of tumor necrosis factor may contribute to fever, cachexia, and hypertriglyceridemia in advanced HIV disease.

If orthostatic hypotension occurs, especially if associated with hyperkalemia, the possibility of adrenal insufficiency, which rarely can result from CMV adrenalitis, should be investigated (see Chapter 67).

Most patients with AIDS-associated cachexia gain weight and achieve a sense of well-being after initiation of effective ART. In instances where cachexia is refractory, weight gain may be enhanced by administration of recombinant growth hormone, nonmethylated androgens, or megestrol, but definitive indications for these therapies have not been established.

ACQUIRED IMMUNODEFICIENCY SYNDROME–ASSOCIATED MALIGNANCIES

Among HIV-infected MSM, the frequency of Kaposi sarcoma fell from 40% at the outset of the epidemic to less than 15% in 1999. Human herpesvirus–8 is the causative agent. In many instances, lesions resolve after institution of effective ART. Systemic chemotherapy can cause remission in many patients with symptomatic visceral disease.

Non-Hodgkin lymphomas (largely B cell, with small non-cleaved or immunoblastic histology) occur 150 to 250 times more often in HIV-infected persons than in the general population. Up to 40% of AIDS-related systemic lymphomas, but virtually all of those in a primary CNS location, are related to EBV. Extranodal presentation of these tumors is the rule, with a high frequency of gastrointestinal or intracranial presentation. Chemotherapy for systemic disease or radiation therapy for CNS disease generally provides a clinical response, which may be maintained if accompanied by effective ART. Other malignancies, including Hodgkin disease, have increased incidence in untreated HIV-infected patients. More recently, and with more treated persons surviving with subclinical immune deficiency, an increasing incidence of a variety of non-AIDS–defining malignancies is being observed. The risk of these other cancers is greater in persons with lower CD4 counts, and incidence is expected to increase with time.

Renal Disorders

Renal insufficiency in AIDS patients may be a consequence of nephrotoxic drug administration, heroin injection, or HIV-associated nephropathy (HIVAN). Renal biopsy is indicated to establish a diagnosis, as certain histologic features such as focal and segmental glomerulosclerosis may distinguish HIVAN from renal failure associated with intravenous heroin use and from other causes of renal failure. In the United States, HIVAN is almost exclusively seen in African Americans and usually manifests as heavy proteinuria and progressive renal insufficiency. Without treatment, most patients develop end-stage renal disease within several months. Short-term, high-dose corticosteroid therapy may slow the progression of HIVAN, but treatment with combination antiretroviral therapies is indicated in this setting, irrespective of CD4 cell count, to arrest the course of this disease. The incidence of this complication has also been decreased by the availability of effective ART.

Rheumatologic Disorders

Musculoskeletal complaints are common; the relationship of circulating autoantibodies to these manifestations is not known. Muscle weakness, if localized, may be indicative of myelopathy-neuropathy (see Table 108-12). When weakness is proximal or is associated with myalgia and tenderness, myopathy should be suspected. The myopathy may be HIV associated or may, rarely, represent zidovudine toxicity. On muscle biopsy, inflammatory changes are more prominent in AIDS-associated myopathy, whereas mitochondrial abnormalities predominate in zidovudine-related myopathy. Arthralgias are common; both a Reiter-like syndrome and a Sjögren-like syndrome occur with increased frequency.

Prevention of Human Immunodeficiency Virus Infection

Three approaches—behavioral modification, treatment of STDs, and ART of seropositive pregnant women—can have a major impact on HIV transmission. In addition, the identification of HIV-infected individuals through HIV counseling and testing remains a cornerstone of prevention efforts.

In several communities at increased risk for HIV (e.g., homosexually active men in the United States and Western Europe, young adults in Uganda and Thailand), adoption of safer sexual practices, specifically the use of condoms during sexual activity, has been associated with a decrease in incidence of HIV infection. Sustaining these behavioral changes over long periods requires behavioral reinforcement.

Several recent controlled trials have demonstrated that male circumcision can decrease, by more than half, the risk of acquiring HIV infection.

Antiretroviral treatment of HIV-infected pregnant women and of their infants during the peripartum period has decreased maternal-child transmission from 25% to less than 4% in North America, without harm to the newborn children.

The use of universal blood and body fluid precautions during the care of all patients irrespective of known HIV status is routinely recommended to protect health care workers. Meticulous attention to use and disposal of sharp instruments is most important, because most nosocomial acquisition of HIV infection has occurred through accidental needlesticks. Prompt administration of antiretroviral drugs is thought to significantly decrease the risk of HIV infection after needlestick injuries. Current provisional recommendations by the U.S. Public Health Service for prophylaxis after high-risk occupational exposure include a combination regimen of three effective antiretroviral drugs, initiated as soon as possible after exposure and continuing for 4 weeks (see www.cdc.gov/mmwr/preview/mmwrhtml/rr5409a1.htm).

The development of an effective vaccine is the target of active research. Early clinical trials of vaccine candidates are ongoing but to date have proved disappointing. Induction of brisk T-cell responses to HIV antigens has neither protected against HIV acquisition nor decreased the magnitude of HIV replication among vaccinated subjects. A legitimate goal for vaccines, the induction of antibody responses that can broadly inhibit or neutralize the infectivity of diverse HIV strains, has to date eluded vaccine developers. Thus other strategies to prevent HIV acquisition are urgently needed. Several agents designed to be applied topically to the anogenital tract (commonly referred to as *microbicides*) are in development as preventive interventions that can be controlled by sexually active persons at the time of high-risk exposures. Some of these agents have proven highly effective in preclinical studies, and some are now being tested in humans. Likewise, preexposure prophylaxis (PREP) strategies with antiretroviral drugs are also being tested among persons at risk for HIV acquisition.

Prospectus for the Future

- Development of more well-tolerated antiretroviral therapies active against drug-resistant strains
- New treatment strategies targeting additional stages of the viral life cycle
- Increased understanding of the mechanisms of disease progression and CD4 depletion
- Heightened awareness of and improved treatment modalities for long-term toxicities of antiretroviral agents
- Increased focus on immunotherapeutic interventions
- Development of new prophylactic and therapeutic vaccine strategies
- Testing of strategies to eradicate reservoirs of HIV
- Tests of novel microbicides
- Continuing evaluation of the optimal timing for starting antiretroviral therapy
- Continued surveillance for and optimized management of risks for long-term complications of treated HIV infection such as cardiovascular and neoplastic events

Infections in the Immunocompromised Host

Tracy Lemonovich, David A. Bobak, and Robert A. Salata

Immunosuppression is an increasingly common byproduct of diseases and modern approaches to their treatment. The immunocompromised host has increased susceptibility to *opportunistic infection*, defined as infection caused by organisms of low virulence that constitute normal mucosal and skin flora or by pathogenic microbial agents that are usually maintained in a latent state. Compromised hosts include patients with congenital immunodeficiencies, those infected with human immunodeficiency virus (HIV), and those who are immunocompromised as a consequence of cancer and its treatment, bone marrow failure, or treatment with steroids, cytotoxic therapy, or other immunosuppressive agents.

Immunocompromise is not an all-or-nothing phenomenon. The extent of immunosuppression varies with the underlying cause and must exceed a threshold to predispose the individual to opportunistic infections. Analysis of the type of immunosuppression can help predict the spectrum and types of agents likely to cause infections in an individual patient. Accordingly, opportunistic infections are usually considered in categories that reflect the nature of the immune deficiency. An important point to remember, however, is that most patients have several interacting risk factors that may cause combinations of defects affecting several different aspects of host defense and immune function.

Disorders of Cell-Mediated Immunity

Cell-mediated immunity is the major host defense against facultative and some obligate intracellular pathogens (see also Chapter 92). A partial list of diseases and conditions that impair cell-mediated immunity is presented in Table 109-1. However, only a certain number of these conditions result

in increased susceptibility to infection with intracellular pathogens. Several forms of congenital immunodeficiencies are associated with severe infections early in childhood (Table 109-2). Foremost among the acquired immunodeficiencies are HIV infection, Hodgkin disease and other lymphomas, hairy cell leukemia, and disseminated solid tumors. Severe malnutrition, as well as treatment with high-dose corticosteroids, cytotoxic drugs, or radiation therapy, can produce a similar predilection to infections. Patients with impaired cell-mediated immunity are especially susceptible to the types of organisms shown in Table 109-3 (**Web Figs. 109-1 to 109-8**).

The relative frequency of infection varies with the underlying disease (e.g., *Mycobacterium avium* complex is common in HIV infection, whereas *Listeria* is not), the geographic area (*Mycobacterium tuberculosis* is more common in developing countries than in developed countries), and the extent and type of immunosuppression (*M. tuberculosis* is an early, and *M. avium* complex a late, complication of HIV infection). Immunosuppressive medications vary greatly in their potency and mechanisms of action. In addition, the duration of immunosuppressive therapy is as important as the potency of the medication in assessing potential risk for opportunistic infection. For example, a patient receiving relatively high doses of corticosteroids for a short period (e.g., for an allergic reaction) is at much less risk for infection compared with a patient with an autoimmune disease receiving much lower doses of the same agent for a prolonged period.

Depression of cell-mediated immunity also permits organisms ordinarily constituting the normal flora, such as *Candida* species, to act as virulent opportunistic pathogens capable of causing aggressive infections. Latent viruses, fungi, mycobacteria, and parasites can reactivate to cause locally progressive or disseminated disease. In many instances the signs, symptoms, and laboratory abnormalities indicating an infection are subtle and nonspecific, an important

distinction to the clinical presentations commonly observed in immunocompetent patients.

In some instances, treatment of the underlying disease causing the immunodeficiency, or progression of the disease itself, produces an increased severe and generalized compromised state, one that predisposes the individual to infection by additional types of microorganisms. For example, during chemotherapy for lymphoma, bacterial infections initially predominate. Disease progression may also alter other factors that favor bacterial infections, such as mucosal breakdown and obstruction by tumor masses of the bronchi, the ureters, or the biliary tract. The result is a marked increase in severe bacterial infection and sepsis syndrome, often caused by multiple-resistant pathogens, late in the course of many diseases associated with impaired cell-mediated immunity.

Disorders of Humoral Immunity

The acquired disorders of antibody production associated with increased frequency of infection in adults are common variable immunodeficiency, chronic lymphocytic leukemia, lymphosarcoma, multiple myeloma, nephrotic syndrome, major burns, and protein-losing enteropathy. The paraproteinemic states belong in this category because of secondary decreases in levels of functioning antibody. Therapy with cytotoxic drugs may produce similar immunocompromised states.

Infections with pneumococci, *Haemophilus influenzae*, meningococci, streptococci, and staphylococci predominate early in the course of the humoral immunodeficiency. As the underlying disease itself progresses, infections with gram-negative bacilli become increasingly frequent. Treatment of the underlying condition with corticosteroids and cytotoxic drugs causes additional defects in cell-mediated immunity and provides susceptibility to infections with the group of pathogens presented in Table 109-3. Some agents predicted to alter humoral immunity may have unexpected effects. For example, the monoclonal antibody rituximab, used for treating certain types of lymphoma, profoundly depletes B lymphocytes but causes increased risk of hepatitis B reactivation,

rather than increased risk of infection by the bacterial pathogens outlined previously.

In sickle cell anemia, heat-labile opsonic activity is diminished. Complement depletion by erythrocyte stroma impairs opsonization of pneumococci and *Salmonella* species and leads to frequent infections with these organisms. Impaired reticuloendothelial system function resulting from erythrophagocytosis and functional asplenia also predisposes patients with sickle cell disease to other serious bacterial infections. The predisposition to infection is related to age; once children with sickle cell disease develop antibodies to pneumococcal capsular polysaccharide, they lose their thousand-fold increased susceptibility to severe pneumococcal infection.

Splenectomy results in a loss of mechanisms for the clearing of opsonized organisms. Splenectomy therefore predisposes patients to fulminant infections caused by encapsulated bacteria. Over a period of years, the liver may partially compensate for certain aspects of splenic function. The splenic tissue also represents a major source of production of antibody, as well as other opsonic factors such as tuftsin, which opsonizes staphylococci. Splenectomized patients are also predisposed to severe and overwhelming infection with *Capnocytophaga* species (found in canine oral flora) and additionally have an increased risk for acquiring babesiosis. Pneumococcal, meningococcal, and possibly *H. influenzae* type b (Hib) vaccines should be administered to adult patients who will be undergoing splenectomy or who have diseases likely to produce functional asplenia. The newer protein conjugate forms of the pneumococcal and meningococcal vaccines may offer increased response rates for splenectomized or functionally asplenic patients. Although the 7-valent pneumococcal conjugate vaccine is currently recommended only for children, with the 23-valent polysaccharide vaccine used for high-risk adults and the elderly (including asplenic patients), the conjugate vaccine has been shown to decrease invasive pneumococcal disease in older adults by herd immunity. Conjugate meningococcal vaccine is recommended for asplenic adults <55 years of age. There is no specific recommendation for the conjugate Hib vaccine in this population, as efficacy is unknown, but the use of the vaccine should be considered. Fever in a patient with asplenia should immediately raise concern for possible underlying sepsis, and such a patient should be immediately treated with empirical antibiotics pending results of cultures and laboratory tests.

Impaired Neutrophil Function

Many types of inherited or acquired diseases impair neutrophil function. The defect may be extrinsic or intrinsic to the neutrophil itself. For example, impaired chemotaxis predisposes patients with inherited C3 and C5 deficiencies to frequent bacterial infections (see also Chapter 92). Corticosteroid therapy is generally associated with defective cell-mediated immunity (see previous discussion) but may also interfere with neutrophil chemotaxis. Even though circulating neutrophil counts are frequently normal or increased in patients receiving corticosteroids, these cells do not localize normally to the site of infection. Leukocyte adhesion defi-

ciencies are caused by mutations in leukocyte integrins needed for binding to endothelial intercellular adhesion molecules, with resulting lack of neutrophils at sites of infection despite elevated serum neutrophil counts. Many other illnesses and conditions are associated with impaired neutrophil function, including myelodysplasia, paroxysmal nocturnal hemoglobinuria, radiation therapy, and cytotoxic drug therapy.

Inherited intrinsic defects in neutrophils are rare but have provided insights into understanding the microbicidal mechanisms of these cells. Neutrophils from patients with chronic granulomatous disease (CGD) cannot develop an oxidative burst. Catalase-negative organisms produce sufficient hydrogen peroxide to facilitate their own killing by CGD neutrophils via the myeloperoxidase pathway. Catalase-producing organisms such as staphylococci, *Serratia*, *Nocardia*, and *Aspergillus*, however, scavenge hydrogen peroxide. These organisms therefore cannot be killed effectively by neutrophils from patients with CGD, and serious recurrent infections can result.

The most severe intrinsic neutrophil defects occur in the Chédiak-Higashi syndrome. The neutrophils of patients with this syndrome have giant and abnormal granules and also exhibit defective microtubule assembly. These defects together cause impaired chemotaxis, abnormal phagolysosomal fusion, and delayed bacterial killing, predisposing patients to recurrent infections. Other phenotypic abnormalities often associated with this rare syndrome include partial albinism, depigmentation of the iris, peripheral neuropathies, and nystagmus.

Neutropenia

Neutropenia is one of the most common and most important risk factors for serious infection in the compromised host. Other alterations in host defense mechanisms frequently coexist with neutropenia, and these additional alterations often further increase the risk of infection. Most data regarding the incidence of fever and risk of infection associated with neutropenia come from studies of patients with leukemia undergoing cytotoxic chemotherapy. As the neutrophil count falls below 500/mcL, an exponential increase occurs in both the frequency and severity of associated infections. Neutrophil counts between 100 and 500/mcL are frequently associated with infections, whereas with neutrophil counts below 100/mcL, fever and some form of infection are almost universal. The duration of neutropenia is also important in determining the level of risk and types of infections in individual patients.

Chemotherapy-associated neutropenia in acute leukemia is usually profound and sustained and occurs in conjunction with other predisposing factors for infection such as mucositis and the presence of indwelling central venous catheters. These patients therefore become susceptible to organisms that are ubiquitous in the environment and are part of the normal flora (Table 109-4). In contrast, in patients with chronic or cyclic neutropenias, the susceptibility to infection varies inversely with the monocyte count because these cells help substitute for some of the antibacterial capacity of the missing neutrophils. This type of neutropenia may be either hereditary (often resulting from neutrophil elastase

mutations) or acquired. In contrast to patients with acute neutropenia caused by chemotherapy, patients with chronic or cyclic neutropenia rarely have life-threatening infection or bacteremia. Common manifestations are recurrent digital and oral ulcers, perineal infections, and relatively low baseline neutrophil counts with more profoundly low nadirs.

Diagnostic Problems in the Compromised Host

PULMONARY INFILTRATES

Pneumonia and bloodstream infections represent the most serious forms of infection for most immunocompromised patients. The immunocompromised patient with pulmonary infiltrates presents a particularly difficult diagnostic problem. Pulmonary infiltrates can represent infection, extension of underlying tumor, a complication of chemotherapy, fluid overload, pulmonary infarction, hemorrhage, or any combination of these conditions. Because of the seriousness of the condition and the variety of possible causes, obtaining a specific diagnosis is essential. Unfortunately, noninvasive serodiagnostic tests are rarely helpful in this setting, and accurate diagnosis can often be made only by direct sampling and examination of lung tissue by bronchoalveolar lavage and/or biopsy.

The clinical setting and radiographic appearance of pulmonary infiltrates will influence the decision about whether to proceed with lung biopsy. For example, in patients with leukemia, parenchymal infiltrates occurring before or within 3 days of initiation of chemotherapy are usually caused by infection from common bacterial pathogens. Major efforts should be directed first at collecting adequate sputum samples to stain and culture for bacterial, mycobacterial, and fungal pathogens. The course of pneumonitis after initial antibiotic therapy indicates whether to proceed with lung

biopsy. Pulmonary infiltrates after chemotherapy and prolonged neutropenia are frequently caused by *Aspergillus* species or mucormycoses.

In contrast, diffuse infiltrates occurring *after* treatment of leukemia are suggestive of infection by opportunistic microorganisms. *Pneumocystis jirovecii* (see Web Fig. 109-6), for example, is an important preventable, treatable cause of diffuse infiltrates and occurs most often after treatment of acute lymphocytic leukemia or in patients with an acquired deficiency of cell-mediated immunity (see Chapter 108). In these settings the diagnosis should be established by examination of induced sputum, by bronchoalveolar lavage, or by transbronchial biopsy. If these diagnostic approaches are not helpful, empirical therapy with trimethoprim-sulfamethoxazole may be initiated. It is important to note that the clinical presentation of *Pneumocystis* pneumonia (PCP) frequently differs in HIV-negative immunocompromised hosts compared with HIV-infected individuals. PCP in HIV-negative patients is often more acute, more severe, and more frequently associated with other concurrent pathogens. In addition, the diagnostic sensitivity of bronchoalveolar lavage for detecting *Pneumocystis* organisms is considerably reduced in HIV-negative patients, and lung biopsy may be needed to obtain the correct diagnosis.

The indication and timing for lung biopsy must be individualized. Delay in proceeding with biopsy may reduce the chances of favorably affecting the outcome of the infection, even if the biopsy shows a potentially treatable disease. Thrombocytopenia and/or coagulopathies frequently coexist in compromised patients with pulmonary infiltrates and need to be corrected to minimize bleeding risk of a biopsy. If a decision has been made to perform a biopsy, several technical options are available. Transbronchial biopsy by fiberoptic bronchoscopy will often provide adequate tissue samples for diagnosis, particularly in the evaluation of diffuse pulmonary lesions. Open-lung biopsy has an additional yield of 50% to 75% in the patient with a nondiagnostic transbronchial biopsy and should be performed without delay if progression of the patient's illness mandates immediate diagnosis. Early treatment of most pulmonary infections in immunocompromised hosts, even aspergillosis (Fig. 109-1), can be associated with an initially favorable outcome.

DISSEMINATED MYCOSES

Disseminated mycoses represent another major diagnostic problem in the immunocompromised host. Fungal infections, particularly in the lungs, are found postmortem in more than one half of patients with leukemia or lymphoma; usually the nature of the infection has not been established antemortem. Culture of a saprophytic organism such as *Candida* from superficial sites does not establish pathogenicity. Even in patients with widespread infection, detectable fungemia may be a late event.

How, then, can the diagnosis of fungal infection be established early, at a time when the infection is potentially curable? Lung biopsy (either transbronchial or open) can be definitive. The physician should search for superficial lesions accessible to scraping, aspiration, or biopsy (Fig. 109-2). Dissemination of *Candida tropicalis* frequently causes hyperpigmented macular or pustular skin lesions that show the organisms within blood vessel walls on punch skin biopsy.

Figure 109-1 Fruiting head of *Aspergillus fumigatus* on a lung biopsy (see Web Fig. 109-1). Aspergillosis usually causes an expanding perihilar pulmonary infiltrate with a characteristic halo sign noted on a computed tomographic scan of the lungs. Prompt institution of potent antifungal therapy is essential in attempting to achieve a good clinical response.

Figure 109-2 Skin lesion in a 76-year-old woman treated with corticosteroids and cytotoxic drugs for chronic lymphocytic leukemia and exhibiting nodular pulmonary infiltrates and lymphocytic meningitis. Fluid expressed from the lesion contained encapsulated yeast seen on India ink preparation and yielded *Cryptococcus neoformans* on culture (see Web Fig. 109-5).

Distinct skin lesions may also represent a disseminated mold infection such as *Fusarium* or *Aspergillus* species that may be diagnosed by biopsy. Hepatosplenic candidiasis is most frequently encountered in patients with fever after recovery from neutropenia. The presence of bull's-eye lesions on computed tomographic scans of the liver and spleen suggests hepatosplenic candidiasis and may be confirmed by biopsy. Cryptococcal polysaccharide antigen is usually present in the serum and/or cerebrospinal fluid of the patient with disseminated cryptococcosis (see Web Fig. 109-5). Specific antigen testing of serum and urine can also be performed for the endemic mycoses histoplasmosis, coccidioidomycosis, and blastomycosis for the diagnosis of both localized and disseminated infection. *Histoplasma* urine antigen testing, in particular, is a sensitive predictor of disseminated histoplasmosis. An assay for β -D-glucan, a cell wall component of many fungi, may become a valuable tool in the diagnosis of

invasive fungal infections. This test appears to be useful in both exclusion of invasive fungal infections and early diagnosis in immunocompromised hosts, although it is nonspecific for type of fungal infection. In general, serologic diagnosis by antibody testing is rarely useful during a patient's initial clinical presentation.

Acute invasive pulmonary aspergillosis occurs most often in patients with prolonged, profound neutropenia who complain of fever and pleuritic chest pain during or after broad-spectrum antibacterial therapy. Accurate diagnosis of invasive disease caused by *Aspergillus* species usually requires examination of affected tissue obtained from a biopsy (see Web Fig. 109-1). The diagnosis of pneumonia caused by *Aspergillus*, or other molds, is also strongly suggested by the appearance of a distinctive halo sign visible on a computed tomographic scan of the lungs in at-risk patients.

In the absence of a definitive diagnosis, empirical use of antifungal drugs is generally indicated in the immunocompromised host with a moderate to high clinical suggestion of invasive fungal disease (e.g., in the febrile patient with neutropenia for more than 3 to 5 days despite empirical broad-spectrum antibacterial therapy). Several new antifungal agents have become available over the last few years (e.g., the echinocandins and newer azoles with broader activity such as posaconazole) and have widened our choices for immunocompromised patients with fungal infection. Current efforts focus on improved strategies for prophylaxis (see later discussion), as well as studying potential synergistic combinations of antifungal agents.

Prevention and Treatment of Infections in the Patient with Neutropenia

PREVENTION

Acute bacterial infections and sepsis caused by organisms comprising the gut flora occur frequently in patients with neutropenia and may have fever as their sole clinical sign. Prophylactic nonabsorbable antibiotics and protective isolation have generally failed to prevent such infection. Certain antibiotics, given prophylactically, may decrease the number of infections and bacteremic episodes in some patients with neutropenia. Prophylactic trimethoprim-sulfamethoxazole also decreases the risk of pneumonia caused by *P. jirovecii* (see Chapter 108). However, the bone marrow toxicity of this drug and selection of resistant organisms decrease the suitability for widespread prophylactic use in patients with neutropenia. Quinolones, such as ciprofloxacin, may be equally effective in preventing bacterial infections and generally have reduced toxicity. Quinolones have no activity against *P. jirovecii*, however, and have also been associated with an increased risk of severe streptococcal (including *Streptococcus viridans* group) infection in some patients. Prophylactic administration of agents to prevent systemic fungal infections is not routine for all patients with neutropenia but is generally used for patients with hematologic malignancies or those undergoing bone marrow or stem cell transplantation. Prophylactic antivirals such as acyclovir or

valacyclovir are often given to prevent reactivation of latent viral infections such as herpes simplex virus and varicella-zoster virus in patients with neutropenia.

Adherence to strict hand-washing procedures by all hospital personnel remains the single best approach to preventing infection in patients with neutropenia.

TREATMENT

Empirical antibiotic therapy is indicated in febrile patients with granulocytopenia because at least two thirds have an underlying infection. Selection of two drugs with activity against gram-negative enteric bacilli and *Pseudomonas* is usually necessary (e.g., use of an antipseudomonal β -lactam and an aminoglycoside). Initial empirical therapy for staphylococci is indicated when clinical concern exists about infections of vascular catheters or of skin or soft tissue. Methicillin-resistant *Staphylococcus aureus* (MRSA) has become a major pathogen in this clinical situation. Antibiotic coverage for MRSA, though, is generally reserved for documented infection, given that empirical addition of an agent such as vancomycin does not affect short-term outcomes in neutropenic febrile patients without a documented source of infection. However, an empirical regimen containing vancomycin should be considered in patients with known MRSA colonization, those with positive blood cultures for gram-positive bacteria before further identification and susceptibility testing, those with evidence of central venous catheter infection, or those with hemodynamic instability. Despite the early use of empirical antibiotics, the clinical outcome of patients with both neutropenia and bacterial infections is poor unless the initial neutrophil count exceeds 500/mcL, the count rises during treatment, or the pathogen is a gram-positive organism. Adjunctive treatment with granulocyte colony-stimulating factors may result in shorter

duration of neutropenia and fewer infectious complications in certain situations. Use of these biologics may also be beneficial in cases of documented or suggested invasive fungal disease (e.g., *Aspergillus* pneumonia) or refractory infection with gram-negative bacilli.

The appropriate duration of antimicrobial therapy of febrile patients with neutropenia is uncertain. If a specific diagnosis is made, narrowing antimicrobial coverage is sometimes appropriate to target the isolated organism, assuming that the neutrophil counts recover. If no causative agent is identified, many physicians continue to administer the empirical antibiotic regimen until the neutropenia resolves. The empirical addition of antifungal therapy is indicated in the patient with neutropenia who remains febrile for at least 3 days despite broad-spectrum antibacterial therapy. In this setting, the best approach is often to continue broad-spectrum antibiotics for the duration of the neutropenia unless the cause of the patient's fever can be clearly defined. In some centers, certain relatively low-risk patients with neutropenia and fever (e.g., highly dependable individuals with absolute neutrophil counts of 500/mcL) are initially managed at home using outpatient intravenous or oral combinations of highly active antibiotics.

With ever-increasing numbers of patients receiving a variety of potent and novel immunosuppressive agents, the number and variety of infections occurring in susceptible individuals can only be expected to increase. In addition to newly recognized pathogenic organisms, increases in antimicrobial resistance among known pathogens will also likely be observed. Newer strategies for dealing with infections in immunocompromised hosts include expanded use of targeted forms of prophylaxis, development of molecular assays permitting diagnosis at an earlier stage, and the evolution of combination therapies for particularly resistant organisms.

Prospectus for the Future

- The increasing use of immunosuppressive drugs with novel modes of action will predispose patients to infections by additional opportunistic pathogens.
- Increased use of prophylactic antimicrobials will lead to parallel increases in antibiotic resistance, increasing the demand for novel antimicrobial agents.

Infectious Diseases of Travelers: Protozoal and Helminthic Infections

Jessica K. Fairley, Keith B. Armitage, and Robert A. Salata

Medical advice for overseas travelers, some common clinical symptoms that may develop on their return, and the diagnosis and treatment of common parasitic diseases endemic in the United States and abroad are reviewed in this chapter.

Preparation of Travelers

More than 12 million Americans travel to developing countries each year. Major increases in international travel and the resurgence of malaria, dengue fever, and other infectious diseases worldwide bring the issues of prevention and management of health problems in travelers into the office of every physician.

Risks associated with international travel are dependent on the destination, duration of the trip, underlying health and age of the traveler, and activities while abroad. In general, destinations within the industrialized world require no specific health precautions. In contrast, travelers to developing areas, especially the tropics, can occasionally be exposed to life-threatening infections. Major issues to be addressed in the pretravel period include required and recommended immunizations, malaria prophylaxis, traveler's diarrhea, and other problems that can be avoided or prevented. Information about health risks in specific geographic areas, updated weekly, can be obtained from the Centers for Disease Control and Prevention (CDC) through its publications or by calling the International Travelers' Hotline (1-877-394-8747; website, www.cdc.gov/travel).

IMMUNIZATIONS

Only yellow fever vaccination may be required by law for international travel. Both polio and meningococcal

meningitis vaccinations may be required during outbreak situations, and the meningococcal vaccine is required for religious pilgrimages (Haji) to Saudi Arabia. Although some immunizations are not generally considered *travel* immunizations, many Americans have allowed routine diphtheria-tetanus immunizations to lapse or may not have been fully immunized against measles and polio. Finally, other immunizations are often strongly recommended, depending on the type and duration of travel. With a few exceptions, vaccines can be given simultaneously. Before immunization, a thorough history should be obtained to determine allergies to eggs or chick embryo cells. Pregnant women and individuals immunocompromised by human immunodeficiency virus (HIV), malignancy, or chemotherapy pose specific and important challenges; most live virus vaccines are contraindicated in these patients.

Hepatitis A

Hepatitis A is a major risk for travelers to areas of poor sanitation, affecting an estimated 1 in 500 to 1000 travelers per 2- to 3-week trip in some areas. Therefore, hepatitis A is the most frequent and important vaccine-preventable infection for travelers. Hepatitis A vaccine should be given at least 2 weeks before departure but remains effective if given up until the time of travel. A single dose provides protection for 1 to 2 years; a booster 6 to 18 months later is required for long-lasting immunity (>15 years).

Yellow Fever

Yellow fever is a live, attenuated virus vaccine that is highly effective and recommended for persons traveling to areas in South America and Africa where yellow fever is endemic. Vaccination is generally safe and lasts for 10 years, but it must be given at designated vaccination centers. Severe adverse events are rare and include yellow fever vaccine-

associated viscerotropic and neurologic disease, both more common in those with thymus disease. Benefits of the vaccine still far outweigh this small risk for most. However, because the adverse events occur more commonly in people over 60 years old, a careful assessment of risks and benefits for these travelers should be done before vaccination.

Cholera

Cholera is endemic in parts of Asia and Africa and has returned to South and Central America, where it is a major concern to travelers. The currently available vaccine is not highly effective and is not routinely recommended for travel into endemic areas. Health education on likely sources of transmission is far more effective in preventing disease than is vaccination.

Measles

Up to 20% of first-year college students have no serologic evidence of prior measles infection or immunization and must be presumed to be susceptible. Individuals born after 1956 with no physician-documented record of immunization are at greatest risk for measles. In addition, a single immunization with measles vaccine at 15 months of age may permit breakthrough infection as a young adult. A second measles vaccination after age 5 is now recommended; international travelers born after 1956 who have not received a booster after early childhood should have a one-time booster.

Diphtheria-Tetanus

Tetanus is a ubiquitous problem and is most prevalent in tropical countries. A booster within the previous 5 years is recommended. This precaution eliminates the need for a tetanus booster if the traveler sustains a tetanus-prone injury overseas. This recommendation is made primarily because of the uncertainty of obtaining sterile, disposable needles in many overseas locations. Given the resurgence of diphtheria in countries of the former Soviet Union and the occurrence of disease in travelers to these areas, diphtheria toxoid should be co-administered with tetanus toxoid. The current recommended booster for adults includes the acellular pertussis component as well.

Polio

Polio remains endemic in some regions of Asia and Africa, and small, geographically restricted, vaccine-associated outbreaks have occurred in the Western Hemisphere. Most young adults were immunized with at least four doses of trivalent oral poliovirus vaccine (OPV) before the elimination of this oral vaccine for use in all age groups in the United States. Many adults (>18 years of age) cannot remember, however, whether they received OPV; such individuals should be given inactivated poliovirus vaccine.

Meningococcal Meningitis

Meningococcal meningitis is a worldwide disease, but cases in international travelers are infrequent except with prolonged contact with the local population. Vaccination with the quadrivalent polysaccharide vaccine (A, C, Y, and W-135) is recommended for travelers to northern India, Nepal, and Saudi Arabia during the Hajj; certain parts of sub-Saharan Africa; and other locations for which travel advisories have been issued (www.cdc.gov/travel/). The

newer quadrivalent A/C/Y/W-135 meningococcal protein-conjugated vaccine was licensed in the United States in 2005 for preferred use in persons 11 to 55 years of age.

Typhoid

American international travelers are at greatest risk for contracting typhoid in the Indian subcontinent, Central America, western South America, and sub-Saharan Africa. Vaccination is recommended for travel to endemic areas where exposure to contaminated food and water is likely. Vaccination is also strongly indicated for travelers with achlorhydria, immunosuppression, or sickle cell anemia and for those taking broad-spectrum antibiotics. Both an oral vaccine (four enteric-coated capsules given over 7 days) and an injectable vaccine (one dose) are available and are essentially equivalent in effectiveness, which ranges from 50% to 70%.

Influenza

Although influenza is not necessarily considered a travel-related illness, the influenza vaccine should be considered in the panel of vaccines offered to the traveler. Influenza seasons can occur at different times of the year than in North America. Therefore, if a traveler is planning a trip to the Southern Hemisphere from April to September or to the tropics at any time of the year, or is traveling in a group, vaccination should be offered if not done already in the fall or winter. Attention should be paid to vaccinating before the end of spring because vaccine supplies may be limited after that time. If a patient cannot be vaccinated or if there is concern regarding exposure to avian influenza, a course of the antiviral medication oseltamivir can be given to take at the first sign of a flulike illness. However, there are limited data to date on the effectiveness of oseltamivir for human cases of avian influenza, and resistance to neuraminidases in strains of seasonal influenza is increasing worldwide.

Other Vaccines

Some travelers, including missionaries, physicians, and anthropologists, need special consideration. These individuals live for prolonged periods in developing countries or are at special risk for contracting certain highly contagious diseases. Consideration should be given to immunization with hepatitis B, Japanese B encephalitis, plague, and rabies vaccines. In general, such travelers should be referred to a qualified travelers' clinic.

MALARIA PROPHYLAXIS

Malaria infection is associated with significant morbidity and mortality, particularly if caused by *Plasmodium falciparum*, especially in nonimmune travelers. Appropriate malaria prophylaxis should be prescribed and strictly adhered to. Malaria prophylaxis is a major problem for international travelers because of the high and increasing prevalence of drug resistance by the parasite. The need for, as well as the type of, prophylaxis is dependent on the exact itinerary within a given country because transmission risk is quite regional. Recommended chemoprophylactic regimens have changed frequently within the last few years. In general, travelers to areas where chloroquine-sensitive *P. falciparum* strains are exclusively found (parts of Central America, the

Caribbean, North Africa, and the Middle East) should take chloroquine phosphate (300-mg base or 500-mg salt) weekly starting 1 week before, continuing during, and for 4 weeks after leaving areas in which malaria is endemic. Travelers to areas where chloroquine-resistant *P. falciparum* is common may take mefloquine (Lariam), atovaquone-proguanil (Malarone), or doxycycline. These areas currently include Southeast Asia, sub-Saharan Africa, South America, and South Asia. Mefloquine, 250 mg/wk starting a week before travel, continuing during travel, and for 4 weeks after, is effective and convenient but may be associated with minor neurologic side effects (dizziness and vivid dreams) and, rarely, significant neuropsychiatric side effects. Some recommend starting mefloquine up to 2 to 4 weeks before travel to determine if there are any intolerable side effects. Mefloquine is not completely effective in Myanmar, rural Thailand, or some parts of East Africa, where resistance is a growing problem. Atovaquone-proguanil and doxycycline are effective in Southeast Asia and may be used in other areas of chloroquine resistance. Atovaquone-proguanil is well tolerated but must be taken every day and is relatively expensive. Doxycycline is inexpensive but must also be taken every day and is associated with photosensitivity and occasionally vaginal candidiasis. Although not yet approved by the U.S. Food and Drug Administration (FDA) for primary prophylaxis, primaquine has been used more frequently in travel to areas of higher *Plasmodium vivax* or *Plasmodium ovale* infections and has the advantage of both preventing acute infection from all malaria parasites, as well as preventing the later recurrent infections of *P. vivax* and *P. ovale*. However, it cannot be used in those with G6PD deficiency, and this needs to be screened for before administration. Although the sickle cell trait provides significant protection from death caused by *P. falciparum* malaria, this protection is not absolute and does not alter recommendations for prophylaxis. Emphasis must also be given to the use of mosquito netting, screens, and insect repellents with at least 30% DEET, as well as to the prompt diagnosis and treatment of any febrile episodes (temperature >102° F [39° C]) in malaria-endemic areas.

TRAVELER'S DIARRHEA

Between 20% and 50% of individuals traveling to developing countries will develop diarrhea during or shortly after their trip. Bacterial infections are most common, with enterotoxigenic *Escherichia coli* topping the list. Viruses and parasites can also be causes. The average duration of an episode of traveler's diarrhea is 3 to 6 days. Approximately 10% of episodes last longer than 1 week. The diarrhea may be accompanied by abdominal cramping, nausea, headache, low-grade fever, vomiting, or bloating. Fewer than 5% of persons have fever greater than 101° F (38° C), bloody stools, or both. Travelers with these symptoms may not have simple traveler's diarrhea and should see a physician at once (see Chapter 103).

Diarrheal illness (including cholera) can be avoided through precautions with food and beverages. All water should be presumed to be unsafe. Salads are often contaminated by protozoal cysts and, along with street vendor foods, are the most dangerous foods encountered by most travelers. Food should be well cooked, including meat, seafood, and vegetables. Dairy products should be avoided.

Diphenoxylate (Lomotil) and loperamide (Imodium) may give symptomatic relief of diarrhea but should be avoided if the diarrhea is severe, fever exists, or blood is present in the stool. First-line treatment includes one of the newer fluoroquinolones, which can be taken orally for 3 days to reduce the duration of symptoms and is effective against a wide variety of bacterial pathogens, including most *Shigella* and *Salmonella* species. In some countries, such as Thailand and Nepal, fluoroquinolone resistance, especially among *Campylobacter* species, has been on the rise; azithromycin is an alternative in these situations (CDC). Prophylactic antibiotics are not generally recommended. Bismuth subsalicylate (Pepto-Bismol) can be used as a prophylactic measure (two tablets 4 times a day) or used to treat acute bouts of diarrhea (1 oz every 30 minutes for eight doses).

AVIAN INFLUENZA

The highly pathogenic H5N1 strain of avian influenza is an emerging concern and public health threat in many Middle East and Southeast Asian countries. Although the avian influenza A viruses remain primarily avian pathogens, cases of human infection have occurred with direct contact with infected poultry. From 2003 to 2008, almost 400 human cases were reported, with a case fatality rate of over 60%. Although the majority of transmission has been from poultry to humans, there have been isolated cases of possible human to human transmission among close contacts. Signs and symptoms can range from conjunctivitis to influenza-like symptoms (fever, myalgias, sore throat) to severe pneumonia and respiratory failure. Occasionally vomiting, diarrhea, and neurologic symptoms can also be present. First-line treatment or prophylaxis for avian influenza is the antiviral medication oseltamivir, as the H5N1 virus is resistant to amantadine and rimantadine. Preventive measures for travelers include avoiding contact with live birds (poultry or wild), not visiting live animal markets, eating properly cooked food, and washing hands frequently. The routine influenza vaccine is not protective for avian influenza, but travel to areas endemic for avian influenza provides an ideal opportunity to discuss immunization against seasonal influenza when appropriate. Vaccination for seasonal influenza should decrease the risk for developing a febrile illness resulting from influenza A and B, which could be confused with avian influenza.

GENERAL HEALTH INFORMATION

Other potentially dangerous activities overseas include exposure to dogs and cats (rabies), swimming in fresh water (schistosomiasis or leptospirosis), walking barefoot (hookworm or strongyloidiasis), and insect bites. In addition to malaria, many diseases, including dengue, sleeping sickness, and yellow fever, are transmitted by insect bites, and avoidance measures should be stressed when applicable. Travelers should also be reminded to use seat belts.

SPECIAL PROBLEMS

Pregnant Women

Live virus vaccines are contraindicated in women during pregnancy, which greatly complicates pretravel prepara-

tions. Chloroquine probably can be used safely. Travel to areas of chloroquine-resistant malaria should be strongly discouraged. If a pregnant woman must travel, mefloquine has been used more frequently in pregnancy and appears to be safe, although data overall, and especially during the first trimester, are lacking. Ideally, if travel is to be undertaken at all, it should be postponed to the second trimester. No drug regimen to prevent or treat chloroquine-resistant malaria is known to be completely safe in pregnant women, and malaria during pregnancy is a medical emergency for both the mother and her fetus. If a pregnant woman must travel, her care should be managed by a travel clinic with experience in this area.

Acquired Immunodeficiency Syndrome

Many countries bar entry to patients with acquired immunodeficiency syndrome (AIDS). As of the fall of 2008, the United States ban was lifted. Several countries require HIV serologic testing for all travelers applying for more than a 3-month visa, which requires official documentation well in advance of travel. Patients with HIV infection need special preparation before travel to developing countries because of their increased susceptibility to certain illnesses (e.g., pneumococcal infection, tuberculosis).

Most international travelers are concerned about the risk of acquiring HIV infection while abroad. Most concerns center on untested blood or nonsterile needles, which might be used in an emergency. Issues of HIV infection and other sexually transmitted diseases should be discussed, especially with young, sexually active adults.

Returning Traveler Fever

With the exception of skin testing for tuberculosis, asymptomatic returning travelers generally do not need screening tests. The clinical problems that most often arise in travelers soon after return are fever and diarrhea, whereas eosinophilia is the most common cause for later referral. Fever is most important because delay in the diagnosis of *P. falciparum* malaria is often fatal. Fever should always prompt consideration of malaria until proved otherwise in travelers returning from countries where malaria is endemic, even if they are still taking prophylactic drugs. Determining the malaria species with a blood film is important because this finding affects therapy. Chloroquine-sensitive *P. falciparum* is treated with 1 g of chloroquine given orally, followed by 500 mg at 6, 24, and 48 hours. For *P. vivax* and *P. ovale* (also generally chloroquine sensitive, although some resistance is emerging in certain areas), this regimen is followed by primaquine daily for 14 days to eradicate latent hepatic forms. Resistant *P. falciparum* is treated with atovaquone-proguanil, four full-strength pills a day for 3 days; or quinine sulfate, 650 mg given orally every 8 hours for 3 days, plus doxycycline, 100 mg orally twice daily for 7 days. Intravenous quinidine is used in patients with severe malaria. Artemisinin compounds are used in many parts of the world to treat chloroquine-resistant malaria but may be associated with a high rate of relapse. All patients with possible resistant malaria infection should be hospitalized, and if intravenous quinidine is warranted, than hospitalization in the intensive care unit with close monitoring of the QTc interval is necessary. If quinidine is not available or contraindicated,

parenteral artesunate is available as an investigational drug through the CDC. If fever is not caused by malaria, then dengue fever (the second most common cause of febrile illness in travelers after malaria), tuberculosis, typhoid fever, amebic liver abscess, leptospirosis, and rickettsial diseases, among other conditions, should be considered. Chikungunya virus, an arbovirus transmitted by mosquitoes, is an emerging pathogen related to several recent outbreaks and can also cause unexplained fever. Joint pains are common and can lead to chronic arthralgias. Evaluation of the febrile returned traveler should take into account the travel itinerary, exposures during the trip, immunization status, and host factors, such as immunosuppression.

Gastrointestinal Symptoms

Persistent traveler's diarrhea that is unresponsive to empiric antibiotics is often caused by *Giardia lamblia*, transmitted by contaminated water or food (fecal-oral route). Three stool specimens for ova and parasites and a stool culture are warranted (**Web Fig. 110-1**). Unfortunately, *G. lamblia* may be missed in up to one third of patients even after this workup. Assessment of stool *Giardia* antigen by enzyme-linked immunosorbent assay is more sensitive than culture. If clinical suggestion is high, an empiric course of metronidazole (500 mg orally three times a day for 7 days) is usually justified. Alternatives include tinidazole administered in one dose, or a 3-day course of nitazoxanide. Antibiotic-resistant bacteria, amebiasis, temporary lactose intolerance, bacterial overgrowth, and tropical sprue should also be considered.

Eosinophilia

Eosinophilia, often accompanied by persistent gastrointestinal symptoms, in a returning traveler usually manifests weeks or months after travel. It is usually caused by one of a wide variety of helminth infections. A stool specimen for ova and parasites is indicated but may be negative during the tissue-migrating phase of many intestinal worms or in tissue nematode infections, such as filariasis or onchocerciasis. Management of the more common parasitic infections encountered in travelers is included in the next section.

Respiratory Symptoms

Respiratory illnesses are common complaints in the returned traveler. Air travel has made the transmission and movement of respiratory microbes even easier, and the incubation period of many infections often exceeds travel time. Although many symptoms can be caused by common respiratory viruses not necessarily particular to the recent travel, there are some infections to consider. Respiratory symptoms, especially when accompanied by fever, may be indicative of influenza or possibly avian influenza if severe and associated with exposure to birds or poultry in a known endemic area. A new or undiagnosed pathogen, as was seen in the severe acute respiratory syndrome (SARS) outbreak, should also be considered in the differential diagnosis in severe, acute cases. Although the usual presentation is more chronic, tuberculosis is a consideration as well. Other infections that can cause respiratory symptoms include histoplasmosis, tularemia, plague, viral hemorrhagic fevers, coccidiomycosis, and Q fever. Helminth infections, such as schistosomiasis, strongyloidiasis, and ascariasis, can occasionally also cause pulmonary infections.

Rash

Skin lesions with or without fever can be a common complaint in the returning traveler. Overall, insect bites and cutaneous larva migrans, erythematous serpiginous pruritic lesions caused by migration of larvae, are the most common causes of skin lesions, with bacterial skin infections being the most common cause in those returning from sub-Saharan Africa. A black eschar in a patient returning from southern Africa is typical of African tick bite fever, a tick-borne rickettsial disease caused by *Rickettsia africae*. Ulcerative lesions can be indicative of cutaneous leishmaniasis (see later), and purpuric or petechial rashes may be signs of more serious illness such as viral hemorrhagic fevers, rickettsial diseases, and invasive meningococcal diseases, among others. Schistosomal dermatitis, which occurs after swimming in fresh water, is characterized by a transient maculopapular, pruritic eruption.

Protozoal and Helminthic Infections

PROTOZOAL INFECTIONS IN THE UNITED STATES

More than two billion people worldwide are infected with helminths. The incidence of protozoan parasitic infections is increasing in part because of the emergence of antimicrobial resistance (e.g., malaria) and an increasing number of susceptible hosts, especially those with HIV infection. Protozoal infections in the United States occur more frequently in immunocompromised hosts than in the general population (Table 110-1) (see Chapter 109). Babesiosis is very severe in asplenic individuals, and *Toxoplasma* encephalitis primarily affects patients with AIDS.

GIARDIASIS AND AMEBIASIS

Giardiasis, although endemic to the United States, is a common cause of persistent (longer than 2 to 3 weeks), nonbloody diarrhea in returning travelers. *G. lamblia* is prevalent throughout much of the developing world. Latin America is the most common site of *Giardia* acquisition by North American travelers. Men who have sex with men also have a high prevalence of infection because of specific sexual practices. Persons who work in day-care centers are also at increased risk for giardiasis because of its relatively high prevalence in young children. The diagnosis and treatment are described in the earlier section on returning travelers.

As with *Giardia*, *Entamoeba histolytica* is transmitted by the fecal-oral route; the vast majority of infected individuals are asymptomatic. When *E. histolytica* causes acute illness, it is generally identified by bloody diarrhea. In the United States, amebic dysentery is occasionally misdiagnosed as ulcerative colitis or Crohn disease, and the administration of corticosteroids may cause significant worsening and toxic megacolon. Stool examination for ova and parasites is generally diagnostic, but sigmoidoscopy may be required. Serologic testing is useful to exclude amebiasis in individuals from industrialized countries because the background antibody positivity is quite low. Treatment

involves a 5- to 10-day course of metronidazole. Extraintestinal amebiasis generally manifests as hepatic liver abscess (see Chapter 102).

PROTOZOAL INFECTIONS COMMON IN TRAVELERS AND IMMIGRANTS

Leishmaniasis

Cutaneous and mucocutaneous leishmaniasis, transmitted by the sandfly (see Table 110-1), should be considered in any traveler returning from the Middle East or endemic areas of Latin America who has a persistent skin or mucous membrane lesion. Diagnosis is made by tissue biopsy. Visceral leishmaniasis should be anticipated in immigrants with fever and splenomegaly. Diagnosis is made by bone marrow biopsy and culture. Cutaneous leishmaniasis is generally self-limited. Other types are treated with sodium stibogluconate (Pentostam), 20 mg/kg/day for up to 20 days. Amphotericin B, paromomycin (for cutaneous infection), and pentamidine have been used in resistant cases.

African Trypanosomiasis

African trypanosomiasis is a protozoal infection, endemic in Africa, which causes sleeping sickness. Rarely imported into developed countries, it should be presumed in systemically ill patients from Africa who exhibit fever, headache, and development of encephalitic and neurologic signs and symptoms (see Table 110-1). Many patients will remember a painful chancre at the site of an insect bite (Web Fig. 110-2). Diagnosis is made by direct examination of the blood, lymph aspirate, or cerebrospinal fluid (Web Figs. 110-3 and 110-4). Treatment is highly toxic and should be supervised by an expert in the field.

Chagas Disease (American Trypanosomiasis)

Trypanosoma cruzi is the most common cause of heart failure in Brazil. Transmission is through contact with feces from infected reduviid bugs (kissing bugs) (Web Fig. 110-5), and cases of transfusion-associated *T. cruzi* infection have been recognized in the United States (see Table 110-1). Most patients are asymptomatic for decades and then exhibit cardiomegaly, megaesophagus, or megacolon. Diagnosis of acute disease is made by direct examination of the blood (Web Fig. 110-6). Serologic testing is also used but requires two to three different assays per patient to maximize sensitivity and specificity. As of 2007, the U.S. blood supply is screened for *T. cruzi* infection. Early diagnosis is critical because patients may respond to nitrofurans or nitroimidazole derivatives, available through the CDC. Treatment of chronic Chagas disease is largely supportive.

HELMINTHIC INFECTIONS COMMON IN THE UNITED STATES

Pinworm

Enterobiasis is common in the United States (Table 110-2), particularly among children. Perianal pruritus is the major clinical presentation. Infection is maintained by fecal-oral contamination. Diagnosis is made by the application of cellophane tape to the anus and subsequent microscopic examination for ova. Treatment is with mebendazole,

Table 110-1 Protozoal Infections

Protozoan	Setting	Vectors	Diagnosis	Special Considerations	Treatment
Endemic in the United States					
<i>Babesia microti</i>	New England	Ixodid ticks, transfusions	Thick or thin blood smear	Severe disease in asplenic persons	Quinine and clindamycin
<i>Giardia lamblia</i>	Mountain states	Humans, small mammals	Microscopic examination of stool or duodenal fluid	Common in homosexual men, travelers, children in day-care centers	Quinacrine, nitazoxanide, or metronidazole
<i>Toxoplasma gondii</i>	Ubiquitous	Domestic cats, raw meat	Clinical; serologic confirmation	Pregnant women, immunosuppressed host (AIDS)	Pyrimethamine and sulfadiazine
<i>Entamoeba histolytica</i>	Southeast	Human	Microscopic examination of stool or touch preparation from ulcer	Common in homosexual men, travelers, institutionalized persons	Metronidazole
<i>Cryptosporidium</i> species	Ubiquitous	Human	Acid-fast stain of stool	Severe in immunosuppressed hosts (AIDS)	Nitazoxanide
<i>Trichomonas vaginalis</i>	Ubiquitous	Human	Wet preparation of genital secretions	Common cause of vaginitis	Metronidazole
Primarily Seen in Travelers and Immigrants					
<i>Plasmodium</i> species	Africa, Asia, South America	Anopheles mosquito	Thick and thin blood smears	Consider in returning travelers with fever	Dependent on regional resistance pattern (see text)
<i>Leishmania donovani</i>	Middle East	Sandfly	Tissue biopsy	Consider in immigrants with fever and splenomegaly	Sodium stibogluconate
<i>Trypanosoma</i> species	Africa, South America	Reduviid bugs, transfusion	Direct examination of blood or CSF	Very rare in travelers, transfusion associated	Dependent on species and stage of disease

AIDS, acquired immunodeficiency syndrome; CSF, cerebrospinal fluid.

100 mg given once. In heavy or recurrent infection, treating all family members is advisable.

Other Intestinal Nematodes

Ascaris (giant roundworm), *Ancylostoma duodenale* and *Necator americanus* (hookworm), and *Trichuris* (whipworms), still endemic in the United States, are extremely common in immigrants and are ubiquitous in the developing world, with co-infection with other helminths being very common (see Table 110-2). Most individuals are asymptomatic. Ascariasis and hookworm may cause transient pulmonary infiltrates with eosinophilia during the tissue migratory phase of infection. Heavy *Ascaris* infection may cause intestinal, biliary, or pancreatic obstruction. Hookworm infection can be associated with iron deficiency, and significant anemia in some cases. Diagnosis is made based on stool examination for ova and parasites (Web Figs. 110-7 and 110-8). Each of these worms can be eradicated with appropriate anthelmintic therapy such as mebendazole, 100 mg orally twice daily for 3 days.

HELMINTH INFECTIONS COMMON IN TRAVELERS AND IMMIGRANTS

Strongyloidosis

Strongyloides stercoralis is a common cause of eosinophilia in returning long-term travelers and immigrants, particu-

larly those from Southeast Asia (see Table 110-2). Infection occurs when the parasite penetrates the skin, migrates to the lungs, and then is swallowed. Infection can persist for years; many men who served in the Pacific theater during World War II or in Vietnam still harbor infections. *S. stercoralis* is unique in its ability to complete its life cycle in the host and produce persistent infection. Although usually asymptomatic, infection can cause diarrhea, abdominal pain, and malabsorption. This helminth can cause life-threatening disseminated infection in individuals who are immunosuppressed from cancer chemotherapy, corticosteroids, or HIV infection. Diagnosis may be made by stool examination (Web Fig. 110-9), but this is not a very sensitive technique. Treatment with thiabendazole, 25 mg/kg (maximum 3 g/day) orally twice daily for 2 days, is curative in more than 90% of immunocompetent hosts. Ivermectin (200 mcg/kg/day) may be more effective than thiabendazole and is now the preferred drug for treatment of strongyloidosis, especially for immunocompromised hosts.

Schistosomiasis

Schistosoma mansoni (Africa, South America, and the Caribbean), *Schistosoma japonicum* (the Philippines, China, and Indonesia), and *Schistosoma mekongi* (Cambodia, Laos, and Vietnam) are the most common causes of hepatosplenic enlargement in the world (see Table 110-2). Chronic infection can lead to periportal hepatic fibrosis, obstruction of

Table 110-2 Helminthic Infections

Helminth	Setting	Vectors	Diagnosis	Treatment
Endemic in the United States				
Pinworm (enterobiasis)	Ubiquitous	Human	Direct examination for ova	Mebendazole, albendazole
<i>Ascaris lumbricoides</i>	Southeast	Human	Stool examination for ova	Mebendazole, albendazole
<i>Trichuris trichiura</i>	Southeast	Human	Stool examination for ova	Mebendazole, albendazole
Hookworm	Southeast	Human	Stool examination for ova	Mebendazole, albendazole
Common in Travelers and Immigrants				
<i>Strongyloides stercoralis</i>	Developing world	Human	Stool examination for larvae	Thiabendazole, ivermectin
<i>Schistosoma</i> species	Developing world	Snails	Stool or urine examination for ova	Praziquantel
<i>Wuchereria</i> and <i>Brugia</i> species	Asia, some parts of Africa	Mosquitoes	Nocturnal blood examination	Ivermectin
<i>Onchocerca volvulus</i>	Africa, South and Central Americas	Black flies	Biopsy	Ivermectin
<i>Loa loa</i>	Africa	Tabanid flies	Blood examination, clinical setting	Diethylcarbamazine or Ivermectin
<i>Clonorchis sinensis</i>	Asia	Undercooked fish and snails	Stool examination for ova, radiology	Praziquantel
<i>Echinococcus</i> species	Worldwide	Canines and livestock	Radiology, serology, biopsy	Surgery, supportive therapy
<i>Taenia solium</i> (cysticercosis)	Developing world	Humans, pigs	Radiology, serology	Surgery, albendazole
<i>T. solium</i> , <i>Taenia saginata</i> , <i>Diphyllobothrium latum</i> (tapeworms)	Worldwide	Pigs, bovine, fish	Stool examination for ova or proglottids	Praziquantel

portal blood flow, and bleeding esophageal varices. Patients in the United States are often misdiagnosed as having hepatitis B or alcohol-induced liver disease. A clue to the correct diagnosis is that the liver is enlarged, in contrast to the small, shrunken liver of alcoholic cirrhosis. *Schistosoma haematobium* (Africa) commonly causes hematuria and leads to urinary obstruction. Diagnosis is made by examination of stool or urine for ova and parasites. Praziquantel is the drug of choice.

Lymphatic Filariasis

Wuchereria bancrofti and *Brugia malayi* cause elephantiasis throughout the tropics (see Table 110-2). Patients may exhibit acute lymphadenitis or asymptomatic eosinophilia. Some patients have pulmonary symptoms, infiltrates, and marked eosinophilia (tropical pulmonary eosinophilia). The diagnosis is made by finding microfilariae in blood specimens obtained at midnight. Treatment currently consists of a single oral dose of ivermectin, 100 to 400 mcg/kg.

Loa loa

Eyeworm is endemic in West and Central Africa (see Table 110-2). Patients exhibit transient pruritic subcutaneous swellings, and less commonly joint manifestations and neurologic symptoms. Eosinophilia is universal. In the United States, patients are often misdiagnosed for years as having chronic urticaria. In rare instances the adult worm can be visualized as it crosses the anterior chamber of the patient's eye, giving this worm its common name. Diagnosis

is generally suggested on clinical grounds and is confirmed by biopsy or presence of microfilaria on peripheral blood samples. Loasis can be treated with diethylcarbamazine or ivermectin.

River Blindness

Infection from *Onchocerca volvulus* occurs in West and Central Africa, as well as in South and Central America (see Table 110-2). Although the most severe manifestations occur in the eye, the most common clinical presentation in the United States is recurrent pruritic dermatitis. The diagnosis can be made by direct examination of skin snips for microfilariae; a specific serologic test is also available. Ivermectin, 150 mcg/kg orally for one dose, is the treatment of choice. Ivermectin should be repeated after 3 to 6 months to suppress cutaneous and ocular microfilariae.

Clonorchiasis

The Chinese liver fluke, *Clonorchis sinensis*, is important to diagnose in Asian immigrants. Symptoms may be confused with those of biliary tract disease. If untreated, infection can lead to cholangiocarcinoma. Praziquantel is curative.

Cysticercosis

The invasive larval form of pork tapeworm (*Taenia solium*) is the most common cause of seizures throughout the world, as well as in young adults in Los Angeles, chiefly among immigrants from Mexico. Typically, patients exhibit new onset of seizures or severe headache. Single or multiple ring-

enhancing lesions are the characteristic finding on computed tomographic scan. The diagnosis may be confirmed by an immunoblot assay using peripheral blood. Treatment includes surgical removal when possible, and antiparasitic treatment in some cases, depending on the site of infection and clinical syndrome. Studies are ongoing for optimal treatment. Management must be individualized in each case. Praziquantel (50 mg/kg/day in three divided doses for 15 days) or albendazole (for 30 days, dosed by weight: >60 kg, 400 mg orally twice daily; <60 kg, 15 mg/kg/day in divided doses twice daily) can be curative in some cases but may precipitate focal cerebral edema and seizures by killing other cysticercariae within the central nervous system. An expert should be consulted before treatment.

Intestinal Tapeworms

Three intestinal tapeworms commonly infect humans: *Taenia saginata* from raw beef, *T. solium* from raw pork, and *Diphyllobothrium latum* from raw fish. Most individuals are asymptomatic, but *T. solium* can cause invasive disease (cys-

ticercosis) if humans ingest ova of the adult worm. *D. latum* is associated with vitamin B₁₂ deficiency. All three infections are treated with praziquantel.

Hydatid Disease and Alveolar Cyst Disease

Hydatid disease, caused by the cestode *Echinococcus granulosus*, commonly produces a cystic liver mass in emigrants from sheep-raising parts of the world. Early diagnosis is important because rupture of the cyst can lead to dissemination. Diagnosis is often suggested from the appearance of the cyst (calcified wall and dependent hydatid sand) on abdominal computed tomographic scan. Serologic testing can be helpful but is occasionally negative if the cyst has not leaked. Currently, primary therapy is the surgical removal of the cyst without spillage of its contents, often with pretreatment with albendazole. *Echinococcus multilocularis*, endemic to more northern climates and far less common, causes alveolar cyst disease, a more severe disseminated syndrome with few treatment options and a worse prognosis.

Prospectus for the Future

- Treatment guidelines for malaria will continue to evolve in response to patterns of drug resistance.
- Increased international cooperative efforts, coupled with promising basic research advances, suggest that an effective malaria vaccine may become available over the next decade.
- Significant drug resistance in helminths has not been seen, but surveillance for the development of resistance is gaining support.
- Active research in helminth vaccines is ongoing, with the goal of better control of many of the neglected tropical diseases endemic to the developing world.
- Antimicrobial resistance among enteric pathogens may complicate the management of traveler's diarrhea.
- Changing patterns of established infections and new and emerging pathogens will continue to challenge travelers and health care providers.

Section XVIII

Bioterrorism

111 Bioterrorism – BRADSHER

Bioterrorism

Robert W. Bradsher, Jr.

Bioterrorism returned to the consciousness of physicians in the days after the attacks on the World Trade Center and the Pentagon on September 11, 2001. Before a month had passed, the first case of inhalational anthrax in more than 50 years was diagnosed in the United States when a man was hospitalized and rapidly died in Florida. Soon thereafter, cases of cutaneous and inhalational anthrax were reported in New York; Washington, DC; New Jersey; Virginia; and Connecticut. The nation's attention was galvanized on the topics of anthrax, the U.S. Postal Service, gas masks, and antibiotic stockpiling, as well as other bioterrorism concerns. The Federal Bureau of Investigation reported 7 years later that it had concluded its case on the source of the outbreak with the suicide death of an anthrax researcher who worked at the U.S. Army Medical Research Institute of Infectious Diseases. Since September 11, 2001, bioterrorism has been a major topic of medical concern. The need to review bioterrorism is obvious; health professionals are unfamiliar with disease manifestations from these biologic agents used as weapons because they no longer occur or occur only rarely in nature. Those health care professionals on the frontline will likely be emergency department personnel, primary care physicians, pediatricians, and nurse practitioners rather than experts from the Centers for Disease Control and Prevention (CDC) or even traditional first responders, public health officers, or military officials. The purpose of this chapter is to highlight the recognition of these weapons, which are designed for use in terrorism.

Definition and Categorization

Bioterrorism is the intentional use of biologic agents to cause disease in humans or animals to provoke terror. The agents can cause disease either by specific infection or by action of a toxin produced by microorganisms. Depending on the microbe or toxin, resulting disease may or may not be contagious. The CDC has categorized bioterrorism agents into three categories (Table 111-1).

Category A includes agents that can be easily transmitted to humans and that can cause substantial mortality and morbidity. These agents have been most strongly considered as bioweapons and would lead to panic and social disruption. Category A agents have been the major focus for public health officials in preparation for bioterrorism episodes. These agents include anthrax, botulism, plague, smallpox, tularemia, and viral hemorrhagic fevers.

Category B agents (see Table 111-1) are moderately easy to transmit with moderate morbidity and mortality. These agents are not well known, and the CDC considers that increased awareness and surveillance are required. In addition, agents associated with water safety threats and food safety threats are included in category B.

Category C agents include emerging pathogens that could be engineered; they are included because of their availability and potential for having a major health impact.

Chemical weapons (see Table 111-1) are divided by the CDC into biotoxins, vesicants, blood agents, caustics, long-acting anticoagulants, metals, organic solvents, toxic alcohols, choking or pulmonary agents, and nerve agents, as well as vomiting, riot control, and incapacitating agents. Finally, the CDC website for bioterrorism provides links to radiation emergencies. This listing of potential biologic, chemical, and radiation weapons is likely to change substantially. Websites from federal agencies or universities will be the most likely sources for up-to-date information in the event of terrorist attacks, rather than textbooks or journal articles (Table 111-2 and **Web Table 111-1**).

History

Biologic weapons are part of the history of warfare. The Roman army is said by historians to have poisoned the wells of their enemies to shorten their military campaigns. The Tartar's siege of Kaffa in the Crimea in the Middle Ages included the use of cadavers who had died from plague being tossed over the walls of the city, presumably along with fleas that were the source of transmission of *Yersinia pestis*. In the

Table 111-1 Biologic and Chemical Weapons

<i>Biologic Weapons</i>			
Category A	Category B	Category C	
Anthrax (<i>Bacillus anthracis</i>)	Brucellosis (<i>Brucella</i> species)	Nipah virus	
Botulism (<i>Clostridium botulinum</i> toxin)	Epsilon toxin— <i>Clostridium perfringens</i>	Hantavirus	
Plague (<i>Yersinia pestis</i>)	Glanders (<i>Burkholderia mallei</i>)		
Smallpox (variola major)	Melioidosis (<i>Burkholderia pseudomallei</i>)		
Tularemia (<i>Francisella tularensis</i>)	Psittacosis (<i>Chlamydia psittaci</i>)		
Viral hemorrhagic fevers (Ebola, Marburg, Lassa, Machupo)	Q fever (<i>Coxiella burnetii</i>)		
	Ricin toxin—castor beans		
	Enterotoxin B— <i>Staphylococcus aureus</i>		
	Typhus fever (<i>Rickettsia prowazekii</i>)		
	Viral encephalitis (Venezuelan equine, Eastern equine, Western equine)		
	Water safety— <i>Vibrio cholerae</i> , <i>Cryptosporidium parvum</i>		
	Food safety— <i>Salmonella</i> , <i>Escherichia coli</i> 0157:H7, <i>Shigella</i>		
<i>Chemical Weapons</i>			
Vesicants	Blood and Pulmonary Agents	Nerve Agents	Other
Distilled mustard	Arsine	G agents	Vomiting agent
Nitrogen mustard	Cyanide	Sarin (GB)	Riot-control agent
Lewisite	Nitrogen oxide	Soman (GD)	Incapacitating agent
Phosgene oxime	Chlorine	Tabun (GA)	
Ethylidichloroarsine	Phosgene	GF	Benzene
Methylidichloroarsine	Diphosgene	GE	Super warfarin
Phosgene oxime	Perfluoroisobutylene	V agents	Arsenic, barium, mercury, thallium
Phenylidichloroarsine	Red phosphorous	VX	
Sesqui mustard	Sulfur trioxide–chlorosulfonic acid	VM	
	Titanium tetrachloride	VE	
		VG	
		V-gas	

Data from the Centers for Disease Control and Prevention (CDC): Emergency Preparedness and Response website. Available at: www.bt.cdc.gov/Agent/Agentlist.asp.

twentieth century, German and Japanese troops investigated the distribution of biologic weapons before and during World Wars I and II. The United States began investigating biologic warfare at Fort Dietrich in 1942 and later at the Pine Bluff, Arkansas, arsenal before President Nixon ended all offensive efforts in biologic warfare in 1969 (microorganisms) and 1970 (toxins). After the termination of these investigative programs, the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) was started to conduct research for medical defense against biologic weapons.

The former Soviet Union had multiple sites for the production of biologic weapons. Even after signing the 1972 treaty on prohibition of biologic weapon development, 55,000 employees in six separate sites were reported to be working on bioweapons under the name *Biopreparate*. An unintentional release of a relatively minute number of spores at the Sverdlovsk bioweapon production site caused anthrax to infect humans and animals over a 2-month period with at least 100 persons dying. Iraq is one of a number of nations considered to have a modern biologic warfare program. Between 1985 and the end of Operation

Desert Storm of the Persian Gulf War, Iraq developed anthrax, botulinum toxin, and aflatoxin for warfare use. In 1990, 200 bombs were produced, with one half containing botulinum toxin and one fourth containing anthrax. The more recent war in Iraq was started, in large part, because of the concern regarding the existence of weapons of mass destruction including bioweapons, although none were identified.

These biologic agents are clearly weapons of mass destruction. It has been estimated that 100 kg of anthrax would lead to the death of up to 3 million individuals if released near a major metropolitan area. Evans and associates estimate that 62,000 individuals would be killed with the release of 5 pounds of anthrax powder in St Louis. This amount compares with the 2 to 3 g of powder estimated to be used in terrorist mailings in 2001. Furthermore, it has been suggested that the release of 100 kg of anthrax spores would cause a number of deaths comparable to the number a hydrogen bomb would cause. However, the agents have also been dubbed “weapons of mass disruption.” To illustrate this fact, in October through November 2001, when anthrax was delivered through the U.S. Postal Service, only

22 confirmed or probable cases of infection were discovered, but the nation was almost paralyzed by the event. Holloway and colleagues have reported that the idea of infection caused by invisible agents is particularly frightening. Feelings of horror, anger, panic, magical thinking about microbes, fear of contagion, scapegoating and xenophobia, paranoia, social isolation, helplessness, and demoralization are considered to be results of terrorist acts such as the discovery of bioterrorism agents.

Biologic Agents

ANTHRAX

Anthrax, named for the appearance of the black eschar of the cutaneous lesions (Greek *anthrakos*, meaning coal), is primarily a disease of grazing animals. The organism exists in a spore form in soil as the reservoir. Humans become infected after contact either with soil or animal material infected with the organisms. The cutaneous form is the most common, accounting for approximately 95% of cases of anthrax. After 1 to 7 days of incubation, a small papule

develops into an ulcer. Edema and erythema surround the ulcer, which develops a blackened eschar that will dry and fall off within 1 to 2 weeks (see **Web Table 111-1**, links 1, 3, 9, 10 for clinical photographs). This form is not as highly lethal as are other forms; response to antimicrobials is prompt. Gastrointestinal anthrax is very rare and follows the ingestion of contaminated meat. Progression to toxemia is thought to be common, with a high mortality rate. Inhalation anthrax follows respiratory inhalation of spores, although the incubation period may be significantly longer (up to 60 days) than in the cutaneous form. Symptoms include fever, malaise, myalgia, substernal pressure, and discomfort, with progression over days to high fever, dyspnea, cyanosis, progressive shock, and death. Hemorrhagic meningitis develops during this stage in approximately one half of patients. Hemorrhagic mediastinitis and pleural effusion are also common at this stage (see **Web Table 111-1**, links 1, 3, 9, 10 for clinical photographs).

The pathogenesis of anthrax involves ingestion of spores by macrophages, followed by sporulation to vegetative organisms in lymph nodes, which drains the initial site of infection. Toxins known as *lethal toxin* and *edema factor* lead to death. This toxin mediation of the disease explains why the mortality is high despite effective antimicrobial therapy.

Penicillin used to be the treatment of choice for anthrax infection; however, because of the production of β -lactamase by the organisms, either doxycycline or a quinolone (ciprofloxacin) is now the first-line treatment. The earlier the treatment is started, the more likely a response to the antimicrobial therapy will occur, because the late manifestations are caused by toxin rather than replication of the organism. Ciprofloxacin or doxycycline for a total of 60 days has been used as postexposure prophylaxis.

The only human vaccine for anthrax is the supernatant from culture of an attenuated strain and is not available for the general population. The U.S. military uses the vaccine for troops; however, some controversy has developed regarding the safety and efficacy of this immunization. It appears to protect against cutaneous disease and possibly inhalational anthrax. A very effective animal vaccine program is used in agricultural settings.

SMALLPOX

The smallpox virus is one of the most feared organisms that could be considered as a biologic weapon because of its 30% mortality rate (with a range toward 100% with certain forms of the disease) and because of its ability to spread person to person with a multiplier effect of 10 to 20. Another reason for the fear of smallpox relates to one of the greatest successes of the twentieth century. The organism was eliminated in the 1970s from natural infection after a worldwide public health vaccination effort. The elimination effort was successful because smallpox has a single, stable serotype, and only human hosts were infected (no animal reservoir). Other factors included the observation that prompt antibody response occurred with vaccination; even exposed individuals were protected if vaccinated early. The disease was easily recognized clinically, which enabled exposed persons to be immunized promptly, and no carrier or subclinical state was observed with smallpox. However, diagnosis of a patient may very likely be missed because smallpox has not been

seen anywhere in the world since 1978. In the last decade, shortages of smallpox vaccine were reported; since the events of 2001, however, an adequate vaccine supply is available.

The virus of variola major and variola minor causes smallpox, named in the fifteenth century to differentiate it from the Great Pox, or syphilis. After an incubation of approximately 2 weeks, smallpox has a prodrome of fever, nausea, headache, and backache, followed by a transient erythematous rash. The typical exanthem then occurs, beginning on the head and upper extremities and spreading to the trunk and lower extremities. The number of lesions on the head and extremities remains greater than on the trunk for the duration of the rash (see **Web Table 111-1**, links 1, 3, 9, 10 for clinical photographs). The lesions begin as macules, which develop into vesicles and then pustules. The pustules dry and shrink in approximately 12 days with a hard crust or scab that then falls off, leaving a sunken scar. The variants of flat smallpox and hemorrhagic smallpox do not have the typical appearance and have a mortality rate approaching 100%. Except for the lesions on the skin and mucous membranes, other organs are not thought to be involved. Secondary bacterial infection is uncommon. Toxemia from the virus is considered to be the most likely cause of death. Complications include encephalitis and blindness from panophthalmitis and keratitis. Cough is not particularly prominent, but it is considered a key element in the transmission of the virus to others.

The differential diagnosis for smallpox includes a number of illnesses with rash. However, the most likely illness to be confused with smallpox is the primary varicella zoster viral infection (chickenpox), which produces crops of lesions, resulting in various stages of papule, vesicle, and pustule that can be observed at the same time in different areas of the body. In addition, chickenpox is more likely to be concentrated on the trunk than it is on the face and extremities as is smallpox.

Smallpox is spread by respiratory droplet nuclei or contaminated clothing or bedding material and is not transmitted during the incubation period but only during the initial fever and through the first week of the rash illness. Cough may transmit the virus in a widespread area. An example reviewed by Henderson is a patient admitted to a first-floor hospital room with subsequent transmission to individuals located on the third floor of the building.

Treatment of patients with smallpox centers on preventing transmission, with respiratory isolation and possibly institution of a quarantine in the setting of a large epidemic. Studies are underway to examine antiviral agents. Cidofovir is licensed for cytomegalovirus and has activity against smallpox; some benefit has been recognized in animals with monkeypox and vaccinia infection, but obviously no trials have been performed.

Prevention of infection with smallpox has been accomplished with vaccinia vaccination. The cutaneous inoculation of this modified virus (cowpox) leads to local infection (Fig. 111-1) with immunity, which should persist for at least a decade or longer. Even when given during the early incubation period, the vaccine can attenuate or abolish the manifestations of smallpox. The National Vaccination Program for the Smallpox Response Plan was ordered in December 2002; a total of 38,440 vaccinations were administered to civilian health care workers and first responders, and the

A

B

Figure 111-1 A, Vaccinia vaccination day 3. B, Vaccinia vaccination day 7.

number of adverse events was smaller than predicted. The complications of vaccine that occurred included skin lesions that ranged from accidental vaccination lesions to generalized vaccinia to eczema vaccinatum. These complications included 29 reports of generalized vaccinia, 3 patients with potential eczema vaccinatum, and 7 individuals with potential progressive vaccinia. The voluntary vaccination program was placed on hold after 21 cases of potential myocarditis or pericarditis were identified (see **Web Table 111-1**, link 1 for further discussion). Vaccinia immune globulin (VIG) can modify or ameliorate the complications. Pregnant women, those with eczema, and individuals who are immunosuppressed should not receive vaccinia vaccination.

PLAGUE

Y. pestis is the cause of plague, which occurs at a rate of 10 to 12 patients per year in the United States, predominantly in the western states. This organism was used by Japan in bioterrorism attempts in the 1940s but with infected fleas rather than airborne distribution. The infection occurs as either the bubonic form or the septicemic form, usually with pneumonia; unlike anthrax, this organism can be spread from person to person with the pneumonic form. The incubation period is from 2 to 8 days after inoculation, followed by the sudden onset of high fever, chills, generalized weakness, and tender regional lymphadenitis, known as *buboes*.

Inguinal, axillary, or cervical lymphadenopathy is most commonly found (see **Web Table 111-1**, links 1, 3, 9, 10 for clinical photographs). With late-stage disease, purpuric lesions develop and may be the source of the name *black plague* in the Middle Ages. The septicemic form can follow either cutaneous disease in a secondary manner or pneumonic infection as a primary disease. The systemic inflammatory response syndrome follows the severe endotoxemia with subsequent multiorgan dysfunction syndromes exhibited as acute respiratory distress syndrome (ARDS), disseminated intravascular coagulation (DIC), shock, and death. The pneumonic form has sudden onset with headache, malaise, fever, myalgia, and prominent cough, and the pneumonia progresses rapidly with pronounced dyspnea, cyanosis, and hemoptysis. Death results from either respiratory collapse or sepsis. Because secondary transmission is possible and likely, contact and droplet isolation precautions should be maintained for at least 48 hours after sputum cultures are negative or pneumonic plague is excluded. Antibiotic therapy with a quinolone, aminoglycoside, or doxycycline is warranted, as is supportive therapy. Prophylaxis with ciprofloxacin, doxycycline, or trimethoprim-sulfamethoxazole is used in contacts of patients with pneumonic plague. In the event of a bioterrorism event, federal authorities will give recommendations regarding the definition of the exposure that should prompt prophylaxis.

BOTULINUM TOXIN

Botulism is caused by toxin from *Clostridium botulinum*, which is a ubiquitous microorganism found in soil. The toxin types A, B, and E are most commonly associated with human disease, of which about 100 cases per year are reported in the United States. This toxin is the most potent lethal substance known to man, with a lethal dose of 1 ng/kg. No person-to-person transmission is observed with this toxin.

The clinical manifestations of botulism occur after an incubation of 18 to 36 hours in a dose-dependent fashion. The patient will be afebrile, alert, and oriented with normal sensory examination findings; the hallmark symptoms of the disease are cranial nerve abnormalities, such as ptosis, blurry or double vision, difficulty swallowing or talking, and decreased salivation. Progressive motor symptoms then develop, with bilateral descending flaccid paralysis and resultant respiratory paralysis (see **Web Table 111-1**, link 1 for clinical photographs). Death rates of 60% are documented in untreated patients, whereas fewer than 5% of patients who are treated die.

The treatment of botulism includes ventilatory assistance and supportive care. Botulinum antitoxin with the trivalent equine product against types A, B, and E, currently available only from the CDC, is recommended. It is most effective if administered early in the course of the illness. Antibiotic therapy with penicillin is used for infantile and wound botulism. The recovery period may be prolonged with supportive care, including mechanical ventilation, necessary for weeks to months. After antitoxin, no new nerve endings are affected, but recovery is dependent on the generation of new motor end plates at the neuromuscular junction. Vaccine for botulism is only investigational and is not available for clinical use.

VIRAL HEMORRHAGIC FEVERS

A number of viruses cause hemorrhagic fever. These include several different viral families of filoviruses (Ebola, Marburg), arenaviruses (Lassa, Junin, Machupo, Sabia, Guanarito), bunyaviruses (Rift Valley fever), and flaviviruses (yellow fever). Each of these has virus-dependent natural vectors of rodents, mosquitoes, or ticks. These viruses have no natural occurrence in the United States; consequently, identification of a patient with this illness will likely be a bioterrorism event.

Signs and symptoms of viral hemorrhagic fevers include fever, headache, malaise, dizziness, myalgias, nausea, and vomiting. Initial signs of infection would be flushing, conjunctival injection, and periorbital edema. A positive tourniquet test with petechiae is an indication of the bleeding propensity. Hypotension from blood loss and intra-abdominal hemorrhage is a marker of the end stages of this infection. Progressive disease is also indicated by prostration; pharyngeal, chest, or abdominal pain or discomfort; mucous membrane bleeding; and skin ecchymosis. Shock and multiorgan dysfunction follow. Usually the patient is either improving or moribund within a week. Clinical bleeding, central nervous system involvement, and significant elevation of hepatic enzymes are indicators of a poor prognosis. The mortality rate is dependent on the infectious agent and ranges from 10% to 90%.

The viruses that cause hemorrhagic fevers are thought to be spread by contact with infected body fluids and not by aerosol or droplet transmission. Therefore standard infection control procedures will prevent the spread of infection to others. The patient should be in a private room with an adjoining anteroom, if available. Particular attention should be paid to strict adherence to hand washing, using an adequate facility with decontamination solution such as Betadine-containing or other hand-washing agents. Negative air pressure rooms should be used, although aerosol transmission is not believed to occur. Strict barrier precautions including protective eyewear and a face shield should be followed. Disposable equipment should be used, with “sharps” being disposed of in rigid containers with disinfectant stored inside and then autoclaved or incinerated. All body fluids should be disinfected because they are believed to be responsible for transmission.

Chemical Agents and Radiation

Chemical weapons are primarily either vesicants similar to nitrogen mustard or nerve agents, although terrorists could use vomiting agents and incapacitating agents such as mace as weapons. As would be expected, a substantial number of individuals would simultaneously exhibit the same symptoms and likely be from the same location. Individuals exposed to chemical warfare would exhibit ocular findings; upper airway symptoms such as rhinorrhea, wheezing, or dyspnea; skin complaints of itching to necrosis; and central nervous system findings from headache to confusion to seizures (see **Web Table 111-1**, links 1, 7, 13 for further discussion).

Illness caused by radiation exposure would initially manifest as acute radiation sickness. The severity and timing of the symptoms would depend on the dose of radiation. Bone marrow, gastrointestinal, vascular, neurologic, or cutaneous manifestations would be found, once again depending on the source and total dose. Suppression of blood elements might result in infection and sepsis. Gastrointestinal injury would result in diarrhea, gastrointestinal hemorrhage, and electrolyte abnormalities. Nervous system radiation might lead to ataxia, central nausea, or seizures. Other effects of blindness, pneumonitis, and cutaneous burns would be observed with acute radiation injury (see **Web Table 111-1**, links 1, 7, 13, 14 for further discussion).

The major difference in chemical weapons or intentional radiation injury from “dirty” bombs and biologic weapons is in the incubation time required for the latter. Illness caused by biologic warfare would not be seen until days to weeks after the release of the weapon. In contrast, chemical weapons would likely cause symptoms within minutes to hours in individuals located near the weapon and would likely be recognized by the traditional first responders. Likewise, radiation from a nuclear device would be immediately obvious. The CDC and other sites linked from the CDC website provide recognition and treatments for these conditions.

Prospectus for the Future

- Development of rapid detection systems for environmental monitoring for biologic, chemical, and radiologic weapons
- Development of newer vaccines and consideration of vaccine strategies to prevent bioterrorism outbreaks
- Construction of local, state, and federal plans to control and manage bioterrorism events
- Upgrading of the local, state, and federal public health infrastructures
- Reeducation of physicians in practice and in training regarding infectious diseases that are extremely rare or no longer occur but which might be used as biologic weapons

Neurologic Evaluation of the Patient

Frederick J. Marshall

To arrive at an accurate neurologic diagnosis, the clinician generates and tests hypotheses about the location and the mechanism of injury to the nervous system. Hypotheses are refined as the clinician progresses from the interview to the physical examination to the laboratory assessment of the patient. The focus is first placed on those entities that are common, serious, and treatable. Typical presentations of common diseases account for 80% of all cases, unusual presentations of common diseases account for 15%, typical presentations of rare diseases account for 5%, and unusual presentations of rare diseases account for less than 1%.

Taking a Neurologic History

The clinician must determine the location, quality, and timing of symptoms. He or she must avoid hearsay and ask the patient to report the progression of actual symptoms rather than a litany of diagnostic procedures and specialty evaluations. Establishing when the patient last felt perfectly normal is important. Ambiguous descriptors such as *dizzy* should be rejected in favor of evocative descriptors such as *light-headed* (which might implicate cardiovascular insufficiency) or *off balance* (which might implicate cerebellar or posterior column dysfunction).

Family members and other witnesses must corroborate historical information when appropriate. Historical information should include the medical and surgical histories; current medications; allergies; family history; review of systems; and social history, including the patient's level of education, work history, possible toxin exposures, substance use, sexual history, and current life circumstance.

Clues to localization are sought during the interview. For example, pain is generally caused by a lesion of the peripheral nervous system, whereas aphasia (disordered language

processing) indicates an abnormality of the central nervous system. Because sensory and motor functions are anatomically relatively distant in the cerebral cortex but progressively closer together as fibers converge in the brainstem, spinal cord, roots, and peripheral nerves, the co-existence of sensory loss and motor dysfunction in a limb implies either a large lesion at the level of the cortex or a smaller lesion lower down in the neuraxis. Small lesions in areas of *high traffic* such as the spinal cord or brainstem can result in widespread neurologic dysfunction, whereas small lesions elsewhere may be asymptomatic.

Table 112-1 lists the potential localizing values of common neurologic symptoms to help settle the issue of lesion localization. Tables 112-2 and 112-3 list symptoms that are commonly associated with lesions at specific locations in the nervous system. Some symptoms can result from a lesion at any of several levels of the nervous system. For example, double vision can result from a focal lesion in the brainstem, peripheral nerves (cranial nerve III, IV, or VI), neuromuscular junction, or extraocular muscles; or it can be nonfocal from an increase in intracranial pressure. Associated symptoms (or the lack thereof) may lead the interviewer to reject certain hypotheses that at first seemed most likely. Table 112-4 lists the most important types of neuropathologic conditions and provides examples of diseases in each category.

Some neuroanatomic locations point to a specific diagnosis or a limited number of diagnoses. For example, disease of the neuromuscular junction is usually caused by an autoimmune process—myasthenia gravis (common) or Eaton-Lambert myasthenic syndrome (uncommon). The exceptions—botulism and congenital myasthenic disorders—are rare. Alternatively, some areas of the nervous system (e.g., the cerebral hemispheres) are vulnerable to practically any of the categories of disease outlined in Table 112-4.

The pace and temporal order of symptoms are important. Degenerative diseases generally progress gradually, whereas

vascular diseases (e.g., stroke, aneurysmal subarachnoid hemorrhage) progress rapidly. Certain symptoms such as double vision almost invariably develop abruptly, even if the underlying disorder has been developing gradually over days to weeks.

Neurologic Examination

Although the performance of the main elements of a general screening neurologic examination is imperative

(Table 112-5), the examination should be tailored to confirm or disprove the clinical hypotheses generated from the patient's history. Unexpected signs must be explained (often with a return to the history for further clarification).

The examination is approached as if only one of two possible injuries has occurred: either the *final common pathway* to a structure is disrupted or the input to that pathway is disrupted (Fig. 112-1). In the case of the motor system, the *final common pathway* includes the anterior horn cells giving rise to axons in a nerve, the nerve itself, the neuromuscular junction, and the muscle. Injury to any of these structures will result in dysfunction of the muscle. Conversely, if these structures are intact, observing the muscle function may be possible under the right circumstances. If all modes of engaging the final common pathway fail to elicit a response, then the clinician can conclude that the lesion is located somewhere within the final common pathway.

For example, a man with paralysis of facial movement on one side that is caused by a lesion of cranial nerve VII cannot smile voluntarily, close his eye, or wrinkle his forehead on the affected side. Spontaneous laughter or smiling as an automatic response to a joke also fails to move the paretic side. If the problem is central, however, then facial movement with involuntary (spontaneous) smiling may be preserved or even increased. This observation is common in patients with facial weakness caused by a stroke.

Central input to a final common pathway in the nervous system is usually tonically inhibitory. Damage to this input typically results in overactivity of the involved muscle group. Signs of damage to central inhibitory systems include

Table 112-1 Potential Localizing Value of Common Neurologic Symptoms

Potential Localizing Value	Sign or Symptom
High	Focal weakness, sensory loss, or pain Focal visual loss Language disturbance Neglect or anosognosia
Medium	Vertigo Dysarthria Clumsiness
Low	Fatigue Headache Insomnia Dizziness Anxiety, confusion, or psychosis

Table 112-2 Use of Symptoms and Signs for Localization in the Central Nervous System

Sign or Symptom	Location
Cerebral Hemispheres	
Unilateral weakness or sensory complaints	Contralateral cerebral hemisphere
Language dysfunction	Left hemisphere (frontal and temporal)
Spatial disorientation	Right hemisphere (parietal and occipital)
Anosognosia (lack of insight into deficit)	Right hemisphere (parietal)
Hemivisual loss	Contralateral hemisphere (occipital, temporal, and parietal)
Flattening of affect or social disinhibition	Bihemispheric (frontal and limbic)
Alteration of consciousness	Bihemispheric (diffuse)
Alteration of memory	Bihemispheric (hippocampus, fornix, amygdala, and mammillary bodies)
Cerebellum	
Limb clumsiness	Ipsilateral cerebellar hemisphere
Unsteadiness of gait or posture	Midline cerebellar structures
Basal Ganglia	
Slowness of voluntary movement	Substantia nigra and striatum
Involuntary movement	Striatum, thalamus, and subthalamus
Brainstem	
Contralateral weakness or sensory complaints in the body with ipsilateral weakness or sensory complaints in the face	Midbrain, pons, and medulla
Double vision	Midbrain and pons
Vertigo	Pons and medulla
Alteration of consciousness	Midbrain, pons, medulla (reticular formation)
Spinal Cord	
Weakness and spasticity (ipsilateral) and anesthesia (contralateral) below a specified level	Corticospinal and spinothalamic tracts
Unsteadiness of gait	Posterior columns
Bilateral (can be asymmetrical) weakness and sensory complaints in multiple contiguous radicular distributions	Central cord

Table 112-3 Symptom Localization in the Motor Unit (Anterior Horn Cell and the Peripheral Nervous System)

Sign or Symptom	Location
Anterior Horn Cell	
Weakness and wasting with muscle twitching (fasciculation) but no sensory complaints	Anterior horn of spinal cord (diffuse or segmental)
Spinal Root	
Weakness and sensory loss confined to a known radicular distribution (pain, a common feature, may spread)	Cervical, thoracic, lumbar, and sacral
Plexus	
Pain, weakness, and sensory loss in a limb; not limited to a single radicular or peripheral nerve distribution	Brachial and lumbosacral (may also be caused by polyradiculopathy)
Nerve	
Pain, distal weakness, and/or sensory changes confined to a single peripheral nerve distribution	Peripheral nerves (mononeuropathy)
Pain, distal weakness, and/or sensory changes affecting both sides symmetrically (generally starting in feet)	Peripheral nerves (polyneuropathy)
Pain, distal weakness, and/or sensory changes affecting scattered single peripheral nerve distributions	Peripheral nerves (mononeuropathy multiplex)
Unilateral special sensory loss	Cranial nerves I, II, V, VII, VIII, and IX
Unilateral facial weakness involving entire one half of face	Cranial nerve VII (ipsilateral)
Neuromuscular Junction	
Progressive weakness with repeated use of a muscle; no sensory complaints	Ocular, pharyngeal, and skeletal
Muscle	
Proximal weakness; no sensory complaints	Diffuse and various patterns

(1) spasticity and hyperreflexia (motor cortex, subcortical white matter, or corticospinal pathways in the brainstem and spinal cord); (2) dystonia, rigidity, tremor, and tic (basal ganglia or extrapyramidal systems); and (3) ataxia and dysmetria (cerebellum). An exception is hypotonia caused by cerebellar disease.

Technologic Assessment

Laboratory investigations and special testing should be used to confirm a clinical suggestion and to finalize the diagnosis. Testing should be selectively performed because of expense, risk, and discomfort to the patient. Frequently helpful tests are discussed in this text; diagnostic tests should never be ordered without a specific differential diagnosis firmly in

Table 112-4 Categories of Neurologic Disease

Disease Category	Example
Genetic	
Autosomal dominant	Huntington disease
Autosomal recessive	Friedreich ataxia
Sex-linked recessive	Duchenne muscular dystrophy
Sporadic	Down syndrome
Neoplastic	
Intrinsic	Glioblastoma
Extrinsic	Metastatic melanoma
Paraneoplastic	Cerebellar degeneration
Vascular	
Stroke	Thrombotic, embolic, lacunar, hemorrhagic
Structural	Arteriovenous malformation
Inflammatory	Cranial arteritis
Infectious	
Bacterial	Meningococcal meningitis
Viral	Herpes encephalitis
Protozoal	Toxoplasmosis
Fungal	Cryptococcal meningitis
Helminthic	Cysticercosis
Prion	Creutzfeldt-Jakob disease
Degenerative	
Central	Parkinson disease
Central and peripheral	Amyotrophic lateral sclerosis
Autoimmune	
Central demyelinating	Multiple sclerosis
Peripheral demyelinating	Guillain-Barré syndrome
Neuromuscular junction	Myasthenia gravis
Toxic and Metabolic	
Endogenous	Uremic encephalopathy
Exogenous	Alcoholic neuropathy
Other Structural	
Trauma	Spinal cord injury
Hydrodynamic	Normal pressure hydrocephalus
Psychogenic	Hysterical paraparesis

mind. Many neurodiagnostic tests disclose diagnoses unrelated to a patient's symptomatic disease process.

LUMBAR PUNCTURE

Investigation of the cerebrospinal fluid (CSF) is indicated in a small number of specific circumstances (usually meningitis and encephalitis) (Table 112-6). A CSF specimen should be routinely sent for laboratory testing to determine cell and differential counts, protein and glucose levels, and bacterial cultures. The CSF should also be examined for its color and clarity. Cloudy or discolored CSF should be centrifuged and examined for xanthochromia in comparison with water. Special studies may be supplemented as appropriate, including Gram stain; fungal, viral, and tuberculous cultures; cryptococcal and other antigens; tests for syphilis; Lyme titers; malignant cytologic patterns; or oligoclonal bands. Polymerase chain reaction for specific viruses holds promise for many conditions. Recording the opening and closing pressures is important. Tissue infection in the region of the puncture site is an absolute contraindication to lumbar puncture. Relative contraindications include known or

Table 112-5 Elements of a General Screening Neurologic Examination**General Systemic Physical Examination**

Head (trauma, dysmorphism, and bruits)
 Neck (tone, bruits, and thyromegaly)
 Cardiovascular (heart rate, rhythm, and murmurs; peripheral pulses and jugular venous distention)
 Pulmonary (breathing pattern and cyanosis)
 Abdomen (hepatosplenomegaly)
 Back and extremities (skeletal abnormalities, peripheral edema, and straight-leg raising)
 Skin (neurocutaneous stigmata and hepatic stigmata)

Mental Status

Level of consciousness (awake, drowsy, and comatose)
 Attention (coherent stream of thought, serial 7s)
 Orientation (temporal and spatial)
 Memory (short- and long-term)
 Language (naming, repetition, comprehension, fluency, reading, and writing)
 Visuospatial skills (clock drawing and figure copying)
 Judgment, insight, thought content (psychotic)
 Mood (depressed, manic, and anxious)

Cranial Nerves

Olfactory (smell in each nostril)
 Optic (afferent pupillary function, fundoscopic examination, visual acuity, visual fields, and structural eye findings)
 Oculomotor, trochlear, and abducens (smooth pursuit and saccadic eye movements, nystagmus, efferent pupillary function, and eyelid opening)
 Trigeminal (jaw jerk, facial sensation, afferent corneal reflex, and muscles of mastication)
 Facial (efferent corneal reflex, facial expression, eyelid closure, nasolabial folds, and power and bulk)
 Vestibulocochlear (nystagmus, speech discrimination, Weber test, and Rinne test)
 Glossopharyngeal and vagus (afferent and efferent gag reflex and uvula position)
 Spinal accessory (power and bulk of sternocleidomastoid and trapezii muscles)
 Hypoglossal (position, bulk, and fasciculations of tongue)

Motor Examination

Pronator drift (subtle corticospinal lesion)
 Tone and bulk of muscles (basal ganglia lesion yields rigidity, cerebellar lesion yields hypotonia, corticospinal lesion yields spasticity, nonspecific bihemispheric disease yields paratonia, hypertrophy indicates dystonia, pseudohypertrophy indicates muscle disease, and atrophy indicates lower motor neuron disease)
 Adventitious movements (tremor, tic, dystonia, and chorea indicate disease of the basal ganglia; asterixis and myoclonus may indicate toxic metabolic process)
 Power of major muscle groups (scale 0-5)
 Upper extremities: deltoids, biceps, triceps, wrist extension and flexion, finger extension and flexion, and interossei
 Lower extremities: hip flexion, extension, abduction, and adduction; knee extension and flexion; ankle dorsiflexion, plantar flexion, inversion, and eversion; toe extension and flexion

Sensory Examination

Light touch (posterior columns)
 Pinprick (spinothalamic tract)
 Temperature (spinothalamic tract)
 Joint position sense (posterior columns)
 Vibration (posterior columns)
 Graphesthesia (cortical sensory)
 Double simultaneous stimulation (cortical sensory)
 Two-point discrimination (posterior columns and cortical sensory)

Table 112-5 Elements of a General Screening Neurologic Examination—Cont'd**Reflex Examination**

Standard reflexes (grades 0-4)
 Biceps
 Triceps
 Brachioradialis
 Knee jerk
 Ankle jerk
 Pathologic reflexes
 Babinski sign (if present)
 Myerson sign (if present)
 Snout (if present)
 Jaw jerk (if brisk)
 Palmomental (if present)
 Hoffmann sign (if brisk)

Coordination and Gait

Finger-nose-finger (intention tremor suggesting cerebellar disease)
 Rapid alternating movements (dysdiadochokinesia suggesting cerebellar disease)
 Fine motor movements (slowness and small amplitude suggesting basal ganglia or corticospinal tract abnormalities)
 Heel-to-shin (ataxia suggesting cerebellar disease)
 Arising from chair with arms folded across chest (inability in advanced basal ganglia, cerebellar, corticospinal, or muscle disease)
 Walking naturally (look for decreased arm swing, spasticity, broad base, festination, waddle, footdrop, start hesitation, and dystonia)
 Tandem gait (look for ataxia)
 Walking with feet everted or inverted (look for latent dystonia)
 Hopping on each foot separately (look for latent dystonia)
 Stand with feet together and eyes open, eyes closed (sensory ataxia and cerebellar disease)
 Response to retropulsive stress (loss of postural righting mechanisms)

probable intracranial or spinal mass lesion, increased intracranial pressure as a result of mass lesions, coagulopathy caused by thrombocytopenia (usually correctable), anti-coagulant therapy, or bleeding disorders. Rare but severe complications include transtentorial or foramen magnum herniation, spinal epidural hematoma, spinal abscess, herniated or infected disk, meningitis, and adverse reaction to a local anesthetic agent. More common and relatively benign complications include headache and backache.

TISSUE BIOPSIES

In select specialty centers, a diagnostic biopsy is performed on various tissues, including brain, peripheral nerve (see Chapter 130), muscle (see Chapter 131), and skin. On occasion, biopsy provides the only means of arriving at a definitive diagnosis.

ELECTROPHYSIOLOGIC STUDIES

Electrophysiologic studies include electroencephalography, electromyography, nerve conduction studies, and evoked potentials. These studies are helpful in situations in which the patient cannot be examined or interviewed adequately.

Figure 112-1 The nervous system can be conceptually reduced to a series of higher-order inputs that converge on final common pathways. For example, upper motor neurons converge on lower motor neurons, whose axons form the final common pathway to an effector muscle.

Table 112-6 Indications for Lumbar Puncture

Urgent (Do Not Wait for Brain Imaging)

Acute central nervous system infection in the absence of focal neurologic signs

Less Urgent (Wait for Brain Imaging)

Vasculitis, subarachnoid hemorrhage, or cryptic process
Increased intracranial pressure in the absence of mass lesion on magnetic resonance imaging or computed tomography
Intrathecal therapy for fungal or carcinomatous meningitis
Symptomatic treatment for headache from idiopathic intracranial hypertension or subarachnoid hemorrhage

Electroencephalography is most often used to investigate seizures (see Chapter 126). It can document encephalopathy, in which case the background electrical activity of the brain is slowed, and it is also used in the evaluation of brain death.

Electromyography is useful in the differential diagnosis of muscle disease, neuromuscular junction disease, peripheral nerve disease, and anterior horn cell disease (see Chapters 130 and 131). Nerve conduction studies (see Chapters 130 and 131) may show decreased amplitude (characteristic of axonal neuropathy) or decreased velocity (characteristic of demyelinating neuropathy).

Visual-evoked potential studies are commonly used in the evaluation of possible multiple sclerosis (see Chapter 129). Asymmetrical slowing of the cortical response to visual pattern stimulation suggests demyelination in the optic nerve or central optic pathways. Brainstem auditory-evoked potential studies are useful in the diagnosis of diseases affecting cranial nerve VIII or its central projections. Lesions at the cerebellopontine angle and the brainstem cause abnormal delay in conduction. Brainstem auditory-evoked potentials are helpful in the diagnosis of deafness in infants. Somatosensory-evoked potentials are used to identify a slowing of central sensory conduction that results from demyelinating disease, compression, or metabolic derange-

Table 112-7 Magnetic Resonance Imaging (MRI) versus Computed Tomography (CT)

MRI

Resolution 1-2 mm (higher with newer 3-Tesla magnets)
Gadolinium contrast relatively safe (except in severe renal insufficiency)
Unaffected by bone
Multiple planes of imaging available
Functional (physiologic) imaging capacity

CT

Resolution >5 mm
Iodine contrast associated with anaphylaxis and rash
Faster acquisition than MRI
Metallic objects such as pacemaker or aneurysm clip preclude MRI
Acute hemorrhage well visualized
Better tolerated by patients who are severely ill or claustrophobic

ments. They are also used to evaluate spinal cord–mediated sensory abnormalities.

IMAGING STUDIES

Magnetic resonance imaging (MRI) and computed tomography (CT) are high-resolution imaging techniques that provide extraordinary diagnostic precision for central nervous system lesions. Most neurologic diseases, however, can have normal CT and MRI findings. Moreover, many abnormal findings on CT and MRI bear no relation to the diagnosis responsible for the patient's symptoms. Table 112-7 compares CT with MRI. MRI is used for most purposes, although CT has the advantage of wider accessibility, greater speed of acquisition, and better tolerability by the patient. CT detects acute hemorrhage and is preferred for emergencies. MRI provides more detail and simultaneously obtains images in the horizontal, vertical, and coronal planes. Contrast media for CT or MRI are useful in the diagnosis of tumors, abscesses, and other processes that derange the blood-brain barrier. MRI can now be used for functional imaging and spectroscopy; both techniques have great promise for the evaluation of cognitive and metabolic disorders, epilepsy, multiple sclerosis, and many other conditions.

Magnetic resonance angiography allows noninvasive visualization of the major vessels of the head and neck. Conventional angiography with an intra-arterial injection of contrast agent is used for evaluation of many intracranial vascular abnormalities, including small aneurysms and arteriovenous malformations and inflammation of small blood vessels.

Noninvasive ultrasonography of the carotid and vertebral arteries can define stenotic vessels and has been supplemented by transcranial Doppler technology, which allows characterization of blood flow in intracranial arteries.

Single-photon emission CT is useful for the evaluation of intracranial blood flow. Moreover, the development of new radioligands makes it possible to visualize the dopamine transporter on nigral-striatal dopaminergic projection neurons by using a ligand (β -CIT) to follow cell loss in patients with Parkinson disease. As the techniques of neural

transplantation for Parkinson disease improve, it may be possible to image restoration of function.

Positron-emission tomography (PET) is a functional imaging technology that can demonstrate specific metabolic derangements. It remains a largely investigational method but is particularly useful for evaluating local abnormalities of glucose and oxygen metabolism. PET is of particular value in defining the site of origin of focal seizures. Customized ligands may be used to identify specific pathologic processes. An example is the thioflavin derivative known as Pittsburgh Compound B (PiB), which binds to the amyloid plaque of Alzheimer disease and may become useful as a clinical diagnostic test in the near future. The high cost of the cyclotron technology needed to generate the radioactive ligands limits the clinical use of PET to specialized centers.

GENETIC AND MOLECULAR TESTING

There are more neurologic diseases than diseases of all other systems combined. Recent discoveries have revolutionized the diagnostic approach to many of these diseases; new genetic tests are discovered every year. Table 112-8 outlines tests that are now commercially available. Genetic testing for a disorder requires that the clinician perform a thoughtful

Table 112-8 Some Neurologic Conditions for Which Genetic Tests Are Available

Peripheral neuropathies (Charcot-Marie-Tooth 1A, Kennedy syndrome)
Neuromuscular diseases (myotonic dystrophy, Duchenne muscular dystrophy, Becker muscular dystrophy, spinal muscular atrophy, MELAS, MERRF, familial amyotrophic lateral sclerosis)
Movement disorders (spinocerebellar ataxia, multiple types; Friedreich ataxia; dystonia DYT1; Huntington disease)
Mental retardation (fragile X)
MELAS, mitochondrial encephalomyelopathy, lactic acidosis, and stroke-like symptoms (syndrome); MERRF, myoclonus epilepsy with ragged red fibers (syndrome).

and caring evaluation of the patient, usually with input from and evaluation of the patient's family. Important ethical issues surround the use of genetic tests, including the ability to ensure privacy, to ensure adequate psychological and social support for patients who may be given devastating news, and to address adequately the appropriateness of prenatal screening or presymptomatic testing when no treatment is available.

Prospectus for the Future

Novel imaging techniques and molecular diagnostic studies are beginning to shed light on the pathogenesis of neurological conditions that have been identifiable only by clinical phenomenology. The dystonias, many degenerative diseases, the epilepsies, headache, and other conditions are not subject to

specific diagnosis and disease localization. Despite these and foreseeable future advances, the clinical aspects of neurological disease remain of fundamental importance in understanding the impact of disease on patients and their families.

Disorders of Consciousness

Roger P. Simon

Coma is a sleeplike state in that the patient is unresponsive and the eyes are closed even with vigorous stimulation. A poorly responsive state in which the eyes are open, or an agitated confused state, or delirium, is not coma, but it may represent early stages of the same disease processes and should be investigated in the same manner.

Consciousness requires an intact and functioning brainstem reticular activating system and its cortical projections. The reticular formation begins in the midpons and ascends through the dorsal midbrain to synapse in the thalamus; it then innervates higher centers through thalamocortical connections. Knowledge of this anatomic substrate provides the short list of regions to be investigated in the search for a structural cause of coma: brainstem or bihemispheric dysfunction satisfies these anatomic requirements. Structural lesions elsewhere are not the cause of the patient's unconsciousness. In addition to structural lesions, meningeal inflammation, metabolic encephalopathy, and seizures diffusely affect the brain and complete the differential diagnosis for the patient in coma.

Pathophysiologic Factors

Meningeal irritation caused by infection or blood in the subarachnoid space is an essential early consideration in coma evaluation because its cause requires immediate attention (especially with purulent meningitis) and may not be diagnosed by computed tomography (CT).

Hemispheric mass lesions result in coma either by expanding across the midline laterally to compromise both cerebral hemispheres or by impinging on the brainstem to compress the rostral reticular formation. These processes—*lateral herniation* (lateral movement of the brain) and *transtentorial herniation* (vertical movement of the brain)—most commonly occur together. At the bedside, clinical signs of an expanding hemispheric mass evolve in a level-by-level, rostral-caudal manner (Fig. 113-1). Hemispheric lesions of adequate size to produce coma are readily seen on CT.

Brainstem mass lesions produce coma by directly affecting the reticular formation. Because the pathways for lateral eye movements (the pontine gaze center, medial longitudinal

fasciculus, and oculomotor—third nerve—nucleus) traverse the reticular activating system, impairment of reflex eye movements is often the critical element of diagnosis of a brainstem lesion. A comatose patient without impaired reflex lateral eye movements does not have a mass lesion compromising brainstem structures in the posterior fossa. CT is not able to show some lesions in this region. Posterior fossa lesions may block the flow of cerebrospinal fluid from the lateral ventricles and result in the dangerous situation of *noncommunicating hydrocephalus*.

Metabolic abnormalities are caused by deficiency states (e.g., thiamine, glucose), by derangements of metabolism (e.g., hyponatremia), or by the presence of *exogenous toxins* (drugs) or *endogenous toxins* (organ system failure). Metabolic abnormalities result in diffuse dysfunction of the nervous system and therefore produce, with rare exceptions, no localized signs such as hemiparesis or unilateral pupillary dilation. The diagnosis of *metabolic encephalopathy* means that the examiner has found no focal anatomic features on examination or neuroimaging studies to explain coma, but it does not state that a specific metabolic cause has been established. Drugs have a predilection for affecting the reticular formation in the brainstem and for producing paralysis of reflex eye movement on examination. *Multifocal structural disorders* may simulate metabolic coma (Table 113-1).

In the late stages of status epilepticus, motor movements may be subtle even though *seizure activity* is continuing throughout the brain (nonconvulsive status epilepticus). Once seizures stop, the so-called *postictal state* can also cause unexplained coma.

Diagnostic Approach

The history and examination are essential in the diagnosis and are not replaced by brain imaging (Table 113-2). History of a premonitory headache supports a diagnosis of meningitis, encephalitis, or intracerebral or subarachnoid hemorrhage. A preceding period of intoxication, confusion, or delirium points to a diffuse process such as meningitis or endogenous or exogenous toxins. The sudden apoplectic onset of coma is particularly suggestive of ischemic or

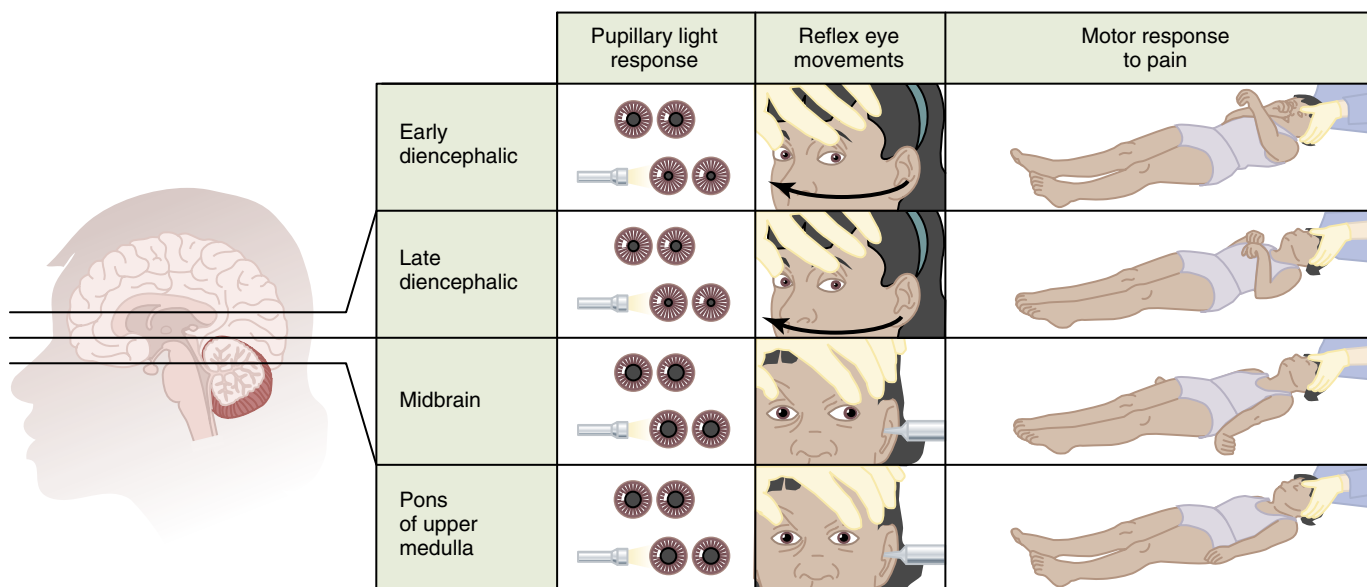

Figure 113-1 The evolution of neurologic signs in coma from a hemispheric mass lesion as the brain becomes functionally impaired in a rostral-caudal manner. *Early* and *late diencephalic* refer to levels of dysfunction just above (early) and just below (late) the thalamus. (From Aminoff MJ, Greenberg DA, Simon RP: Clinical Neurology. Stamford, CT, Appleton and Lange, 1996).

hemorrhagic stroke affecting the brainstem or of subarachnoid hemorrhage or intracerebral hemorrhage with intraventricular rupture. Lateralized symptoms of hemiparesis or aphasia before coma occur in patients with hemispheric masses or infarctions.

The physical examination is critical, quickly accomplished, and diagnostic. The issues are three: (1) Does the patient have meningitis? (2) Are signs of a mass lesion present? (3) Is this condition a diffuse syndrome of exogenous or endogenous metabolic cause? Emergency management should then be instituted accordingly (Table 113-3).

IDENTIFICATION OF MENINGITIS

Although signs of meningeal irritation are not invariably present and have differing sensitivity with regard to cause (extremely common with acute pyogenic meningitis and subarachnoid hemorrhage, less common with indolent, fungal meningitis), the presence of these signs on examination is the central clue to the diagnosis. Missing these signs results in time-consuming additional tests such as brain imaging and the potential loss of a narrow window of opportunity for directed therapy. Passive neck flexion should be carried out (Fig. 113-2) in all comatose patients unless a history of head trauma exists. When the neck is passively flexed, by attempt-

ing to bring the chin within a few fingerbreadths of the chest, patients with irritated meninges reflexively flex one or both knees. This sign (*Brudzinksi reflex*) is usually asymmetrical and not dramatic, but any evidence of knee flexion during passive neck flexion requires that the cerebrospinal fluid be examined. Is CT required before lumbar puncture in this setting? In the absence of lateralized signs (such as hemiparesis) supporting a superimposed mass lesion, a spinal puncture should be performed immediately. Although rare cases of herniation after lumbar puncture have been reported in children with bacterial meningitis, the urgency of diagnosis and treatment at the point of coma is paramount. The time needed for CT may result in a fatal therapeutic delay. An alternative approach involves obtaining blood cultures and immediately initiating antibiotic therapy with subsequent lumbar puncture; cerebrospinal fluid cell count, glucose determination, and protein content are unchanged, and Gram stain and culture often remain positive despite a short period of antibiotic treatment. Bacterial antigens in the cerebrospinal fluid or blood can also be detected.

SEPARATION OF STRUCTURAL FROM METABOLIC CAUSES OF COMA

The goal of this differential diagnosis is achieved by neurologic examination. Because the evaluation and potential treatments for structural and metabolic coma are widely divergent and the disease processes in both categories are often rapidly progressive, initiating the evaluation medically or surgically may be life saving. Identification of a structural versus a metabolic case is accomplished by focusing on three features of neurologic examination: the *motor response* to a painful stimulus, *pupillary function*, and *reflex eye movements*.

Motor Response

Asymmetrical or reflex function of the motor system provides the clearest indication of a mass lesion. Elicitation of a

motor response requires that a painful stimulus be applied to which the patient will react. The patient's arms should be placed in a semiflexed posture, and a painful stimulus should be applied to the head or trunk. Strong pressure on the supraorbital ridge or pinching of the skin on the anterior chest or inner arm is the most useful method; finger nail bed pressure is also used, but it makes the interpretation of upper limb movement difficult.

The neurologic examination of a patient with an expanding hemispheric mass lesion is shown in Figure 113-1. Hemi-

Table 113-3 Emergency Management

Ensure airway adequacy.

Support ventilation and circulation.

Obtain blood for glucose, electrolytes, hepatic and renal function, prothrombin and partial thromboplastin times, complete blood count, and drug screen.

Administer 100 mg of thiamine intravenously (IV).

Administer 25 g of dextrose IV (typically 50 mL of 50% dextrose) to treat possible hypoglycemic coma.*

Treat opiate overdose with naloxone (0.4-1.2 mg IV).

The specific benzodiazepine antagonist flumazenil (0.2 mg IV repeated once and followed by 0.1 mg IV to 1-3 mg total) should be given for the reversal of benzodiazepine-induced coma or conscious sedation.[†]

*The glucose level is poorly correlated with the level of consciousness in hypoglycemia; stupor, coma, and confusion are reported with blood glucose concentrations ranging from 2 to 60 mg/dL.

[†]Not recommended in coma of unknown origin because seizures may be precipitated in patients with polydrug overdoses which include benzodiazepines with tricyclic antidepressants or cocaine.

spheric masses at their early stage (*early diencephalic*, i.e., compromising the brain above the thalamus) produce appropriate movement of one upper extremity, that is, movement toward the painful stimulus. The attenuated contralateral arm movement reflects a hemiparesis. This lateralized motor response in a comatose patient establishes the working diagnosis of a hemispheric mass. As the mass expands to involve the thalamus (*late diencephalic*), the response to pain becomes reflex arm flexion associated with extension and internal rotation of the legs (*decorticate posturing*); asymmetry of the response in the upper extremities is seen. With further brain compromise at the midbrain level, the reflex posturing changes in the arms such that both arms and legs respond by extension (*decerebrate posturing*); at this level, the asymmetry tends to be lost. At this point, the pupils become midposition in size, and the light reflex is lost, first unilaterally and then bilaterally. With further progression to the level of the pons, no response to painful stimulation is the most frequent finding, although spinal-mediated movements of leg flexion may occur. The classic postures illustrated in Figure 113-1, and particularly their asymmetry, strongly support the presence of a mass lesion. These motor movements, especially early in coma, are, however, most frequently seen as fragments of the fully developed, asymmetrical flexion or extension of the arms illustrated as decorticate and decerebrate postures in Figure 113-1. A small amount of asymmetrical flexion or extension of the arms in response to a painful stimulus carries the same implications as the full-blown postures of decortication or decerebration.

Metabolic lesions do not compromise the brain in a progressive, level-by-level manner as do hemispheric masses, and they rarely produce the asymmetrical motor signs typical of masses. Reflex posturing may be seen, but it lacks the asymmetry of decortication from a hemispheric mass and is not associated with the loss of pupillary reactivity at the stage of decerebration.

Pupillary Reactivity

In metabolic coma, one feature is central to the examination: Pupillary reactivity is present. This reactivity is seen both early in metabolic coma, when an appropriate motor

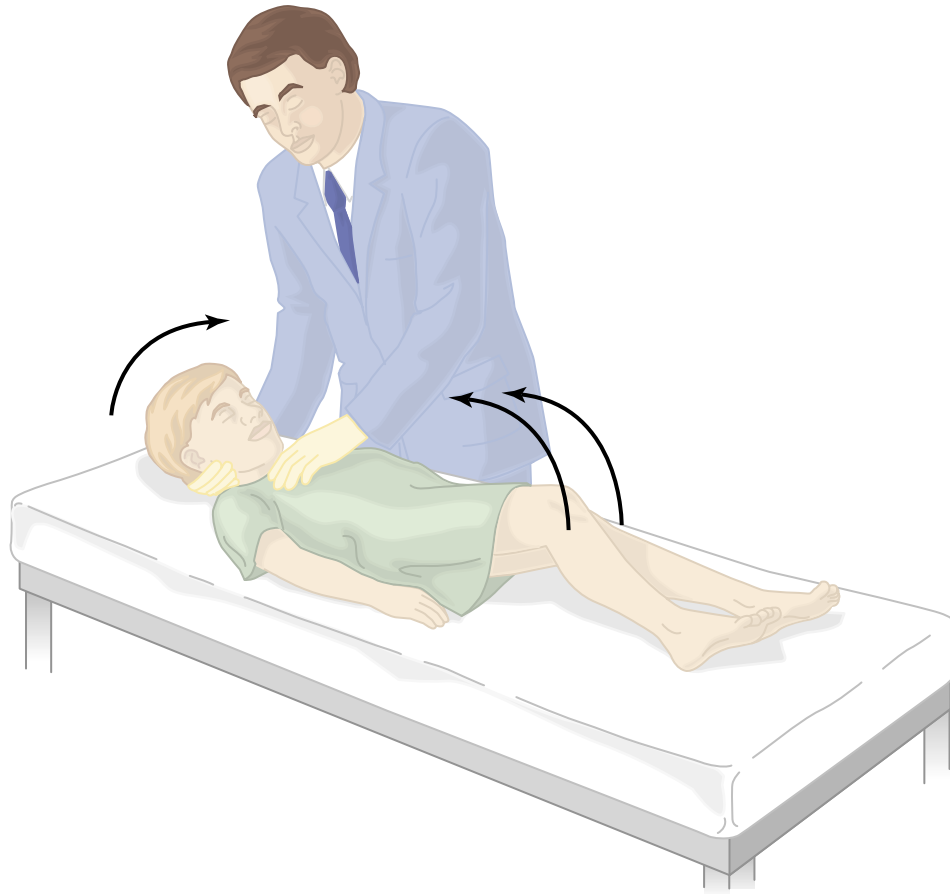

Figure 113-2 Elicitation of Brudzinksi's sign of meningeal irritation as seen in infectious meningitis or subarachnoid hemorrhage. (From Aminoff MJ, Greenberg DA, Simon RP: *Clinical Neurology*. Stamford, CT, Appleton and Lange, 1996).

response to pain may be retained, and late in coma, when no motor responses can be elicited. The pupillary reaction in metabolic coma is lost only when coma is so deep that the patient requires ventilatory and blood pressure support.

Reflex Eye Movements

The presence of inducible lateral eye movements reflects the integrity of the pons and midbrain. These reflex eye movements (see Fig. 113-1) are brought about by passive head rotation to stimulate the semicircular canal input to the vestibular system (so-called *doll's eyes maneuver*) or by inhibiting the function of one semicircular canal by infusion of ice water against the tympanic membrane (caloric testing).

In metabolic coma, reflex eye movements may be lost or retained. Lack of inducible eye movements with the doll's eyes maneuver, in the setting of preserved pupillary reactivity, is virtually diagnostic of drug toxicity. With metabolic coma of non-drug-induced origin, such as organ system failure, electrolyte disorders, or osmolar disorders, reflex eye movements are preserved.

Brainstem mass lesions are most commonly caused by hemorrhage or infarction. Reflex lateral eye movements, the pathways for which traverse the pons and midbrain, are particularly affected, and the reflex postures of decortication and decerebration typical of brainstem injury are common. Lesions restricted to the midbrain (e.g., embolization from the heart to the top of the basilar artery) cause sluggish

pupillary reflexes or their absence, with or without impaired medial eye movements (both are controlled by the third cranial nerve). With lesions restricted to the pons (e.g., intrapontine hypertensive hemorrhage), pupils are reactive but very small (pinpoint or pontine pupils), which reflects focal impairment of sympathetic innervation; pinpoint pupils are rare. Ocular bobbing (spontaneous symmetrical or asymmetrical rhythmic vertical ocular oscillations) is most often seen as a manifestation of a pontine lesion.

Seizures occurring in a patient with acute brain injury (e.g., that resulting from encephalitis, hypertensive encephalopathy, hyponatremia or hypernatremia, hypoglycemia or hyperglycemia) or chronic brain injury (e.g., dementia, mental retardation) often result in prolonged postictal coma. The examination shows reactive pupils and inducible eye movements (in the absence of overtreatment with anticonvulsants) and often up-going toes or focal signs (Todd paresis). Nonconvulsive seizures, particularly spike-wave stupor, may occur in a patient without a history of epilepsy. The diagnosis is made by electroencephalogram (see Chapter 126).

Prognosis in Coma

In coma after cardiac arrest, the prognosis for meaningful recovery can be assessed from clinical signs. Return of pupillary reactivity within 24 hours and purposeful motor

movements within the first 72 hours after cardiac arrest are highly correlated with a favorable outcome (Table 113-4). Rare late recoveries, however, have been reported.

Coma-like States

Locked-in patients are those in whom a lesion (usually a hemorrhage or an infarct) transects the brainstem at a point below the reticular formation (therefore sparing consciousness) but above the ventilatory nuclei of the medulla (therefore maintaining cardiopulmonary function) (Table 113-5). Such patients are awake, with eye opening and sleep-wake cycles, but the descending pathways through the brainstem necessary for volitional vocalization or limb movement have been transected. Voluntary eye movement, especially vertically, is preserved, and patients open and close their eyes or produce appropriate numbers of blinking movements in answer to questions. The electroencephalogram is usually normal, reflecting normal cortical function.

Psychogenic unresponsiveness is a diagnosis of exclusion. The neurologic examination shows reactive pupils and no reflex posturing in response to pain. Eye movements during the doll's eyes maneuver show volitional override rather than the smooth, uninhibited reflex lateral eye movements of coma. Ice water caloric testing either arouses the patient because of the discomfort produced or induces cortically mediated nystagmus rather than the tonic deviation typical of coma. Slow, conjugate roving eye movements of metabolic coma cannot be imitated and therefore rule out psychogenic unresponsiveness. In addition, the slow, often asymmetrical, and incomplete eye closure seen after passive eye opening of a comatose patient cannot be feigned. These signs therefore rule out psychogenic coma. In contrast, conscious patients usually exhibit some voluntary muscle tone in the eyelids during passive eye opening. The electroencephalogram in psychogenic unresponsiveness is that of

*A vegetative state may not necessarily begin with coma but can also develop as the end stage of neurodegenerative diseases (e.g., Alzheimer disease) of adults or children and can accompany severe congenital developmental abnormalities of the brain such as anencephaly.

normal wakefulness with reactive posterior rhythms on eye opening and eye closing. In patients with catatonic stupor, lorazepam administration may produce awakening.

In *persistent vegetative states* (PVSs), patients have awakened from coma but have not regained awareness. Wakefulness is exhibited by eye opening and sleep-wake cycles. The reticular activating system of the brainstem is intact to produce wakefulness, but the connections to the cortical mantle are interrupted, precluding awareness.

Clinical features do not differ by cause (Table 113-6). Patients in a PVS open their eyes diurnally and in response to loud sounds; blinking occurs with bright lights. Pupils react and eye movements occur both spontaneously and with the doll's eyes maneuver. Yawning, chewing, swallowing, and, uncommonly, guttural vocalizations and lacrimation may be preserved. Spontaneous roving eye movements (very slow, constant velocity) are particularly characteristic and distressing to the patient's visitors because the patient appears to be looking about the room. The brainstem origin of the eye movements is documented by their being readily redirected by the oculocephalic (doll's eyes) reflex. The limbs may move, but motor responses are only primitive; pain usually produces decorticate or decerebrate postures or fragments of these movements.

A vegetative state is termed *persistent* after 3 months if the brain injury was medical and after 12 months if the brain injury was traumatic. The determination as to when

Table 113-7 Criteria for Cessation of Brain Function*

Anatomic Region Tested	Confirmatory Sign
Hemispheres	Unresponsive and unresponsive to sensory stimuli including pain [†]
Midbrain	Unreactive pupils [‡]
Pons	Absent reflex eye movements [§]
Medulla	Apnea [¶]

*Sequential testing is necessary for a clinical diagnosis of brain death; at least 6 hr for all cases and at least 24 hr in the setting of anoxic-ischemic brain injury.

[†]The patient does not rouse, groan, grimace, or withdraw limbs; purely spinal reflexes (deep tendon reflexes, plantar flexion reflex, plantar withdrawal, and tonic neck reflexes) may be maintained.

[‡]Most easily assessed by the bright light of an ophthalmoscope viewed through its magnifying lens when focused on the iris; unreactive pupils may be either midposition (as they will be in death) or dilated, as they often are in the setting of a dopamine infusion.

[§]No eye movement toward the side of irrigation of the tympanic membrane with 50 mL of ice water; the oculocephalic response (doll's eyes) will always be absent in the setting of absent oculovestibular testing.

[¶]No ventilatory movements in the setting of maximum CO₂ stimulation (≥60 mm Hg; with apnea, PCO₂ will passively rise 2-3 mm Hg/min); disconnect the ventilator from the endotracheal tube and insert cannula with 6 L of oxygen per minute.

CO₂, carbon dioxide; PCO₂, partial pressure of carbon dioxide.

persistent equals *permanent* cannot be stated absolutely. Prediction of which patients early in the vegetative state will remain persistently vegetative is particularly difficult in trauma. Lesions of the corpus callosum and dorsolateral brainstem seen on magnetic resonance images 6 to 8 weeks after trauma correlated with persistence of the vegetative state at a year. In rare cases, patients show late improvement, but none of these patients returns to normal. Slight recovery to a minimally responsive state has also been described.

Brain imaging studies depict the sequelae of the causative injury but are not diagnostic of PVS. Magnetic resonance spectroscopy has shown a decrease in the neuronal marker of *N*-acetylaspartate. Positron-emission tomographic studies have shown decreased glucose usage and cerebral blood flow. Bilateral absence of somatosensory-evoked responses in the first week predicts death or vegetative state.

Brain death characterizes the *irreversible cessation* of brain function. Therefore death of the organism can be determined based on death of the brain. Although local laws may

EEG, electroencephalogram.

dictate some details, the standard definition permits a diagnosis of brain death based on documentation of irreversible cessation of all brain function, including function of the brainstem (Table 113-7).

Documentation of *irreversibility* requires that the cause of the coma be known, that the cause be adequate to explain the clinical findings of brain death, and that exclusionary criteria are absent (Table 113-8). Confirmatory tests are sometimes used but are not required for diagnosis (Table 113-9).

Brain death results in asystole, usually within days (mean, 4) even if ventilatory support is continued. Recovery after appropriate documentation of brain death has never been reported. Removal of the ventilator results in terminal rhythms (most often complete heart block without ventricular response), junctional rhythms, or ventricular tachycardia. Purely spinal motor movements may occur in the moments of terminal apnea (or during apnea testing in the absence of passive administration of oxygen): arching of the back, neck turning, stiffening of the legs, and upper extremity flexion.

Prospectus for the Future

Functional imaging (positron-emission tomography and functional magnetic resonance imaging) is now being employed for study of acute coma and stupor in emergency rooms and the intensive care units. These techniques will provide a better

understanding of the metabolic derangements occurring in acute brain dysfunction. As specific ion channels of brain neurons are characterized, targeted molecular therapies will enter clinical trials.

Disorders of Sleep

Lynn Liu

Neurobiology of Sleep

Sleep is essential for life. Rat models with complete sleep deprivation die within 10 to 30 days. Although the function of sleep is not clearly understood, there are demonstrable physiologic, psychological, and social consequences of chronic sleep deprivation. Recent advances in sleep medicine have enhanced recognition of sleep disorders, improved understanding of their pathophysiology, and resulted in development of new treatment strategies. The International Classification of Sleep Disorders (ICSD-2) divides sleep disorders into six major clinical categories.

Sleep and wakefulness include three states: wake, non-rapid eye movement (NREM) sleep, and rapid eye movement (REM) sleep. The entry and termination of each of these states are under active neurologic control. Wakefulness is maintained by activation of the cortex via the reticular activating system through the thalamus and the posterior hypothalamus. The ventrolateral preoptic nucleus (VLPO) of the anterior hypothalamus signals the onset of NREM sleep by descending inhibitory projections to the brainstem nuclei responsible for maintaining wakefulness, and the lateral dorsal tegmentum (LDT) and parabrachial tegmentum (PPT) activate the transition into REM sleep.

Sleep stages can be differentiated by their physiologic characteristics and polysomnographic (PSG) criteria (Fig. 114-1). The transition from wake into sleep is cyclic. Each cycle takes approximately 90 to 120 minutes, and there are about four to six sleep cycles over the course of a nocturnal sleep period. These cycles can be graphically represented as a hypnogram. Sleep is entered through NREM stage 1 (N1), followed by a descent into deeper stages of sleep including stage 2 (N2), slow-wave sleep (N3), and then REM sleep (R). Physiologically, REM sleep represents a relatively activated state similar to waking and can be further subdivided into tonic stage, quiet periods of muscle atonia, and phasic stage, characterized by bursts of REM, small muscle twitches, penile erections, and labial engorgement. Of subjects awakened from REM sleep, 80% reported vivid dreaming, in comparison with only 20% of subjects awakened from NREM sleep.

Insomnia

ICSD-2 defines insomnia as difficulty initiating or maintaining sleep, early morning awakenings, or chronically nonrestorative or poor-quality sleep, despite adequate opportunity and circumstances for sleep, leading to daytime impairment. Insomnias can be categorized as acute or chronic and according to the timing of sleep disruption: sleep onset, sleep maintenance, or early awakening. In the National Sleep Poll 2005, 54% of U.S. respondents reported experiencing insomnia on a regular basis. Most can identify with *adjustment sleep disorder* (acute insomnia), which occurs in the setting of acute stressors such as death of a family member or work or social issues. Most acute insomnias resolve once the acute stressor has resolved. If the insomnia is severe, hypnotics are indicated for short-term use. Choice of hypnotic depends on matching the symptoms with the pharmacokinetic profile of the hypnotic; patients with sleep onset insomnia should use a short-acting medication, whereas those with sleep maintenance insomnia should use a longer-acting medication.

The most common chronic insomnia, *psychophysiological insomnia*, is related to poor sleep hygiene (Table 114-1) and maladaptive sleep habits. Clinical characteristics include altered arousal threshold and rumination with precipitating and perpetuating factors. Treatment involves reeducating the patient about his or her attitudes and beliefs about sleep through cognitive behavioral therapy (CBT) by a trained sleep behaviorist. Sleep can also be disrupted by medical conditions, other sleep disorders, psychiatric disorders, and drugs.

Sleep-Related Breathing Disorders

At sleep onset the control of respiration changes from voluntary control to predominantly automatic control based on chemoreceptors and mechanoreceptor reflexes. Apnea is defined as a cessation of breathing lasting longer than 10

Figure 114-1 Physiologic characteristics and polysomnographic (PSG) criteria for stages of sleep.

Table 114-1 Sleep Hygiene

1. Maintain a regular schedule each day.
2. Wake at the same time each morning.
3. Exposure to natural light entrains the circadian rhythm.
4. Exercise in the morning or early afternoon; avoid vigorous exercise in the evening.
5. Avoid napping during the day, especially after 3 PM.
6. Avoid stimulants such as caffeine, nicotine, and alcohol too close to bedtime.
7. Avoid large meals close to bedtime.
8. Maintain regular and relaxing routines at bedtime.
9. Maintain a comfortable sleep environment.
10. Reserve the bed for sleep; avoid other activities (TV, radio, or reading).
11. Sleep only when sleepy.
12. Do not worry in bed, resolve issues before sleeping.
13. Get out of bed if not sleeping in 20 minutes.

seconds. There are three types of apnea: obstructive, central, and mixed. Obstruction of the upper airway results in a loss of airflow with maintained effort. Loss of a central signal to initiate a breath results in the loss of airflow signal and no signs of respiratory effort. Mixed apnea is the combination of these two types.

Obstructive sleep apnea syndrome is the most common sleep-related breathing disorder. It affects 2% to 5% of the adult population of the United States, as many as 20% of whom are not diagnosed. The typical patient with sleep apnea is an overweight middle-aged man, and its incidence increases with age; however, sleep apnea occurs in young children and people with a normal body mass index. Untreated sleep apnea increases the risk of cardiovascular disease, cerebrovascular disease, depression, and accidents. ICSD-2 criteria include complaints of unintentional sleep episodes during wakefulness, daytime sleepiness, unrefreshing sleep, fatigue or insomnia, or periods when the individual awakens with breath holding, gasping, or choking or the bed partner reports loud snoring or breathing interruptions. Polysomnography quantifies respiratory events per sleep hour, and a patient with more than five events per sleep hour with clinical complaints should receive treatment. Other factors that can exacerbate sleep apnea include crowding of the oropharyngeal space, oromaxillofacial disproportions, body position (supine position exacerbates airway patency), and sedatives that reduce the tone of the soft tissue. Treatment targets the opening of the airway. Weight loss is critical but difficult for most patients to achieve. Continuous positive airway pressure (CPAP) splints the airway, allowing uninterrupted respiration through the

night and symptomatic improvement. Surgery including tonsillectomy and adenoidectomy, uvulopalatopharyngoplasty (UPPP), and mandibular advancement procedures can also be helpful in appropriate situations. Dental devices that advance the mandible and pull the soft tissue forward can also be used.

Hypersomnia Syndromes

The ICD-2 defines hypersomnia as the inability to stay awake and alert during the major waking episodes of the day, resulting in unintended lapses into drowsiness or sleep. Although there are many causes, the classic condition, narcolepsy with cataplexy, has been estimated to affect 0.02% to 0.18% of the U.S. population. It is a disorder of dysregulated REM sleep in which features of REM intrude into wakefulness. The patient complains of almost daily excessive daytime sleepiness and experiences cataplexy, a sudden and transient episode of atonia triggered by emotion, typically laughter. Associated features include hypnagogic hallucinations, during which dream imagery intrudes into wakefulness or light sleep, and sleep paralysis, which is the persistence of REM atonia on awakening. A multiple sleep latency test (MSLT) to determine a mean sleep latency less than or equal to 8 minutes and two or more sleep onset REM periods (SOREMP) confirms the diagnosis, although an overnight polysomnography should precede the MSLT to ensure sufficient sleep and exclude other sleep disorders. Adjunctive laboratory testing includes hypocretin-1 levels in the cerebrospinal fluid (CSF) (less than 110 pg/mL or one third of mean normal control values). Hypocretin is a neuromodulator found in the posterior hypothalamus. In some cases of narcolepsy with cataplexy, the number of hypocretin neurons is reduced. Furthermore, human leukocyte antigen (HLA) subtype DQB1*0602 occurs at a higher frequency in these patients than in the general population.

Symptomatic treatment for narcolepsy minimizes daytime sleepiness and reduces cataplectic attacks. Scheduled naps are helpful because most patients find the naps to be refreshing and to help the patients continue to function. Stimulants, methylphenidate and amphetamines, improve daytime sleepiness, but patients may develop tolerance, weight loss, and jitteriness. Also of benefit is modafinil, a novel wakefulness-promoting agent that may enhance aminergic transmission in the anterior hypothalamus. It has a modest side effect profile that includes headache and nausea. The pontine inhibition of motor control during REM is thought to be under cholinergic control. Tricyclic antidepressants, specifically clomipramine, reduce the frequency of cataplectic attacks. Other antidepressants including selective serotonin reuptake inhibitors (SSRIs) have also been used. Sodium oxybate, a controlled substance, consolidates sleep and improves both the symptoms of excessive daytime sleepiness and cataplexy.

Circadian Rhythm Sleep Disorders

The circadian clock in the suprachiasmatic nucleus of the anterior hypothalamus maintains the appropriate timing for

many physiological cycles including the sleep-wake cycle. When sleep is disrupted because the clock is faulty or there is a misalignment between the clock and the environment such as seen in shift workers or in jet lag, symptoms of excessive sleepiness, insomnia or both can impair function. Factors that help to entrain the clock include bright light exposure and melatonin, a hormone released from the pineal gland during darkness. A combination of genetics and behavior determines whether one is apt to be a morning lark or a night owl. When the timing of the sleep period becomes extreme as in some adolescents who stay awake until 3 to 4 AM and have difficulty waking at 8 AM to go to school, this *delayed sleep phase syndrome* can interfere with school performance, but if allowed to sleep a normal period until 12 noon, they would not have any sleep complaints. As society works 24 hours a day, *shift work sleep disorders* have become prevalent. For example, those on night shift often have difficulty sleeping when they get off of work in the morning and staying awake to work at night. Treatment for these disorders is aimed at resetting the circadian clock. Strategies include setting of strict sleep habits, exposure to bright light before periods of wakefulness, avoidance of bright light before sleep, melatonin to signal sleep onset, and pharmacologic agents such as stimulants, modafinil, and hypnotics appropriately timed to enhance either wakefulness or sleep (Tables 114-2 and 114-3).

Parasomnias

Parasomnias are events ranging from simple movements to complex behaviors without conscious awareness. They arise from transitions into or out of sleep. They can be categorized by the stage of sleep from which they arise. Most common childhood parasomnias arise from slow wave sleep and

Table 114-2 Hypnotics

	Dose Range	Half-Life
Benzodiazepines		
Estazolam (Prosom)	1-2 mg	10-24 hr
Flurazepam (Dalmane)	15-30 mg	2-3 hr
Quazepam (Doral)	7.5-30 mg	39 hr
Temazepam (Restoril)	7.5-30 mg	3.5-18.4 hr
Triazolam (Halcion)	0.125-0.15 mg	1.5-5.5 hr
Clonazepam (Klonopin)	0.25-2 mg	30-40 hr
Nonbenzodiazepines		
Zolpidem (Ambien, Ambien CR)	5-10 mg; CR: 6.25, 12.5 mg	2.5-2.8 hr
Zaleplon (Sonata)	5-20 mg	1 hr
Eszopiclone (Lunesta)	1-3 mg	6 hr
Ramelteon (Rozerem)	8 mg	1-2.6 hr

Table 114-3 Wakefulness Promoting Agents

Drug	Dose Range
Amphetamine (Dexedrine, Desoxyn, Adderall, Adderall XR)	5-40 mg
Methylphenidate (Ritalin, Metadate, Methylin, Concerta)	10-60 mg
Modafinil (Provigil)	200-400 mg

include *confusional arousals*, *sleepwalking*, and *sleep terrors*. Sleep terrors are episodes of intense autonomic arousal characterized by loud vocalization and fear with associated papillary dilation, diaphoresis, tachycardia, and tachypnea, all without recall. Although these events are thought of as childhood disorders, 2% to 5% of adults sleepwalk, and many have a family history. In contrast, events arising from REM sleep such as *nightmares* and *REM behavior disorders* (RBDs) typically involve vivid recall of dream content before arousal. During RBDs there is loss of the protective atonia of REM sleep, which inhibits dream enactment. This disorder tends to affect middle-aged or older men and may precede the diagnosis of a degenerative neurologic condition by a decade. Autopsy studies suggest that pontine lesions may be responsible for the release from motor inhibition. The physical behavioral response to the characteristically violent dream imagery can result in injuries to the patient or his or her bed partner. Treatment strategies are prevention of sleepwalkers from getting into dangerous situations such as by opening windows and doors. If the behaviors are persistent and affect daytime functioning, suppressing arousals with the use of a benzodiazepine can be particularly successful for RBDs.

Sleep-Related Movement Disorders

Sleep-related movement disorders involve abnormal movements that occur during sleep and result in an arousal or

Table 114-4 Dopamine Agonists

Drug	Dose Range
Levodopa or carbidopa (Sinemet)	50-200 mg
Ropinirole (Requip)	0.25-4.0 mg
Pramipexole (Mirapex)	0.125-0.5 mg

disruption in the continuity of sleep. The clinical characteristics of *restless legs syndrome* (RLS), the most common sleep-related movement disorder, include the urge to move the legs because of an unpleasant sensation in the legs that tends to begin during periods of rest or inactivity, especially in the evening, and that is relieved by movement. Most cases are idiopathic, but some are familial and tend to have an earlier onset. Secondary causes include iron deficiency anemia, renal disorders, pregnancy, neurologic conditions such as peripheral neuropathies, radiculopathies, parkinsonian syndromes, rheumatoid arthritis, and fibromyalgia. Diagnosis is made by clinical history, although polysomnography can demonstrate increased periodic limb movements of sleep, repetitive movements of the lower extremities that result in arousals from sleep. The workup should exclude secondary causes including serum ferritin levels or iron saturations studies. The treatment for secondary causes entails iron replacement or symptomatic treatment of the underlying condition. For those with idiopathic RLS, the treatment of choice is a dopamine agonist such as levodopa, ropinirole, or pramipexole. Alternative medications include opioids, anticonvulsants for neuropathic pain, and hypnotics (Table 114-4).

Prospectus for the Future

Sleep medicine is a rapidly growing specialty bolstered by an increasing respect for the need to sleep well. As the basic science of how and why we sleep expands, pharmacologic

management of certain sleep complaints will improve. Soon we will be able to target the pathophysiology in addition to the symptomatology of sleep disorders.

Cortical Syndromes

Sinéad M. Murphy and Timothy J. Counihan

Anatomy

The paired cerebral hemispheres are connected by a large band of white matter fibers, the *corpus callosum*. Each hemisphere consists of four anatomically and functionally distinct regions: frontal, temporal, parietal, and occipital lobes. The two cerebral hemispheres supplement each other functionally in a variety of behavioral and sensorimotor tasks; however, certain functions, particularly language, manual dexterity, and visuospatial perception, are strongly lateralized to one hemisphere. Language function, for instance, is lateralized to the left hemisphere in 95% of the population; although 15% of the population is left-handed, only a minority possesses a right hemisphere that is dominant for language. Visuospatial functions are largely subserved by the right (nondominant) hemisphere.

The Rolandic fissure separates the motor cortex (precentral gyrus) from the sensory cortex (postcentral gyrus). In these regions, cortical representations of the different parts of the body are arranged as the motor (in the frontal lobe) and sensory (in the parietal lobe) homunculi.

Regional Syndromes

Because many neurologic disorders affect the cerebral hemispheres in a regionally specific or focal manner, a careful history and clinical examination that includes the Mini-Mental State Examination are helpful not only in localizing brain lesions (Fig. 115-1), but also in establishing the cause. Tables 115-1 to 115-4 summarize some of the core clinical features involved with damage to individual hemispheres. The rate of onset of symptoms and the tempo of progression influence the extent of the clinical deficit. The homuncular arrangement of cortical motor and sensory representation may allow for more precise localization of a lesion. For instance, motor or sensory signs confined to the lower extremities may suggest a parasagittal lesion, whereas signs involving the face and upper limb may be found in laterally placed cortical lesions.

APHASIA

Aphasia or *dysphasia* refers to a loss or impairment of language function as a result of damage to the specific language centers of the dominant hemisphere. It is distinct from dysarthria, which is a disturbance in the articulation of speech. The principal types of aphasia are summarized in Table 115-5. A good bedside screening test for aphasia is to have the patient read and write a sentence; writing is almost invariably affected in patients with disturbances of language (Fig. 115-2). An exception to this occurs in the syndrome of *alexia without agraphia*; this syndrome results from a vascular lesion of the dominant hemisphere's posterior cerebral artery, in which the patient's language center is "disconnected" from the contralateral (unaffected) visual cortex. Such patients can write a sentence but are unable to read what they have written. Clinical assessment for aphasia requires testing of fluency, comprehension, repetition, naming, reading, calculation, and writing. *Anomia* (difficulty in recalling the names of objects) in isolation has little localizing value.

Broca aphasia is characterized by a severe disruption in the fluency of speech, with profound impairments in expression in both speech and writing. Comprehension may be mildly affected. The language disturbance is almost invariably accompanied by contralateral face and arm weakness as a result of the proximity of the motor homunculus to Broca's speech area.

Wernicke aphasia is characterized by an inability to comprehend spoken or written language. Affected patients speak fluently but the content is meaningless; they may use words that are close in meaning to the intended word (semantic paraphasias) or words that sound like the intended word (literal paraphasias). Some patients with Wernicke aphasia have an associated contralateral homonymous hemianopia.

Conduction aphasia is characterized by an inability to repeat a spoken phrase such as "no ifs, ands, or buts," although patients have normal comprehension. The responsible lesion lies in the arcuate fasciculus connecting Broca's and Wernicke's areas. *Global aphasia* results from large

Figure 115-1 Computed tomography of the brain showing (A) large cystic lesion in right frontal lobe in a young man with seizures and a dysexecutive syndrome; (B) infarction in the right occipital lobe (posterior cerebral artery territory) in a man with a left homonymous hemianopia; and (C) hemorrhagic infarction in the left parietal lobe caused by venous sinus thrombosis (note thrombus in superior sagittal sinus) in a woman with headache and seizures. Magnetic resonance imaging of the brain showing (D) infarction in the left frontal and parietal lobes (middle cerebral artery territory) caused by internal carotid artery dissection in a man with right-sided neglect and hemiparesis; (E) high signal in the right temporal lobe in a patient with herpes simplex encephalitis; and (F) swollen right temporal lobe with mass effect in a woman with acute herpes simplex encephalitis.

Table 115-1 Frontal Lobe Syndromes

Symptoms and Signs	Site of Lesion
Contralateral spastic weakness	Primary motor or premotor cortex
Broca aphasia	Dominant inferior frontal lobe
Forced eye deviation	Frontal eye fields
Executive dysfunction, poor sequencing	Dorsolateral prefrontal lobe
Akinetic mutism, urinary incontinence	Medial frontal cortex
Disinhibition, emotional lability	Orbitofrontal cortex

Table 115-2 Parietal Lobe Syndromes

Symptoms and Signs	Site of Lesion
Contralateral sensory loss	Postcentral gyrus
Contralateral sensory neglect	Postcentral gyrus (nondominant)
Wernicke aphasia, apraxia	Inferior parietal or superior temporal cortex
Acalculia, finger agnosia, right-left confusion, agraphia (Gerstmann syndrome)	Angular gyrus

Table 115-3 Syndromes of Temporal Lobe Lesions

Symptoms and Signs	Site of Lesion
Anomic or sensory aphasia	Lateral temporal lobe (dominant)
Contralateral superior quadrantic anosmia	Superior lateral temporal lobe
Amnesia	Hippocampus
Oral-exploratory behavior, passivity, hypersexuality (Klüver-Bucy syndrome)	Amygdala (bilateral)
Visual delusions (déjà vu, jamais vu), olfactory hallucinations	Inferomedial temporal lobe

Table 115-4 Occipital Lobe Syndromes

Symptoms and Signs	Site of Lesion
Contralateral homonymous hemianopia	Striate cortex
Alexia without agraphia	Primary visual cortex (dominant) and splenium of corpus callosum
Visual agnosia, denial of blindness (Anton syndrome), visual hallucinations	Medial occipital lobe
Optic apraxia, absent optokinetic nystagmus	Lateral (visual association) cortex

Table 115-5 Principal Types of Aphasia

Type	Lesion Site	Fluency	Comprehension	Repetition	Naming	Other Signs
Broca	Inferior frontal lobe	↓	Good	↓	↓	Contralateral weakness
Wernicke	Posterior superior temporal lobe	Good	↓	↓	↓	Homonymous hemianopia
Conduction	Supramarginal gyrus	Good	Good	↓	↓	None
Global	Frontal lobe (large)	↓	↓	↓	↓	Hemiplegia

lesions of the frontal lobe, in which all aspects of language are affected. Lesions of the nondominant hemisphere language areas result in *dysprosody*. For instance, patients with lesions in the inferior frontal lobe of the nondominant (usually right) hemisphere, analogous to Broca's area, speak with a monotonous voice, losing the natural cadence of speech.

In *dysarthria*, language function is intact (which can be confirmed by having the patient write a sentence), but patients are unable to articulate speech. Dysarthria results from either supranuclear, nuclear, or peripheral lesions of the lower cranial nerves or from lesions of the bulbar musculature or neuromuscular junction.

AGNOSIA AND APRAXIA

Agnosia is the inability to recognize a specific sensory stimulus despite preserved sensory function. For instance, visual agnosia is the inability to recognize a visual stimulus despite normal visual acuity. Similar syndromes include the inability to recognize sounds (auditory agnosia), color (color agnosia), and familiar faces (prosopagnosia). Usually the responsible lesions are located in the occipitotemporal region.

Apraxia refers to an inability to perform learned motor tasks despite sufficient memory and sensorimotor function to understand the command (Fig. 115-3). The responsible lesions are usually in the dominant inferior parietal lobe. Lesions of the right parietal lobe often result in hemispatial neglect: The patient does not attend to stimuli in the left visual field or on the left side of the body. In a milder form of neglect, called *extinction*, patients can attend to stimuli contralateral to the side of the brain with the lesion (and the lesion is usually on the right side), but when presented with bilateral stimuli simultaneously, they respond only on the ipsilateral (right) side. Anosognosia, or the lack of awareness of one's deficit, frequently accompanies hemispatial neglect.

AMNESIA

Memory and mechanisms for recall are located in the hippocampus of the temporal lobe. The common memory disorders are summarized in Table 115-6. Degeneration of the hippocampus or its connections results in the inability to form new memories and is a central accompaniment of Alzheimer disease. Concussion injuries typically induce severe retrograde amnesia (the inability to recall events that

Keys

Camera

pen

watch

bag

boots

boots

Figure 115-2 Neologisms written by a patient with aphasia attempting to name mobile phone, keys, camera, watch, pen, bag, boots.

occurred before the injury) and mild anterograde amnesia (the inability to recall events that occur after the injury).

Transient global amnesia typically affects persons older than 65 years and consists of abrupt onset of amnesia for time, place, and recent memory and lasts less than 12 hours. Patients are distressed and repeatedly require reorientation to their environment. They are, however, able to carry out complex, previously learned tasks such as driving. A number of precipitants have been identified, including extreme emotion, physical activity, sexual intercourse, and immersion in cold water. Recurrent episodes are rare.

Prospectus for the Future

There have been many recent advances in functional neuroimaging technology, which allows neuroscientists to study not only the functional anatomy of a particular brain structure, but also its metabolic activity. Functional magnetic resonance imaging (fMRI) now permits mapping of the metabolic anatomy of subcortical gray and white matter structures, such as the basal ganglia, and their role in conditions such as dystonia. These imaging modalities are now able to study white matter

Figure 115-3 Attempts to draw a cube by a patient with a neurodegenerative disorder.

Table 115-6 Common Disorders of Memory

Benign forgetfulness of aging
Alzheimer disease and other dementias
Head trauma
Transient global amnesia
Korsakoff syndrome (thiamine deficiency)
Encephalitis (herpes simplex)
Stroke (posterior cerebral artery)
Temporal lobe seizures
Psychogenic disorders

Korsakoff syndrome is the end result of untreated or partially treated Wernicke encephalopathy caused by thiamine deficiency. Patients (many of whom are alcoholic or malnourished) demonstrate confusion, gait ataxia, nystagmus, and ophthalmoparesis. The condition may be precipitated by the administration of glucose unless thiamine is given in advance. If the condition is untreated, a profound inability to form new memories results, with devastating consequences for the patient. In the chronic phase, patients confabulate freely in an attempt to fill the memory void.

Psychogenic amnesia often affects long-term memory as well as recent memory, and patients are occasionally unable to recall their own names. This is in contrast to most organic amnesic states, in which only short-term memory is affected and disorientation is greatest for time and place, but never for self.

Dementia and Memory Disturbances

Frederick J. Marshall

Major Dementia Syndromes

Dementia is defined as the progressive loss of intellectual function. Memory loss is the central feature, and specific dementia syndromes characteristically cause particular forms of memory impairment. Dementia syndromes also produce specific abnormalities of cognition: language, spatial processing, *praxis* (learned motor behavior), and *executive function* (the ability to plan and sequence events). *Cortical dementia* and *subcortical dementia* subdivide the dementias (Table 116-1). Table 116-2 provides the differential diagnosis of neurodegenerative causes of dementia, and Table 116-3 outlines other causes of dementia. Neurodegeneration is the most common underlying cause of dementia and is seen in Alzheimer disease (AD), frontotemporal dementia, and diffuse Lewy body disease, among others. Most causes of dementias are currently untreatable. Potentially correctable causes account for less than 5% of all cases of dementia. Structural processes or infections must be considered, along with metabolic and nutritional diseases. Every patient with dementia should have tests of serum electrolytes and vitamin B₁₂, as well as assessments of liver, renal, and thyroid function; serologic studies for syphilis should be done if risk factors are identified. Chronic infections (see Chapter 128) and normal-pressure hydrocephalus should be considered. Brain imaging should be performed.

Neuropsychological testing characterizes the pattern of cognitive and memory impairments and is helpful in the differential diagnosis. The Mini-Mental State Examination (Table 116-4) is a standard test that can be used as a bedside or office screening tool for identifying patients with dementia. This examination emphasizes memory and language and is best at detecting cortical rather than subcortical dementia. In addition to the Mini-Mental State Examination, patients with dementia should have tests of visuospatial processing (clock drawing), *praxis* (*show how you would comb your hair; show how you would blow out a match*), and verbal fluency (*name as many animals as you can in 60 seconds*).

ALZHEIMER DISEASE

AD accounts for approximately 70% of all cases of dementia in older adults. Nearly 5 million persons in the United States are affected, and this number will double by 2020 as the population ages. AD places enormous burdens on the patient, on the family, and on society; annual direct and indirect expenditures are estimated to exceed \$100 billion. The disease occurs in up to 30% of persons older than 85 years of age.

AD has many causes, but none are fully defined. All causes, however, produce similar clinical and pathologic findings. Pathologically, the disease is characterized by the progressive loss of cortical neurons and the formation of amyloid plaques and intraneuronal neurofibrillary tangles. β -amyloid (A β) is the major component of the plaques, whereas hyperphosphorylated tau protein is the major constituent of the neurofibrillary tangles. The process starts in the hippocampus and entorhinal cortex and spreads to involve diffuse areas of association cortex in the temporal, parietal, and frontal lobes. The relative deficiency of cortical acetylcholine (resulting from the loss of neurons in the nucleus basalis) provides the rationale for symptomatic treatment of the disease with centrally acting acetylcholinesterase inhibitors.

Pathogenesis

AD is often categorized into two forms: (1) a young-onset hereditary or familial form, which is extremely uncommon and for which three specific genetic abnormalities have been determined, and (2) a more common, sporadic form that typically occurs in persons older than 65 years of age (Table 116-5).

The autosomal-dominant, early-onset forms of AD have provided clues to the molecular pathogenesis of sporadic AD. Progressive dementia and pathologic changes characteristic of AD are almost universal in older patients with Down syndrome (trisomy 21). This observation suggested that chromosome 21 harbors a gene responsible for AD. A β is a

Table 116-1 Distinguishing Characteristics of Cortical and Subcortical Dementias

Cortical Dementia
Symptoms: major changes in memory, language deficits, perceptual deficits, praxis disturbances
Affected brain regions: temporal cortex (medial), parietal cortex, and frontal lobe cortex
Examples: Alzheimer disease, diffuse Lewy body disease, vascular dementia, frontotemporal dementias
Subcortical Dementia
Symptoms: behavioral changes, impaired affect and mood, motor slowing, executive dysfunction, less severe changes in memory
Affected brain regions: thalamus, striatum, midbrain, striatofrontal projections
Examples: Parkinson disease, progressive supranuclear palsy, normal-pressure hydrocephalus, Huntington disease, Creutzfeldt-Jakob disease, chronic meningitis

Table 116-3 Other Causes of Progressive Dementia in Adults

cleavage product of the amyloid precursor protein, coded by a gene on chromosome 21. Abnormal processing of amyloid precursor protein into the amyloidogenic fragment Aβ₄₂ may be important in the pathogenesis of AD. The *apolipoprotein E* (*ApoE*) gene was found to be a susceptibility locus

for sporadic AD in late-onset familial AD pedigrees. The gene is polymorphic (ε2/3/4), and persons who inherit one or both ε4 alleles are at increased risk for developing AD. ApoE-ε4 interacts selectively with Aβ and with tau protein, but how ApoE-ε4 increases the risk of AD is still unknown.

Table 116-5 Familial versus Sporadic Alzheimer Disease

Chromosome or Gene	Age at Onset (yr)	Percentage of All FAD Cases	Percentage of All AD Cases
FAD: Early Onset, Autosomal Dominant			
1/presenilin 2	40-80	5-10	<0.5
14/presenilin 1	30-60	70	<1
21/amyloid precursor protein	35-65	5	<0.5
Sporadic AD: Late Onset, Possibly Polygenetic ± Possibly Environmental			
No single determinant gene*	Usually >60	—	98

*Apolipoprotein E-ε4 allele on chromosome 19 yields increased risk compared with ε2 or ε3 allele.
AD, Alzheimer disease; FAD, familial Alzheimer disease.

Table 116-6 Diagnostic Criteria for Probable Alzheimer Disease

Progressive functional decline and dementia established by clinical examination and mental status testing and confirmed by neuropsychological assessment
Cognitive deficits in two or more domains (including memory impairment)
Normal level of consciousness at presentation
Not developmentally acquired; onset between 40 and 90 years of age
Absence of other illnesses capable of causing dementia

Clinical Features

AD begins gradually and affects memory, orientation, language, visuospatial processing, praxis, judgment, and insight. Depression is frequent early in AD; frank psychosis with agitation and behavioral disinhibition often occur in advanced stages. Patients become dependent on others for all activities of daily living. The rate of progression of AD is variable, usually taking 5 to 15 years to progress from presentation to advanced illness. Diagnostic criteria are outlined in Table 116-6. Although a definitive diagnosis of AD requires biopsy (rarely done) or autopsy confirmation, these diagnostic criteria establish the diagnosis with more than 85% specificity in moderately demented patients. The positron emission tomography (PET) ligand Pittsburgh Compound B (PiB), which binds to amyloid, is currently being developed as a promising diagnostic and clinical marker of disease progression.

Treatment

Although their benefits are modest, the cholinesterase-inhibiting drugs tacrine (Cognex), donepezil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl, Razadyne) represent important advances. Tacrine can be hepatotoxic and must be given 4 times a day; donepezil is given once a day and has fewer side effects than tacrine; rivastigmine may be given as a once-daily transdermal patch; and galantamine now has an extended release form that can also be given once a day. In clinical trials, cholinesterase inhibitors benefited fewer than 50% of patients. The glutamate antagonist memantine (Namenda) has been shown to prolong daily function in patients with moderate-to-advanced AD.

Nursing services provide oversight of hygiene, nutrition, and medication compliance. Antipsychotics, antidepressants, and anxiolytics are useful for patients with behavioral

disturbances, which are the most common cause of nursing home placement. Acetylcholinesterase inhibition may also benefit the behavioral disorder. Patients and families can be referred to a local Alzheimer's Association chapter for further information on available community supports.

DIFFUSE LEWY BODY DISEASE

Lewy bodies are pathologic inclusions that are the hallmark of Parkinson disease when they are restricted to the brainstem (see Chapter 122). Patients with diffuse Lewy body disease have clinical parkinsonism (slow movement, rigidity, and balance problems) combined with early and prominent dementia. Pathologically, Lewy bodies are found in the brainstem, limbic system, and cortex. Visual hallucinations and cognitive fluctuations are common, and patients are unusually sensitive to the adverse effects of neuroleptic medication. Diffuse Lewy body disease may represent the second most common cause of dementia after AD. However, the common concurrence of the pathologic features of diffuse Lewy body disease with the classic neuritic plaques and neurofibrillary tangles of AD complicates the identification of the cause of dementia in a given patient.

VASCULAR DEMENTIA

Approximately 10% to 20% of older patients with dementia have radiographic evidence of focal stroke on magnetic resonance imaging (MRI) or computed tomography (CT), combined with focal signs on the neurologic examination. When the dementia syndrome begins with a stroke, and when the progression of the illness is stepwise (suggesting recurrent vascular events), the diagnosis of *vascular dementia* is likely. Patients typically develop early incontinence, gait disturbances, and flattening of affect. A subcortical dementing process attributed to small vessel disease in the periventricular white matter has been referred to as *Binswanger disease*, but it may merely be a radiographic finding rather than a true disease. Appropriate treatment of risk factors for vascular disease—blood pressure control, smoking cessation, diet modification, and anticoagulation (in select settings such as atrial fibrillation)—is clearly mandatory and may be of benefit.

FRONTOTEMPORAL DEMENTIAS

Unlike AD, in which the presenting symptom is typically memory loss, frontotemporal dementia often begins with

significant behavioral disturbances. Patients with *Pick disease*, the classic form of frontotemporal dementia, are frequently irascible and socially disinhibited. As in AD, the illness progresses for years; no intervention slows the inevitable decline of these patients. Approximately 50% of patients have a family history of the disease; in some families, a mutation in the tau protein gene on chromosome 17 is the cause.

PARKINSON DISEASE

Nearly 50% of patients with Parkinson disease (see Chapter 122) become demented by the time they reach the age of 85 years. The dementia of Parkinson disease affects executive function out of proportion to its impact on language and visuospatial processing. Thought processes appear to slow down (*bradyphrenia*), analogous to the slowing of movement (*bradykinesia*). Because dementia occurs relatively late in the progression of Parkinson disease, most patients are taking drugs to improve their movement disorder by enhancing dopaminergic neurotransmission. These drugs can induce psychosis. Dose reductions should be attempted before the diagnosis of underlying dementia in these patients is made. Acetylcholinesterase inhibition has been shown to be helpful in patients with dementia caused by Parkinson disease.

NORMAL-PRESSURE HYDROCEPHALUS

The triad of dementia (typically subcortical), gait instability, and urinary incontinence suggests the possibility of *normal-pressure hydrocephalus*. These patients appear to walk with their feet stuck to the floor, without lifting up the knees and with a broad base. Symptoms evolve over the course of weeks to months, and brain imaging reveals ventricular enlargement out of proportion to the degree of cortical atrophy. Numerous diagnostic tests have been described, including radionuclide cisternography and MRI flow studies. The most important test remains the clinical response to removal of large volumes of cerebrospinal fluid, either through serial lumbar punctures or through the temporary placement of a lumbar drain, followed by examination of the patient's gait and cognitive function. Neurosurgical placement of a permanent ventriculoperitoneal shunt may correct the problem. Patients likely to benefit from shunt placement have a clear response to the removal of 30 to 40 mL of spinal fluid, with improved gait and alertness within minutes to hours of the procedure. The cause of normal-pressure hydrocephalus is a derangement of the cerebrospinal fluid hydrodynamics. Shunt placement is most likely to be effective if normal-pressure hydrocephalus occurs after severe head trauma or subarachnoid hemorrhage.

PRION INFECTION, CHRONIC MENINGITIS, DEMENTIA RELATED TO ACQUIRED IMMUNODEFICIENCY SYNDROME

Creutzfeldt-Jakob disease (CJD) is a subacute, dementing, transmissible illness with typical onset between 40 and 75 years of age and an incidence of 1 in 1,000,000 (see Chapter 128). The disease causes spongiform degeneration

and gliosis in widespread areas of the cortex. Clinical variants of the disorder are differentiated by the relative predominance of cerebellar symptoms, extrapyramidal hyperkinesias, or visual agnosia and cortical blindness (*Heidenhain variant*). Ninety percent of patients with CJD have myoclonus, compared with 10% of patients with AD. Patients with all forms of the disease share a relentlessly progressive dementia and disruption of personality over weeks to months. The electroencephalogram develops characteristic abnormalities, including diffuse slowing and periodic sharp waves or spikes. The transmissible agent, a prion protein, is invulnerable to routine modes of antiseptics. Cerebrospinal fluid can be tested for the 14-3-3 protein, although this test is not 100% sensitive or specific for CJD (see Chapter 128). Diffusion-weighted MRI images show characteristic cortical ribbon changes.

Certain *infectious agents* can cause the subacute or chronic development of subcortical dementia. These chronic meningitides are discussed in Chapter 128.

Human immunodeficiency virus accesses the central nervous system through monocytes and the microglial system and causes associated neuronal cell loss, vacuolization, and lymphocytic infiltration. The dementia associated with this infection is characterized by bradyphrenia and bradykinesia. Patients have executive dysfunction, impaired memory, poor concentration, and apathy. Treatment of the underlying viral infection with protease inhibitors and reverse transcriptase inhibitors may slow the progression of the dementia (see Chapter 128).

Other Memory Disturbances

STRUCTURE OF MEMORY

Memory function is divided into introspective processes (declarative, explicit, aware memories) and processes that are not accessible to introspection (nondeclarative, implicit, procedural memories). Short-term memory (e.g., for words on a list) is a form of *declarative memory*. Other forms include the conscious recall of episodes from personal experience (*episodic memory*), and factual knowledge (*semantic memory*) that can be consciously recalled and stated (declared). Declarative memories involve consciously *knowing that*. . . . Patients with amnesia resulting from lesions of the medial temporal lobes or midline diencephalic structures have deficits of declarative memory.

Nondeclarative memory encompasses several distinct and neuroanatomically less clearly localized functions related to the performance of specific learned motor, cognitive, or perceptual tasks. Nondeclarative (procedural) memories involve unconsciously *knowing how*. . . . Deficits in nondeclarative memory may involve various areas of association neocortex, depending on the nature of the task (e.g., parieto-temporal-occipital junction cortex for visual perceptual tasks, frontal association cortex for motor tasks). Patients with amnesia resulting from lesions of the medial temporal lobes tend to perform normally on tests of nondeclarative memory.

Anterograde amnesia refers to the inability to learn new information. It commonly occurs after brain injury or in

association with dementia. The inability to recollect prior information is known as *retrograde amnesia*. Both types of amnesia usually occur together in brain injury syndromes, although the extent of one type or the other may vary. The degree of anterograde amnesia after head injury is correlated with the severity of the injury.

ISOLATED DISORDERS OF MEMORY FUNCTION

Memory can be impaired in relative isolation as a consequence of head injury, thiamine deficiency (Korsakoff syndrome), benign forgetfulness of aging, transient global amnesia, or psychogenic disease.

Head injury typically results in retrograde amnesia in excess of anterograde amnesia, with both forms stretching out in time away from the discrete event. As time passes, these disrupted memories generally gradually return, although rarely to the point at which the events immediately surrounding the trauma are recalled.

Korsakoff syndrome is characterized by the near-total inability to establish new memory. Patients often confabulate responses when they are asked to convey the details of their current circumstance or to relay the content of a recently presented story. Deficiency of thiamine and other nutritional deficiencies in the context of chronic alcoholism are the most common underlying causes. Thiamine is a necessary cofactor in the metabolism of glucose, and for this reason, thiamine must be replenished at the same time glucose is administered whenever a comatose patient is presented to the emergency department.

Aging is associated with mild loss of memory, exhibited by difficulty in recalling names and by forgetfulness for dates. Population-based assessments of neuropsychological

function have demonstrated that poor performance on delayed-recall tasks is the most sensitive indicator of cognitive change with advancing age. Verbal fluency, in contrast, remains intact with advancing age, and vocabulary may increase with time, even into old age.

Transient global amnesia is a dramatic memory disturbance that affects older patients (>50 years of age). Patients usually have only one episode; occasionally, episodes recur over the course of several years. Patients have complete temporal and spatial disorientation; orientation for person is preserved. Near-total retrograde and anterograde amnesia persists for variable periods, typically 6 to 12 hours. Patients are often anxious and may repeat the same question over and over again. Transient global amnesia may be confused with psychogenic amnesia, fugue state, or partial complex status epilepticus. Transient global amnesia is thought to reflect underlying vascular insufficiency to the hippocampus or midline thalamic projections.

Unlike patients with organic memory disturbances, patients with *psychogenic amnesia* typically have inconsistent loss of recent and remote memory, relatively more loss of emotionally charged memory (rather than relatively less loss of such memory in organic disease), and an apparent indifference to their own plight—they ask few questions. Most characteristically, patients with psychogenic amnesia tend to express disorientation to person (asking, *Who am I?*), a phenomenon seldom seen in organic memory disturbance.

Patients with *severe depression* may exhibit *pseudodementia*. Vegetative signs, including changes in appetite, weight, and sleep pattern, are common, whereas signs of cortical impairment, such as aphasia, agnosia, and apraxia, are rare. Memory and bradyphrenia improve with antidepressant therapy. Depression often coexists with other causes of dementia: AD, Parkinson disease, and vascular dementia.

Prospectus for the Future

Molecular Genetics and the Future of the Diagnosis and Treatment of Dementia

Breakthroughs in the fields of proteomics, information processing of megadata sets, and messenger-RNA expression profiling promise to improve the diagnosis and treatment of dementia in the future. In all likelihood, Alzheimer disease (AD) will be subcategorized into more precise etiologic categories, and patients will be offered selective treatments based on their particular pharmacogenetic background. Drug development will be enhanced by emerging knowledge about the molecular mechanisms of A β deposition, synaptic loss, and tau protein

hyperphosphorylation. Treatment strategies currently in clinical trials include decreasing A β peptide production by blocking α -secretase or β -secretase or upregulating cleavage of the amyloid precursor protein at the α -secretase site. In addition, studies of active and passive immunization designed to lower brain A β levels are ongoing. Although acetylcholinesterase inhibition has not been shown to be effective in the treatment of mild cognitive impairment (considered to be a precursor condition to AD), these novel molecular and immunologic approaches continue to hold promise for disease-modifying treatments in the future.

Major Disorders of Mood, Thoughts, and Behavior

Jeffrey M. Lyness

Introduction to and Classification of Mental Disorders

Mental (psychiatric) disorders are defined as alterations in mood, thoughts, and behavior that produce substantive subjective distress or affect the patient's functional status. Many mental disorders are caused by the direct effects of drugs, systemic disease, or neurologic disease on brain physiology. These may be broadly considered as secondary psychiatric disorders, as opposed to the primary or idiopathic psychiatric disorders. Table 117-1 shows the types of psychiatric disorders with an identified cause. The distinguishing feature of cognitive disorders is impairment in intellectual functions such as level of consciousness, orientation, attention, or memory; however, these disorders also often include disruption of mood, thoughts, and behaviors similar to that seen in other psychiatric syndromes. Cognitive disorders are the focus of Chapters 113 and 116.

The noncognitive secondary syndromes by definition cause psychiatric phenomenology similar to their idiopathic counterpart. Therefore, during the evaluation of any patient with new or worsened psychiatric symptoms, it is essential to conduct a thorough evaluation for specific "organic" causes, including at least a careful history and physical examination (with screening neurologic examination), often supplemented by laboratory evaluations. Table 117-2 outlines important causes of psychiatric syndromes. Although some conditions are more likely to produce certain psychiatric syndromes, many may manifest as any of several psychiatric syndromes. Conversely, a psychiatric syndrome may be caused by any of a wide range of conditions.

Because the cause of primary psychiatric disorders is not known, approaches to classification depend on reliable empirical observations of phenomenology, clustered into recognizable syndromes. Table 117-3 shows the most important psychiatric syndromes and the disorders in which they may manifest. Table 117-4 shows the major idiopathic disorders excluding substance use disorders (see Chapter 135).

Many psychiatric disorders can be present with multiple syndromes. For example, major depression with psychotic features, classified as a mood disorder, manifests with both a depressive syndrome and a psychotic syndrome. Therefore, in evaluating a patient with new or worsened psychiatric symptoms, one must construct a differential diagnosis based on syndromes alongside the differential diagnosis based on potential ("organic" or secondary) causes.

Mood Disorders

Mood disorders are characterized by idiopathic episodes of depression ("unipolar") or mania ("bipolar"). The core symptoms of depressive episodes include emotional symptoms (dysphoria, irritability, anhedonia, loss of interests), ideational symptoms (thought content of hopeless, worthless, guilty, or suicidal themes), and neurovegetative symptoms and signs (altered sleep, appetite, and weight; anergia; psychomotor slowing or agitation; decreased concentration). Major depressive disorder is defined by episodes of at least five such symptoms, including depressed mood or anhedonia or loss of interests, present most of the day for most days over at least 2 consecutive weeks, sufficient to cause significant distress and affect functional status. Other prominent symptoms may include associated anxiety, somatic worry or somatoform symptoms, and, in the most severe cases, psychotic symptoms including nihilistic or self-deprecatory ("mood-congruent") delusions. Major depression is common, with a point prevalence of 3% to 5% in men and 8% to 10% in women, and a lifetime prevalence approximately double the point prevalence. True disorder incidence is difficult to estimate in the population given the high recurrence rates, but new episodes have an annual incidence of approximately 3%. First onset may occur at any age but is most common in the third through fifth decades of life. Whereas most episodes of major depression fully remit spontaneously or with treatment, the lifetime risk of recurrence may be as high as 90%, and up to 20% of patients may experience chronic symptoms over many years. Major

Table 117-3 Important Psychiatric Syndromes

Syndrome	Main Symptoms and Signs	Present in These Disorders
Cognitive	Impairment in intellectual functions (e.g., level of consciousness, orientation, attention, memory, language, praxis, visuospatial, executive functions)	Cognitive disorders Mental retardation (if onset in childhood)
Mood	Depressive: lowered mood, anhedonia, negativistic thoughts, neurovegetative symptoms Manic: elevated or irritable mood; grandiosity; goal-directed hyperactivity with increased energy; pressured speech; decreased sleep need	Cognitive disorders Mood disorders (primary or secondary) Psychotic disorders (schizoaffective disorder)
Anxiety	All include anxious mood and associated physiologic signs and symptoms (e.g., palpitations, tremors, diaphoresis). May include various types of dysfunctional thoughts (e.g., catastrophic fears, obsessions, flashbacks) and behaviors (e.g., compulsions, avoidance behaviors)	Cognitive disorders Mood disorders (primary or secondary) Psychotic disorders (primary or secondary) Anxiety disorders (primary or secondary)
Psychotic	Impairments in reality testing: hallucinations, thought process derailments	Cognitive disorders Mood disorders (primary or secondary) Psychotic disorders
Somatoform	Somatoform symptoms: physical symptoms from psychogenic causes	Mood disorders (primary or secondary) Anxiety disorders (primary or secondary) Somatoform disorders
Personality pathology	Dysfunctional enduring patterns of emotional regulation, thought patterns, interpersonal behaviors, impulse regulation	Cognitive disorders (dementia) Personality change from general medical condition Personality disorders

Based on data from *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)*.

depression is a leading correlate of disability worldwide, is an important determinant of death by suicide, and is associated with increased risk of death from comorbid physical illnesses. Dysthymic disorder is a condition defined by chronic depressive symptoms of insufficient severity to meet criteria for major depression.

Depressive disorders are heterogeneous, with many potential pathogenic mechanisms. Genetic factors, such as polymorphisms of the serotonin transporter protein, affect vulnerability to depressive episodes in the face of psychosocial stressors. Depression is both polygenic and

multifactorial, with genetic factors accounting for about 50% of the risk for depression onset. Alterations in the functioning of brain serotonergic and noradrenergic systems and of the hypothalamic-pituitary-adrenal axis are present in depression; neuroimaging studies show smaller hippocampal volumes and altered metabolic activity in several regions including the anterior cingulate cortex. However, at present such studies are not accurate in making the clinical diagnosis, which depends on identification of the clinical syndrome. Improvement in regional cerebral metabolic activity is seen with successful treatment of depression, with different

patterns of improvement visible on functional neuroimaging scans after psychotherapy versus pharmacotherapy. Dysfunctional negativistic patterns of thinking, impaired social relationships, and stressful life events also contribute to depression.

Mild to moderate forms of depression respond to focused psychotherapies or antidepressant medications (Table 117-5). Other psychosocial interventions, including exercise, also may produce benefit. More severe forms of depression will not respond to psychosocial interventions alone. Severe or refractory depression may be treated safely and effectively with electroconvulsive therapy. Other evidence-based somatic therapies include light therapy (for depression with a seasonal component) and possibly vagal nerve stimulation.

Table 117-5 Psychotherapies for Depression and Antidepressant Medications

Psychotherapy

Name	Approach
Cognitive psychotherapy	Identify and correct negativistic patterns of thinking
Interpersonal psychotherapy	Identify and work through role transitions or interpersonal losses, conflicts, or deficits
Problem-solving therapy	Identify and prioritize situational problems; plan and implement strategies to deal with top-priority problems

Commonly Used Antidepressants

Name	Mechanism of Action
SSRIs (selective serotonin reuptake inhibitors)	Inhibit presynaptic reuptake of serotonin
Citalopram and escitalopram	
Fluoxetine	
Paroxetine	
Sertraline	
SNRIs (serotonin and norepinephrine reuptake inhibitors)	Inhibit presynaptic reuptake of serotonin and norepinephrine
Duloxetine	
Venlafaxine and desvenlafaxine	
TCA s (tricyclic antidepressants)	Inhibit presynaptic reuptake of serotonin and norepinephrine (in varying proportions depending on the specific TCA)
Amitriptyline	
Desipramine	
Doxepin	
Imipramine	
Nortriptyline	
MAOIs (monoamine oxidase inhibitors)	Inhibit monoamine oxidase, the enzyme that catalyzes oxidative metabolism of monoamine neurotransmitters
Isocarboxazide	
Phenelzine	
Selegiline	Selective MAO-B inhibitor
Tranylcypromine	
Other	
Bupropion	Unknown, although it is weak inhibitor of presynaptic reuptake of norepinephrine and dopamine
Mirtazapine	Antagonist at α_2 and 5HT ₂ receptors
Trazodone	Inhibits presynaptic reuptake of serotonin; antagonist at 5HT ₂ and 5HT ₃ receptors

Bipolar disorder (bipolar I) is characterized by recurrent episodes of mania, usually with episodes of major depression as well. Manic episodes include elevated (euphoric) or irritable mood, goal-directed hyperactivity (often with poor judgment leading to substantial adverse consequences, e.g., sexual, spending, or gambling sprees), grandiose thought content, pressured speech, increased energy level with decreased need for sleep, and racing thoughts that may

progress to objectively observable flight of ideas or more severe thought process derailments such as loose associations. Compared with unipolar depression, bipolar disorder has a lower point prevalence (approximately 1%), an approximately equal gender distribution, and a younger average age of onset (typically late teens to twenties). There are few data regarding incidence rates beyond studies of the peak years of disease onset, with wide variability also depending on other characteristics of the study sample. Most patients return to baseline functioning between acute mood episodes, but some have a deteriorating course; others have rapid cycling, defined as four episodes per year. Genetic factors play a greater role in the pathogenesis of bipolar disorder than in major depressive disorder; twin studies indicate that genetic factors again account for approximately 50% of the risk for bipolar disorder, representing a 50-fold increase over the population base rate (as compared with a fivefold to 10-fold increase for major depression). Bipolar disorder is polygenic and has been linked in individual families to different loci. The pathogenesis is unclear, but functional neuroimaging evidence suggests dysregulation of frontostriatal systems. Structural neuroimaging studies (computed tomography [CT] and magnetic resonance imaging [MRI] scans) show increased ventricular-brain ratios consistent with parenchymal agenesis or atrophy, similar to many other psychiatric disorders. Psychosocial stressors often play a role in precipitating episodes of both mania and depression. The mainstay of treatment for bipolar disorder is mood stabilizer medications (e.g., lithium, anticonvulsants such as valproic acid and carbamazepine) for both acute episodes and maintenance therapy. The anticonvulsant lamotrigine may be particularly useful for bipolar depression. Antipsychotic medications are useful for acute manic episodes and may have a role in maintenance therapy. Benzodiazepines may be used to treat acute agitation and aggression while waiting for more definitive antimanic therapies to take effect. Antidepressants have long been used for depressive episodes, although they may precipitate manic episodes and their efficacy for depression in bipolar patients is not established. Electroconvulsive therapy is effective for both refractory mania and depression. Psychosocial treatments alone do not effectively treat mania and may be less effective for bipolar depression, but psychoeducation and support to manage psychosocial stressors and encourage medication compliance improve longer-term outcomes.

A spectrum of less severe bipolar disorders includes conditions marked by episodes of hypomania (i.e., low-level manic symptoms without psychosis or significant impairment in functioning). These disorders include bipolar II disorder (bipolar disorder not otherwise specified [NOS]), characterized by episodes of hypomania and major depression, and cyclothymic disorder, characterized by hypomania and low-level depression not meeting criteria for major depression. Patients with bipolar II disorder are most likely to seek care during depressive episodes, so it is important to inquire about a prior history of manic symptoms to avoid precipitating mania with the use of antidepressant medications. Bipolar II appears to have heritability somewhat distinct from that of bipolar (“I”) and major depressive disorders. The pathogenesis of these less severe mood disorders is unknown.

Anxiety Disorders

The idiopathic anxiety disorders manifest with troublesome thoughts and somatic symptoms (Table 117-6) along with the emotional sensation of anxiety. A panic attack is a transient episode of crescendo anxiety, catastrophic thoughts (e.g., fears of dying, going insane, or losing self-control), and somatic symptoms. If panic attacks or other clinically significant anxiety symptoms occur only in predictable response to environmental stimuli, the anxiety disorder is known as a *phobia*, which may further be classified as agoraphobia (anxiety about being in places from which escape might be difficult or embarrassing, e.g., being alone, in crowds, in tunnels, or on bridges); social phobia (anxiety in interpersonal situations); and specific phobia (anxiety provoked by other situations or objects, e.g., blood, animals, heights). Panic disorder manifests with recurrent panic attacks of which at least some are unexpected and unpredictable, along with anticipatory anxiety (i.e., fears of having another attack) and avoidance behaviors (i.e., avoiding situations that might provoke a panic attack or in which having an attack is perceived to be embarrassing or dangerous).

Other anxiety disorders may not cause discrete panic attacks. Obsessive-compulsive disorder is characterized by recurrent obsessions (thoughts, impulses, or mental images that are anxiety-producing, perceived as intrusive and inappropriate, and resistant to attempts to suppress or neutralize them) and compulsions (repetitive behaviors or mental acts performed in response to obsessions or other rigid rules). Individuals exposed to severely stressful events (typically involving the actual or threatened loss of life or limb) may experience any of a wide variety of psychiatric sequelae. If the sequelae include symptoms of reexperiencing of the traumatic event (e.g., intrusive memories, nightmares, flashbacks), avoidance phenomena (e.g., avoiding reminders of the event, sense of foreshortened future), and hyperarousal symptoms (e.g., irritability, exaggerated startle response), the disorder is termed *acute stress disorder* (if the duration is

up to 1 month) or *post-traumatic stress disorder* (if the duration is >1 month). Enduring anxiety symptoms that are not captured by these diagnoses (or by diagnoses of cognitive, mood, or psychotic disorders) may be diagnosed as generalized anxiety disorder. Anxiety disorders are common, with point prevalences of 1% to 2% each for panic disorder and obsessive-compulsive disorder and up to 10% for phobias. Although there are fewer data on long-term outcome than for mood disorders, many anxiety disorders tend to have a chronic waxing and waning course. There are few data that provide clear incidence rates, but it is clear that most anxiety disorders have first onset in the teens, 20s, and 30s; although new-onset anxiety is common in later life, the cause is only rarely a primary anxiety disorder (see Table 117-3).

The pathogeneses of most anxiety disorders may be understood as inappropriate activation of the stress response system involving a variety of neuroendocrine and autonomic outputs, coordinated by the central nucleus of the amygdala and other brain structures. The amygdala receives excitatory glutamatergic inputs from cortical sensory areas and the thalamus and has outputs to the major monoaminergic centers (e.g., noradrenergic neurons of the locus coeruleus, dopaminergic neurons of the ventral tegmental area, serotonergic neurons of the raphe nuclei) that in turn project to the many brain regions subserving the symptoms of anxiety. Unlike the other anxiety disorders, obsessive-compulsive disorder appears to be related more specifically to altered functioning of striatofrontal connections, leading to patterns of altered regional cerebral metabolism, visible on functional neuroimaging scans, that improve with successful psychotherapy or pharmacotherapy. The identification and correction of dysfunctional patterns of thinking (“cognitive therapy”) and the extinction of pathologic behaviors and positive reinforcement of more functional behaviors (“behavior therapy”) are evidence-based psychotherapies useful in most anxiety disorders. Such psychotherapies are the sole therapies for specific phobias and may be the sole or primary therapy for most other anxiety disorders. Antidepressant, anxiolytic, and other drug therapies are also used in treatment. Increasingly, antidepressant medications have replaced anxiolytics as the mainstay of pharmacotherapy for panic disorder, post-traumatic stress disorder, generalized social phobia, and generalized anxiety disorder. For obsessive-compulsive disorder, only antidepressant agents with pronounced activity on the serotonergic system (selective serotonin reuptake inhibitors [SSRIs; see Table 117-5], and also clomipramine) are efficacious.

Psychotic Disorders

Psychosis is defined as a loss of reality testing, manifested as hallucinations (false sensory perceptions), delusions (fixed false beliefs), and thought process derailments. Schizophrenia is the prototypic psychotic disorder; it includes acute episodes of psychosis (“positive” symptoms) and often declining overall functioning over time related to the presence of “negative symptoms” such as affective flattening, abulia, apathy, and social withdrawal. The point prevalence of schizophrenia is approximately 1%, and its chronic, debilitating course takes a considerable toll on patients, families, and society. Peak onset is in late adolescence to young

adulthood, slightly younger for males than females. The annual incidence is approximately 15 per 100,000, but with marked variability across study samples and populations. The pathogenesis of schizophrenia remains unknown, despite there being neurobiologic abnormalities. Twin studies show that the disease is multifactorial; genetic factors account for approximately 50% of the risk, and multiple gene loci appear to be involved. Studies of postmortem brains indicate a nonglionic neuropathologic process with subtle disruptions of cortical cytoarchitecture. It is likely that psychosocial factors and neurodevelopment interact with a nonlocalizable brain “lesion” either present at birth or acquired early in life. Dopaminergic mesocortical and mesolimbic pathways are important in the production of psychotic symptoms. Antipsychotic medications, often with adjunctive benzodiazepines, are used to treat acute psychotic episodes. Although maintenance antipsychotic medications help reduce the severity and frequency of acute psychotic episodes, comprehensive psychosocial rehabilitation programs are required to help patients manage interpersonal and other stressors and to improve overall clinical outcomes. In the past decade, second-generation (“atypical”) antipsychotic medications have replaced first-generation antipsychotics because of their greater short-term tolerability and much lower rates of extrapyramidal side effects including tardive dyskinesia. However, there is concern that the second-generation drugs may contribute to the increase of obesity and metabolic syndrome among chronic schizophrenia patients.

Patients with single schizophrenia-like psychotic episodes of briefer duration, with subsequent return to asymptomatic baseline functioning, may be diagnosed with brief psychotic disorder (<1 month) or schizophreniform disorder (1 to 6 months). Schizoaffective disorder is a chronic recurrent disorder, with a prevalence slightly lower than that of schizophrenia, characterized by episodes of non-mood psychosis and also mood episodes (manic or depressed) with psychotic features. Its diagnosis therefore cannot be based on the patient’s presentation at any one point in time, but requires knowledge of overall course. The outcomes of schizoaffective disorder are heterogeneous but on average are intermediate between schizophrenia and mood disorders. Treatment is symptomatic, using antipsychotic, mood stabilizing, and antidepressant medications to target specific psychotic and mood symptoms. Delusional disorder is characterized by potentially plausible (“nonbizarre”) delusions such as marital infidelity, in the absence of thought process disorder, prominent hallucinations, or the negative symptoms of schizophrenia. Delusional disorder has a point prevalence of approximately 0.03% and a lifetime prevalence of 0.05% to 0.1%. It often is only partially responsive to antipsychotic medications, but patients’ functioning may be largely unimpaired if they are able (with the aid of antipsychotics and psychotherapy) to not publically speak of or act on their delusions. The pathogeneses of the nonschizophrenic primary psychotic disorders remain largely unknown.

Somatiform Disorders

Somatiform symptoms, often broadly referred to as “somatization,” resemble symptoms from systemic or neurologic

diseases but are thought to arise from unconscious psychogenic rather than identifiable physical causes. Somatization may range from normal human experiences (e.g., abdominal cramping in response to an acute stressor) to time-limited episodes to chronic, disabling conditions. The somatoform disorders are classified as pain disorder (pain); conversion disorder (other neurologic symptoms or signs, e.g., alteration in sensory functioning, motor functioning, coordination, or cognitive functioning); somatization disorder (Briquet syndrome: chronic recurrent somatoform symptoms of multiple organ systems); and undifferentiated somatoform disorder (somatoform symptoms not meeting criteria for the other disorders). The somatoform disorders also include hypochondriasis, manifested by inappropriate illness worry rather than somatoform symptoms per se, and body dysmorphic disorder, characterized by preoccupation with a perceived bodily defect (“imagined ugliness”), which may have more in common with the obsessions of obsessive-compulsive disorder than with the other somatoform disorders. The prevalence of somatoform disorders varies widely with both population being studied and the method of research diagnosis ascertainment. Somatization disorder may have a lifetime prevalence of 0.2% to 2% in females and <0.2% in males. Prevalence estimates for conversion disorder are as low as 0.01% in the general population but may be much higher (1% to 14%) in medical or surgical inpatient samples. Management of patients with somatoform disorders is often difficult, as physicians need to simultaneously maintain an appropriate level of vigilance for undiagnosed physical illness while avoiding unnecessary tools and therapies. Keys to ongoing care include maintaining an ongoing therapeutic alliance, setting regular office visits, conveying empathy for the patient’s very real distress without colluding with the patient’s belief in an identifiable physical disorder, and assertive treatment of depression, anxiety, or other comorbid psychopathology. Antidepressant medications may have some benefit in selected patient populations (e.g., some chronic pain syndromes) even in the absence of comorbid psychiatric disorders.

Somatoform symptoms and disorders should be distinguished from two conditions in which psychological

factors lead to presentations resembling physical disorders. Factitious disorder (Munchausen syndrome) is a mental disorder in which patients consciously produce stigmata of disease (e.g., simulated or artificially induced fever or hypoglycemia) for the unconscious gain of assuming the sick role. Malingering is the conscious feigning of illness for conscious gain and therefore is not a mental disorder.

Personality Disorders

Personality is defined as the total repertoire of enduring patterns of thinking, feeling, and behaving, including affect and impulse regulation, defense and coping mechanisms, and interpersonal relatedness. Personality traits must be distinguished from time-limited states; for example, a patient who exhibits dependent features solely while acutely depressed does not have a dependent personality. A personality disorder is diagnosed when personality trait repertoires lead to enduring (if variable) subjective distress or dysfunction in social role performances. The major personality disorders are listed in Table 117-4. Personality and personality disorders are the result of complex interactions among genetic, environmental, and developmental factors. Approaches to patients with personality disorders will vary greatly depending on the specific type, but in most clinical circumstances other than longer-term psychotherapy, the realistic goal is not to alter fundamental personality structure but to help the patient maximize use of personality strengths (e.g., optimal defense mechanisms) while minimizing the harmful effects of emotional dysregulation, unhelpful defenses, and destructive behaviors. Although not the mainstay of most treatments for personality disorders, pharmacotherapy can be useful in selected patients (e.g., antipsychotics to target escalating paranoia in paranoid personality disorder; mood stabilizers; or antidepressants to target emotional dysregulation in borderline personality disorder). As well, patients with personality disorders are prone to mood, anxiety, eating, substance use, and other treatable psychiatric disorders.

Prospectus for the Future

Advances in neuroscience will lead to better pharmacologic or other somatic therapies. One example, deep brain stimulation, is currently under study for severe refractory mood and anxiety disorders. In the future, specifically tailored regimens for each individual may be based on genetic, pharmacogenomic, or proteomic profiles. These same advances may help identify patients for whom evidence-based psychotherapies or other psychoso-

cial interventions are most likely to be effective. Identification of more specific and powerful risk markers may lead to the development of preventive interventions for at-risk individuals or groups. The current U.S. health care system, however, provides both barriers and disincentives that often prevent implementation of mental health treatments.

Disorders of Thermal Regulation

William P. Cheshire, Jr.

Core body temperature is tightly regulated to within half of one degree from its set point near 37° C (98.6° F). Serious and potentially fatal organ dysfunction ensues when temperatures depart from that range by more than a few degrees.

Hypothermia

Hypothermia is defined as a core body temperature <35° C (95° F) and may be therapeutic (induced for neuroprotective or cardioprotective purposes) or accidental. Prolonged environmental cold exposure leads to life-threatening hypothermia, particularly under conditions of impaired thermoregulation. At increased risk are neonates and elderly adults, whose ability to vasoconstrict and shiver is diminished; injured winter wilderness explorers; and the homeless, whose mobility is restricted. Water contact accelerates heat loss. Additional causes (Table 118-1) include drugs that depress the sensorium (alcohol abuse and sedative overdose), disorders that impair the anterior hypothalamus (Wernicke encephalopathy), and conditions that decrease the sympathetic thermoregulatory and shivering responses (hypoglycemia, hypothyroidism).

Initial signs of hypothermia consist of shivering, increased muscle tone, impaired judgment, slurred speech, and incoordination. With further temperature reduction, shivering ceases and hypometabolism leads to lethargy, stupor, and multisystem complications (Table 118-2). Atrial arrhythmias occur with moderate hypothermia, and ventricular arrhythmias with severe hypothermia. Even mild hypothermia can provoke cardiac arrhythmias in those with underlying cardiovascular disease. Severe cases can mimic death, as the skin is cold to the touch, the pupils dilate, and the pulse, respirations, and blood pressure may be barely detectable. For this reason, determination of death requires a core temperature <32.2° C (90° F). Hypothermic neurologic abnormalities are reversible with rewarming.

Treatment should be initiated promptly, beginning with passive external warming (blankets, reflective metallo-

plastic sheets, heating lamps) for mild hypothermia. For moderate hypothermia, active surface (heated blankets, hot air circulators, hot tubs) and core warming methods (heated hemodialysis, hemodiafiltration, or peritoneal lavage) are recommended. Severe hypothermia with cardiac arrest may require cardiopulmonary bypass. Hypothermic patients are hypovolemic and require intravenous hydration.

Hyperthermia

Hyperthermia is defined as a core body temperature >40.5° C (105° F). It results from uncompensated body warming with or without exertion and manifests as heat exhaustion or heat stroke. The cause may be environmental, pharmacologic, metabolic, or neurologic. Unlike fever, which elevates the hypothalamic set point, hyperthermia does not subside when treated with cyclo-oxygenase inhibitors.

Heat exhaustion or heat stroke can occur during strenuous exertion in hot and/or humid climates, often occurring to healthy young athletes or military recruits. Lightheadedness, fatigue, and weakness can progress to confusion and coma as body temperature rapidly rises. Flushing and tachycardia are present. Profuse sweating in heat exhaustion may be followed by loss of sweating in heat stroke (Table 118-3). Predisposing factors include deficient thermoregulatory sweating (e.g., Ross syndrome, Sjögren syndrome, after bilateral sympathectomy). Also at risk are older adults during summer heat waves, particularly those unable to dissipate heat generated at rest because of drugs that inhibit sweating (tricyclic antidepressants, antihistamines, neuroleptics and other M3 anticholinergics; carbonic anhydrase inhibitors such as topiramate and zonisamide). Some drugs may cause hyperthermia via idiosyncratic reactions (drug fever), central dopamine antagonism (neuroleptic malignant syndrome), or dysregulation of skeletal muscle calcium transport in genetically susceptible patients given volatile anesthetic agents or succinylcholine (malignant hyperthermia). Drugs that enhance serotonin neurotransmission (serotonin syndrome) or sympathetic outflow

(psychomotor stimulant abuse) may also cause hyperthermia. Hyperthermia can complicate status epilepticus.

Neuroleptic malignant syndrome is a hypermetabolic state occurring in 0.2% of patients taking dopamine 2 receptor antagonists (e.g., haloperidol). CYP2D6 polymorphisms may determine vulnerability. Onset is over hours to days. Hyperthermia, rigidity, profuse sweating, tachycardia, labile blood pressure, delirium, tremors, dysphagia, and dysarthria can progress to coma. Creatine kinase is elevated. Treatment consists of reversing dopamine blockade by removing the offending drug. Although not FDA-approved for this purpose, effective treatment has been described using bromocriptine (2.5 to 10 mg three times daily) or, in severe cases, dantrolene (1 to 2.5 mg/kg intravenously [IV] every 6 hours until muscular relaxation occurs, followed by 4 to 8 mg/kg every 6 hours for 24 to 48 hours).

Table 118-1 Causes of Hypothermia*

Alcohol abuse	43%
Wernicke encephalopathy	18%
Age >70	26%
Sepsis or shock	25%
Exposure without other causes	14%
Hypoglycemia	12%
Sedative overdose	10%
Hepatic encephalopathy, uremia	8%
Structural brain disorder, head trauma, hypothyroidism, diabetic ketoacidosis, renal failure, ethylene glycol poisoning	<5%

Table 118-2 Effects of Hypothermia

	Mild (90°-95° F; 32°-35° C)	Moderate (82°-90° F; 28°-32° C)	Severe (<82° F; <28° C)
Cardiovascular	Tachycardia, increased blood pressure, PR and QT interval prolongation	Atrial fibrillation	Bradycardia, hypotension, ventricular arrhythmias, asystole at <20° C
Respiratory	Tachypnea	Hypopnea	Pulmonary edema, apnea at <24° C
Muscular	Shivering	Loss of shivering	Hypotonia
Neurologic	Impaired judgment, dysarthria, ataxia	Progressive lethargy, hallucinations, sluggish pupils	Stupor or coma, areflexia, dilated pupils, electroencephalographic silence at <26° C
Renal	Diuresis		Oliguria
Hematologic	Hemoconcentration, coagulopathy		
Gastrointestinal	Ileus, gastric stress ulcer, pancreatitis, hepatic dysfunction		
Metabolic	Declines by 5% for each 1° C		

Table 118-3 Effects of Hyperthermia

	Heat Stress (>100° F; >38° C)	Heat Exhaustion (>102° F; >39° C)	Heat Stroke (>104° F; >40° C)
Skin	Sweating, flushing	Profuse sweating, flushing	Anhidrosis,* flushing
Neurologic	Fatigue, postural syncope	Weakness, muscle cramps, paresthesia, headache, agitation, mild confusion	Encephalopathy, hallucinations, coma, seizures, focal deficits
Cardiovascular	Tachycardia	Tachycardia	Cardiac failure
Metabolic	Dehydration	Oliguria	Myoglobinuria, renal failure, acidosis, vomiting, coagulopathy

*Half of patients with heat stroke may sweat initially.

Malignant hyperthermia is an autosomal dominantly inherited syndrome in which exposure to volatile anesthetic agents (e.g., halothane) or succinylcholine provokes hyperthermia and muscle rigidity involving the limbs, trunk, and masseter muscles. The most frequent causal mutations involve the *RYR1* gene on chromosome 19q13.1. Onset is usually within 30 minutes but can be delayed by hours. Treatment consists of drug discontinuation and dantrolene (as described earlier).

Serotonin syndrome is a dose-related syndrome that occurs in patients taking serotonin-selective reuptake inhibitors (e.g., fluoxetine, sertraline) multiply or in combination with other medications (e.g., monoamine oxidase inhibitors, meperidine, tramadol, fentanyl) that enhance the availability of serotonin in the brain. Onset is within hours. Initial signs of agitation, tremor, and hyperreflexia can progress to hyperthermia, rigidity, sweating, and muscle and eye twitching. The offending drug should be promptly withdrawn.

Recreational abuse of psychomotor stimulants such as cocaine, amphetamine, 3,4-methylenedioxymethamphetamine (MDMA or “ecstasy”), and heroin can cause heat stroke via pathologic brain warming combined with peripheral vasoconstriction. Onset is within 1 hour. Chest pain, dilated pupils, or seizures can occur.

Hyperthermia in each of these conditions is a medical emergency, and rapid reduction of core temperature is mandatory. Evaporative cooling (tepid water sponging with fans) or cooling blankets are preferred for lowering core temperature to 38° to 39° C. Cold water immersion has occasionally been used for heat stroke. Benzodiazepines are useful to inhibit shivering.

Prospectus for the Future

Accumulating evidence is showing that induction of mild hypothermia (32° to 35° C) improves neurologic outcome after cardiac arrest or anoxic brain injury. Perfection of this tech-

nique in the neurocritical care setting will broaden the clinical understanding of the relationship between brain function and temperature.

Headache, Neck Pain, and Other Painful Disorders

Timothy J. Counihan

Headache

PAIN-SENSITIVE INTRACRANIAL STRUCTURES

Headache is caused by irritation of pain-sensitive intracranial structures, including the dural sinuses; the intracranial portions of the trigeminal, glossopharyngeal, vagus, and upper cervical nerves; the large arteries; and the venous sinuses. Many structures are insensitive to pain, including the brain parenchyma, the ependymal lining of the ventricles, and the choroid plexuses. That the brain parenchyma itself is insensitive to pain accounts for the common clinical observation of patients who have large intracerebral lesions (such as intracerebral hematomas or malignant brain tumors) but little or no headache. Painful stimuli arising from brain tissue above the tentorium cerebelli are conveyed by means of the trigeminal nerve, whereas the glossopharyngeal, vagus, and first two cervical nerves convey impulses from the posterior fossa. The term “cervicogenic” headache is sometimes used to indicate that the source of headache (usually occipital in location) arises from an abnormality in the cervical spine.

EVALUATION OF THE PATIENT WITH HEADACHE

It is important to distinguish benign from ominous causes of headache. A detailed history (the quality, location, duration, and time course of the headache) helps in determination of which patients have a symptomatic structural intracranial lesion (Table 119-1). What exacerbates or relieves it? Pain intensity is not of much diagnostic value, except for the patient who complains of the acute onset of the worst headache of his or her life. This headache suggests subarachnoid hemorrhage (SAH). The quality of pain (“throbbing,” “pressure,” “jabbing”) and the location may also be helpful, especially if the pain is of extracranial origin, such as temporal in temporal arteritis. Posterior fossa lesions cause occipitocervical pain, occasionally associated with unilateral retro-orbital pain. In general, multifocal pain

usually implies a benign cause. It is most important to clarify the acuity of onset of the headache; patients who describe the onset of pain as “like being hit on the head with a bat” should be suspected of having the sentinel headache of subarachnoid headache. Equally important is to establish the time course of the headache. Is this paroxysmal, nonprogressive headache (typical of migraine or tension-type headache)? Or is the headache daily persistent (such as in temporal arteritis) or progressive (suggesting the presence of a structural brain lesion)? Patients should be asked about any known triggers for the headache, such as menses, particular foods, caffeine, alcohol, or stress. Positional headache (headache that is maximal in the upright position and disappears rapidly on lying down) is characteristic of intracranial hypotension (low pressure headache). Diurnal variation in headache severity may give a clue to cause; morning headache or headache that awakens a patient from sleep may indicate raised intracranial pressure or sleep apnea as a cause. The presence of associated symptoms such as visual disturbances, nausea, or vomiting should be noted. The history should include inquiries about medications, especially use of analgesics and over-the-counter remedies. Information regarding the patient’s past medical history as well as family history should also be taken into consideration. In the majority of patients with headache, the physical and neurologic examination findings are normal, although special attention may be directed toward examination of the eyes for papilledema, as well as the temporal arteries for a palpable nonpulsatile artery.

HEADACHE SYNDROMES

Headache is classified into primary and secondary headache syndromes (Table 119-2).

Migraine Clinical Features

Migraine is an episodic headache disorder characterized by various combinations of neurologic, gastrointestinal, and autonomic changes. The diagnosis is based on the

Table 119-1 Key Questions in the Assessment of Headache

1. For how long have you been having headaches?
2. What were they like when they first began? Were they intermittent, daily persistent, or progressive from the beginning?
3. What is the length of time from the start of the headache until its peak intensity?
4. Are there any warning symptoms (aura)?
5. Does the headache interfere significantly with normal activity (work, school, etc)?
6. What aggravates the headache (such as light, noise, odors)?
7. What do you do for relief from the headache (rest, move around, take medication)?
8. What time of day are the headaches most likely to occur? Do they regularly awaken you from sleep?
9. Are you aware of any specific triggers (foods, stress, lack of sleep, menstrual cycle)?
10. Does anyone else in the family have headaches?

Table 119-2 Classification of Headache Syndromes

Primary	Secondary

Other primary cephalgias	Substance use or withdrawal Infection Other secondary causes Skull and sinus disease

headache's characteristics and associated symptoms. Results of the physical examination as well as the laboratory studies are usually normal.

The prevalence of migraine is up to 16% in women and 8% in men. It is estimated that 28 million Americans have disabling migraine headaches. All varieties of migraine may begin at any age from early childhood on, although peak ages at onset are adolescence and early adulthood.

Seven types of migraine are described (Table 119-3). The two most common are migraine without aura and migraine with aura; migraine without aura accounts for 80% of patients. Migraine auras are focal neurologic symptoms that precede, accompany, or, rarely, follow an attack. The aura usually develops over 5 to 20 minutes, lasts less than 60 minutes, and can involve visual, sensorimotor, language or brainstem disturbances. The most common aura is typified by positive visual phenomena (such as scintillating scotomata) that often precede the headache; they resemble the effect of being too close to a photographer with a flash camera (*phosphenes*). The differential diagnosis of an aura includes a focal epileptic seizure arising from the visual cortex of the occipital lobe, or a transient ischemic attack (TIA). In the latter, there is no evolution of symptoms, and the symptoms themselves are typically "negative" (such as hemianopia) rather than the "positive" visual phenomenon

Table 119-3 Classification of Migraine

Basilar migraine

of phosphenes that is characteristic of the migrainous aura. The pain of migraine is often pulsating, unilateral, and frontotemporal in distribution and often accompanied by anorexia, nausea, and, occasionally, vomiting. In characteristic attacks, patients are markedly intolerant of light (photophobia) and seek rest in a dark room. There may also be intolerance to sound (phonophobia) and occasionally to odors (osmophobia). The diagnosis of migraine requires the presence of at least one of these features, particularly in the absence of gastrointestinal symptoms. The presence of these symptoms results in a syndrome that is invariably disabling for the patient, to the extent that for the duration of the attack he or she is unable to function normally. In children, migraine is often associated with episodic abdominal pain, motion sickness, and sleep disturbances. Onset of typical migraine late in life (older than age 50) is rare, although recurrence of migraine that had been in remission is not uncommon. Recurrent migraine headache associated with transient hemiparesis or hemiplegia occurs rarely as a clearly genetically determined (Mendelian) disease (familial hemiplegic migraine).

Basilar migraine is unusual and occurs primarily in childhood. Severe episodic headache is preceded, or accompanied by, signs of bilateral occipital lobe, brainstem, or cerebellar dysfunction (e.g., diplopia, bilateral visual field abnormalities, ataxia, dysarthria, bilateral sensory or motor disturbances, other cranial nerve signs, and occasionally coma). *Vestibular migraine* or migrainous vertigo is characterized by symptoms of vertigo with or without the other typical migraine symptoms. The term *complicated migraine* refers to migraine attacks with major neurologic dysfunction (e.g., migraine with hemiplegia or coma) separate from the visual aura; in these cases, neurologic dysfunction outlasts the headache by hours to 1 or 2 days. Acute severe headache can reflect serious central nervous system disease (Table 119-4). Certain symptoms raise suspicion for a structural brain lesion (Table 119-5).

Causes

A migraine attack is the end result of the interaction of a number of factors of varying importance in different individuals. These factors include a genetic predisposition, a susceptibility of the central nervous system to certain stimuli, hormonal factors, and a sequence of neurovascular events. A positive family history is reported in 65% to 91% of cases. Familial hemiplegic migraine is associated with mutations in a gene for *P/Q* type calcium channel on chromosome 19 and a gene encoding a sodium-potassium ion pump on chromosome 1. Thus, mutations of diverse channels result in a common phenotype. The cause of migraine in the majority of patients remains uncertain.

Table 119-4 Differential Diagnosis of Acute Headache—Major Causes

Migraine
Cluster headache
Stroke
Subarachnoid hemorrhage
Intracerebral hemorrhage

Progressive
Onset >50 years of age
Worse in early morning—awakens patient
Marked exacerbation with straining
Focal neurologic dysfunction
Signs
Nuchal rigidity
Fever
Papilledema
Pathologic reflexes or reflex asymmetry
Altered state of consciousness

The traditional view has been that the neurologic phenomena of migraine were caused by spasm of cerebral vessels and the pain was caused by subsequent dilation of extracranial arteries. There is good evidence that diminished cerebral blood flow accompanies the aura of the migraine attack. One of the key structures in the mechanism of pain in all migraine is the trigeminal vascular system. Stimulation of the trigeminal nerve or its ganglion can activate serotonin receptors and nerve endings on small dural arteries and result in a state of neurogenic inflammation. It is postulated that, in migraine, these processes in turn stimulate perivascular nerve endings, with resultant orthodromic stimulation of trigeminal nerve and pain referred to its *distribution*. The precise role of other factors such as female sex hormones, environmental triggers, and stress in the pathogenesis of migraine remains unclear.

Treatment

The goals of treatment are (1) making an accurate and confident diagnosis of migraine to reassure the patient that there is no more sinister cause for the headache; (2) relieving acute attacks; and (3) preventing pain and associated symptoms of recurrent headaches. The first step is to inform the patient that he or she has a migraine. The benign nature of the disorder and the patient's central role in the treatment plan should be emphasized. It is important that the patient keep a headache diary, which serves several functions: it helps identify covert headache triggers; it assists in monitoring

headache frequency and response to treatment, and it actively involves the patient in the management of the condition.

Acute Migraine Attack

Acute attacks are alleviated with single agents or varying combinations of drugs (Fig. 119-1) as well as with behavioral modification therapy. Many attacks of migraine respond to simple analgesics, such as acetaminophen, aspirin, or non-steroidal anti-inflammatory agents. Opioid drugs have a limited use in the migraine attack. Overuse of analgesics is particularly frequent in headache patients; one of the most important aspects of therapy of migraine patients, therefore, is the monitoring of amounts of analgesic used. In patients who are nauseated, it is often helpful to prescribe an antiemetic agent early in an attack. Phenothiazine drugs have antiemetic, prokinetic, and useful sedative properties, but they can produce involuntary movements as an acute adverse effect (acute dystonic reaction).

A number of *migraine-specific* serotonin agonist drugs have become available. These agents, commonly referred to as “triptans,” are useful in the acute treatment of migraine, having a rapid onset of action; sumatriptan, available as a subcutaneous preparation, results in a headache response rate of close to 70% (see Fig. 119-1). Although many are highly effective in alleviating migraine, patients must be carefully instructed in their appropriate use. Moreover, a response to these medications does not confirm a diagnosis of migraine.

Migraine Prevention

A number of agents have been used in the prevention of migraine (Table 119-6). The use of these agents should be restricted to patients who have frequent attacks (usually more than four per month) and who are willing to take daily medication. With any of the medications, an adequate trial period should be given, using adequate doses, before it is declared ineffective. Combination therapy is occasionally required but is not routinely prescribed. For a preventative drug to be considered successful, it should reduce the headache frequency rate by 50%. Magnesium supplementation, the plant extract feverfew, and high-dose riboflavin (vitamin B₂) have been effective in some patients.

The Future of Migraine Treatment

Given the increasing experimental evidence that neurogenic inflammation is the principal cause of migraine pain, there has been a predictable increase in the use of anticonvulsant medication (see Table 119-6) for prevention. Clinical trials using an antagonist to calcitonin gene-related peptide (CGRP) have shown some efficacy for the treatment of acute migraine.

Cluster Headache

Clinical Features

Cluster headache is the prototypic trigeminal autonomic cephalgia, consisting of a group of symptoms with a relatively specific temporal course. It is uncommon, occurring in less than 10% of all people with headache. Unlike migraine, it is much more common in men than in women, and its mean age at onset is later in life than migraine. Also, unlike migraine, cluster headache rarely begins in childhood,

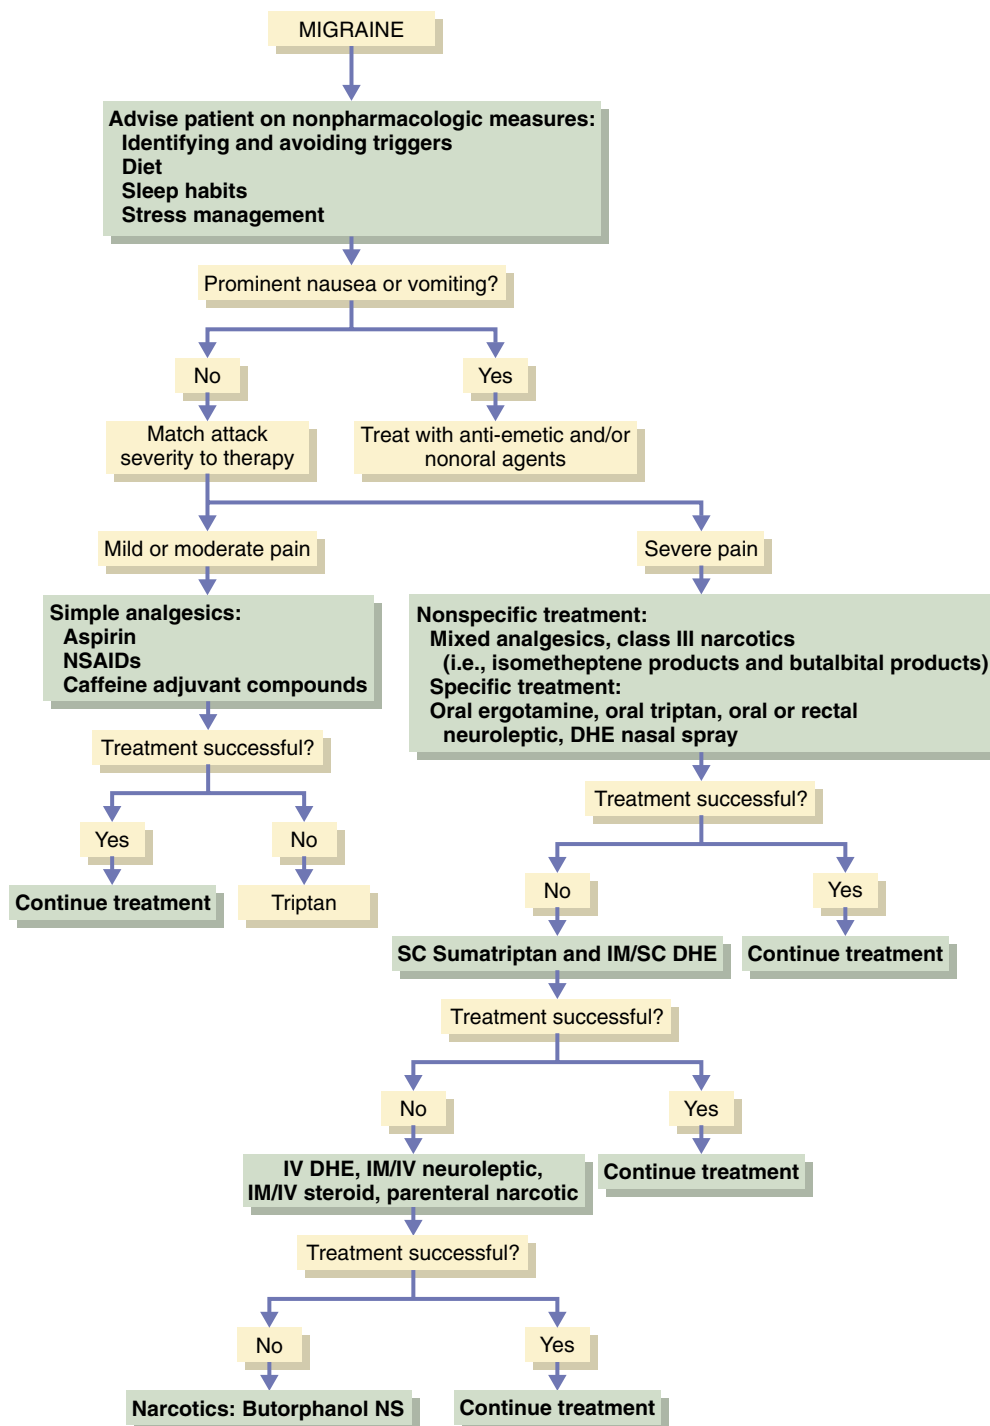

Figure 119-1 Algorithm for the treatment of migraine. DHE, dihydroergotamine; IM, intramuscular; IV, intravenous; NS, normal saline; NSAIDs, nonsteroidal anti-inflammatory drugs; SC, subcutaneous. (From Silberstein SD, Young WB, Lipton RB: Migraine and cluster headaches. In Johnson RT, Griffin JW [eds]: Current Therapy in Neurologic Disease, 5th ed. St Louis, Mosby, 1997, p 88).

and there is less often a family history. The pain in cluster headache is of extreme intensity, is unilateral, and is associated with congestion of the nasal mucosa and injection of the conjunctiva on the side of the pain. Increased sweating of the ipsilateral side of the forehead and face may occur. There may be associated ocular signs of Horner syndrome: miosis, ptosis, and the additional feature of eyelid edema. The pain is usually steady, nonthrobbing, and invariably localized retro-orbitally on one side of the head; it may

occasionally spread to the ipsilateral side of the face or neck. Attacks often awaken patients, usually 2 to 3 hours after the onset of sleep (“alarm-clock headache”). In contrast to migraineurs, the pain is not relieved by resting in a dark, quiet area; on the contrary, patients sometimes seek some activity that can distract them. The duration of headache is usually around 1 hour, although it may recur several times in a day, recurring paroxysmally (in *clusters*) for several weeks.

Table 119-6 Preventive Therapy for Migraine

Drug Class	Agent	Dose	Adverse Effects
β-adrenergic receptor blockers	Propranolol	40-160 mg/day	Contraindicated in asthma; nightmares, fatigue, syncope
	Nadolol	40-160 mg/day	
Tricyclic antidepressants	Amitriptyline	10-75 mg qhs	Dry mouth, confusion, palpitations
Serotonin reuptake inhibitors	Paroxetine	10-50 mg/day	Insomnia, somnolence, sexual dysfunction
	Sertraline	50-200 mg/day	
Calcium-channel blockers	Verapamil	120-900 mg/day	Constipation, edema, hypotension Parkinsonism
	Flunarizine*	5 mg/day	
Serotonin antagonists	Methysergide	2-8 mg/day	Prolonged use associated with fibrotic reactions
	Pizotifen*	0.5-1.5 mg/day	
Anticonvulsants	Divalproex sodium	500-1000 mg/day	Weight gain, tremor Somnolence Renal calculi
	Gabapentin	300-900 mg/day	
	Topiramate	50-200 mg/day

Table 119-7 Clinical Features Distinguishing Migraine from Tension Headache

	Migraine with Aura	Migraine without Aura	Tension Headache
Aura	Focal neurologic deficit (visual, sensory, language) Onset over 4 min Lasts <60 min	No focal neurologic deficit	No focal neurologic deficit
Headache	Unilateral Throbbing or pulsating Aggravated by activity Inhibits or prohibits activity Onset within 60 min of aura	Unilateral Throbbing or pulsating Aggravated by activity Inhibits or prohibits activity	Bilateral Nonpulsating ("pressure") Not aggravated by activity May inhibit but not prohibit activity
Associated symptoms	Nausea ± vomiting Photophobia Phonophobia	Nausea ± vomiting Photophobia Phonophobia	No nausea or vomiting Minimal photophobia

These periods of frequent headaches are separated by headache-free periods of varying duration, often several months or years. Attacks have a striking tendency to be precipitated by even small amounts of alcohol. There are rare variants of cluster headache: a "chronic variety" in which remissions are brief (less than 14 days); "*chronic paroxysmal hemicrania*," in which attacks are shorter and strikingly more prevalent in women; and "*hemicrania continua*," in which there is continuous, moderately severe, unilateral headache. The cause of all these syndromes is unknown, although the distribution of the pain suggests dysfunction of the trigeminal nerve.

Treatment

Therapy for cluster headache may be abortive for acute headache or prophylactic to prevent headache. Acute headache may respond to oxygen by mask (7 to 10 L/min for 15 minutes), which is effective within several minutes in 70% of patients. Sumatriptan and dihydroergotamine are also effective. Preventive medications include lithium, divalproex sodium, verapamil, methysergide, and corticosteroids. Paroxysmal hemicrania and related syndromes are often strikingly sensitive to indomethacin.

Tension-Type Headache

In contrast to migraine, tension-type headache is featureless (Table 119-7). The pain is usually not throbbing but rather steady and often described as a "pressure feeling" or a "vice-like" sensation. It is usually not unilateral and may be frontal,

occipital, or generalized. There is frequently pain in the neck area, unlike in migraine. Pain commonly lasts for long periods of time (e.g., days) and does not rapidly appear and disappear in attacks. There is no "aura." Photophobia and phonophobia are usually absent (see Table 119-2). Although tension-type headache may be related by the patient to occur or be exacerbated at times of particular emotional stress, the pathophysiology may relate to sustained cranio-cervical muscle contraction; hence, a more appropriate term for this syndrome is *muscle-contraction headache*.

A careful evaluation should be made of the patient's psychosocial milieu and the presence of anxiety or depression. The tricyclic antidepressant drugs in low doses have proven the most useful for prevention of tension-type headache; although the best documented is amitriptyline, newer agents with fewer side effects may be equally effective. Nonpharmacologic therapies such as relaxation therapy, massage, physiotherapy, or acupuncture may be useful in refractory cases. Intramuscular botulinum toxin injections have been used both in migraine and tension-type headache but are not of established benefit.

Other Defined Primary Headache Syndromes

Several acute short-lasting headache syndromes need to be differentiated from migraine, cluster, or tension headache. These include "thunderclap" headache, *primary stabbing headache*, *primary exertional headache*, "ice cream" headache, and coital headache. The latter may be indistinguish-

able from the headache of SAH and requires computed tomography (CT) and lumbar puncture to exclude SAH. All of these headache syndromes are more common in migraineurs. Two additional rare short-lasting headache syndromes deserve mention: short-lasting unilateral neuralgiform headache with conjunctival tearing (SUNCT); and *hypnic* headache. The latter refers to multiple episodes of very brief headache that awaken the patient (typically an older woman) from sleep. The syndrome of SUNCT causes multiple very brief (seconds to minutes) episodes of cluster-like headache and autonomic disturbance.

Chronic daily headache is defined arbitrarily as headache lasting for more than 4 hours on more than 15 days in the month for more than 3 months. In clinical practice this means that the patient has a headache more often than not. In these cases it is important to establish whether the headache syndrome began as an episodic disorder (as in migraine or tension-type headache) or whether it consists of new daily persistent headaches.

New Daily Persistent Headache

New daily persistent headache needs to be distinguished from both tension-type and migraine headaches that have transformed into chronic daily headache; new daily persistent headaches need investigation to exclude a secondary cause.

Headache may be a manifestation of underlying structural brain disease (Table 119-8). Headache can be seen in all forms of cerebrovascular disease: infarction, TIAs, and intracerebral hemorrhage and SAH. The headache in SAH is usually extremely severe and often described by the patient as “the worst headache of my life.” Nuchal rigidity, third nerve palsy (usually involving the pupil), and retinal, pre-retinal, or subconjunctival hemorrhages may be found. CT

of the head usually shows subarachnoid, intraventricular, or other intracranial blood.

The patient with headache and fever presents a common diagnostic problem in the emergency department. Neck stiffness is a common symptom. Meningismus is confirmed by eliciting Brudzinski and Kernig signs. Vomiting occurs in about 50% of patients. Suspicion for meningitis should prompt further investigation, including a lumbar puncture. If the patient shows focal signs, papilledema, or profound alteration in level of consciousness, CT of the head before lumbar puncture is required to rule out focal disease such as an abscess or subdural empyema. These lesions, however, are rare.

Acute Sinusitis

Head and face pain is the most prominent feature of sinusitis. Malaise and low-grade fever are usually present. The pain is dull, aching, and nonpulsatile; is exacerbated by movement, coughing, or straining; and is improved with nasal decongestants. The pain is most pronounced on awakening or after any prolonged recumbency and is diminished with maintenance of an upright posture.

The location of the pain depends on the sinus involved. Maxillary sinusitis provokes ipsilateral malar, ear, and dental pain with significant overlying facial tenderness. Frontal sinusitis produces frontal headache that may radiate behind the eyes and to the vertex of the skull. Tenderness to frontal palpation may be present with point tenderness on the undersurface of the medial aspect of the superior orbital rim. In ethmoidal sinusitis, the pain is between or behind the eyes with radiation to the temporal area. The eyes and orbit are often tender to palpation, and, in fact, eye movements themselves may accentuate the pain. Sphenoidal sinusitis causes pain in the orbit and at the vertex of the skull and occasionally in the frontal or occipital regions. Given that the trigeminal nerve mediates pain perception from the sinuses, many patients who complain of “sinus headaches” are probably suffering from the trigeminovascular disturbance of migraine, rather than sinusitis. Chronic sinusitis is seldom a cause of headache.

Brain Tumors

Posterior fossa tumors (particularly of the cerebellum) frequently produce headache, especially if hydrocephalus occurs because cerebrospinal fluid (CSF) flow is partially obstructed. Supratentorial tumors, however, are less likely to cause headache and are more frequently heralded by altered mental status, focal deficits, or seizures. Although increased intracranial pressure is often associated with headache, it is usually not the primary mechanism, because uniform pressure elevations do not usually produce distortions of pain-sensitive structures.

Idiopathic Intracranial Hypertension

Idiopathic intracranial hypertension (IIH), also called *benign intracranial hypertension*, is defined as a syndrome of elevated intracranial pressure without evidence of focal lesions, hydrocephalus, or frank brain edema. It occurs usually between the ages of 15 and 45 and is more frequent in obese women. The disorder is characterized by headache with features of raised intracranial pressure. The headache is usually insidious in onset, is typically generalized, is relatively mild

in severity, and is often worse in the morning or after exertion (e.g., straining or coughing).

At times, patients have visual disturbances, such as restricted peripheral visual fields, enlarged blind spots, slight visual blurring, or diplopia secondary to abducens nerve palsies. Funduscopic examination shows papilledema, which is often more impressive than the clinical picture. IIH is usually a benign and self-limited disorder, but it may lead to visual loss, including blindness.

The condition has been associated with drugs—vitamin A intoxication, nalidixic acid, danazol (Danocrine), and isotretinoin (Accutane)—as well as corticosteroid withdrawal and systemic disorders such as hypoparathyroidism and lupus.

CT scans are usually normal but can show small ventricles and an “empty sella” in some cases. CSF opening pressure is elevated, usually in the range of 250 to 450 mm of water, with the pressure fluctuating markedly when monitoring occurs over a prolonged period. There is increasing evidence that some cases of IIH are caused by cerebral venous sinus occlusion. These cases can occur in hypercoagulable states, including peripartum, in association with the combined oral contraceptive pill, and in association with antiphospholipid antibody syndrome.

Treatment

After secondary causes of IIH have been eliminated, the patient should have dietary counseling for weight loss. Carbonic anhydrase inhibitors (acetazolamide) and corticosteroids have proved useful in headache control. As a second-line agent, furosemide also acts to lower CSF production. Serial lumbar punctures are understandably unpopular with patients even though transient headache relief is obtained. CSF shunting procedures (ventriculoperitoneal shunt) are occasionally necessary. For patients with progressive visual loss, optic nerve sheath fenestration has been shown to preserve or restore vision in 80% to 90% and provide headache relief in a majority. Intracranial hypotension (usually secondary to a CSF leak after trauma or lumbar puncture) may also cause headache, exacerbated by standing.

Idiopathic Intracranial Hypotension

Also known as *low pressure headache*, idiopathic intracranial hypotension is commonly encountered as a sequela of lumbar puncture, resulting from leakage of CSF through the dural sac. Low pressure headaches may also occur spontaneously as a result of rupture of subarachnoid cysts. The headache is initially characteristically positional, being severe on standing but relieved rapidly on lying down. Occasionally the headache is associated with focal or “false localizing” signs, especially abducens nerve palsies.

Post-Traumatic Headache

Headache in individuals who have experienced trauma has no specific quality and is associated with irritability, concentration impairment, insomnia, memory disturbance, and light-headedness. Anxiety and depression are present to variable degrees. Multiple treatment options are available, and amitriptyline and nonsteroidal anti-inflammatory agents are useful. Occasionally, muscle relaxants and anxiolytics are beneficial.

Giant Cell Arteritis

Headache occurs in 60% of patients with giant cell arteritis, a granulomatous vasculitis of medium and large arteries. More than 95% of patients are 50 years of age or older. Malaise, fever, weight loss, and jaw claudication occur early, in addition to headache. Polymyalgia rheumatica, a syndrome of painful stiffness of the neck, shoulders, and pelvis, is found in half the patients. Visual impairment secondary to ischemic optic neuritis may occur. The headache is usually described as aching and is exacerbated at night and after exposure to cold. The superficial temporal artery is frequently swollen and very tender, and may be pulseless. The erythrocyte sedimentation rate is usually elevated; the mean is 100 mm/hr. Anemia is frequently present. Temporal artery biopsy usually confirms the diagnosis, but, because the arteritis is segmental, large or multiple sections may be required. Prednisone therapy is often dramatically effective and must be given promptly to preserve vision on the affected side.

HEADACHE ASSESSMENT IN THE EMERGENCY ROOM

Assessment of the patient with acute nontraumatic headache in the emergency room can be challenging; it is essential to establish how the headache evolved. Acute-onset severe headache should prompt investigation to exclude SAH, intracranial hemorrhage, acute obstructive hydrocephalus, and meningitis. Appropriate initial investigations should include brain imaging with CT or magnetic resonance imaging (MRI). Patients with suspected meningitis without focal neurologic signs or impaired consciousness should not have their lumbar puncture delayed unnecessarily before imaging. All patients should have standard blood tests including blood cultures if bacterial meningitis is suspected.

HEADACHE IN SYSTEMIC DISEASE

A wide variety of systemic diseases have headache as a prominent symptom; some of the more prevalent disorders are summarized in Table 119-9.

Table 119-9 Headache Secondary to Systemic Disease

Cranial Neuralgias

Neuralgias are differentiated from other head pains by the brevity of the attacks (usually 1 to 2 seconds or less) and by the distribution of the pain.

Trigeminal Neuralgia

In trigeminal neuralgia (*tic douloureux*), stabbing, spasmodic pain occurs unilaterally in one of the divisions of the trigeminal nerve. It lasts seconds, but it may occur many times a day for weeks at a time. It is characteristically induced by even the lightest touch to particular areas of the face, such as the lips or gums. Trigeminal neuralgia is the most frequent neuralgia of the elderly and is thought to be caused by compression of the trigeminal nerve root in the pons by an aberrant arterial loop. A very small minority of cases are caused by multiple sclerosis, cerebellopontine angle tumors, aneurysms, or arteriovenous malformations, although in these cases (unlike “true” trigeminal neuralgia) there are usually objective signs of neurologic deficit, such as areas of diminished sensation. In these cases of “symptomatic” neuralgia, the pain is often atypical. MRI is indicated in patients who have sensory loss, those who are under 40, and those with bilateral or atypical symptoms. Trigeminal neuralgia may be life threatening when it interferes with eating. Neuralgic pain is often responsive to treatment with standard doses of an anticonvulsant such as phenytoin, carbamazepine, gabapentin, pregabalin, and, occasionally, baclofen. Antidepressant drugs such as amitriptyline and, more recently, duloxetine may also be useful in this setting. Combination therapy including an antidepressant, anticonvulsant, and opiate analgesic has been shown to have synergistic effects.

If medical treatments are unsuccessful, a variety of surgical procedures are used, including microvascular decompression and radiofrequency lesioning of the sensory portion of the trigeminal nerve.

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia is much less common than trigeminal neuralgia. Brief paroxysms of severe, stabbing, unilateral pain radiate from the throat to the ear or vice versa and are frequently initiated by stimulation of specific “trigger zones” (e.g., tonsillar fossa or pharyngeal wall). Swallowing often provokes an attack; yawning, talking, and coughing are other potential triggers. Microvascular decompression is necessary if medical treatment is ineffective.

Postherpetic Neuralgia

Herpes zoster produces head pain by cranial nerve involvement in one third of cases. In some cases a persistent intense burning pain follows the initial acute illness. The discomfort may subside after several weeks or persist (particularly in the elderly) for months or years. The pain is localized over the distribution of the affected nerve and associated with exquisite tenderness to even the lightest touch. The first division of the trigeminal nerve is the most frequent cranial nerve involved (ophthalmic herpes) and is occasionally associated with keratoconjunctivitis. When the seventh nerve is affected (“geniculate herpes”), the pain involves the external auditory meatus and pinna. Occasionally, concomitant facial paralysis may occur (Ramsay Hunt syndrome).

Occipital Neuralgia

Occipital neuralgia is a syndrome that includes occipital pain starting at the base of the skull and often provoked by neck extension. Physical examination shows tenderness in the region of the occipital nerves and altered sensation in the C2 dermatome. Treatment includes the use of a soft collar, muscle relaxants, physical therapy, and local injections of analgesics and anti-inflammatory agents.

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS), formerly known as *reflex sympathetic dystrophy*, is a syndrome that consists of pain and hyperesthesia and autonomic changes. Almost any type of injury can lead to CRPS, including blunt trauma, lacerations, and burns. Patients often suffer from coexisting emotional disturbances, which may contribute to as well as result from the pain.

Neck and Back Pain

Most patients with acute neck or back pain have a musculoskeletal disorder that is self-limiting and does not require specific therapy. The pain may originate from a number of sources, including the vertebrae and intervertebral disks, facet joints, and muscles and ligaments of the vertebral column.

Because the thoracic spine is designed for rigidity rather than mobility, thoracic disk rupture is exceedingly rare. Acute-onset pain in the thoracic region may be a result of dissection of the aorta or anterior spinal artery thrombosis.

CERVICAL SPONDYLOSIS

Cervical spondylosis is a degenerative disorder of the cervical intervertebral disks leading to osteophyte formation and hypertrophy of adjacent facet joints and ligaments. In contrast to the lumbar spine, herniation of cervical intervertebral disks (nucleus pulposus) accounts for only 20% to 25% of cervical root irritation. Cervical spondylosis is probably the most common pathology seen in office practice of neurologists and is present radiographically in over 90% of the population older than 60. For unknown reasons, the degree of anatomic abnormality is not directly correlated with the clinical signs and symptoms. Clinical disease may represent a combination of normal, age-related, degenerative changes in the cervical spine and a congenital or developmental stenosis of the cervical canal; the process may be aggravated by trauma. It may manifest as a painful stiff neck, with or without symptoms or signs of cervical root irritation or spinal cord compression. Patients with root irritation (cervical radiculopathy) complain of pain and paresthesias radiating down the arm roughly in the dermatomal distribution of the affected nerve root. More typically, the pain radiates in a myotomal pattern, whereas numbness and paresthesias follow a dermatomal distribution. Discrete sensory loss is uncommon and certainly less prominent than symptoms (Table 119-10). For relief, patients often adopt a position

Table 119-10 Common Root Syndromes of Intervertebral Disk Disease

Disk Space	Root Affected	Muscles Affected	Distribution of Pain	Distribution of Sensory Symptoms	Reflex Affected
C4-5	C5	Deltoid, biceps	Medial scapula; shoulder	Shoulder	Biceps
C5-6	C6	Wrist extensors	Lateral forearm	Thumb; index finger	Triceps
C6-7	C7	Triceps	Medial scapula	Middle finger	Brachioradialis
C7-T1	C8	Hand intrinsic	Medial forearm	Fourth and fifth fingers	Finger flexion
L3-4	L4	Quadriceps	Anterior thigh	Across knee joint	Knee jerk
L4-5	L5	Peronei	Great toe, dorsum of foot	Great toe	
L5-S1	S1	Gastrocnemius, glutei	Calf	Lateral sole of foot	Ankle jerk

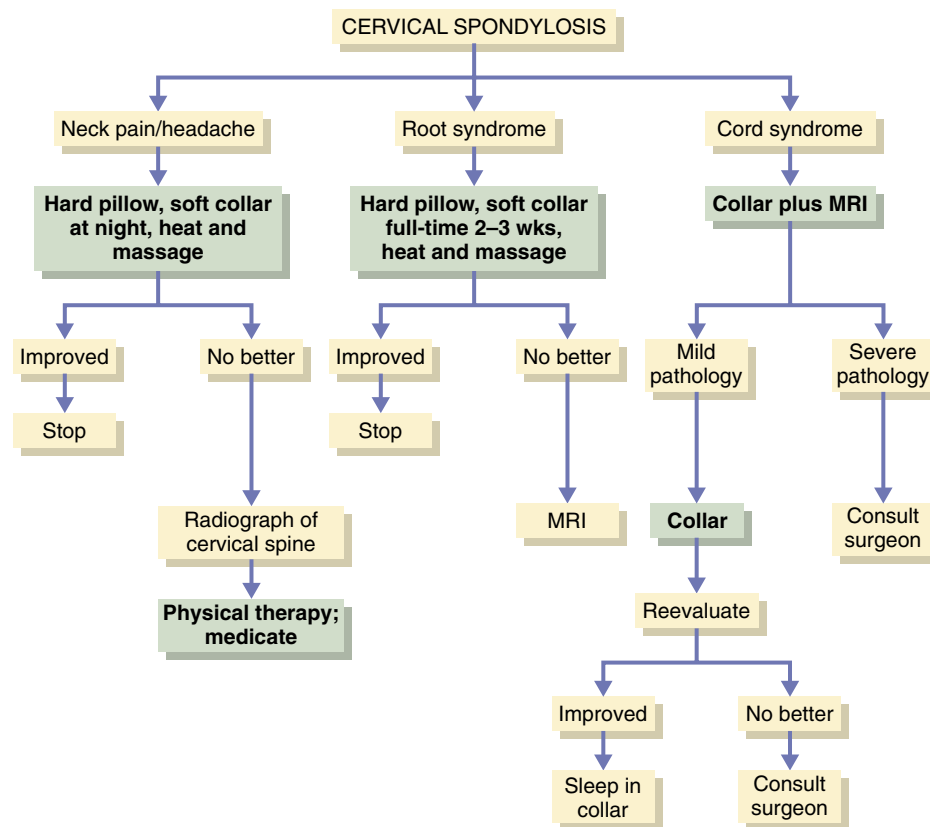

Figure 119-2 Algorithm for the treatment of cervical spondylosis. MRI, magnetic resonance imaging. (From Ronthal M, Rachlin JR: Cervical spondylosis. In Johnson RT, Griffin JW [eds]: *Current Therapy in Neurologic Disease*, 5th ed. St Louis, Mosby, 1997, p 77).

with the arm elevated and flexed behind the head. Pain is exacerbated by turning the head, ear down, to the side of the pain (Spurling maneuver). Objective neurologic findings may be limited to reflex asymmetry because weakness may be obscured by pain. Patients who have some degree of spinal cord compression demonstrate gait and bladder disturbances and evidence of spasticity on examination of the lower extremities. These patients require investigation with an imaging study, ideally MRI or CT myelography. Plain radiographs of the cervical spine add little information except in patients with rheumatoid arthritis in whom basilar invagination or atlantoaxial subluxation is suspected.

Cervical spondylosis is so common in the general population that it may be present coincidentally in a patient with another disease of the spinal cord. Among other diseases that may mimic cervical spondylosis are multiple sclerosis, amy-

otrophic lateral sclerosis, and, rarely, subacute combined system disease (vitamin B₁₂ deficiency). Conservative treatment includes the use of anti-inflammatory medication, cervical immobilization, and physical therapy for isometric strengthening of neck muscles once pain has subsided (Fig. 119-2). Surgery should be considered if there is progression of the neurologic deficit, especially the emergence of signs of cervical cord compression.

ACUTE LOW BACK PAIN

Low back pain without sciatica (radiating radicular pain) is common, with a reported point prevalence of up to 33%. Acute low back pain lasting several weeks is usually self-limiting, with a low risk for serious permanent disability. Risk factors for prolonged disability include psychological

Table 119-11 Clinical Features of Low Back Pain Suggestive of Structural Pathology

} Cauda equina syndrome

distress, compensation conflict over work-related injury, and other coexistent pain syndromes. The evaluation of patients with acute low back pain should center around distinguishing pain of mechanical origin from neurogenic pain caused by nerve root irritation (Table 119-11). The same pathologic changes that affect the cervical spine may also affect the lumbar spine. Because the spinal cord ends at the level of the first lumbar vertebra, lumbar canal stenosis from intervertebral disk disease and degenerative spondylosis will affect the roots of the cauda equina. The most common levels for lumbar degenerative disk disease are at L4 to L5 and L5 to S1, resulting in the common complaint of sciatica caused by irritation of the lower lumbar roots. Pain tends to improve with sitting or lying down, in contrast to the pain from spinal or vertebral tumors, which is aggravated by pro-

longed recumbency. Examination shows loss of the normal lumbar lordosis, paraspinal muscle spasm, and exacerbation of pain with straight leg raising, owing to stretching of the lower lumbar roots. About 10% of disk herniations occur lateral to the spinal canal, in which case the more rostral root is compressed. Percussion of the spine may cause focal tenderness of one of the vertebrae, suggesting bony infiltration by infection or tumor.

Spinal stenosis of the lumbar region may manifest as “neurogenic claudication,” which is usually described as unilateral or bilateral buttock pain that is worse on standing or walking and relieved by rest or flexion at the waist. Patients may have pain that is worse when walking downhill, in contrast to patients with vascular claudication, whose pain is maximal when walking up an incline.

MRI in many patients with isolated low back pain shows nonspecific findings; MRI early in the course of an episode of low back pain does not improve clinical outcome. MRI should be performed in patients with back pain who have associated neurologic symptoms or signs, especially new onset disturbances of bladder or bowel continence or perineal sensory symptoms suggestive of a *cauda equina syndrome*. Patients with risk factors for malignancy, infection, or osteoporosis, as well as those with pain maximal at rest (or nocturnal pain) require imaging (see Table 119-11).

Treatment strategies for lumbar pain are similar to those for cervical pain, with surgery reserved for patients with neurologic signs and clear pathologic processes seen on imaging studies. Most cases of acute low back pain, even with rupture of an intervertebral disk, can be treated conservatively with a short period of rest, muscle relaxants, and analgesics. Prolonged bed rest is no longer recommended except for patients in severe pain. Patient education regarding proper posture and appropriate back exercises is helpful, as is a formal physical therapy program. Chiropractic manipulation should be reserved for patients who have no evidence of neurologic injury or spine instability.

Prospectus for the Future

A number of novel therapeutic approaches hold promise for the treatment of medically refractory headache. Electrical stimulation of the occipital nerve has been effective in some patients with severe cluster headache, as has deep brain stimulation of the hypothalamic region. Some patients with chronic daily headache respond to local intramuscular botulinum toxin

injection. The association between patent foramen ovale (PFO) and migraine headache has prompted treatment trials of PFO closure. Thus far there is inadequate evidence to support this approach. Nonetheless the association merits further investigation.

Disorders of Vision and Hearing

Allan McCarthy and Timothy J. Counihan

Disorders of Vision and Eye Movements

EXAMINATION OF THE VISUAL SYSTEM

Acuity

The clinical examination of visual function should begin with the testing of visual acuity. The patient should wear corrective lenses if they are available, and, if possible, testing should be performed with a Snellen chart at a distance of 20 feet to minimize the influence of pupil size and lens accommodation on visual acuity. When errors of refraction are responsible for decreased visual acuity, vision may be improved by having the patient look through a pinhole. Corrected vision in one eye of less than 20/40 suggests damage to the lens (cataract) or retina or a disorder of the anterior visual (prechiasmatic) pathway. Color vision in each eye should also be tested; even when visual acuity is normal, patients with lesions of the optic nerve may complain that colors appear “washed out” in the affected eye.

Visual Fields

Thorough examination of the visual fields (Fig. 120-1) can often localize lesions interrupting the afferent (sensory) visual system. Visual fields in all four quadrants should be tested by comparing the patient’s field with that of the examiner (confrontation). The examiner’s head should be level with that of the patient’s, and a white pin used to map peripheral visual fields and a red pin to assess for the presence of a scotoma. Asking the patient to count the number of the examiner’s extended fingers is more sensitive than presenting moving objects in detecting visual field deficits. The field should be tested first unilaterally and then bilaterally because uncovering a defect (particularly in the left hemifield) with bilateral testing only (extinction) suggests a lesion in the contralateral parietal lobe.

Partial or complete visual loss in one eye only implies damage to the retina or optic nerve anterior to the optic chiasm, whereas a visual field abnormality involving both eyes implies a defect at or posterior to the optic chiasm. Scotomas are areas of partial or complete visual loss and may be central or peripheral; central scotomas reduce visual acuity as a result of damage to macular fibers. A scotoma impairing half of a visual field is known as a *hemianopia*. A homonymous hemianopia implies a postchiasmatic lesion. Quadrantanopias are smaller defects in the visual field and may be superior (which suggests a temporal lobe lesion) or inferior (which suggests a parietal lobe lesion). Bitemporal hemianopia implies a lesion at the chiasm, such as a pituitary tumor. An altitudinal hemianopia occurs with vascular damage to the retina. Scintillating scotomas are hallucinations of flashing lights. If they are monocular, they may be caused by retinal detachment; binocular scintillations suggest occipital oligemia (as in migraine) or seizure. Any suspicious findings on bedside confrontation testing warrant formal visual field testing using perimetry.

Pupils

Pupil constriction results from stimulation of parasympathetic system of the oculomotor (third cranial) nerve, whereas dilation is mediated by the sympathetic system. If the balance of these systems is upset, pupillary inequality (anisocoria) results. The pupils should be examined in both dim and bright light; if the anisocoria increases going from dim to bright light, a lesion of the parasympathetic system is likely (Fig. 120-2). *Physiologic anisocoria* is characterized by a difference in pupil size that appears less in bright light and has no associated pathologic findings.

Both the direct and consensual light responses should be noted for each eye; in the latter, when the light is shone in one eye, both pupils should constrict. This is best tested using the “swinging light test,” in which the light is moved quickly from one eye to the other. If there is dilation of one

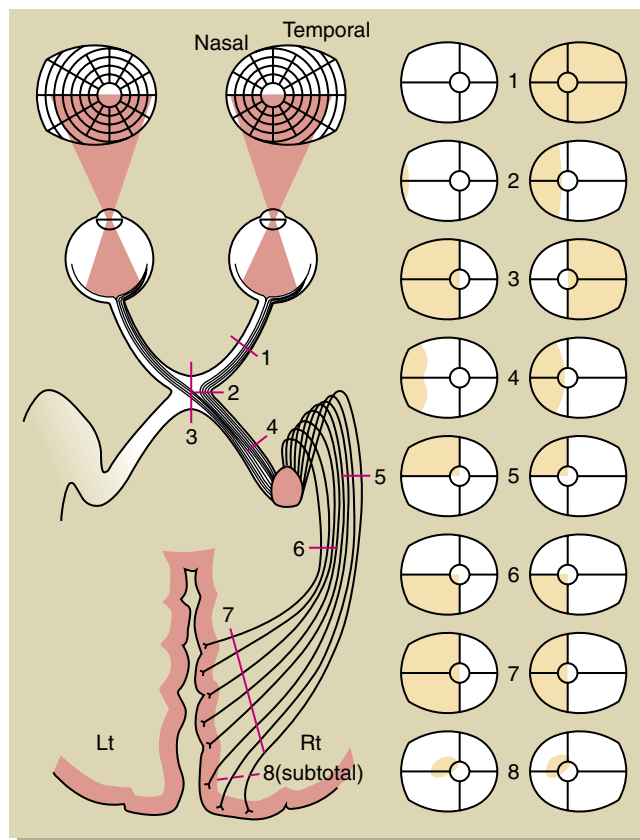

Figure 120-1 Visual fields that accompany damage to the visual pathways: 1, Optic nerve: unilateral amaurosis. 2, Lateral optic chiasm: grossly incongruous, incomplete (contralateral) homonymous hemianopia. 3, Central optic chiasm: bitemporal hemianopia. 4, Optic tract: incongruous, incomplete homonymous hemianopia. 5, Temporal (Meyer) loop of optic radiation: congruous partial or complete (contralateral) homonymous superior quadrantanopia. 6, Parietal (superior) projection of the optic radiation: congruous partial or complete homonymous inferior quadrantanopia. 7, Complete parieto-occipital interruption of optic radiation: complete congruous homonymous hemianopia with psychophysical shift of foveal point often sparing central vision, giving “macular sparing.” 8, Incomplete damage to visual cortex: congruous homonymous scotomas, usually encroaching at least acutely on central vision. (From Baloh RW: *Neuro-ophthalmology*. In Goldman L, Bennett JC [eds]: *Cecil Textbook of Medicine*, 21st ed. Philadelphia, WB Saunders, 1998, p 2236).

pupil as the light is moved to it from the other side, an abnormality of the optic nerve in that eye should be suspected. This abnormality is referred to as an *afferent pupillary defect*. The accommodative pupillary response is tested by asking the patient to look first in the distance and then at the examiner’s finger, held 12 inches away. The pupils should constrict symmetrically and rapidly.

The presence of ptosis should be noted. A large, unreactive pupil with ptosis indicates a lesion of the oculomotor nerve (*third cranial nerve palsy*) interrupting the parasympathetic nerve supply to the pupil. The associated paralysis of the medial and inferior rectus and inferior oblique muscles (see later discussion) results in distortion of the eye (inferolaterally, “down and out”) and a subjective complaint of diplopia by the patient. Common causes of a third nerve palsy include compression by an aneurysm of the posterior

communicating artery, by transtentorial herniation, or from ischemia, usually in the setting of diabetes or vasculitis. A third nerve palsy caused by ischemia often spares the pupil but results in complete paralysis of the oculomotor and eyelid levator muscles. An acute painful third nerve palsy should be treated as an emergency, with the need to investigate for an intracranial aneurysm.

A small, poorly reactive pupil with associated ptosis is known as *Horner syndrome* and results from damage to the sympathetic fibers to the pupil. There may be associated unilateral anhidrosis resulting from damage to sympathetic fibers. Horner syndrome may result from lesions of the hypothalamus, brainstem, cervical spinal cord, or sympathetic fibers to the pupil. Horner syndrome from sympathetic fiber involvement may be the first sign of an apical lung tumor (Pancoast) or may occur in diseases affecting the carotid artery.

Argyll-Robertson pupils are small, irregular pupils that constrict to near vision but not in response to light. They are associated with neurosyphilis, diabetes, and other disorders. This so-called *light-near dissociation* may also occur in rostral dorsal midbrain lesions, in which there are abnormalities of vertical gaze, eyelid retraction, and convergence retraction nystagmus. This uncommon constellation of clinical findings is frequently secondary to a pineal lesion.

Tonic (Adie) pupils constrict slowly and incompletely in response to light; this is usually an incidental finding on examination but may be associated with areflexia (Adie syndrome). Reaction to accommodation is preserved, and it has been suggested that the disorder is a result of parasympathetic denervation. *Hippus* refers to pupillary unrest with synchronous oscillation of the pupil size; it is considered a normal phenomenon.

Eye Movements

The history helps in evaluating the patient with diplopia. Is the diplopia primarily horizontal or vertical, or is it greater looking to the right or to the left? Double vision that varies during the day suggests myasthenia gravis. Is the diplopia maximal with near or distant vision? Greater difficulty with near vision suggests impairment of the medial rectus, oculomotor nerve, or convergence system, whereas abducens nerve weakness results in horizontal diplopia when objects are viewed at a distance. Diplopia that worsens on going down stairs may suggest a fourth nerve lesion. Monocular diplopia is usually caused by diseases of the retina or lens and is corrected by having the patient look through a pinhole, unless the cause is psychogenic.

The examination should begin by determining the position of the head and eyes with the eyes in primary gaze. Both smooth pursuit and (voluntary) saccadic eye movements in horizontal and vertical directions are checked to determine whether the movements are conjugate or disconjugate. Disconjugate eye movements suggest a disorder of the brainstem (at the level of the ocular motor nuclei or their connections), the peripheral nerves (cranial nerves III, IV, or VI), individual eye muscles (ocular myopathy), or the neuromuscular junction (myasthenia gravis or botulism). A large deficit in the range of eye movements may provide sufficient diagnostic information. However, in many cases, although the patient complains of diplopia, no clear misalignment is visible on testing eye movements. The corneal

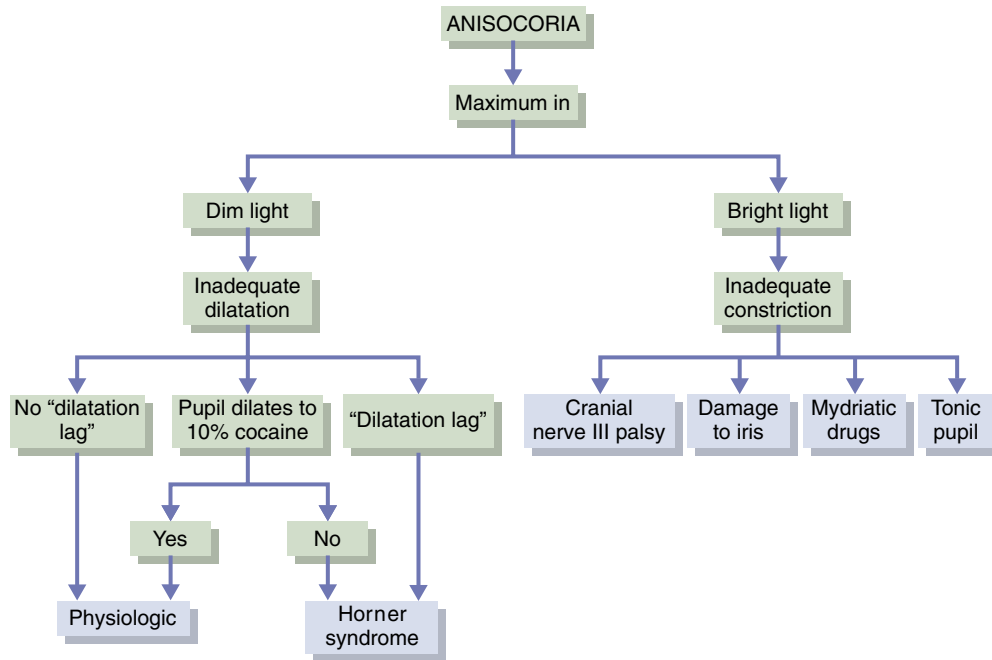

Figure 120-2 Algorithm for the approach to unequal pupils (anisocoria).

reflection test may help identify misalignment in these cases. The patient is instructed to look at a light shining directly at the eyes. If the eyes are normally aligned, the light reflection will be about 1 mm nasal to the center of the cornea. If one eye is deviated medially, the reflection will be displaced outward; the reflection will be displaced inward if the eye is deviated outward.

The abducens (sixth cranial) nerve supplies the lateral rectus muscle. The trochlear (fourth cranial) nerve subserves the superior oblique muscle, which intorts the eye as well as depresses the eye in adduction (such as when a patient tries to look downstairs). All other muscles are supplied by the oculomotor nerve. Abnormalities of the cranial nerves in the brainstem are usually accompanied by other signs, such as weakness, ataxia, or dysarthria. The abducens nerve has a long ascending course through the posterior fossa, where it is prone to compression at multiple sites and as a result of raised intracranial pressure; hence, a sixth nerve palsy may be a false localizing sign. Table 120-1 lists the major causes of acute ophthalmoplegia.

Conjugate eye movement is regulated by supranuclear pathways from the cerebral hemisphere to the medial longitudinal fasciculus in the brainstem. A lesion in the cerebral hemisphere resulting from hemorrhage, infarction, or tumor disrupts conjugate gaze to the contralateral side, so that the eyes “look away” from the hemiplegia. Lesions of the brainstem cause conjugate paralysis to the ipsilateral side (eyes looking toward the side of the hemiplegia). Lesions of the medial longitudinal fasciculus, which connects the nuclei of the oculomotor and abducens nerves, leads to *internuclear ophthalmoplegia*. In this case, horizontal gaze results in failure of adduction in one eye and nystagmus in the abducting eye. The lesion is on the side of failed adduction; bilateral lesions are frequently seen in multiple sclerosis.

Table 120-1 Major Causes of Acute Ophthalmoplegia

Condition	Diagnostic Features
Bilateral	
Botulism	Contaminated food; high-altitude cooking; pupils involved
Myasthenia gravis	Fluctuating degree of paralysis; responds to edrophonium chloride (Tensilon) IV
Wernicke encephalopathy	Nutritional deficiency; responds to thiamine IV
Acute cranial polyneuropathy	Antecedent respiratory infection; elevated CSF protein level
Brainstem stroke	Other brainstem signs
Unilateral	
P Comm aneurysm	Third cranial nerve, pupil involved
Diabetic-idiopathic	Third or sixth cranial nerve, pupil spared
Myasthenia gravis	As above
Brainstem stroke	As above

CSF, cerebrospinal fluid; IV, intravenous; P Comm, posterior communicating artery.

Funduscopy

The retina should be carefully examined in each patient by direct ophthalmoscopy, which provides a magnified view of the fundus without the necessity for dilation of the pupil.

UNILATERAL VISUAL LOSS

Loss of vision in one eye may be caused by lesions of the cornea, lens, vitreous, retina, or optic nerve. Careful funduscopy examination will usually reveal ocular and

a second and recur frequently or which appear to be in constant motion. These can arise from dysfunction within the optic pathways at any point from the eye to the cortex. Glaucoma, incipient retinal detachment, retinal ischemia, or macular degeneration can cause simple visual hallucinations based on dysfunction in the eye. Lesions of the occipital lobe are often associated with simple hallucinations; classic migraine is by far the most common condition of this type. Complex visual hallucinations such as seeing objects as people, animals, landscapes, or various indescribable scenes occur most frequently with temporal lobe lesions or parieto-occipital association areas. Visual hallucinations of epileptogenic origin are typically stereotyped.

Hearing and Its Impairments

SYMPTOMS OF AUDITORY DYSFUNCTION

The main symptoms of lesions within the auditory system are hearing loss and tinnitus. Hearing loss can be classified as conductive, sensorineural, mixed, or central, based on the anatomic site of pathology (Fig. 120-3). Tinnitus can be either subjective or objective. Conductive hearing loss results from lesions involving the external or middle ear. Patients with a conductive hearing loss can hear speech in a noisy background as well as in a quiet background, because they can understand loud speech as well as anyone. The ear often feels full, as if it is blocked. The Weber test localizes to the deaf ear, if the deafness is unilateral.

Sensorineural hearing loss usually results from lesions of the cochlea or the auditory division of the vestibulocochlear (eighth cranial) nerve (Table 120-2). Patients with sensorineural hearing loss often have difficulty hearing speech that is mixed with background noise and may be annoyed by loud speech. They usually hear low tones better than high-frequency ones. Distortion of sounds is

common with sensorineural hearing loss. Central (“retrocochlear”) hearing disorders are rare and result from bilateral lesions of the central auditory pathways, including the cochlear and dorsal olivary nuclear complexes, inferior colliculi, medial geniculate bodies, and auditory cortex in the temporal lobes. Damage to both auditory cortices may result in pure word deafness, in which patients are selectively unable to discriminate language but may be able to hear nonverbal sounds.

Tinnitus is the perception of a noise or ringing in the ear that is usually audible only to the patient (subjective), although, rarely, an examiner can hear the sound as well. The latter, so-called *objective tinnitus*, can be heard when the examining physician places a stethoscope against the patient’s external auditory canal. Tinnitus that is pulsatory and synchronous with the heartbeat suggests a vascular abnormality within the head or neck (Fig. 120-4). Aneurysms, arteriovenous malformations, and vascular tumors can produce this type of tinnitus.

Subjective tinnitus, heard only by the patient, can result from lesions involving the external ear canal, tympanic membrane, ossicles, cochlea, auditory nerve, brainstem, and

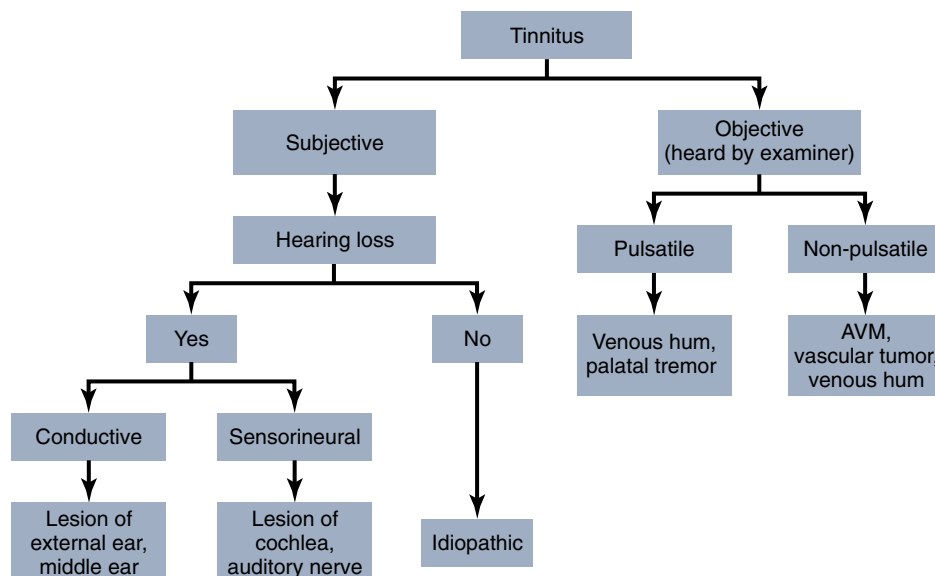

Figure 120-4 Algorithm for the approach to the patient with tinnitus. AVM, arteriovenous malformation; CNS, central nervous system.

cortex. The character of the tinnitus does not usually aid in determining the site of the disturbance. For this, one must rely on associated symptoms and signs. When tinnitus results from a lesion of the external or middle ear, it is usually accompanied by a conductive hearing loss. The patient may complain that his or her voice sounds hollow and that other sounds are muffled. Because the masking effect of ambient noise is lost, the patient may be disturbed by normal muscular sounds such as chewing, tight closure of the eyes, or clenching of the jaws. The characteristic tinnitus associated with Ménière syndrome is low pitched and continuous, although fluctuating in intensity. Often the tinnitus becomes very loud immediately preceding an acute attack of vertigo and then may disappear after the attack. Tinnitus resulting from lesions within the central nervous system is usually not associated with hearing loss but is nearly always associated with other neurologic symptoms and signs. High-dose salicylates frequently result in tinnitus.

EXAMINATION OF THE AUDITORY SYSTEM

A quick test for hearing loss in the speech range is to observe the response to spoken commands at different intensities (whisper, conversation, and shouting). The examiner must be careful to prevent the patient from reading his or her lip movement. A high-frequency stimulus such as a watch tick should also be used, because sensorineural disorders often involve only the higher frequencies. Tuning fork tests permit a rough assessment of the hearing level for pure tones of known frequency. The Rinne test compares the patient's hearing by air conduction with that by bone conduction. A 512-cps tuning fork is first held against the mastoid process until the sound fades. It is then placed 1 inch from the ear. Normal subjects can hear the fork about twice as long by air conduction as by bone conduction. If hearing by bone con-

duction is longer than by air conduction, a conductive hearing loss is suggested. The Weber test compares the patient's hearing by bone conduction in the two ears. The fork is placed at the center of the forehead, and the patient is asked where he or she hears the tone. Normal subjects hear it in the center of the head, patients with unilateral conductive loss hear it on the affected side, and patients with unilateral sensorineural loss hear it on the side opposite the loss. Otososcopic examination may reveal impacted cerumen as a cause of conductive hearing loss.

CAUSES OF HEARING LOSS

The bilateral hearing loss commonly associated with advancing age is called *presbycusis*. Presbycusis is not a distinct disease entity but rather represents multiple effects of aging on the auditory system. Presbycusis may include conductive and central dysfunction, although the most consistent effect of aging is on the sensory cells and neurons of the cochlea; as a result, higher tones are lost early.

Otosclerosis is a disease of the bony labyrinth that usually manifests itself by immobilizing the stapes and thereby producing a conductive hearing loss. Seventy percent of patients with clinical otosclerosis notice hearing loss between the ages of 11 and 30. There is a family history of otosclerosis in approximately 50% of cases. *Stapedectomy*, a procedure in which the stapes is replaced with a prosthesis, is effective in correcting the conductive component of hearing loss.

A lesion of the cerebellopontine angle, such as a vestibular schwannoma (Fig. 120-5), often causes unilateral hearing loss that progresses slowly; symptoms are caused by compression of the nerve in the narrow confines of the canal. The most common symptoms associated with vestibular schwannomas are slowly progressive hearing loss and tinnitus from compression of the cochlear nerve. Vertigo occurs in fewer than 20% of patients, but approximately 50% complain of imbalance or disequilibrium. Next to the

Figure 120-5 Magnetic resonance imaging scan of the brain showing coronal and axial views of a tumor of the left cerebellopontine angle, consistent with a schwannoma.

auditory nerve, the cranial nerves most commonly involved by compression are the seventh (facial weakness) and fifth (sensory loss). Loss of the corneal reflex on the affected side is often the first clinical sign. Treatment in most cases is surgical removal.

Ménière syndrome (endolymphatic hydrops) is characterized by fluctuating hearing loss and tinnitus, episodic vertigo, and a sensation of fullness or pressure in the ear. Typically the patient develops a sensation of fullness and pressure, along with decreased hearing and tinnitus in one ear. Vertigo rapidly follows, reaching a maximum intensity within minutes and then slowly subsiding over the next several hours. The patient is usually left with a sense of unsteadiness and dizziness for days after the acute vertiginous episode. In the early stages the hearing loss is completely reversible, but in later stages a residual hearing loss remains. Up to 50% of patients with idiopathic Ménière syndrome frequently have a positive family history, suggesting genetic predisposing factors. The key to the diagnosis of Ménière syndrome is to document fluctuating hearing levels in a patient with the

characteristic clinical history. Medical therapy for endolymphatic hydrops includes dietary sodium restriction and oral diuretics.

Acute unilateral deafness usually results from damage to the cochlea and may be caused by viral or bacterial labyrinthitis or vascular occlusion in the territory of the anterior inferior cerebellar artery. Perilymphatic fistulas may also cause abrupt unilateral deafness, usually in association with tinnitus and vertigo.

Drugs that cause acute irreversible bilateral hearing loss include aminoglycosides, cisplatin, and furosemide. Salicylates may cause reversible hearing loss and tinnitus.

TREATMENT OF HEARING LOSS

The best treatment is prevention, particularly by the appropriate use of earplugs for those working in a noisy environment. Hearing aids help patients with conductive hearing loss, and developments with cochlear implants may help patients with sensorineural hearing loss.

Prospectus for the Future

There has been accumulating evidence that a substantial minority of patients with symptoms of idiopathic intracranial hypertension (IIH) have underlying anatomic abnormalities of cerebral venous sinuses. In patients who have demonstrable abnormalities on cerebral venography, endoluminal venous sinus stenting has been reported as effective. This approach is receiving further study. In patients with sudden idiopathic sensorineural hearing loss who do not respond to oral corticosteroid therapy, intratympanic steroid injection has emerged as a

potential therapeutic option. Aminoglycoside antibiotics are known to be associated with ototoxicity; a small study has found that co-administration of aspirin appears to attenuate the ototoxic potential of gentamicin, possibly through an antioxidant effect. This finding, if substantiated in larger studies, may have implications for parts of the world where appropriate monitoring facilities for aminoglycoside levels are not readily available.

Dizziness and Vertigo

Kevin A. Kerber

Vestibular System

Understanding the vestibular system and common peripheral vestibular disorders is of central importance in the evaluation of patients with dizziness. This is because the dilemma is often discriminating a benign peripheral vestibular disorder from a small focal brain lesion. The vestibular system is a common source of confusion. Many clinicians assume a “peripheral” cause in the absence of motor, sensory, or language deficits, but this approach is flawed. A more effective approach is to aim to “rule in” a *specific* peripheral vestibular disorder. When a specific peripheral vestibular disorder does not fit, then a workup for a central nervous system lesion is usually warranted. The three common peripheral vestibular disorders all have highly characteristic history and examination features, thus enabling this approach.

BASIC VESTIBULAR SYSTEM CONCEPTS

The peripheral vestibular system maintains a balanced tonic input to the brain. The input represents the circuitry that links the inner ear to eye movements, the vestibulo-ocular reflex (VOR). A normal functioning VOR is important for balance and maintaining clear vision when moving. When an imbalance is caused by a lesion or aberrant stimulation, then vertigo ensues. A characteristic sign of vestibular system imbalance is nystagmus: rhythmic slow and fast movements of the eyes in opposite directions. The location of pathology determines the pattern of nystagmus (Table 121-1). Dysfunction at the semicircular canal level leads to nystagmus in the plane of the affected canal. Therefore problems in the vertical canals (i.e., posterior and anterior canals) lead to vertical and torsional nystagmus, whereas problems in the horizontal canal lead to horizontal nystagmus. At the vestibular nerve level a mixed horizontal-torsional nystagmus is generated because input from all the semicircular canals converge at this level and the signals from the vertical canals mostly cancel each other out. The pathways and thus the patterns of eye movements become less predictable with lesions of the central vestibular pathways, although some general rules apply. Pure vertical

(downbeat or upbeat) spontaneous nystagmus, bidirectional gaze-evoked nystagmus (look left, beats left; look right, beats right) (**Web Video 121-1**), and persistent downbeating positional nystagmus are signs of central dysfunction (see Table 121-1).

Another characteristic sign of vestibular disturbance is a positive head-thrust test (**Web Video 121-2**). A subject with an intact VOR will maintain gaze on a stationary, straight-ahead target after a brief, small-amplitude, high-acceleration movement of the head to one side. A subject with vestibular impairment on one side loses this reflex on the ipsilateral side and therefore, after the quick head movement, will need to make a re-fixation voluntary eye movement (i.e., a “saccade”) back to the target because the eyes moved with the head. This so-called “catch-up” or “corrective” saccade is easily appreciated at the bedside and indicates vestibular deafferentation.

PERIPHERAL VESTIBULAR DISORDERS

There are three common peripheral vestibular disorders: vestibular neuritis, Ménière disease, and benign paroxysmal positional vertigo (BPPV). An understanding of these three disorders is important because each one is the primary consideration for the cause of one of the three common dizziness presentation categories (Table 121-2). In addition, these disorders are the prototypes for most pathology that involves the peripheral vestibular system.

Vestibular neuritis manifests with the abrupt onset of severe vertigo, nausea, and imbalance without other neurologic symptoms. The disorder is caused by a viral disturbance of the vestibular nerve, analogous to Bell palsy. On examination, the acute peripheral vestibular pattern of nystagmus is seen (see Table 121-2) (**Web Video 121-3**). A positive head-thrust test in the direction of the affected ear (but in the direction opposite the fast phase of nystagmus) further supports a vestibular nerve localization. If the nystagmus changes direction with gaze (i.e., look left, beat left; then look right, beat right), then vestibular neuritis is not the diagnosis because these findings localize to the central nervous system. Small strokes of the cerebellum or brainstem can closely mimic vestibular neuritis. Symptoms may

Table 121-1 Common Types and Patterns of Nystagmus

Types	Patterns	Localization	Principal Causes
Spontaneous	Unidirectional horizontal >> torsional	Vestibular nerve, or rarely the brainstem	Vestibular neuritis, or rarely stroke
	Downbeat, upbeat, or pure torsional	Brain	Stroke
Gaze-evoked	Unidirectional	Vestibular nerve	Vestibular neuritis (recovery pattern)
	Bidirectional	Brain	Stroke, cerebellar syndrome, medication side effect*
Positional	Burst of upbeat torsional with DH	Posterior SCC	BPPV
	Horizontal with supine positional testing	Horizontal SCC or rarely the brainstem	BPPV, brainstem lesion
	Persistent downbeat	Brain	Chiari malformation, cerebellar degeneration

*Most common with antiepileptic drugs.

BPPV, benign paroxysmal positional vertigo; DH, Dix-Hallpike positional test; SCC, semicircular canal; >>, greater than.

Table 121-2 Common Categories of Dizziness Presentations

	Acute Severe Dizziness	Recurrent Spontaneous Attacks	Recurrent Positional Attacks
Primary consideration	Vestibular neuritis	Ménière disease	BPPV
Key features	Constant vertigo, unidirectional horizontal nystagmus,* positive head-thrust test [†]	Vertigo lasting hours, unilateral auditory symptoms	Positionally triggered, brief (<1 min) attacks Upbeat-torsional burst of nystagmus in DH position, cured by Epley maneuver [‡]
Red flags	Other CNS features, other patterns of nystagmus, imbalance as the principal symptom, chest pain, cardiovascular risk factors	Other CNS features, CNS patterns of nystagmus, imbalance as the principal symptom, attacks lasting only minutes, chest pain, cardiovascular risk factors, recent onset and crescendo pattern	Other CNS features, CNS patterns of nystagmus
Other considerations	Stroke, myocardial infarction, metabolic disturbances, demyelinating attack	TIA, cardiac arrhythmia, migraine, panic attacks	Horizontal or anterior canal BPPV, migraine, Chiari malformation, posterior fossa tumor, orthostatic hypotension

*This nystagmus never changes direction. Gaze in the direction of the fast phase will increase the velocity of the nystagmus, whereas gaze in the opposite direction will decrease the velocity of the nystagmus.

[†]The head-thrust test will be positive in the direction of the affected ear, which is opposite the direction of the fast phase of nystagmus.

[‡]These features apply to BPPV stemming from the posterior canal.

BPPV, benign paroxysmal positional vertigo; CNS, central nervous system; DH, Dix-Hallpike; TIA, transient ischemic attack.

respond to a short course of corticosteroids and vestibular rehabilitation.

Ménière disease is characterized by recurrent episodes of vertigo, nausea, and imbalance typically lasting hours; prominent auditory features must be present to make the diagnosis. Early in the course, auditory symptoms fluctuate along with vertigo attacks, but later they become a fixed symptom. The auditory symptoms are nearly always unilateral at the onset and consist of hearing loss, roaring tinnitus, or severe fullness in one ear. If attacks are brief (i.e., minutes rather than hours), then transient ischemic attacks should be considered. The dizziness of migraine can also closely mimic Ménière disease. The initial treatment of Ménière disease is a low-salt diet or a diuretic. However, neither of these treatments is of established efficacy. Ablative surgical procedures are appropriate in refractory vertigo cases.

Patients with BPPV report very brief episodes (<1 minute) of vertigo triggered by head movement—most often tilting the head back to look up, getting in or out of bed, or rolling over in bed. Dizziness from any cause may worsen after certain movements, but the dizziness of BPPV is *triggered* by certain movements. The most common form of BPPV

occurs when otoliths enter the posterior canal. Posterior canal BPPV is identified at the bedside using the Dix-Hallpike test (Fig. 121-1). In response to the Dix-Hallpike test, otoliths move in the canal and lead to a burst of upbeat-torsional nystagmus lasting about 20 to 30 seconds (**Web Video 121-4**). This disorder is cured in minutes by using the repositioning maneuver described by Epley. BPPV is less commonly caused by otoliths in the horizontal canal and very rarely the anterior canal. When the otoliths are in one of these other canals, the pattern of nystagmus is different from that of posterior canal BPPV, as are the repositioning maneuvers. Positional vertigo and nystagmus are common in patients with migraine. If a persistent downbeating nystagmus is seen during the Dix-Hallpike test, then a central nervous system cause (e.g., Chiari malformation, cerebellar tumor, or cerebellar degeneration) should be considered.

Approach to the Patient

“Dizziness” means different things to different people, so first start by defining the symptom. Is it true vertigo (i.e.,

Figure 121-1 Repositioning treatment for benign positional vertigo designed to move endolymphatic debris out of the posterior semicircular canal (PSC) of the right ear and into the utricle (UT). The patient is seated, and the patient's head is turned 45 degrees to the right (A). The head is then lowered rapidly to below the horizontal (B). The examiner shifts hand positions (C), and the patient's head is rotated rapidly 90 degrees in the opposite direction, so it now points 45 degrees to the left, where it remains for 30 seconds (D). The patient then rolls onto the left side without turning the head in relation to the body and maintains this position for another 30 seconds (E) before sitting up. The treatment is repeated until nystagmus is abolished. The procedure is reversed for treating the left ear. The patient must avoid the supine position for 2 days. (Adapted from Foster CA, Baloh RW: Episodic vertigo. In Rakel RE [ed]: *Conn's Current Therapy*. Philadelphia, WB Saunders, 1995).

visualized spinning of the environment), lightheadedness, imbalance, or some other symptom? The next step is to define the characteristics of the symptom. When did it start? Is it constant or episodic? If episodic, what are the duration and frequency of the episodes, and are there any triggers? This information helps categorize the patient's presentation (see Table 121-2). Next, ask about aggravating or alleviating factors and about accompanying symptoms. The patient's past medical history may identify a risk for certain disorders. The list of medications should be carefully scrutinized, because dizziness is a common medication side effect. The family history may reveal a familial pattern of similar symptoms. Whenever possible it is always preferable to examine the patient with dizziness at the time of active symptoms. Hearing should be tested one ear at a time with either tuning

forks or finger rub. If the general examination is unrevealing, then the focus should shift to the ocular motor examination to search for signs of vestibular or brain dysfunction. Does the patient have nystagmus? If so, what type and pattern? Is the head-thrust test result positive? Instruct the patient to follow your finger back and forth and assess whether the eyes move smoothly. This is a test of the smooth pursuit system, and pathologically impaired smooth pursuit is a central nervous system sign. If the patient reports that symptoms are triggered by head or body turns, then positional testing should be performed.

True vertigo suggests a disturbance of the vestibular system but does not discriminate a peripheral from a central vestibular localization. If the patient's features do not fit with a common peripheral vestibular disorder then central

nervous system causes should be considered. If the patient reports imbalance as the principal symptom and has a gait disorder, then the following causes should be considered: stroke (if the onset was acute), a musculoskeletal disorder, peripheral neuropathy, bilateral vestibulopathy, or a neurodegenerative disorder involving the cerebellum. When the dizziness is described as lightheadedness, wooziness, or a similar symptom, and the neurologic examination findings are normal, then general medical causes should be considered. Dizziness can be a prominent symptom of anxiety and panic disorders. Migraine should be on the differential diagnosis of any dizziness presentation. When none of these seem to fit, the examination findings are normal, and the symptom has been present for more than several months,

then the patient likely has chronic dizziness—typically considered a benign hypersensitivity disorder.

Treating Dizziness

Unless a specific disorder can be identified, symptomatic treatment is usually needed: meclizine, a benzodiazepine, or an antiemetic. However, these are not appropriate long-term treatment regimens. Patients with chronic dizziness may benefit from lifestyle modifications (e.g., exercise, optimizing sleep and diet, and stress management). Migraine prophylactic agents are reasonable to try, but their effectiveness for dizziness has not been established.

Prospectus for the Future

To optimize patient care and health care system usage, we need rigorous research to better define the clinical utility of diagnostic tests in dizziness—with a focus on defining which

patients will benefit from having which test. Understanding the underlying mechanisms of migraine dizziness would be a major breakthrough.

Disorders of the Motor System

Frederick J. Marshall

The voluntary motor system originates in the motor areas of the frontal lobe cortex that send their output caudally in the corticospinal tract. The basal ganglia and cerebellum have additional integrating, postural, and coordinating influences (Fig. 122-1). Descending influences from the red nuclei, vestibular nuclei, and brainstem reticular formation converge with descending corticospinal pathways on bulbospinal motor neurons to activate functionally automatic motor programs. At every level, afferent feedback provides input from muscle, nerves, spinal segment, brainstem, cerebellum, basal ganglia, and cortex to guide the efferent messages from the motor cortex. Figures 122-2 and 122-3 indicate the corticobasal ganglia connections and corticocerebellar loops that unconsciously precede movement.

Disease can selectively affect every level of the motor system from brain to muscle. Table 122-1 lists the anatomic locations of diseases affecting the motor system.

Symptoms and Signs of Motor System Disease

The patient with motor system disease usually complains of difficulty with accomplishing specific tasks. Patients with central nervous system (CNS) disorders (see Table 122-1) typically have difficulty with coordination, balance, and rapid movements. Muscle strength is frequently normal, and muscle atrophy (wasting) is usually lacking. Muscle tone is usually increased, characterized by spasticity or rigidity. Patients with peripheral nervous system (PNS) disorders (see Table 122-1) usually complain of difficulty with tasks; if weakness is proximal, there is impairment in climbing or descending stairs, rising from a chair, or lifting heavy objects above the head. If weakness is distal, then the patient complains of stumbling and tripping or of having problems fastening buttons or opening locks or doors with the hands.

The patient with weakness of gradual onset may not recognize it, emphasizing the useful axiom that “signs of muscle weakness precede symptoms of weakness.” A patient with weakness who is unfamiliar with what is taking place may use words such as *numbness*, *deadness*, *tiredness*, or *fatigue*. In contrast, when a patient complains of *weakness*, it often results from systemic rather than neurologic disease. In such patients, strength is often normal or only mildly reduced because the complaint is usually a loss of stamina and endurance. The patient with a complaint of fatigue should be asked to distinguish between true weakness and the less specific symptoms of lassitude and asthenia. If the patient is unable to perform a specific normal activity, then true weakness is suggested. Objective evidence of weakness is established if symptoms exceed the boundaries of normal variation (e.g., double vision, drooping eyelids, difficulty swallowing, repeated aspiration of food or liquids into the airway), as opposed to the more subjective complaints of inability to lift, carry, or push an object.

CNS motor disorders (see Table 122-1) can result from focal brain or spinal cord diseases such as those that occur with stroke, tumor, or inflammatory or demyelinating disease, each of which is covered in specific chapters elsewhere in this text. CNS motor disorders can also be the result of a widespread, nonfocal *system* degeneration, which is considered in this chapter. Focal brain disease usually produces abnormalities on neuroimaging procedures. System degeneration, in contrast, seldom produces detectable abnormalities on neuroimaging and other neurodiagnostic tests until long after patients first report symptoms and have signs of abnormal function on examination.

Corticospinal diseases from system degeneration are uncommon and are characterized by upper motor neuron signs (spasticity and hyperreflexia). The most common is amyotrophic lateral sclerosis, which differs from other CNS motor diseases by the prominent involvement of both the CNS and PNS. The hereditary spastic paraplegias are rare diseases with only upper motor neuron signs.

Figure 122-1 Normal human voluntary motor system.

Movement Disorders and Ataxia

Central motor systems are divided into three constituents: pyramidal, extrapyramidal, and cerebellar. The pyramidal system (named for the pyramidal cross-section of fiber tracts in the medulla) is the major outflow from motor cortex to spinal cord. Lesions of the pyramidal system cause motor weakness (paresis), spasticity, and hyperreflexia. Although lesions of this system disturb motor function, they are not considered *movement disorders*. Movement disorders are caused by extrapyramidal or cerebellar dysfunction. The term *extrapyramidal* refers to the basal ganglia and their projections. The main components of the extrapyramidal system are noted in Table 122-2, and their major interconnections are depicted in Figure 122-4.

The basal ganglia receive input from the cortex and give feedback to the cortex through projections from the

thalamus. Multiple neurotransmitters are involved in complex feedback loops. The basal ganglia modulate not only motor cortical activity but also the activity of association cortex, particularly in the frontal lobes. Many movement disorders therefore involve complex neurobehavioral symptoms (e.g., dementia in Huntington disease, attentional deficits and obsessive-compulsive behavior in Tourette disorder, depression in Parkinson disease). Clinicoanatomic correlations between lesions in a component of the system and development of a characteristic movement disorder or neurobehavioral syndrome remain elusive. An exception is hemiballismus, a dramatic flailing movement of the extremities on one side of the body usually caused by a lesion of the contralateral subthalamic nucleus. Neurosurgical interventions designed to ablate or stimulate specific nuclei, and neuropharmacologic treatments designed to modulate selective receptor systems are increasingly widespread.

Movement disorders entail either too little movement (hypokinesia) or too much movement (hyperkinesia). Table 122-3 outlines the hypokinetic disorders in the differential diagnosis of akinetic-rigid syndrome. The disorders listed in Table 122-3 cause progressive immobility. *Rigidity* refers to increased muscular tone throughout the range of motion. It does not vary with passive acceleration of the limb by the examiner. Lead-pipe rigidity connotes the ductile quality of metal being passively bent. Cogwheel rigidity is the superimposition of tremor on underlying rigidity. Paratonic rigidity or paratonia is a velocity-dependent resistance to passive movement. Such resistance increases as the speed of passive limb displacement increases. Patients with paratonic rigidity demonstrate *gegenhalten*, an inability to fully relax a limb for passive range-of-motion testing. This group of patients also demonstrates *mitgehen*, the tendency to *help out* as the examiner attempts to move the limb passively. Paratonia is clinically nonspecific; it is common in patients with diminished cerebral function resulting from a variety of causes. True rigidity always implies basal ganglia dysfunction on the contralateral side.

Many different hyperkinetic movements may be exhibited (Table 122-4). Accurate identification of these movements is required for proper diagnosis and treatment of extrapyramidal diseases. For example, chorea occurring in successive generations is most likely caused by Huntington disease (hereditary chorea). Parkinson disease is most likely the cause of resting tremor in an older patient with rigidity and bradykinesia (slow movement). Essential tremor (a common, often inherited disorder) is most likely the cause of action tremor in a patient without rigidity or bradykinesia).

Table 122-5 outlines a number of signs commonly associated with lesions of the cerebellar system. Disorders of proprioceptive function may result in *sensory ataxia* caused by impairment of the spinocerebellar inputs.

Hypokinetic Movement Disorders

IDIOPATHIC PARKINSON DISEASE

James Parkinson, an English physician, first described the clinical triad of tremor, bradykinesia, and muscular rigidity in 1817. Later, physicians recognized that postural instability

Figure 122-2 Anatomy of the basal ganglia and their connections. The feedback loop proceeds from cerebral prefrontal areas to the basal ganglia and eventually back from the basal ganglia to the thalamus to the motor cortex. This ultimately regulates the descending corticospinal motor system. ACH, acetylcholine; DA, dopamine; GABA, γ -aminobutyric acid; GLU, glutamate; GP, globus pallidus (e, external; i, internal); SN, substantia nigra (c, compacta; r, reticulata); VL, ventrolateral. Figure 122-3 Corticocerebellar loop. The major cerebellar input is from the spinocerebellar tract. Outflow is to the motor cortex via the mesencephalon and thalamus.

was also a fundamental aspect of the illness. These four signs remain the diagnostic criteria for Parkinson disease. Parkinson disease affects 500,000 to 750,000 people in the United States and is a leading cause of neurologic disease in individuals older than 65 years of age. Premature death of pigmented dopaminergic neurons in the pars compacta of the substantia nigra is the underlying basis of the disease, but the cause remains unclear. Neuronal loss occurs in the substantia nigra, with characteristic eosinophilic hyaline intraneuronal inclusions called Lewy bodies. Dopamine-containing neurons with cell bodies in the substantia nigra

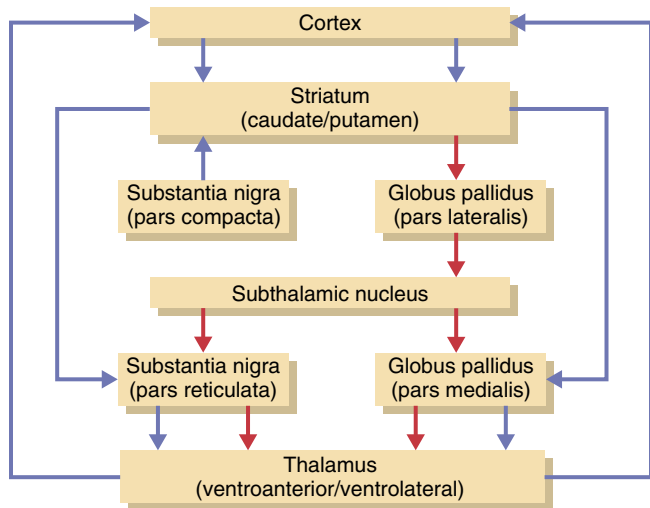

Figure 122-4 In this simplified version of the basal ganglia wiring diagram, information flows in one of two ways, either facilitating motor output by means of the direct pathway (red lines) or inhibiting motor output by means of the indirect pathway (blue lines). In Parkinson disease, loss of neurons in the pars compacta of the substantia nigra shifts the balance away from the direct pathway and toward the indirect pathway, resulting in hypokinesia. Conversely, in Huntington disease, loss of select neurons in the striatum shifts the balance away from the indirect pathway and toward the direct pathway, resulting in hyperkinesia.

Table 122-4 Descriptive Terms of the Hyperkinesias	
Asterixis	Transitory loss of motor tone resulting in rapid movement of a joint (the conceptual opposite of myoclonus) (Web Video 122-2)
Athetosis	Slow writhing movement
Ballism	Flailing movement (typically unilateral—hemiballism)
Chorea	Irregular flicking, dancelike movement (Web Video 122-3)
Choreoathetosis	The combination of chorea and athetosis
Dyskinesia	Nonspecific term for hyperkinesia (generally chorea, athetosis, and dystonia, alone or in combination)
Dystonia	Sustained contortion resulting from excess muscular activity across a joint: generalized, segmental, or focal (Web Video 122-4)
Myoclonus	Rapid jerking muscular movement: multifocal or segmental, rhythmic or irregular (Web Video 122-5)
Tic	Semi-suppressible motor or vocal gestural movement (may be simple, such as eye blinking or throat clearing, or complex, such as hopping or swearing)
Tremor	Rhythmic oscillating movement: predominantly at rest or with action

Table 122-3 Differential Diagnosis of the Akinetic-Rigid Syndrome
Idiopathic Parkinson disease
Drug-induced parkinsonism
Diffuse Lewy body disease
Progressive supranuclear palsy
Corticobasal-ganglionic degeneration

Catatonia (psychosis)

MPTP, methyl-phenyl-tetrahydropyridine.

project to the striatum (caudate and putamen), where they synapse on a variety of cell types. Early in the course of the disease, dopamine receptors in the striatum are upregulated in response to decreased dopaminergic input from the substantia nigra. This compensatory ability of the striatum is eventually overwhelmed, and progressive clinical dysfunction ensues.

In the past decade a number of monogenic causes have been identified, including the following causative genes: α -synuclein (*SNCA*), parkin, PTEN-induced kinase 1 (*PINK1*), *DJ-1*, and leucine-rich repeat kinase 2 (*LRRK2*). However, altogether, these gene defects likely account for only 2% to 3% of all cases of classic parkinsonism. Characterization of the encoded proteins suggests a pathogenic role

Table 122-5 Signs of Cerebellar System Impairment	
Ataxia	Poorly coordinated, broad-based, lurching gait
Ataxic dysarthria	Abnormal modulation of speech velocity and volume
Dysmetria	Irregular placement of voluntary limb or ocular movement
Hypometria	Movement falling short of the intended target
Hypermetria	Movement overshooting the intended target
Dysdiadochokinesis	Breakdown in precision and completeness of rapid alternating movements (as with a pronation-supination task)
Dysrhythmokinesis	Irregularity of the rhythm of rapid alternating movements or planned movement sequences
Dyssynergia	Inability to perform movement as a coordinated temporal sequence
Hypotonia	Decreased resistance to passive muscular extension (seen immediately after injury to the lateral cerebellum)
Intention tremor	Tremor orthogonal to the direction of intended movement (tends to increase in amplitude as the target is approached)
Titubation	Rhythmic rocking tremor of the trunk and head

Table 122-6 Clinical Features of Parkinson Disease**Primary Features**

Bradykinesia, rest tremor, rigidity, postural instability, therapeutic response to levodopa

Secondary Features

Masked facies (facial hypomimia)
 Dysphagia; hypophonia or palilalia, micrographia, stooped posture, festinating gait, start hesitation, dystonic cramps
 Autonomic dysfunction: orthostatic hypotension, urinary incontinence, constipation
 Behavioral alterations: depression, dementia, sleep disorders including restless legs syndrome
 Sensory complaints: aching, numbness, tingling

in the process of protein degradation and in mitochondrial function.

Symptoms and signs of Parkinson disease are listed in Table 122-6. The patient notes unilateral symptoms initially: characteristically, hand tremor, decreased arm swing, foot dragging, or micrographia. Symptoms and signs subsequently spread to involve both sides. Gradually worsening postural instability ultimately results in wheelchair confinement. Symmetrical onset of symptoms and early falls caused by postural instability are atypical of idiopathic Parkinson disease, whereas they are common in other causes of the akinetic-rigid syndrome (see Table 122-3). Tremor may be a prominent feature of idiopathic Parkinson disease, but it is not usually a prominent feature of other akinetic-rigid disease states (**Web Video 122-1**).

Treatment of Parkinson disease is outlined in Table 122-7. Carbidopa-levodopa (Sinemet) remains the mainstay of treatment for advanced Parkinson disease. Failure of bradykinesia and rigidity to improve in response to a trial of levodopa treatment raises the possibility of another disease (see Table 122-3) because these diseases typically involve primary pathologic deterioration at the level of the striatum rather than the substantia nigra.

Levodopa requires enzymatic conversion to dopamine within substantia nigra neurons. Unlike levodopa, the dopamine agonists do not compete with other amino acids to cross the blood-brain barrier; they require no enzymatic conversion and act directly at the level of the striatum, bypassing the substantia nigra. Concern has been expressed that treatment with levodopa may eventually provoke motor complications, such as *on-off* fluctuations and dyskinesias. Initiating therapy with dopamine agonists allows the physician to reserve levodopa treatment for later stages of the illness. The co-administration of a dopamine agonist in the later stages of illness may reduce the amount of levodopa required.

Selegiline delays the need for levodopa treatment in patients with early Parkinson disease. Selegiline inhibits monoamine oxidase type B, an enzyme that breaks down dopamine. Toxic free radicals generated in the normal catabolism of dopamine may damage dopaminergic neurons in the substantia nigra, which may cause Parkinson disease in patients who are vulnerable as a result of a combination of inherited risk and as yet undetermined environmental exposures. It has been postulated that selegiline may act as a neuroprotective agent if the formation of free radicals is

Entacapone-carbidopa-levodopa (Stalevo)

inhibited. Rasagiline is a second generation selective monoamine oxidase type B inhibitor. Patients may tolerate it better because it is not metabolized to amphetamine. Alternatively, selegiline is now available as an orally disintegrating tablet, which decreases production of amphetamine from first-pass hepatic metabolism.

The aromatic amino acid decarboxylase inhibitor carbidopa and the catechol-O-methyltransferase (COMT) inhibitors entacapone and tolcapone block the breakdown of levodopa. Co-administration of levodopa with carbidopa and a COMT inhibitor suppresses levodopa's peripheral catabolism, maximizing the amount available to cross the blood-brain barrier and prolonging its effective half-life. Tolcapone has been associated with rare but potentially lethal liver toxicity; the hepatic function of patients undergoing treatment with this drug must be monitored closely. Entacapone has no adverse effect on liver function and is now in widespread use.

Because enhancing dopaminergic neurotransmission is the underlying rationale of drug treatments for Parkinson disease, most antiparkinsonian drugs have unwanted dopaminergic side effects. These include nausea, orthostatic hypotension, hallucinations, psychosis, and dyskinesia (i.e., abnormal involuntary hyperkinetic movements such as chorea and dystonia). Management of progressive Parkinson disease requires a careful balance between the potential beneficial effects of medication and these potential side effects.

In the past decade, great advances have been made in the surgical treatment of Parkinson disease. Most centers of excellence in the care of Parkinson disease now offer deep-brain stimulation (DBS) of the subthalamic nuclei (STN) as a treatment option. This procedure is performed with the

patient awake, using the combined expertise of the stereotactic neurosurgeon and an electrophysiologist and clinical neurologic assessment. Parameters such as the pulse frequency, pulse width, amplitude, and electrical port can be modulated to achieve dynamic suppression of output from the STN to the thalamus. This procedure can be performed bilaterally. Documented benefits in rigidity, tremor, and bradykinesia can occur; gait and postural instability are relatively refractory to treatment. Although dyskinesia increases initially, overall dyskinesia is reduced in a majority of patients with DBS by improvement of other symptoms and consequently reduction in the levodopa and dopamine agonist doses. The ideal patient is young, free of dementia or neuropsychiatric complications, and highly responsive to medications for Parkinson disease. Patients with a poor response to levodopa are less likely to benefit from DBS surgery.

DRUG-INDUCED PARKINSONISM

The most common cause of drug-induced parkinsonism is treatment with neuroleptic medication. A number of other agents may provoke a bradykinetic-rigid syndrome (Table 122-8).

DIFFUSE LEWY BODY DISEASE

Lewy body disease may be classified into three types based on the pathologic distribution of underlying Lewy bodies: brainstem, transitional, and diffuse. Restriction of Lewy bodies to the brainstem defines *Parkinson disease*. In the *transitional phase*, Lewy bodies spread to involve the limbic system. In *diffuse Lewy body disease*, clinical parkinsonism combined with prominent dementia occurs. Visual hallucinations are common, patients may be extremely sensitive to the adverse effects of neuroleptic medication, and cognitive fluctuations occur (see Chapter 116).

PROGRESSIVE SUPRANUCLEAR PALSY

In the early 1960s Steele, Richardson, and Olszewski described a series of patients who exhibited gait disturbance, falls, bradykinesia, and rigidity. Unlike patients with idiopathic Parkinson disease, patients with progressive supranuclear palsy typically do not have tremor. A progressive loss of voluntary eye movements occurs with the preservation of oculocephalic reflex eye movements (the hallmark of a supranuclear eye movement abnormality). Patients develop

dementia, pseudobulbar affect (i.e., affective lability without correlative underlying emotional content), and frontal release signs. Progression is faster than it is in patients with idiopathic Parkinson disease, and symptomatic response to dopaminergic agents is limited. The cause of progressive supranuclear palsy remains unknown. Tau-containing neurofibrillary tangles develop, with neuronal loss and gliosis involving the globus pallidus, subthalamic nucleus, substantia nigra, pons, oculomotor complex, medulla, and dentate nucleus of the cerebellum.

CORTICOBASAL-GANGLIONIC DEGENERATION

Like progressive supranuclear palsy, corticobasal-ganglionic degeneration is also a tauopathy involving neurofibrillary tangles, neuronal loss, and gliosis. Classically the disease manifests with marked asymmetry of motor dysfunction characterized by bradykinesia, rigidity, and apraxia (failure of learned motor movements) on one side of the body or in a single limb. The “alien hand” syndrome can be a hallmark of the disorder; the limb adopts seemingly deliberate movements that are not under the direct voluntary control of the patient. As the disease progresses, a combination of cortical dementia (aphasia, agnosia, apraxia) and basal-ganglia dysfunction (bradykinesia, rigidity, and postural instability, with or without tremor) becomes increasingly disabling. Asymmetry persists late into the course.

MULTISYSTEM ATROPHY

Three entities are included under the term *multisystem atrophy* (see Table 122-3). Abnormal glial cytoplasmic inclusions containing α -synuclein are the pathologic hallmark of the disorder, with progressive loss of neurons—in particular, brain nuclei—determining the particular clinical presentation. All eventually progress to a profoundly akinetic-rigid state. In olivopontocerebellar atrophy, the predominant early manifestations are cerebellar dysmetria and ataxia, with abnormalities of vocal modulation, appendicular coordination, and smooth pursuit eye movements. A dramatic and progressive loss of neurons occurs in the olivary nucleus of the medulla, pons, and cerebellum, giving rise to characteristic atrophy of these regions on computed tomography (CT) or magnetic resonance imaging (MRI). In striatonigral degeneration, predominant bradykinesia, symmetrical rigidity, and postural instability develop relatively early, typically without prominent resting tremor. These signs are relatively refractory to levodopa treatment, differentiating these from similar signs caused by idiopathic Parkinson disease. In Shy-Drager syndrome, bradykinesia, rigidity, and postural instability are combined with early and prominent loss of autonomic function. Severe orthostatic hypotension results in syncopal events. Cardiac arrhythmias, urinary incontinence, constipation, diarrhea, sudomotor instability, and disordered central temperature regulation may occur. Recently, a reclassification of multisystem atrophy has been proposed, outlining predominantly cerebellar, parkinsonian, or mixed cerebellar-parkinsonian subtypes—all of which have prominent dysautonomia as a core feature. Multisystem atrophy is a sporadic disease in which dementia, if it occurs, is a late-stage finding. A positive family history for

Phenytoin
Angiotensin-converting enzyme inhibitors

a similar disorder should suggest an alternative diagnosis such as a dominant spinocerebellar degeneration.

VASCULAR PARKINSONISM

Vascular parkinsonism is a controversial entity because its findings are varied and its pathogenesis is ill defined. Patients have signs of Parkinson disease and have microangiopathic changes in the basal ganglia that cause periventricular high T2-weighted signals on MRI. However, such changes are commonly seen on MRI in older individuals, regardless of whether they have bradykinesia and rigidity. Vascular parkinsonism is often diagnosed whenever vascular risk factors are known and periventricular white matter lesions that are evident on MRI accompany clinical evidence of parkinsonism. A lack of improvement with levodopa therapy or the overt evidence of stroke involving the basal ganglia supports this diagnosis.

TOXIC PARKINSONISM

Carbon monoxide intoxication may cause bilateral necrosis of the basal ganglia, leading to an akinetic-rigid state. Chronic exposure to manganese has also been associated with the development of parkinsonism. An intriguing clue to a possible toxic basis for idiopathic Parkinson disease was discovered in the 1970s with the report of a series of formerly asymptomatic individuals who developed bradykinesia, postural instability, tremor, and rigidity after exposure to the designer street drug 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Selective uptake of this agent into pigmented cells of the substantia nigra, with conversion by monoamine oxidase type B to the toxic free radical MPP(+), accounts for selective cell death of dopaminergic neurons. MPTP has been widely studied in animal models of Parkinson disease.

Hyperkinetic Movement Disorders

ESSENTIAL TREMOR

The most common cause of tremor is *essential tremor*. This condition is inherited and ranges in severity from cosmetic to disabling. Unlike the tremor of Parkinson disease, essential tremor typically affects both sides of the body symmetrically and is more prominent with action than it is at rest. The frequency of the tremor oscillation is relatively constant, but the amplitude may vary. As with all forms of tremor, stress, sleep deprivation, and stimulants (e.g., caffeine) make the condition worse. Alcohol often relieves essential tremor. When essential tremor occurs in the context of a dominant family history, it is called *familial tremor*. Essential tremor starts somewhat earlier than it does with Parkinson disease and may affect the neck and head muscles and the voice, as well as the arms and hands. The most useful medications for essential tremor include propranolol (Inderal), primidone (Mysoline), and topiramate (Topamax). DBS surgery with electrode placement in the ventral intermedialateral nucleus of the thalamus is highly effective but should

be reserved for patients whose condition is refractory to pharmacotherapies.

OTHER CAUSES OF TREMOR

Parkinson disease tremor is worse at rest, is often slower than essential tremor, and responds best to anticholinergic treatment rather than to medications for essential tremor. Cerebellar tremor has a more irregular rhythm, is coarser than either essential tremor or the tremor of Parkinson disease, and is more pronounced as the limb approaches a target (action tremor). So-called *rubral tremor* is an extremely coarse tremor with significant intention dysmetria that occurs with lesions in the area of the red nucleus in the mesencephalon. Numerous drugs can provoke tremor, including stimulants (e.g., theophylline, methylphenidate), dopamine receptor–blocking drugs, lithium, tricyclic antidepressants, anticonvulsants (e.g., valproate, phenytoin, carbamazepine), cardiac agents (e.g., amiodarone, calcium channel blockers, procainamide), and immunosuppressive agents (e.g., cyclosporin A, corticosteroids).

DYSTONIA

Dystonia consists of sustained muscle contractions that result in abnormal postures and contortions. It may occur as a primary process or as a secondary symptom of an underlying neurologic disease (e.g., Wilson disease, Huntington disease, cerebral anoxia). Derangements in the physiologic makeup of the dopamine synapse may lead to acute drug-induced dystonic reactions. Such reactions can be life threatening if respiratory function is compromised, but they generally respond to emergent treatment with anticholinergic medication. Metoclopramide (Reglan), commonly prescribed for nausea and vomiting, may induce dystonia. DBS with implantable electrodes has been used experimentally for dystonia.

Although the primary dystonias presumably involve basal ganglia dysfunction, no underlying pathologic structure has been convincingly documented. Mutations of the *DYT* gene on chromosome 9 have been defined in some families with generalized dystonia. Five percent to 10% of patients with primary generalized dystonia are responsive to treatment with levodopa (i.e., dopa-responsive dystonia as a result of mutations of the GTP-cyclohydrolase gene), and all patients with symptoms of generalized dystonia should receive a therapeutic trial of levodopa.

A large number of common focal dystonias were once considered emotional disorders: writer's cramp, spasmodic dysphonia, and torticollis (Table 122-9). Intramuscular injection of botulinum toxin is the treatment of choice for symptomatic control of focal dystonia.

WILSON DISEASE

Wilson disease is a rare (approximately 1 per 40,000 births) but treatable autosomal recessive disorder that is debilitating and eventually fatal if left untreated. It should be considered in the differential diagnosis of new-onset hyperkinesia or parkinsonism in the young adult. Wilson disease almost never develops after the age of 50 years. Wilson disease may also exhibit neuropsychiatric manifestations. Psychosis is

Table 122-9 Features of the Primary Dystonias

Feature	Description
Generalized (Usually Childhood Onset, Autosomal Dominant with Variable Penetrance)	
Idiopathic torsion dystonia	Intorsion of a foot, followed by progressive spread of dystonia to involve the muscles of the limbs, trunk, neck, and face
Dopa-responsive dystonia	As above, with bradykinesia and rigidity common and hyperreflexia in 25%. Dramatic response to low-dose levodopa (50-200 mg)
Focal (Usually Adult Onset, Sporadic)	
Spasmodic torticollis	Involuntary contraction of neck musculature resulting in various combinations of twisting, tilting, extension, or flexion
Meige syndrome	Lower facial or mandibular dystonia with dyskinetic movements of the tongue and lips
Blepharospasm	Involuntary forced eyelid closure
Spasmodic dysphonia	Dystonic vocal cord contraction resulting in hoarse or breathy whisper
Writer's cramp	Task-specific contortion of the hand or forearm during attempts to write

common. The disease is a systemic disorder of copper metabolism. In addition to the neurologic signs and symptoms, hepatic dysfunction (including death from fulminant hepatic failure) occurs in variable degrees. All young adult patients with a movement disorder should be screened for Wilson disease by means of a ceruloplasmin level. In patients with suspected Wilson disease, slit-lamp examination for Kayser-Fleischer rings (i.e., characteristic depositions of copper pigment in the limbus of the iris), 24-hour urine collection for copper, determination of serum copper level, and hepatic biopsy are indicated. Treatment with copper chelation and zinc can arrest further neurologic decline and can occasionally improve neurologic deficits. Mobilization of copper from liver stores can result in neurologic worsening during initial treatment with standard chelation regimens. Patients should be referred to experienced centers for initiation of treatment.

HUNTINGTON DISEASE

Huntington disease is an inexorably progressive autosomal dominant neurodegenerative disorder affecting motor function, cognition, and behavior. The mean age at onset is 40 (10% of cases begin in childhood), and the mean duration of illness is 20 years. In the adult-onset form, chorea affects the limbs and trunk. Other movement abnormalities commonly occur, including dystonia, rigidity, postural instability, and myoclonus. Bradykinesia and rigidity predominate in the juvenile-onset form. Eye movements are often abnormal early in the disease, with slowing of saccadic initiation and velocity and eventual breakdown of smooth pursuit movements. The disease involves premature death of specific neurons in the caudate and putamen.

An abnormal expansion in the number of trinucleotide CAG repeat sequences occurs in a 350-kD gene on chromosome 4, coding for the protein huntingtin. Excessive CAG sequences encode an overly expanded number of polyglutamine repeats in the protein. CAG expansion in excess of 37 repeats is diagnostic of the disease. On average, the higher the CAG-repeat expansion, the earlier the age at onset. Despite this inverse correlation between CAG expansion length and age at onset, the variability in age at onset for a given CAG expansion is too high to enable precise prognostication regarding onset for individual patients. No

treatment currently exists that slows the progression of Huntington disease. Downregulation of dopaminergic neurotransmission by means of neuroleptic agents may suppress chorea but often worsens underlying postural instability and rigidity. The U.S. Food and Drug Administration (FDA) has recently approved the vesicular monoamine transport (VMAT) inhibitor tetrabenazine for treatment of chorea associated with Huntington disease. This drug, widely available in Europe for several years, functions by depleting dopamine from the presynaptic neuron. The therapeutic window for tetrabenazine can be low, however, because it also has the potential to deplete serotonin and norepinephrine and can increase depression, parkinsonism, and akathisia (a restless hyperkinetic movement disorder). Treating depression and psychosis may enhance the patient's quality of life. Use of antenatal diagnosis and presymptomatic genetic testing of adult patients at risk for the disease raises ethical and personal questions. Presymptomatic testing of at-risk children is not indicated.

OTHER CAUSES OF CHOREA

Sydenham chorea occurs in childhood as a postinfectious complication of group A β -hemolytic streptococcal pharyngitis. The illness is usually self-limited, but prolonged chorea may occur, as may other neuropsychiatric symptoms. The caudate and STN are affected, presumably on an autoimmune basis. Some patients respond to a short course of corticosteroids. Treatment with intravenous immunoglobulin is also an option.

A number of drugs occasionally cause chorea, including isoniazid, lithium, oral contraceptives, and reserpine. Metabolic causes include thyrotoxicosis, hypoparathyroidism, and hypomagnesemia. Hemichorea may result from stroke or tumor, and autoimmune or vascular mechanisms may underlie the chorea sometimes observed in patients with lupus erythematosus.

MYOCLONUS

Myoclonus occurs in many neurologic disorders, but it may also occur in isolation. *Physiologic (hypnagogic) myoclonus* occurs in healthy individuals as they fall asleep. *Essential myoclonus* is a nonprogressive, generalized disorder that can

occur as an autosomal dominant trait. Patients experience multifocal, large-amplitude lightning jerks that are provoked by action and are disabling, or they may have mild, small-amplitude jerks that do not disrupt their function. Patients with essential myoclonus almost always also have some degree of underlying dystonia. Myoclonus also occurs in generalized epilepsy syndromes that are not inherently progressive (e.g., benign myoclonus of infancy, juvenile myoclonic epilepsy) or in tonic-clonic epilepsy and progressive encephalopathy (e.g., progressive myoclonic encephalopathy). Static myoclonic encephalopathy occurs most commonly as a consequence of severe anoxia (Lance-Adams syndrome) or head trauma and may be spontaneous or action induced, multifocal, or generalized. Secondary causes of focal or multifocal myoclonus include underlying structural lesions of the nervous system (e.g., stroke, arteriovenous malformation, demyelinating disease, tumor, abscess, other infectious processes) or toxic-metabolic conditions (e.g., hypoxia, uremia, hepatic encephalopathy, sepsis, electrolyte disturbances, hormonal abnormalities). Treatment should be directed to the underlying cause. Valproate or clonazepam are commonly prescribed for symptomatic treatment of myoclonus.

TOURETTE DISORDER

In 1885, Gilles de la Tourette described a series of patients with motor and vocal tics, some of whom had coprolalia (foul language). For most of the ensuing century, Tourette disorder was considered a rare curiosity, existing on the border zone of neurology and psychiatry. Although coprolalia is an uncommon manifestation, Tourette disorder and its related primary tic disorders (e.g., chronic motor tics, chronic vocal tics, transient tic disorder) have been increasingly recognized in the past decade as common entities. A substantial proportion of children with learning disorders have Tourette disorder.

Transitory tics are a normal part of child development. Tourette disorder is defined as the history of both motor and vocal tics (for more than 1 year) with onset before the age 18 years. The tics are associated with obsessions and compulsive behavior in 50% of patients and are accompanied by attention-deficit disorder in 50% of patients. Tourette disorder is probably an autosomal dominant condition with variable penetrance.

Treatment focuses on the most functionally incapacitating aspect of the disorder (not necessarily the tics), and patients and families should be reassured that the disorder is not progressive or fatal. Approximately two thirds of patients outgrow their tics (but not necessarily the other neuropsychiatric manifestations of the illness) by adulthood. Useful medications are outlined in Table 122-10. Strategies to reduce stress on the patient, including education of parents, peers, and teachers, are frequently preferable. Treatment of attention deficit with stimulants may exacerbate tics; treatment of tics with neuroleptic drugs may blunt affect, disrupt learning, provoke depression, and lead to unwanted weight gain.

OTHER CAUSES OF TICS

Tics may be drug induced (i.e., stimulants or neuroleptic medications causing tardive tics), or they may be sympto-

Table 122-10 Medications Used in the Management of Incapacitating Tourette Disorder

matic of developmental, degenerative, toxic-metabolic, or infectious neurologic disorders. Patients with chromosomal abnormalities (e.g., Down and fragile X syndromes) frequently have tics, as do those with pervasive developmental delay, anoxic encephalopathy, and autism. Tics occasionally occur in patients with Huntington disease, progressive supranuclear palsy, Creutzfeldt-Jakob disease, and encephalitis, as well as those with sequelae of carbon monoxide poisoning or hypoglycemia.

Cerebellar Ataxias

The cerebellum receives input from the spinal cord (spino-cerebellar tracts), from the vestibular nuclei in the brainstem, and from pontine relays, carrying information from the motor and premotor cortex. The cerebellar cortex is made up of four main neuronal types. Granule cells input onto Purkinje cells, whose axons form the sole output of the cerebellar cortex, terminating in cerebellar nuclei or select brainstem nuclei. Golgi cells and stellate-basket cells function as inhibitory interneurons within the cerebellar cortex. The cerebellar cortex is organized into three main sagittal zones. The most medial (vermal) zone projects to the fastigial nuclei, which in turn project to the vestibulospinal and reticulospinal tracts. Injuries to this zone or its projections lead to abnormal stance and gait, truncal titubation, and disturbances of extraocular movement. The intermediate (paravermal) zone projects to the interposed nuclei, which in turn project to the red nucleus and the thalamus. Isolated injuries to this zone are rare, and clinical manifestations generally overlap with medial or lateral cerebellar syndromes. The lateral zone projects to the dentate nuclei, which in turn project to the thalamus and cerebral cortex. Injuries to this zone or its projections result in abnormal stance and gait, appendicular dysmetria, eye movement dysmetria, dysdiadochokinesia, dysrhythmokinesia, intention tremor, ataxic dysarthria, and hypotonia.

NONHEREDITARY ATAXIAS

Lesions of the cerebellum, its inflow tracts, or its outflow tracts may all be associated with ataxia. The rapid onset

Table 122-11 Hereditary Ataxias

Disease	Onset	Associated Signs
Autosomal Recessive Inheritance		
Ataxia-telangiectasia	Childhood	Telangiectasia, recurrent sinus and pulmonary infections, choreoathetosis, mental retardation in 30%, neoplasms (lymphoma, lymphocytic leukemia)
Abetalipoproteinemia (Bassen Kornzweig syndrome or acanthocytosis)	Childhood	Absent serum apolipoprotein B leads to fat malabsorption with decreased vitamins A, E, and K; retinitis pigmentosa; nystagmus
Friedreich ataxia	Childhood	Scoliosis, cardiomyopathy, dysarthria, areflexia, Babinski signs, loss of joint position and vibration sense in legs, dysmetria
Autosomal Dominant Inheritance		
Spinocerebellar ataxia types 1-8, 10-23, and 25-27	Adulthood	Variable combinations of long-tract signs, parkinsonism, dementia
Dentatorubral-pallidoluysian atrophy		Sensory loss, myoclonus, chorea
Other forms of olivopontocerebellar atrophy		Dystonia and seizures

of ataxia suggests an underlying structural condition, an immune-mediated process, drug intoxication, or conversion disorder. Structural lesions of the cerebellum or its connecting tracts include tumors, demyelinating plaques, abscesses, and vascular events such as vertebrobasilar occlusion, cerebellar parenchymal hemorrhage, traumatic hematoma, and arteriovenous malformation. Immune-mediated processes include acute postinfectious cerebellitis or myoclonic encephalopathy with neuroblastoma in children, and paraneoplastic cerebellar degeneration in adults. Migraine headaches, particularly in childhood, may be accompanied by ataxia. Radiographic studies, drug screening, and cerebrospinal fluid analysis will clarify the diagnosis in most patients with acute-onset ataxia.

Chronic or progressive ataxia may result from slow-growing brain tumors (e.g., cerebellar astrocytoma, hemangioblastoma, ependymoma, medulloblastoma, supratentorial tumors), congenital malformations (e.g., basilar impression, Dandy-Walker malformation, Chiari malformation), drug effects (e.g., alcoholic cerebellar vermal degeneration, chronic phenytoin toxicity), or hereditary ataxias.

HEREDITARY ATAXIAS

Progressive ataxia is a feature of numerous hereditary neurologic diseases (Table 122-11). Determining which hereditary disease is responsible depends on a thorough assessment

of the familial pattern of inheritance and knowledge of the typical age at onset and progression of symptoms and signs associated with these conditions.

Molecular tests for a number of specific hereditary ataxias have become available within the past decade, but caution should be used to ensure adequate informed consent, support services, and follow-up before such tests are used to determine a potentially fatal diagnosis, especially in presymptomatic individuals. Genetic test results have immediate implications for the risk status of extended family members. Definitive therapies are generally lacking, genetic testing is expensive, and few mechanisms can ensure against genetic testing results being used by insurers or employers to the disadvantage of the patient or family.

Similar to Huntington disease, several of the autosomal dominant spinocerebellar ataxias are caused by abnormal expansions in the number of repeated CAG codons within unique genes. These diseases display the phenomenon of *anticipation*: the age at onset is progressively younger in successive generations of a family. This phenomenon occurs because the CAG repeat length of the abnormal genes is upwardly unstable during gametogenesis, and higher CAG repeat burden results in younger age at onset. Other dominant spinocerebellar ataxias are caused by noncoding regions, through mRNA mechanisms like those elucidated in myotonic dystrophy (see Chapter 131), or through conventional mutations.

Prospectus for the Future

Advances in molecular genetics, gene profiling, stem cell research, and fetal tissue transplant techniques are all proceeding rapidly and promise to improve the diagnosis and therapy of many movement disorders in the coming decade. Initial studies of fetal nigral tissue transplantation in patients with Parkinson disease have been controversial. A number of patients developed disabling dyskinesias after receiving fetal nigral grafts. Nonetheless, the fact that these grafts survived, developed connections to target structures in the striatum, and had a functional impact on patients' parkinsonian symptoms is encouraging. More work will need to be done in animal models

of parkinsonism in which dyskinesia develops. Great interest exists in developing gene therapy for Parkinson disease because creating viral vectors with relative tropism for the striatum, specifically targeting the molecular biochemistry of dopamine production and metabolism, is possible. Experimental gene therapy in animal models (e.g., rodents, primates) is promising, and early trials of gene transfection using adeno-associated virus are underway in humans. Studies of co-affected siblings with Parkinson disease have revealed new genetic loci of interest. Similar approaches hold promise in most other motor system disorders.

Developmental and Neurocutaneous Disorders

Emily C. de los Reyes and E. Steve Roach

Advances in magnetic resonance imaging and genetic microarray technology have improved our understanding of neurodevelopmental disorders. High-resolution neuroimaging now detects congenital and developmental abnormalities that were previously unrecognized. Moreover, neurodevelopmental disorders in one group are now being diagnosed with alarming frequency: the autistic spectrum disorders. Although the exact cause of these disorders is unclear, this chapter will discuss the various syndromes associated with autistic spectrum disorders.

Neural Tube Defects

Neural tube defects are developmental defects associated with failure of the anterior and posterior neuropore to close during the 24th to 26th days of gestation. Disturbances of neural tube closure manifest with a spectrum of abnormalities including anencephaly, encephalocele, and myelomeningocele with Chiari II malformation. Genetic factors may play a role, because there is a higher incidence in trisomy syndromes. However, folic acid affects cell division, and folic acid supplementation during pregnancy has been advocated in pregnancies as a preventive measure.

Chiari malformation is the displacement of the hindbrain (cerebellar) tonsils more than 5 mm below the foramen magnum. Chiari I malformation is frequently asymptomatic, but some individuals develop headaches or lower cranial neuropathies. Additional signs include syringomyelia or scoliosis. Surgical decompression may be necessary when the symptoms are severe.

Chiari II malformations are characterized by displacement of the cerebellum and lower brainstem through the foramen magnum. These malformations typically occur in conjunction with a myelomeningocele and hydrocephalus, so seizures, cognitive delay, paraplegia, and sphincter dysfunction are common. Treatment is surgical repair of the myelomeningocele with subsequent shunting of the hydrocephalus. Bladder dysfunction may necessitate intermittent

catheterization and treatment of urinary tract infections and genitourinary reflux.

Spinal Malformations

Developmental anomalies of the vertebral bodies are common and cause pain and neurologic symptoms when they cause scoliosis or accelerated degenerative changes of the spine. Neurologic disability is likely when cord anomalies are present or when they compress neural structures or alter cerebrospinal fluid flow.

Tethered Spinal Cord

A tethered spinal cord results from an anomalous filum terminale that causes either lack of normal ascent of the conus medullaris to the L1 vertebral level or an ischemic or metabolic disturbance of the caudal spinal cord. Associated spinal anomalies are common: diastematomyelia (split cord), spinal lipomas, dermal sinuses, and fibrolipomas of the filum terminale. Affected individuals exhibit bladder and sexual dysfunction and leg extremity weakness or spasticity. Symptoms develop more often in childhood or adolescence. Cutaneous hypertrichosis, hemangiomas, and/or dimpling often occurs in the lumbar area. Treatment involves surgical release of the tethered cord.

Syringomyelia

Syringomyelia is a cystic cavitation of the central portion of the spinal cord, whereas hydromyelia is the dilatation of the central canal. Both are usually located in the cervical cord but may extend in to the medullary region (syringobulbia) or toward the thoracic cord. A syringomyelia may develop in association with Chiari malformations, trauma, tumor, or a tethered cord. The classic presentation is a dissociated

sensory loss (pain and temperature loss with preservation of light touch and proprioception) in the neck, arms, or legs. A cervical lesion produces a capelike dissociated sensory loss of the arms and shoulder, along with atrophy of the hands and arms with increased tone and hyperreflexia in the legs. Extension into the medulla may cause lower cranial neuropathies. Diagnosis is confirmed by magnetic resonance imaging. If the cause is associated with Chiari II malformation, then posterior fossa decompression and shunting of the hydrocephalus may improve the symptoms. Rarely, a large syrinx unassociated with a Chiari malformation may require shunting

Brain Malformations

Malformations of cortical development can be identified with accuracy through neuroimaging procedures. Most such lesions develop during the first trimester. Disorders of ventral induction include holoprosencephaly, agenesis of the corpus callosum, and septo-optic dysplasia. Holoprosencephaly is the failure of the prosencephalon to divide into two separate structures. The disorder is heterogeneous with a spectrum of abnormalities ranging from alobar holoprosencephaly (cortex with a single ventricle) to lobar holoprosencephaly (cerebral hemispheres are mostly separated except for the frontal lobes).

Migrational abnormalities occurring during the second to the fourth month of gestation include lissencephaly, schizencephaly, and polygyria and pachygyria. Diagnosis is established by magnetic resonance imaging. Symptoms include cognitive delay, spasticity, and seizures. Intractable seizures may require resection of the focal cortical dysplasias. These disorders may be caused by congenital intrauterine infections, gene mutations, or teratogenic agents. The identification of various gene mutations (Table 123-1) has allowed genetic counseling for families of affected children. X-linked gene mutation is milder in women because of X inactivation.

Autism and Autism Spectrum Disorders

Autism spectrum disorders are characterized by impaired social communication, delayed expressive and receptive language, and repetitive, stereotypic behavior. Although these disorders are increasingly diagnosed, their cause remains unclear. Autism is clearly genetic in individuals with tuberous sclerosis complex (TSC), Rett syndrome, and fragile X syndrome. The treatment that has shown the most promise is intensive behavioral intervention. Speech therapy is helpful. Alternative medicine is popular but has not been studied in a well-designed manner. Genetic syndromes that have a high risk of autistic spectrum disorders are discussed in the following paragraphs.

RETT SYNDROME

Rett syndrome is an X-linked dominant disorder caused by a mutation of the methyl-cytosine binding protein (MeCP2) that functions as a transcriptional repressor. The identification of this gene has permitted characterization of the phenotypic spectrum of Rett syndrome. Patients with Rett syndrome develop normally until the first year of life, when they manifest loss of communication skills and deceleration of head growth. A classic feature is loss of hand function and stereotypic hand wringing. Seizures are common. Diagnosis is confirmed by DNA testing. Treatment is currently limited to treatment of seizures and spasticity.

FRAGILE X SYNDROME

Next to Down syndrome, fragile X syndrome is the most common genetic cause of mental retardation and is caused by expanded CGG triplet repeats (>200 CGG repeats) in the first exon of the fragile X mental retardation gene (*FMR1*). Symptomatic females have a milder mental

Table 123-1 Malformations of Central Nervous System Cortical Development Recognized on Magnetic Resonance Imaging

Malformation	Locus	Gene(s)	Clinical Manifestations

deficiency compared with their male counterparts. Children have a distinctive appearance: macrocephaly with a long narrow face, and prominent ears, pubertal macroorchidism, and joint laxity. Neurobehavioral features include autism and attention deficit disorder. Some individuals with 55 to 200 CGG repeats develop ataxia and tremor and cognitive dysfunction beginning in adulthood, which may mimic parkinsonism.

Neurocutaneous Disorders

Neurocutaneous disorders are congenital, often hereditary disorders characterized by pathognomonic cutaneous and central nervous system lesions that uniquely distinguish each disease. The most important of these syndromes are neurofibromatosis (types 1 and 2), TSC, Sturge-Weber syndrome, and von Hippel-Lindau disease. There is considerable variability in the spectrum of clinical manifestations.

NEUROFIBROMATOSIS TYPE 1

Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder with a prevalence of 1 in 3000 births. Almost half of the cases are sporadic mutations. The *NF1* gene on chromosome 17q expresses neurofibromin, a tumor-suppressor protein. In NF1, there is loss of expression of neurofibromin, leading to dysregulated cell growth and differentiation. Mutations in the *NF1* gene are identified in approximately 75% of patients, but no correlation exists between a particular genotype and phenotype. Many manifestations of NF1 appear during childhood and adult life. The criteria for the diagnosis include two or more of the following: (1) six or more café-au-lait macules larger than 5 mm in prepubertal patients or more than 15 mm in postpubertal individuals, (2) two or more neurofibromas of any type or one plexiform neurofibroma, (3) axillary or inguinal freckling, (4) sphenoid bone dysplasia, (5) optic nerve glioma, (6) Lisch nodules, and (7) a family history of NF1. Diagnosis is based on clinical criteria, supplemented by neuroimaging findings, or by DNA testing. Other manifestations include learning disabilities, attention deficit disorder, macrocephaly, and epilepsy. Important complications include scoliosis, gastrointestinal neurofibromas, pheochromocytomas, and renal artery stenosis. Most individuals with NF1 do not require treatment. Painful subcutaneous neurofibromas can be excised. Intraspinal and intracranial tumors are typically benign and treated surgically. Genetic counseling should be provided to all patients and families. New mutations occasionally occur in the germline of an unaffected parent and can be transmitted to more than one offspring.

NEUROFIBROMATOSIS TYPE 2

Neurofibromatosis type 2 (NF2) is an autosomal-dominant disease that occurs less frequently than NF1 (approximately 1 in 50,000 individuals). The *NF2* gene is located on chromosome 22q. The gene product (merlin) is a cytoskeletal protein. Most NF2 patients have bilateral VIII nerve

schwannomas. However, multiple meningiomas and multiple other tumors are common. Skin lesions are present in a minority of patients with NF2, and the diagnosis is based on the following criteria: (1) bilateral VIII nerve tumors detected by magnetic resonance imaging, (2) a family member with either NF2 or unilateral VIII nerve schwannoma, and (3) juvenile posterior subcapsular lens opacities. Symptoms of NF2 begin in the second to fourth decades. Removal of the schwannomas and other tumors is often usually indicated, and early recognition is important for successful treatment of VIII nerve tumors.

TUBEROUS SCLEROSIS COMPLEX

TSC causes hamartomatous lesions involving multiple organs at different stages in the course of the disease. Transmission is autosomal dominant, but sporadic cases are frequent because of spontaneous mutations. The incidence is 1 in 6000. The *TSC* gene loci are at chromosome 9p34 for *TSC1* and chromosome 16p for *TSC2*. The gene product for *TSC1* is hamartin and for *TSC2*, tuberin. Both gene products interact with the mammalian target of rapamycin (mTOR), which is essential in cell growth, proliferation, and angiogenesis. Hereditary cases not linked to these two loci also occur.

The most significant organs affected include the brain (cortical tubers, subependymal giant cell astrocytomas), heart (cardiac rhabdomyomas), skin (facial angiofibromas, hypomelanotic skin macules or “ash leaf spot,” shagreen patches, and subungual fibromas), kidney (renal angiomyolipoma), eye (retinal hamartoma), and lung (pulmonary lymphangiomyomatosis).

Seizures, most commonly infantile spasms, are the usual early clinical presentation. Treatment is directed toward the epilepsy, especially for infantile spasms. A surgical approach may be necessary for intractable epilepsy. Subependymal nodules may enlarge and cause hydrocephalus. The lesions enlarge especially during adolescence. Renal angiomyolipomas are prone to hemorrhage. Pulmonary lymphangiomyomatosis may be life threatening, especially in females. Cognitive disability may require special education.

STURGE-WEBER SYNDROME

Sturge-Weber syndrome is variably characterized by an upper facial vascular nevus (port-wine stain), a leptomeningeal angioma, and ocular abnormalities (glaucoma and choroidal hemangioma). The disorder occurs sporadically in less than 1 in 20,000 births. Clinical features include focal epilepsy, cognitive impairment, and, less frequently, hemiparesis, hemianopia, or glaucoma. If antiepileptic drugs do not control seizures, surgical excision of epileptogenic areas may be indicated.

The diagnosis is usually made by the port-wine stain and neuroimaging confirmation of the intracranial abnormality. Magnetic resonance imaging is a more reliable tool for diagnosis because calcifications on computed tomographic scans are classic but unnecessary for the diagnosis. However, 80% of people with a facial port-wine stain have no associated brain involvement. Laser treatment of the port-wine stain is of cosmetic benefit.

VON HIPPEL–LINDAU DISEASE (CENTRAL NERVOUS SYSTEM ANGIOMATOSIS)

Von Hippel–Lindau disease is an autosomal-dominant disorder caused by a defective tumor suppressor gene (*VHL* gene) on chromosome 3p25-p26. It is variably associated with retinal angiomas, brain and spinal cord hemangioblastomas, renal cell carcinomas, pheochromocytomas, angiomas of the liver and kidney, and cysts of the pancreas, kidney, liver, and epididymis. The diagnosis is established if patients have more than one central nervous system hemangioblastoma, one hemangioblastoma with a visceral manifestation

of the disease, or one manifestation of the disease and a known family history.

Symptoms typically begin during the third or fourth decade. Retinal inflammation with exudates, hemorrhage, and retinal detachment may antedate cerebellar symptoms (headache, vertigo, and vomiting) or signs (incoordination, dysmetria, and ataxia).

Retinal detachments and tumors are treated by laser therapy. Brain tumors, renal cell carcinomas, pheochromocytomas, and epididymal tumors are treated surgically. Early evaluation and repeated imaging studies are indicated once the diagnosis has been made, and genetically at-risk individuals should also be evaluated.

Prospectus for the Future

Understanding of the neurocutaneous disorders associated with tumor development is increasing. As the molecular signals causing tumors are clarified, novel genetic treatment strategies

will become feasible. Improved imaging and surgical techniques are already making it possible to treat some aspects of the neurocutaneous disorders.

Cerebrovascular Disease

Sinéad M. Murphy and Timothy J. Counihan

The term *cerebrovascular disease* refers to disorders of the arterial or venous circulatory systems of the central nervous system. Stroke is a clinical syndrome defined by the World Health Organization as “rapidly developing clinical signs of focal or global disturbance lasting 24 hours or longer or leading to death with no apparent cause other than of vascular origin.” Approximately 80% of strokes are ischemic in origin. *Focal* ischemic stroke is caused by either thrombotic or embolic occlusion of a major artery, whereas *global* ischemia usually results from inadequate cerebral perfusion such as that occurring after cardiac arrest or ventricular fibrillation. Rarely is isolated cerebral hypoxia (such as occurs in carbon monoxide poisoning or asphyxiation) a cause of stroke.

Epidemiology

Stroke remains the third leading medical cause of death and the leading cause of acquired physical disability in developed countries. Since 1990 the incidence of stroke in the United States has declined, with an annual incidence of approximately 250 per 100,000 population, accounting for about 1 in every 16 deaths. Mortality from stroke has also declined with advances in medical care. Rates of stroke among men and women are similar. The incidence and rate of mortality from stroke are higher in blacks than whites. Although the reasons for the decline in the incidence of stroke remain unclear, a greater understanding of the importance of controlling risk factors in stroke prevention may be in part responsible. This decrease in incidence is coincident with the decline of cardiovascular deaths and better control of hypertension and other risk factors (Table 124-1). In addition, the increasing public awareness of the warning symptoms of stroke as constituting a *brain attack* (analogous to chest pain as a warning of a *heart attack*) is beginning to result in earlier presentation and therefore access to acute stroke treatments.

Anatomy

Two pairs of major arteries, the carotid (anterior circulation) and vertebral (posterior circulation) arteries, supply the brain (Fig. 124-1).

ANTERIOR CIRCULATION

The common carotid artery bifurcates into an internal and an external branch at the level of the thyroid cartilage in the neck. The internal carotid artery (ICA) gives off no branches within the neck, enters the skull through the carotid canal in the petrous part of the temporal bone, and passes through the cavernous sinus as the carotid siphon. Within the cavernous sinus the ICA is in close proximity to the oculomotor, trochlear, and abducens nerves (cranial nerves III, IV, and VI) as well as the ophthalmic and maxillary branches of the trigeminal nerve (cranial nerve V). Small branches are given off to supply the adjacent meninges and posterior lobe of the hypophysis before the ICA pierces the dura. The ICA then gives off the ophthalmic, posterior communicating, and anterior choroidal arteries before bifurcating into the anterior cerebral artery (ACA) and middle cerebral artery (MCA). The ACA supplies the medial surfaces of the cerebral hemispheres, and the MCA supplies the lateral surface (convexity), in addition to much of the basal ganglia and subcortical white matter.

POSTERIOR CIRCULATION

The vertebral arteries (VAs) arise from the subclavian arteries and course upward within the transverse processes of the cervical vertebrae. The extracranial VA gives off a branch to form the anterior spinal artery. The first intracranial branch of the VA is the posterior inferior cerebellar artery (PICA), which supplies the posterolateral medulla, inferior vermis, choroid plexus of the fourth ventricle, and inferior cerebellum. The two VAs unite to form the basilar artery (BA) at

(Modified from Lord R: *Surgery of Occlusive Cerebrovascular Disease*. St Louis, Mosby, 1986).

the pontomedullary junction. The BA supplies the remainder of the cerebellum via the anterior inferior cerebellar artery (AICA) and superior cerebellar artery (SCA). The BA also supplies the pons via the paramedian, long and short circumferential branches before bifurcating into the posterior cerebral arteries (PCAs) at the level of the pontomesencephalic junction.

CIRCLE OF WILLIS

The circle of Willis is formed at the base of the brain by the union of both ACAs via the anterior communicating artery

Figure 124-2 Autoregulatory cerebral blood flow (CBF) response to changes in mean arterial pressure in normotensive and chronically hypertensive persons. Note the shift of the curve toward higher mean pressures with chronic hypertension. (From Pulsinelli WA: *Cerebrovascular diseases-principles*. In Goldman L, Bennett JC [eds]: *Cecil Textbook of Medicine*, 21st ed. Philadelphia, WB Saunders, 2000, p 2097).

and the union of the ICA with the PCA via the posterior communicating artery (see Fig. 124-1). Hence communication exists between both anterior circulations, as well as between the posterior and anterior circulations on each side. Congenital anomalies of the circle are frequent; they include hypoplasia or atresia of a PCA or ACA, which may reduce collateral blood supply if an adjacent vessel becomes occluded.

CEREBRAL VENOUS CIRCULATION

Superficial veins drain into the transverse, superior sagittal, and cavernous sinuses. The deep venous drainage is via the great vein of Galen, which drains into the straight sinus, which in turn drains into the torcula along with the sagittal sinus. Blood drains from the torcula to the transverse sinus, then to the sigmoid sinus, and thereafter the jugular vein. Anterior venous drainage is via the cavernous sinus, which communicates with the contralateral cavernous sinus, the transverse sinus via the superior petrosal sinus, and the inferior petrosal sinus, which drains directly into the jugular bulb.

Physiologic Factors

Unlike other body tissues, the brain has few energy stores but relies on a sizable and reliable cerebral blood flow (CBF) to meet its energy demands. CBF averages 50 mL/100 g of brain tissue per minute. A complex system of neural pathways regulates CBF in a process known as *autoregulation*, which maintains CBF at a constant level despite wide fluctuations in cerebral perfusion pressure (CPP) (Fig. 124-2). CBF remains relatively constant when the mean arterial pressure (MAP) remains between 50 and 150 mm Hg. In the

case of chronic systemic hypertension, however, both the upper and lower levels of autoregulation are raised, which indicates a higher tolerance of hypertension but a greater susceptibility to the effects of hypotension. CPP is the difference between MAP and intracranial pressure (ICP). CPP is usually approximately 80 mm Hg. When CPP falls below 50 mm Hg there is evidence of ischemia and reduced cellular channel activity.

Ischemic Stroke

PATHOGENESIS

Cerebral ischemia may result from thrombotic or embolic occlusion of a major vessel that reduces blood flow within the involved vascular territory, or it may be a consequence of diminished systemic perfusion. Prolonged brain ischemia results in infarction, characterized histologically by necrosis of neurons, glia, and endothelial cells. Cerebral infarcts are classified as either *pale* (anemic) or *hemorrhagic* (in areas of endothelial necrosis). In transitional zones between normally perfused tissue and the infarcted central core is a rim of moderately ischemic tissue known as the *ischemic penumbra*, which is the target area for treatment trials of neuroprotective agents.

Global cerebral ischemia usually results from cardiac arrest or ventricular fibrillation. Some neuronal populations are selectively vulnerable to transient global ischemia, particularly neurons of the hippocampus, cerebellar Purkinje cells, and the deeper layers of the cerebral cortex (inducing so-called *laminar necrosis*). Pure hypoxia causes cerebral dysfunction (exhibited clinically as lethargy and confusion) but rarely produces irreversible brain injury unless accompanied by other factors such as hypoglycemia.

When CBF falls to 20 mL/100 mg of brain per minute, neuronal function is affected and electrical activity of cortical cells ceases. The critical threshold for irreversible cell damage is about 10 mL/100 g of brain per minute. At this level of hypoperfusion mitochondrial metabolism is inhibited and anaerobic metabolism of glucose occurs, causing a rise in lactate and thus acidosis. Intracellular membranes are no longer able to control ion fluxes. Potassium leaks out of cells; sodium, water, and calcium enter cells, causing cytotoxic edema (see later). Activation of membrane lipases further compromises cell membrane integrity and leads to release of excitatory neurotransmitters, which in turn may further exacerbate tissue injury. For a short period of time the cells may remain viable if perfusion is restored.

CEREBRAL EDEMA

Cerebral edema may be intracellular (cytotoxic) or interstitial (vasogenic). Intracellular edema develops rapidly in ischemic neurons as energy-dependent ion-channel pumps fail, whereas vasogenic edema occurs as a result of damage to endothelial cells, disrupting the blood-brain barrier and allowing macromolecules such as plasma proteins to enter the interstitial space. Fluid accumulates over 3 to 5 days after an ischemic stroke and can increase brain water content by as much as 10%; such large volume increases can lead to transtentorial herniation and death.

Table 124-2 Causes of Cerebral Ischemia

- Antiphospholipid syndrome (lupus anticoagulant, anticardiolipin antibodies)
- Protein C or protein S deficiency
- Paraneoplastic disorder

Undetermined or cryptogenic

Global

Hypoperfusion

Cardiac arrest

Ventricular fibrillation

ETIOLOGIC FACTORS

Table 124-2 lists the major causes of acute cerebral ischemia. The TOAST classification system is often used for classification of stroke mechanism. This includes large artery atherosclerosis, which accounts for approximately one quarter of strokes, either through embolization of plaque to distal vessels (artery-to-artery embolus) or by in situ thrombosis. Certain sites of the cerebral vasculature are more prone to the development of atheromatous plaques (Fig. 124-3). Cardioembolism makes up 20% to 30% of ischemic strokes, arising most commonly as a result of atrial fibrillation. Mural thrombi, valvular vegetations, and atrial myxomas are also potential sources of embolus, as are *paradoxical emboli* (emboli of venous origin passing through a patent foramen ovale [PFO]). Small vessel disease accounts for another 20% to 30% of strokes, with a small proportion having other causes, including arterial dissection, vasculitis, and illicit drug use such as cocaine; in 20% to 30% of stroke patients the mechanism remains unclear (*cryptogenic stroke*).

Certain conditions predispose younger patients to stroke (Table 124-3).

TRANSIENT ISCHEMIC ATTACK VERSUS STROKE

A transient ischemic attack (TIA) is a brief episode of neurologic dysfunction caused by focal brain or retinal ischemia, with clinical symptoms typically lasting less than 1 hour. The previous 24-hour time window has largely been abandoned; some patients with only transient symptoms may have

Figure 124-3 Sites of predilection for atheromatous plaque. ACA, anterior cerebral artery; CCA, common carotid artery; ICA, internal carotid artery; MCA, middle cerebral artery; PCA, posterior cerebral artery. (From Caplan LR: *Stroke—A Clinical Approach*. Boston, Butterworth-Heinemann, 1993).

imaging evidence of established infarction. In most instances the maximal clinical deficit occurs at the onset of symptoms, with subsequent recovery. Several factors may contribute to symptom progression (often referred to as a *stroke in evolution*), including propagation of a thrombus or progression of cerebral edema or hemorrhage into an infarcted area. Coexistent medical conditions such as systemic hypotension, fever, hyperglycemia, or hypoxemia may further adversely affect the outcome.

LACUNAR STROKE

A *cerebral lacuna* is a small, deep infarction involving a penetrating branch of a large cerebral artery. Lacunae are usually associated with chronic hypertension, although they are occasionally found in normotensive patients, presumably as a result of microatheroma of penetrating arteries, especially of the basal ganglia, thalamus, and white matter of the internal capsule and pons.

Probably the most common clinical syndrome caused by a lacunar stroke is *pure motor hemiparesis*, resulting from a lesion in the internal capsule. Another common lacunar syndrome is *ataxic hemiparesis* with both unilateral weakness and ataxia; the responsible lesion is usually in the internal capsule or pons. Other lacunar syndromes include *pure sensory stroke* and *dysarthria-clumsy hand* syndromes. The clinical pattern of weakness in lacunar syndromes is typically that of face-arm-leg paresis affected in equal proportion.

BRAINSTEM SYNDROMES

A number of brainstem syndromes have been described, with a combination of contralateral hemiplegia and cranial nerve dysfunction. *Weber syndrome*, caused by a midbrain lesion, is associated with an ipsilateral cranial nerve III palsy and contralateral weakness; *Claude syndrome*, caused by a lesion in the red nucleus, consists of a cranial nerve III palsy with a contralateral *rubral* tremor. *Millard-Gubler syndrome* results from a lesion of the ventral pons, manifesting with a contralateral hemiplegia and ipsilateral cranial nerve VI and VII palsies. *Raymond syndrome*, also caused by a ventral pontine lesion, causes an ipsilateral sixth nerve palsy with a contralateral hemiplegia. In the lateral medulla, a syndrome involving cranial nerves IX and X, Horner syndrome, cerebellar ataxia, and crossed hemibody pain and temperature loss is known as *Wallenberg syndrome*. This syndrome is most often the result of occlusion of the ipsilateral VA with resulting ischemia in the territory of the PICA.

Major Stroke Syndromes

The clinical manifestations of ischemic stroke are summarized in Table 124-4.

INTERNAL CAROTID ARTERY

TIAs that occur in the anterior circulation affect either the retinal artery or MCA distribution most frequently. Symptoms of retinal artery involvement consist of several seconds of a *graying out* of vision in one eye or monocular blindness (*amaurosis fugax*), often described as being like a curtain coming down over the affected eye. An important finding on retinoscopy is the presence of refractile arterial lesions, which represent cholesterol crystals (*Hollenhorst plaques*)

Table 124-4 Clinical Manifestations of Ischemic Stroke

Occluded Vessel	Clinical Signs
ICA	Ipsilateral blindness (variable) MCA syndrome
MCA	Contralateral hemiparesis, hemisensory loss (face or arm more than leg) Aphasia (dominant) or anosognosia (nondominant) Homonymous hemianopsia (variable)
ACA	Contralateral hemiparesis, hemisensory loss (leg more than arm) Abulia (especially if bilateral)
VA or PICA	Ipsilateral facial sensory loss, hemiataxia, nystagmus, Horner syndrome Contralateral loss of temperature or pain sensation Dysphagia
SCA	Gait ataxia, nausea, vertigo, dysarthria
BA	Quadriparesis, dysarthria, dysphagia, diplopia, somnolence, amnesia
PCA	Contralateral homonymous hemianopsia, amnesia, sensory loss

ACA, anterior cerebral artery; BA, basilar artery; ICA, internal carotid artery; MCA, middle cerebral artery; PCA, posterior cerebral artery; PICA, posterior inferior cerebellar artery; SCA, superior cerebellar artery; VA, vertebral artery.

that have become detached from a more proximal cholesterol plaque. Most anterior circulation TIAs occur in the setting of significant stenosis or ulceration of the ICA (>75%); cardiogenic embolism accounts for some of the remainder. Other causes to consider include traumatic or spontaneous arterial dissection.

Acute occlusion of a previously widely patent ICA usually results in contralateral hemiplegia and hemisensory loss, reflecting ischemia in the MCA territory. Headache frequently accompanies ICA occlusion. The extent of the deficit depends on the availability of collateral circulation; in the case of occlusion of a previously severely stenotic ICA, little or no clinical deficit may be apparent, because of extensive collateral circulation. Severe bilateral ICA stenosis may occasionally cause *border zone (watershed)* ischemia (between the ACA and MCA) in the setting of systemic hypotension; this results in a well-recognized clinical syndrome consisting of bilateral proximal limb weakness (*man-in-a-barrel* syndrome). The clinical recognition of ICA stenosis or occlusion may be unreliable because although the presence of a bruit in the region of the angle of the jaw suggests significant extracranial vascular disease, it does not distinguish the external carotid artery from the ICA.

ANTERIOR CEREBRAL ARTERY

Occlusion of the ACA distal to the anterior communicating artery causes weakness and sensory loss in the contralateral leg. Other clinical manifestations include urinary incontinence and *abulia*, a state of akinetic mutism reflecting bilateral frontal lobe dysfunction.

MIDDLE CEREBRAL ARTERY

Embolism accounts for the majority of MCA occlusions. Emboli may be either cardiogenic or artery to artery from the ICA. Occlusion of the main MCA trunk results in contralateral hemiplegia, hemianesthesia, and homonymous hemianopsia with a gaze preference away from the side of the hemiplegia. The hemiplegia usually affects the face and arm more than the leg. A global aphasia occurs with dominant hemisphere lesions, and anosognosia occurs with nondominant hemisphere involvement. Occasionally, selective occlusion of the lenticulostriate branches from the proximal MCA causes capsular infarction without evidence of cortical infarction, as a result of collateral filling of the distal MCA. Occlusion of the superior division of the MCA causes facio-brachial weakness; an expressive (Broca) aphasia results from dominant hemisphere lesions, or a motor neglect (characterized by motor imperistence and spatial disorientation) results from lesions in the nondominant side. Inferior division occlusion usually produces impairment of sensory perception (astereognosis) and occasionally a visual field disturbance. Dominant hemisphere lesions result in a fluent (Wernicke) aphasia.

VERTEBROBASILAR ISCHEMIA

Vertebrobasilar ischemia produces various combinations of symptoms such as dizziness (vertigo), diplopia, ataxia, bilateral sensory or motor symptoms, and fluctuating episodes of drowsiness. Scintillations or transient visual field deficits may indicate ischemia in the PCA distribution. Distinguishing the vertigo of vertebrobasilar ischemia from labyrinthine vertigo can be difficult, although isolated positional vertigo is more likely to be of labyrinthine origin.

VERTEBROBASILAR OCCLUSION

Occlusion of the vertebral or basilar arteries or their branches (PICAs, AICA, and SCA) results in discrete syndromes (see Table 124-4). Acute infarction of the cerebellum from occlusion of any of its three supplying vessels may result in its swelling within the posterior fossa, causing obstruction of the fourth ventricle, and obstructive hydrocephalus. Such patients require close monitoring and occasionally neurosurgical intervention.

BA occlusion produces massive brainstem dysfunction and is often fatal. If the medulla is spared, a number of syndromes can occur, including the *locked-in syndrome*, in which patients are fully awake yet quadriplegic and can communicate only by means of vertical eye movements and blinking.

POSTERIOR CEREBRAL ARTERY OCCLUSION

Proximal PCA occlusions cause contralateral hemiparesis (from damage to the cerebral peduncle), hemisensory loss (thalamus), amnesia (medial temporal lobe), and hemianopsia. Macular (central) vision may be spared because of collateral vessels from the MCA. Dominant thalamic involvement may cause aphasia and thus simulate an anterior circulation stroke.

Dehydration

CEREBRAL VENOUS THROMBOSIS

Occlusion of the cerebral venous sinuses may occur in several settings, often in association with a hyperviscosity or hypercoagulable state (Table 124-5). The condition is associated with pregnancy. The clinical picture varies: patients may have headache, seizures, or focal neurologic symptoms; they often have papilledema on examination. The diagnosis frequently rests on imaging findings: bilateral hemorrhagic infarctions in a parasagittal distribution are common, as are areas of extensive white matter edema. Contrast-enhanced computed tomography (CT) may demonstrate the *empty delta* sign, suggesting a filling defect in the sagittal sinus. Magnetic resonance venography (MRV) or formal cerebral angiography should confirm the sinus filling defect.

Diagnosis

Evaluation of the patient with a suspected stroke should seek to answer three questions: Is it a stroke? Where is the lesion? And what is the mechanism? Some useful bedside pointers that may be elicited from the history and help define the stroke mechanism include the time of symptom onset and the temporal course and progression of symptoms. The type of activity preceding symptom onset and the presence of accompanying symptoms (such as headache, vomiting, or syncope) are also useful, as is the presence or absence of stroke risk factors.

The physical examination determines lesion localization and identifies clues to pathogenesis. A thorough cardiovascular examination, including blood pressure and cardiac rhythm, is essential. Palpation of the facial artery occasionally discloses reversal of flow, which suggests ICA occlusion. Ophthalmoscopy can detect platelet and cholesterol emboli, as well as giving information about the chronicity and sever-

ity of systemic hypertension. Papilledema may accompany cerebral venous thrombosis.

Ancillary blood tests include a complete blood count, sedimentation rate, glucose, coagulation screen, and fasting lipid profile. Toxicology screen (e.g., for cocaine) may be useful in young patients with unexplained stroke, especially in the setting of intracerebral hemorrhage (ICH). In young patients and those with unexplained venous sinus thrombosis, a search for a hypercoagulable state is necessary (see Tables 124-3 and 124-5).

Brain imaging with CT is the most reliable test for differentiating ischemic stroke from hemorrhage. With advances in technology it is now possible to detect early infarct signs on CT within the first 6 hours after symptom onset. These include hyperdense MCA sign, attenuation of the lentiform nucleus, loss of the insular ribbon, and sulcal effacement (Fig. 124-4). Magnetic resonance imaging (MRI) may be used to verify infarction if the diagnosis remains in doubt, and can be useful in determination of stroke mechanism (Fig. 124-5).

The extracranial carotid arteries can be assessed with duplex ultrasonography or magnetic resonance angiography (MRA). Cerebral angiography is reserved for such indications as cerebral vasculitis and cerebral aneurysms.

Differential Diagnosis

TIA's need to be distinguished from other paroxysmal events affecting the nervous system. In rare cases, patients with migraine headache have weakness contralateral to the side of the headache (*hemiplegic migraine*). Some partial-onset seizures are followed by a transient hemiparesis (*Todd paralysis*). Metabolic conditions such as hyponatremia, hypoglycemia, and hyperglycemia can all cause focal neurologic disturbance, which may be mistaken for stroke; however, in such cases routine blood tests should make the diagnosis clear.

The acute onset of a stroke generally distinguishes it from other brain lesions, although hemorrhage into a primary or metastatic tumor may simulate stroke. Strokes and seizures may coexist, and 10% of strokes are associated with seizure at the time of onset. As a general rule, a single, unilateral stroke rarely produces an alteration of consciousness.

Primary Stroke Prevention

The identification and reduction of stroke risk factors (see Table 124-1), including therapy for hypertension, cessation of smoking, and treatment of diabetes and hyperlipidemia, as well as treatment with antiplatelet agents for individuals with vascular risk factors have led to a decline in the incidence of stroke.

ATRIAL FIBRILLATION

Atrial fibrillation occurs in approximately 10% of people over the age of 80. The most devastating complication of atrial fibrillation is thromboembolic stroke. Twenty percent

Figure 124-4 Early signs of infarction on computed tomography of the brain. **A**, Hyperdense middle cerebral artery sign (*red arrow*) and **B**, hypodattenuation of the left caudate and lentiform nuclei, loss of the insular ribbon, and sulcal effacement (*outlined in red*).

Figure 124-5 Magnetic resonance imaging scan of the brain of the same patient shown in Figure 124-4. **A**, Diffusion-weighted image (DWI) shows bright signal in the left middle cerebral artery territory. **B**, Apparent diffusion coefficient (ADC) shows dark signal in the same area, confirming acute infarction.

to 30% of ischemic strokes are cardioembolic in origin. The risk of stroke in patients with atrial fibrillation depends on a wide variety of risk factors, including age, sex, and the presence of comorbid conditions. All patients with atrial fibrillation require investigation with electrocardiography, thyroid function tests, and transthoracic echocardiography. In general, the presence of valvular heart disease increases the annual risk of stroke 17-fold. For these patients, anticoagulation with warfarin to an international normalized ratio (INR) of 2 to 3 is recommended. Patients with prosthetic heart valves require long-term anticoagulation. Patients with

paroxysmal (self-terminating) atrial fibrillation have the same risk of stroke as patients in permanent atrial fibrillation. Patients with an episode lasting less than 48 hours may be candidates for electrical cardioversion without the need for anticoagulation. The CHADS score is used to estimate the risk of stroke in patients with nonvalvular atrial fibrillation. The presence of congestive cardiac failure (C), hypertension (H), age >75 years (A), and diabetes (D) each scores one point, and a history of prior stroke or TIA (S) scores two points. A CHADS score of two or more is associated with an annual risk of stroke of over 4%. International treatment

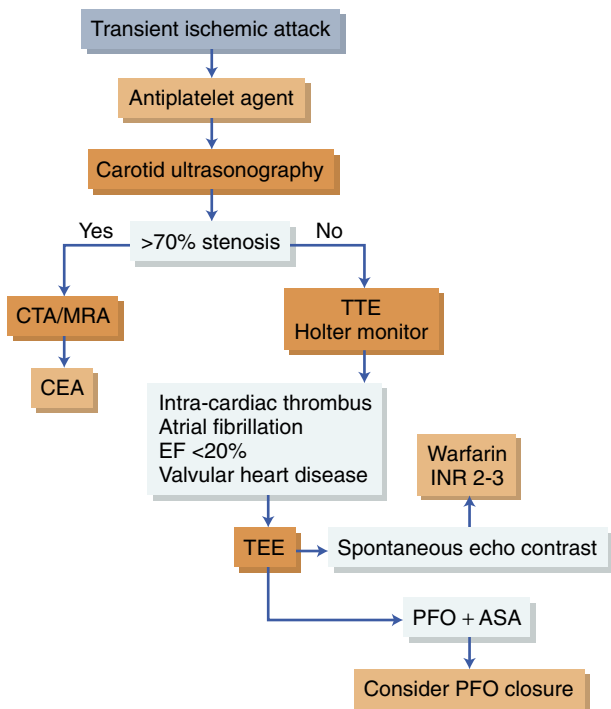

Figure 124-6 Algorithm for the treatment of transient ischemic attacks (TIAs). recommendations are aspirin 325 mg/day for those with a CHADS score of 0; for those with a CHADS score of 1, aspirin or warfarin may be used depending on patient preference. Patients with a CHADS score of 2 or more should be anticoagulated unless there is a specific contraindication. Patients with bacterial endocarditis should not receive warfarin because of the risk of cerebral hemorrhage from septic embolization. New direct thrombin inhibitors such as dabigatran are being evaluated as possible oral alternatives to warfarin for the future.

TRANSIENT ISCHEMIC ATTACK

The occurrence of a TIA or stroke is a significant risk factor for recurrent stroke, with an average 5% risk per year, although the annual risk of stroke after an episode of amaurosis fugax is only 1% to 2%.

Hospital admission is advisable for new-onset and recurrent TIAs unless a confident diagnosis of the cause of the event can be made. Imaging studies (carotid Doppler ultrasound or MRA of the neck) and cardiac investigations should be performed and a decision made promptly to treat the patient as appropriate (Fig. 124-6).

Antiplatelet therapy with aspirin, with or without dipyridamole, or clopidogrel has been shown to reduce the risk of recurrent events. Patients with a significant risk for cardiogenic thromboembolism should be treated with warfarin.

CAROTID STENOSIS

For patients with extracranial ICA stenoses of more than 70% (with or without symptoms of ischemia in that vascular

distribution), *carotid endarterectomy* reduces the risk of stroke. In high-risk patients, carotid artery stenting has emerged as an alternative to endarterectomy. For patients with moderate (60% to 70%) asymptomatic carotid stenosis, evidence that early endarterectomy is superior to deferred surgery is increasing, but only if the surgical center has a very low complication rate. In patients with an asymptomatic bruit or extracranial carotid stenosis of less than 60%, treatment with antiplatelet therapy may be effective.

Management of Acute Ischemic Stroke

GENERAL MEASURES

Specific medical and nursing measures should be initiated in cases of acute stroke, with particular emphasis on reducing the risk of complications from immobility, such as pneumonia, deep venous thrombosis, and urinary tract infection. The early introduction of physical, occupational, and speech therapy and a thorough evaluation of swallowing ability reduce morbidity. Judicious treatment of hypertension and hyperglycemia and correction of dehydration should be instituted. Prevention and prompt treatment of hyperthermia with antipyretics may reduce the extent of the deficit. Early awareness of poststroke depressive symptoms is especially important in preparing patients for rehabilitation.

USE OF ANTICOAGULANTS

No evidence has been found to support the use of anticoagulation (heparin) in the management of acute stroke. Although heparin might reduce the risk of early recurrent stroke, any benefit is offset by the increased risk of intracranial hemorrhage. Antiplatelet therapy remains the treatment of choice to prevent recurrent thromboembolism in the majority of patients with stroke. Anticoagulation may be appropriate in selected patients with cervical artery dissection, basilar thrombus, or suspected propagation of thrombus or stroke in evolution. Cranial CT is necessary before institution of heparin to confirm or rule out intracerebral or subarachnoid hemorrhage. Baseline prothrombin time, partial thromboplastin time, and platelet count, as well as tests for hypercoagulable states, should be obtained before initiation of therapy. A history of active peptic ulceration or uncontrolled hypertension (systolic blood pressure consistently >200 mm Hg) precludes the use of anticoagulants, unless the benefits clearly outweigh the risks.

THROMBOLYSIS

Patients who are within 3 hours of the onset of ischemic stroke should be considered for intravenous recombinant tissue-type plasminogen activator (rt-PA). A thorough clinical evaluation is essential to determine whether the patient is an appropriate candidate for the treatment (Fig. 124-7). The risks (6% risk of symptomatic intracranial hemorrhage) and benefits (50% chance of little or no disability at 3 months, compared with 38% chance without rt-PA) must be fully explained to the patient and family so that an informed decision can be made rapidly. The odds for a favorable outcome at 3 months improve the earlier the

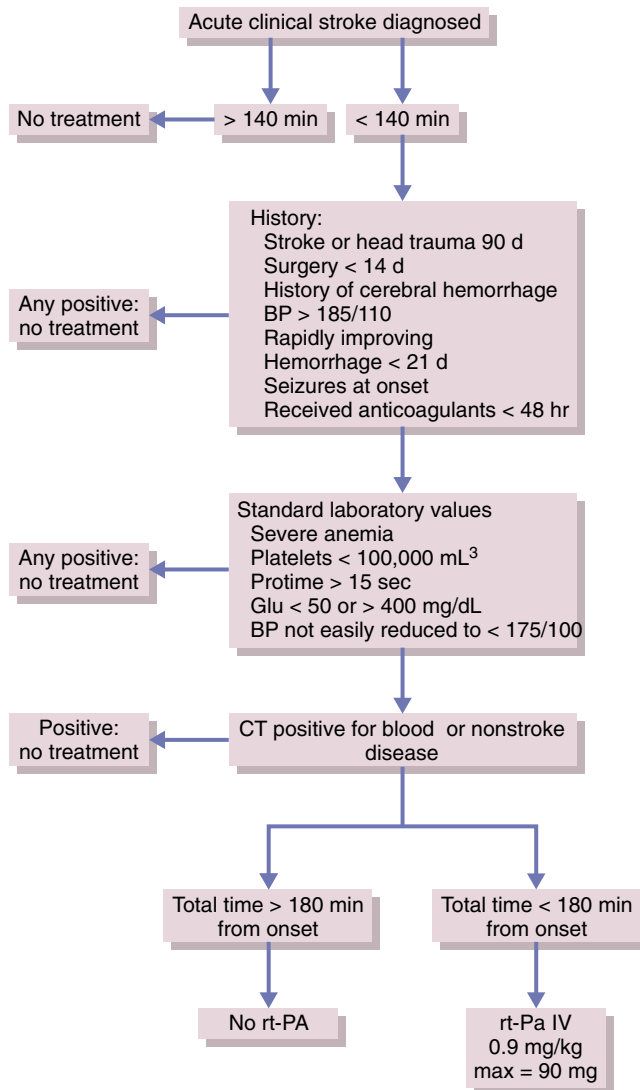

Figure 124-7 Evaluating acute stroke for safe recombinant tissue-type plasminogen activator (rt-PA) therapy. BP, blood pressure; CT, computed tomography; Glu, glucose; IV, intravenous. (Data from National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group: Tissue plasminogen activator for acute ischemic stroke. *N Engl J Med* 333:1581-1587, 1996.)

treatment is administered within the 3-hour window. There is increasing evidence that the benefit of thrombolysis exists up to 4.5 hours after symptom onset. Careful monitoring of blood pressure and avoidance of anticoagulants and antiplatelet agents are required for 24 hours after rt-PA administration.

There is increasing evidence that intra-arterial thrombolysis is effective for acute stroke treatment up to 6 hours after stroke onset. A potential future development of thrombolytic therapy may be combination therapy with neuroprotective agents (such as glutamate antagonists and magnesium), which may extend the therapeutic time window beyond 3 hours. Use of platelet glycoprotein IIb/IIIa complex antagonists is also under study.

MANAGEMENT OF HYPERTENSION

In the setting of an acute stroke, care must be taken regarding blood pressure control. Antihypertensive therapy is

instituted if the blood pressure persistently exceeds 220 mm Hg systolic or 120 mm Hg diastolic (except in patients undergoing thrombolysis, in whom more stringent guidelines apply). Less marked elevations of blood pressure should not be treated acutely. Ideally an agent with a short half-life that can be easily titrated, such as intravenous labetalol, is used in the acute setting when necessary.

MANAGEMENT OF CEREBRAL EDEMA

Only in large hemispheric infarction is ischemic cerebral edema sufficient to cause brain shift and transtentorial herniation. This is termed *malignant MCA syndrome* and usually results from infarction of the entire MCA territory in younger patients. If signs of herniation appear, airway intubation and mechanical hyperventilation produce transient cerebral vasoconstriction and may reduce ICP. Mannitol acts by reducing the volume of the surrounding unaffected brain, but its effects are also transient. Corticosteroids are of no benefit in cytotoxic edema.

Decompressive hemicraniectomy has been shown to reduce mortality and increases the number of patients with a favorable functional outcome in patients with malignant MCA syndrome.

HYPERTENSIVE ENCEPHALOPATHY

The term *hypertensive encephalopathy* refers to the diffuse cerebral effects of severe hypertension that are not caused by infarction or hemorrhage and that are potentially reversible with control of blood pressure. Patients experience headache, visual blurring (obscurations), confusion, and drowsiness. Seizures may develop. The blood pressure is typically very high (250/150 mm Hg), and papilledema and retinal hemorrhages are usually apparent on fundoscopic examination. CT and MRI show diffuse cerebral edema with a predilection for the occipital lobes. A related disorder, *reversible posterior leukoencephalopathy syndrome*, has been described in hypertensive patients taking cyclosporin, tacrolimus, and erythropoietin.

Hypertensive encephalopathy is a medical emergency. Treatment should be directed to the prompt but controlled lowering of blood pressure (e.g. with sodium nitroprusside), with care taken to avoid hypotension. The condition is clinically and pathophysiologically analogous to eclampsia.

REHABILITATION

The majority of stroke-related deaths result from medical complications (e.g., pneumonia, myocardial infarction, sepsis) rather than the neurologic deficit. Admission to a specialist stroke unit improves functional outcome and reduces medical complications that follow stroke.

TREATMENT OF CEREBRAL VENOUS SINUS THROMBOSIS

Acute anticoagulation with heparin is indicated for treatment of cerebral venous sinus thrombosis, even in the presence of hemorrhage. Interventional therapy with intrasinus rt-PA has been used in situations where the patient does not respond to anticoagulation. Warfarin is indicated

for prevention of recurrent cerebral venous sinus thrombosis; patients are usually treated for a minimum of 6 months.

SECONDARY PREVENTION OF ISCHEMIC STROKE

Recent multicenter clinical trials have shown that aggressive control of stroke risk factors reduces the rate of recurrence. The use of cholesterol-lowering agents and angiotensin-converting enzyme inhibitors reduces the rate of stroke recurrence, even in normotensive patients.

Antiplatelet Therapy

Prophylactic therapy with aspirin, with or without dipyridamole, or clopidogrel prevents recurrent events. Aspirin inhibits platelet aggregation by blocking platelet cyclooxygenase and thus prevents formation of thromboxane. Dipyridamole is a phosphodiesterase inhibitor that blocks uptake and metabolism of adenosine by vascular endothelial cells as well as potentiating the antiaggregating effects of prostacyclin. Clopidogrel inhibits ADP-induced platelet aggregation. All may be used for secondary stroke prevention. The addition of aspirin to clopidogrel does not confer added benefit for stroke prevention, as there is a significantly increased risk of hemorrhage.

Anticoagulation

Warfarin is indicated for secondary stroke prevention in the setting of atrial fibrillation, in patients with severely reduced ejection fraction, and in those with valvular heart disease. Warfarin has not yet been proven any more effective than aspirin for secondary prevention of stroke in patients with PFO or intracranial ICA stenosis, although trials are ongoing.

Hypertension

Hypertension is a well-recognized risk factor for ischemic and hemorrhagic stroke. A target blood pressure of less than 140/90 mm Hg is appropriate. Studies have indicated that the use of angiotensin-converting enzyme inhibitors in combination with a thiazide diuretic reduces the risk of stroke recurrence, even in normotensive patients.

Lipid-Lowering Agents

There is evidence that treatment with 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (“statins”) reduces stroke recurrence. This seems to be independent of their cholesterol-lowering effects and may result in part from upregulation of endothelial nitric oxide synthase and anti-inflammatory properties. All patients with TIA or stroke should be treated with a statin regardless of cholesterol level.

Intracerebral Hemorrhage

ICH may be diffuse (subarachnoid hemorrhage) or focal (intraparenchymal) and accounts for 20% of all strokes. Table 124-6 lists the causes of spontaneous ICH. The acute rise in ICP from arterial rupture frequently results in loss of consciousness at the outset; some patients die from herniation.

Table 124-6 Causes of Spontaneous Intracerebral Hemorrhage

Intraparenchymal Hemorrhage
Hypertension
Amyloid (congoophilic) angiopathy
Arteriovenous malformation
Bleeding diathesis
Drugs (amphetamines, cocaine, anticoagulants, thrombolytics)
Tumors
Cerebral venous sinus thrombosis
Hemorrhagic transformation of ischemic stroke
Cerebral vasculitis
Subarachnoid Hemorrhage
Congenital saccular aneurysm (85%)
Mycotic aneurysm
Arteriovenous malformation
Unknown (10%)

HYPERTENSIVE INTRACEREBRAL HEMORRHAGE

Hypertensive ICH often occurs at the same sites that are affected in lacunar infarction. Pathologically, microaneurysms known as *Charcot-Bouchard aneurysms* have been identified in some patients. The most common sites for hypertensive hemorrhage are the putamen (40%), thalamus (12%), lobar white matter (15% to 20%), caudate (8%), pons (8%), and cerebellum (8%). Although CT readily identifies the hemorrhage, several clinical findings may help localize the site (Table 124-7). In general, severity of headache correlates with the size of the lesion. Diminished level of alertness is caused by mass effect, increased ICP, or direct involvement of the brainstem reticular-activating system. Seizures are slightly more frequent during the acute phase in ICH than in ischemic stroke. Both basal ganglia and thalamic hemorrhages may rupture into the adjacent ventricle and result in secondary hydrocephalus; cerebellar hemorrhage may cause obstructive hydrocephalus as a result of compression of the fourth ventricle.

With intracerebral hematoma, the patient's level of consciousness often deteriorates during the first 24 to 48 hours after the initial symptoms, usually because of the development of edema around the lesion or expansion of the hematoma. Edema that is sufficient to cause significant brain shift results in herniation of brain tissue. In addition to causing direct pressure on vital brainstem structures, herniation may cause compression of adjacent blood vessels (particularly the PCAs and ACAs), resulting in infarction.

LOBAR HEMORRHAGE

Lobar hemorrhages occur in a peripheral distribution of the cerebral cortex. They are usually smaller than hypertensive ICHs and have a more benign prognosis. In young persons, lobar hemorrhages may be secondary to arteriovenous malformations or ingestion of sympathomimetic drugs. In elderly persons, they may occur because of congophilic amyloid angiopathy (CAA). The diagnosis of CAA is suggested by the finding of multiple *microbleeds* on gradient

Table 124-7 Clinical Manifestations Related to Site of Intracerebral Hemorrhage

	Site		Manifestation		
	Headache	Pupils	Eye Movements	Sensorimotor Signs	Other
Basal ganglia	Severe	Normal	Normal	Hemiparesis	Confusion, aphasia
Thalamus	Moderate	Small, poorly reactive to light	Hyperconvergence Absent vertical gaze	Hemisensory > motor loss	Hypersomnolence
Pons	Severe	Small, reactive	Horizontal gaze paresis	Quadriplegia	Coma
Cerebellum	Severe, occipital	Normal	Normal	Ataxia	Early vomiting

echo MRI. Patients with CAA often have associated dementia and seizures.

DIAGNOSIS, MANAGEMENT, AND PROGNOSIS

CT remains the diagnostic test of choice in the diagnosis of acute ICH, showing a hyperintense area with mass effect and (later) hypointense surrounding edema. MRI is less sensitive than CT for detecting hemorrhage in the early stages. The management of ICH depends on the size and location of the lesion. In the acute phase, the mass effect of a cerebral hematoma is far greater than in a large cerebral infarction, with a greater risk of herniation and death. In the chronic phase, however, the prognosis for recovery in patients who survive is much better for those with hemorrhage than for those with ischemic stroke. Therefore therapy for acute hemorrhage is directed at reducing mass effect either by medical decompression with controlled hyperventilation or mannitol or, in rare cases, by surgical decompression. This latter option should be considered urgently in cases of cerebellar hemorrhage in which patients are especially at risk of sudden deterioration either because of acute obstructive hydrocephalus (from compression of the fourth ventricle) or as a result of direct pressure on the caudal brainstem.

Intracranial Aneurysms

Intracranial aneurysms occur in three forms: fusiform, mycotic, and saccular (congenital *berry*) aneurysms.

Fusiform aneurysms represent ectatic dilations of large arteries, usually the basilar or intracranial carotid arteries. They rarely rupture but may compress adjacent brain tissue or cranial nerves and cause local neurologic dysfunction. Fusiform aneurysms are rarely accessible to surgical repair.

Mycotic aneurysms occur in the context of bacterial endocarditis when septic emboli lodge in a peripheral vessel (see Chapter 100). They are often multiple and located distally in the arterial tree, and thus they are accessible to surgical repair should they fail to respond to antibiotic therapy.

Saccular aneurysms form at arterial bifurcations (Fig. 124-8); 80% are located in the anterior circulation. They are thought to arise from a combination of a congenital defect in the arterial media and elastic lamina and gradual

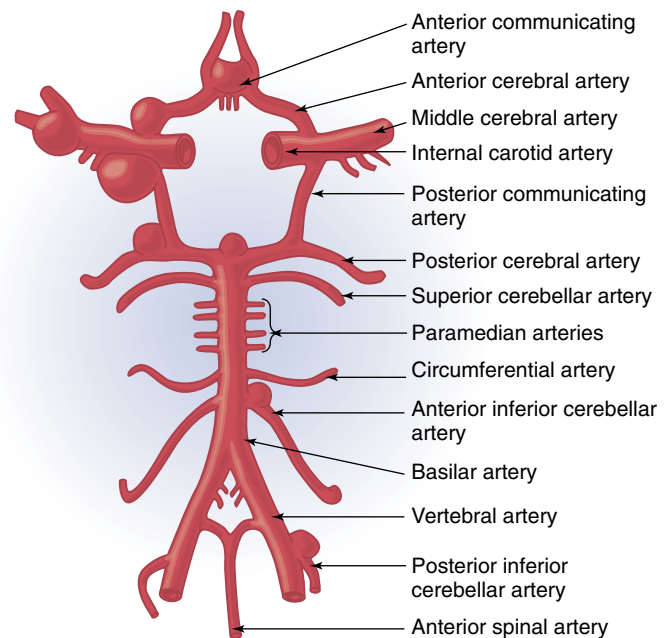

Figure 124-8 The more common sites of berry aneurysms. The diagrammatic size of the aneurysm at the various sites is directly proportional to its frequency at that locus.

deterioration from hemodynamic stress. Their incidence is higher in patients with polycystic kidney disease and Marfan syndrome.

Approximately 6% of the population harbors an unruptured saccular aneurysm; 25% of patients have multiple aneurysms. Fortunately, the annual incidence of rupture is only approximately 10 per 100,000. The risk of rupture is 1% per year. Of individuals with aneurysms that do rupture, 33% die before reaching a hospital, and another 20% die in the hospital. Overall, only 30% of patients recover without significant disability.

Incidental aneurysms of the anterior circulation smaller than 7 mm have a very low risk of rupture (<0.05% per year); the risk of rupture rises with increasing size of aneurysm and location within the posterior circulation. Within families, aneurysms tend to be at the same site and to rupture during the same decade. The risk of an unruptured aneurysm in a first-degree relative of a patient with subarachnoid hemorrhage is 4% to 5% with one affected relative and 8% to 10% with two or more affected relatives. The natural history of

aneurysms is unknown. Whether they pose an early high risk after formation or whether a constant risk of rupture exists over time is unknown.

Treatment of Unruptured Intracranial Aneurysms

Treatment of asymptomatic aneurysms remains controversial. Aneurysms may be treated by open surgical clipping or by endovascular coiling. The latter procedure has emerged as the treatment of choice in the majority of patients and has a low morbidity and mortality. The risk-benefit ratio of treatment depends on life expectancy. In older persons the risk of rupture over their remaining lifetime may be very low and not warrant intervention.

CLINICAL MANIFESTATIONS OF SUBARACHNOID HEMORRHAGE

Aneurysms may rupture at any time but especially during periods of strenuous activity, such as exercise, coitus, or strenuous physical work. The most common manifestation is sudden severe headache (“the worst headache of my life”), often accompanied by neck pain and rigidity. Loss of consciousness and vomiting are common sequelae. Occasionally, with so-called *sentinel hemorrhages*, the onset of symptoms is less cataclysmic, and the headache gradually resolves over 24 to 48 hours. Aneurysms may also manifest by compression of adjacent cranial nerves, such as compression of cranial nerve III by an aneurysm of the posterior communicating artery. *Giant aneurysms* (>2.5 cm) may compress cranial nerves III, IV, and VI in the cavernous sinus. Aneurysms occasionally produce a TIA as a result of embolization from a thrombus within an aneurysm.

DIAGNOSIS

CT of the brain shows subarachnoid hemorrhage in nearly all patients, and its location may suggest a site of rupture. A normal CT scan may not totally exclude subarachnoid hemorrhage and mandates a lumbar puncture in patients with suggestive symptoms. Care must be taken to centrifuge cerebrospinal fluid to detect true xanthochromia, the yellow coloration that develops by 6 hours after subarachnoid hemorrhage. Contrast CT or MRI identifies aneurysms larger than 5 mm as well as arteriovenous malformations. Cerebral angiography remains the *gold standard* for diagnosing intracranial aneurysms, and it is usually performed when surgery is being contemplated and deferred in severe cases in which significant risk of vasospasm exists. A small group of patients with predominantly peri-mesencephalic hemorrhage on CT have normal cerebral angiograms and a more benign outcome. The electrocardiogram may show deep, symmetrical T-wave inversion. Once the diagnosis of subarachnoid hemorrhage has been made (or if clinical suspicion persists, even with inconclusive testing), the patient should be managed under the guidance of a neurosurgical team.

Table 124-8 Complications of Subarachnoid Hemorrhage

Hypertension (systemic and intracranial)
Vasospasm
Hemorrhage (rebleeding)
Hydrocephalus
Hyponatremia (syndrome of inappropriate antidiuretic hormone; cerebral salt wasting)

MANAGEMENT AND PROGNOSIS

An essential part of management of patients with subarachnoid hemorrhage is to prevent its complications (Table 124-8). To reduce the risk of rebleeding, patients are placed on bed rest with analgesics for pain relief, mild sedation, and the use of laxatives to reduce straining. Management of hypertension requires balancing the need to maintain a steady CPP in the context of raised ICP and possible vasospasm and, in contrast, the risk of rebleeding. Most rebleeding occurs within the first 3 days after rupture. The peak timing for vasospasm is between 5 and 9 days after the hemorrhage, and it may be accompanied by an alteration in the neurologic status. Oral nimodipine, a calcium channel blocker, should be given for 21 days after subarachnoid hemorrhage to prevent vasospasm.

Vascular Malformations

Vascular malformations of the brain and spinal cord are grouped according to vessel size and composition. *Venous angiomas* are the most common and tend to lie close to the brain surface. Malformations composed of capillaries are called *capillary telangiectases* and are typically located within the brainstem. *Cavernous angiomas* are composed of dilated sinusoidal channels, are readily detectable on CT, and rarely bleed.

Arteriovenous malformations are composed of tangles of arteries connected directly to veins without intervening capillaries. They may produce headache, seizures, or hemorrhage, accounting for 1% of all strokes. The initial hemorrhage typically occurs before the fourth decade, with a 7% risk of rebleeding within the first year afterward. Hemorrhage may occur into the brain parenchyma, subarachnoid space, or intraventricular space.

Treatment of arteriovenous malformations is guided by individual factors, such as the age of the patient, location and composition of the lesion, and manifestations. As the natural history of unruptured arteriovenous malformations is unknown, treatment of asymptomatic patients is controversial. In general, arteriovenous malformations in older patients (>55 years) are treated conservatively, whereas younger patients are treated by surgical excision, embolization, or, less commonly, if small, by irradiation.

Prospectus for the Future

The risk of both ischemic and hemorrhagic strokes can be reduced by vascular risk factor modification. Additional progress can be expected in this area, particularly in defining genetic factors that may increase stroke susceptibility. Important clinical trials are ongoing in the areas of treatment of PFO, warfarin in heart failure, and alternatives to warfarin for anticoagulation. Improved public recognition of stroke symptoms and better access to acute stroke units should result in

greater use of thrombolysis and reduced morbidity from stroke. Trials of neuroprotective agents have been disappointing to date, although animal models were promising; research in this area is ongoing. Hemorrhagic stroke has been somewhat neglected in the past. The natural history of unruptured aneurysms and arteriovenous malformations is unknown, which makes treatment decisions difficult. These areas require further study.

Traumatic Brain Injury and Spinal Cord Injury

Geoffrey S. F. Ling

Traumatic brain injury (TBI) and traumatic spinal cord injury (TSCI) are leading causes of traumatic death and disability. Over 8 million patients undergo TBI each year, with approximately 52,000 patients in the United States dying as a direct consequence. An additional 11,000 patients are severely disabled by TSCI. The majority of TBIs and TSCIs are a result of falls, motor vehicle accidents, sports-related occurrences, and assaults. Among the almost 5.5 million TBI and TSCI survivors, most require prolonged rehabilitation.

Types of Traumatic Brain Injury

Certain lesions necessitate neurosurgical intervention, whereas others do not. TBI conditions for which emergency neurosurgery is needed are penetrating wounds, intracerebral hemorrhage with mass effect including subdural and epidural blood, bony injury such as displaced fracture, and vertebral subluxation. However, focal, hypoxic-anoxic, diffuse axonal, and diffuse microvascular injuries typically do not necessitate surgery.

Traumatic Brain Injury Management

The initial goals in TBI care are the ABCs of airway, breathing, and circulation. Next is D for disability (neurologic). Every patient should undergo a detailed neurologic examination to ascertain the level of neurologic disability. An initial Glasgow Coma Score (GCS) should be assigned to each patient. The GCS (Table 125-1) categorizes TBI patients and provides a quantifiable measure of impairment.

Patients with mild or moderate TBI typically recover quickly and fully. In the early stage of management, it is important to determine the duration of amnesia or loss

of consciousness a patient may have experienced. The American Academy of Neurology Guideline uses a grading scale for concussion that is based primarily on the length of these intervals (Table 125-2). Longer periods of abnormal sensorium are associated with higher grades. Higher grades necessitate longer periods of convalescence. Other clinical guides that are used include the Cantu Grading System and the Colorado Medical Society Guidelines.

In general, patients with mild or moderate TBI will not require major medical intervention, and almost all will do well after adequate convalescence. It is essential that patients have adequate recovery even from mild TBI. A subsequent head injury before full recovery may be catastrophic as it could result in “second impact syndrome” (SIS), which leads to worse clinical outcome including death.

Severe TBI is defined as an injury that results in a GCS score of eight or less. This is a serious condition so to optimize outcome, medical management should adhere to currently accepted clinical guidelines such as the Brain Trauma Foundation “Clinical Guidelines for Severe TBI.” An important early intervention is airway protection, usually by endotracheal intubation. If elevated intracranial pressure (ICP) is suspected or if GCS < 8, the ICP should be monitored. Options for ICP monitoring are epidural fiberoptic catheter, subdural bolt, intraparenchymal fiberoptic catheter, or intraventricular catheter (IVC). All of these devices require drilling a small burr hole through the skull. The fiberoptic catheters are closed system devices and thus are associated with very low infection rates. However, measurements can drift after 5 days of use. As they cannot be zeroed, fiberoptic monitors are usually changed at this time. The subdural bolt can be zeroed but is associated with a slightly higher incidence of infection. The IVC or external drainage device is the most invasive as it requires inserting a catheter through brain parenchyma into a lateral cerebral ventricle. It can be zeroed and has the highest incidence of infection. The greatest benefit of the IVC is that it provides a therapeutic option in that CSF can be drained, which helps reduce intracranial volume and thus ICP.

If there is elevated ICP, the patient's head should be elevated to 30 degrees and kept midline, with a rigid neck collar used (until the cervical spine can be evaluated for stability). Mannitol should be given intravenously at a dose of 0.5 to 1.0 g/kg. Hyperventilation may also be used, with a goal of P_{CO_2} of 34 to 36 mm Hg. ICP should be kept less than 20 mm Hg, with the cerebral perfusion pressure (CPP) greater than 60 mm Hg. CPP is the mathematical difference between mean arterial pressure (MAP) and ICP. Thus, CPP represents the arterial pressure that globally perfuses the brain. A head CT without contrast should be done as soon as possible both to identify lesions that will require surgery and to determine the extent of injury.

If ICP remains poorly controlled, one can consider administering an intravenous bolus of 23% hypertonic saline (30 ml) followed by continuous infusion of 2% or 3% hypertonic saline (75 to 125 ml/hr) through a central venous catheter. If these interventions are unsuccessful, pharmacologic coma or surgical decompression should be considered. Pharmacologic coma can be induced with pentobarbital. This is given as a loading dose of 5 mg/kg, intravenously.

followed by an infusion of 1 to 3 mg/kg/hr. Alternatively, propofol can be administered as a loading dose of 2 mg/kg intravenously, followed by an infusion of up to 200 μ g/kg/min. Continuous electroencephalographic (EEG) monitoring is helpful, as the limit of drug-induced coma is achieving ICP control or cerebral electrical burst-suppression. Persistently elevated ICP after all these efforts is ominous. Consideration should be made regarding frontal or temporal lobe decompression and hemicraniectomy.

To meet CPP goals, patients must first be adequately hydrated. The goal of TBI fluid management is to increase the osmolar gradient between systemic vasculature and brain, not dehydration. For this purpose, hyperosmolar intravenous solutions, such as normal saline, are used. Other options are hypertonic saline (e.g., 3% sodium solutions). If meeting CPP goals is difficult with intravenous fluids alone, vasoactive pharmacologic agents such as norepinephrine and phenylephrine can be administered. These two agents are preferred because they are considered to have the least effect on cerebral vasomotor tone. Barbiturates and propofol are myocardial depressants, and therefore aggressive cardiovascular management entailing close cardiac monitoring and maintenance of euvolemia with appropriate fluid hydration and vasopressors as needed to maintain CPP will probably be necessary in the event of pharmacologic coma.

Agitation can be treated with lorazepam or haloperidol. If these are inadequate, then infusions of midazolam or propofol may be used. Pain should be treated adequately. Acetaminophen and nonsteroidal anti-inflammatory agents may be adequate, but for moderate to severe pain, a narcotic analgesic such as fentanyl or morphine should be used. A benefit of opioids is that they can be reversed by naloxone, which allows reassessment of neurologic status.

Hypoxia, seizures, and fever must be avoided. Maintaining P_{O_2} at approximately 100 mm Hg is sufficient. Phenytoin is administered for the first 7 days after injury, as it reduces early onset seizures. After 7 days, this medication should be stopped. It can be restarted if late-onset seizures occur. Fever should be reduced with antipyretics such as acetaminophen, with cooling blankets used as needed. Other important

Table 125-1 Glasgow Coma Score

Best Eye Response	Best Verbal Response	Best Motor Response
1 = No eye opening	1 = No verbal response	1 = No motor response
2 = Eye opening to pain	2 = Incomprehensible sounds	2 = Extension to pain
3 = Eye opening to verbal command	3 = Inappropriate words	3 = Flexion to pain
4 = Eyes open spontaneously	4 = Confused	4 = Withdrawal from pain
	5 = Oriented	5 = Localizing pain
		6 = Obeys commands

Score = Eye Response + Verbal Response + Motor Response.

Table 125-2 American Academy of Neurology Concussion Management

Grade 1 (Mild)	Grade 2 (Moderate)	Grade 3 (Severe)
Remove from duty, work, or play	Remove from duty for the rest of the day	Take to emergency department
Examine immediately and at 5-min intervals	Examine frequently for signs of CNS deterioration	Neurologic evaluation, including appropriate neuroimaging
May return to duty or work if clear within 15 min	Physician's neurologic examination ASAP (within 24 hr) Return to duty after 1 full asymptomatic week (after being cleared by physician)	Consider hospital admission
Grade of Concussion	Return to Play or Work	
Grade 1 (first injury)	15 minutes	
Grade 1 (second injury)	1 week	
Grade 2 (first injury)	1 week	
Grade 2 (second injury)	2 weeks	
Grade 3 (first injury) (brief LOC)	1 week	
Grade 3 (first injury) (long LOC)	2 weeks	
Grade 3 (second injury)	1 month	
Grade 3 (third injury)	Consult a neurologist	

ASAP, as soon as possible; CNS, central nervous system; LOC, loss of consciousness.

management considerations include prevention of gastric stress ulcers, deep vein thrombosis (DVT), and decubitus ulcer. Nutrition should be maintained, ideally with enteral feeds. However, if hyperosmolar therapy is used, then one should use concentrated enteral feeds that minimize free water content.

After the first few hours have elapsed, efforts should be made to reduce hyperventilation. This therapy should be reserved only for initial emergency management. If the therapy is continued over 12 hours, metabolic compensation negates the ameliorative effects of respiratory alkalosis caused by a hypocapnic state.

Regular neurologic examinations and continuous ICP and CPP measurements should be made. Generally, the peak period of cerebral edema is from 48 to 96 hours after TBI. Thereafter, this spontaneously resolves and clinical improvement should follow.

A complication of TBI is “postconcussive syndrome.” The most common symptoms are headache, difficulty concentrating, appetite changes, sleep abnormalities, and irritability. Depending on the patient and the severity of TBI, postconcussive syndrome has a variable presentation and duration. In general, this condition lasts only a few weeks after injury. However, uncommonly, it can persist beyond a year or more. Therapies are focused on managing symptoms. For headache, nonsteroidal anti-inflammatory agents, migraine drugs, and biofeedback can be effective. For cognitive dysfunction, neuropsychologic testing may be helpful in determining appropriate intervention.

Traumatic Spinal Cord Injury Management

The emergency management of traumatic injury to the spinal cord has improved with the measures recommended by the “Guidelines for the Management of Cervical Spine and Spinal Cord Injuries” from the American Association of Neurological Surgeons. As with TBI, therapy begins with the ABCs of airway, breathing, and circulation. For patients with high cervical lesions, spontaneous ventilation will be lost. Lesions lower than C5 may also be associated with insufficient ventilatory capability. If there is any concern that the airway or if ventilatory efforts are compromised, then emergency intubation is required. In a patient in whom the cervical spine has not been adequately imaged, the preferred method is nasotracheal intubation using fiberoptic guidance. Other approaches are nasotracheal (blind) or orotracheal intubation, but traction must be applied to maintain spinal column alignment.

Maintaining adequate intravascular volume is of particular importance in the spinal cord–injured patient. Hypotension may result from either neurogenic shock or hypovolemia. For neurogenic shock, vasopressive pharmacologic agents such as phenylephrine may be needed. If tachycardia is present, then hypovolemia is the more likely cause, and fluid administration is the appropriate initial management. As with TBI, normal saline is the preferred fluid.

After these issues have been addressed, a neurologic assessment should be made. An accompanying TBI needs to be considered. Up to 50% of TSCI patients have an associated

TBI. History with complete neurologic examination is the best method for diagnosis. Neuroimaging is often indicated for diagnostic evaluation, but not all patients need radiographic study. Normal neurologic history and examination findings in patients with a clear sensorium obviates the need for imaging studies. However, complaints of pain over the spine or of numbness, tingling, or weakness should raise the suspicion of spinal cord injury. In particular, a complaint of burning hands suggests cervical spinal cord injury. As accurately as possible, the time of injury should be recorded. A detailed neurologic examination is needed to identify the level of the injury and the completeness of any deficits and to document the degree of neurologic dysfunction at the earliest time possible. The level of the injury is the lowest spinal cord segment with intact motor and sensory function. The prognosis for neurologic improvement is better if the lesion is incomplete than if it is complete. During this acute period, serial examinations must be made frequently.

If spinal cord injury is suspected, the patient should be immediately and appropriately immobilized, that is, with a rigid collar or back board or both. Radiologic evaluation should begin with plain x-ray films of the bony spine. Abnormalities on x-ray films should lead to further neuroimaging. Bony vertebrae should be examined with computed tomography (CT), and the spinal cord with magnetic resonance imaging (MRI). Intervertebral and paravertebral soft tissue are best studied with MRI. A chest radiograph should also be obtained in order to visualize the lower cervical and thoracic vertebrae. Presence of a pleural effusion in the setting of a possible thoracic spine injury suggests a hemothorax.

If the C-spine radiograph is normal but the patient complains of neck pain, then ligamentous injury may be present. Ligamentous injury is evaluated by flexion-extension C-spine x-ray studies. However, in the acute period, pain may prevent an adequate study. Such patients should be kept in a rigid cervical collar for at least 24 to 48 hours until the pain and neck muscle spasm resolve. At that time, the study may be performed. If abnormal, the patient will need surgical evaluation.

If spinal cord injury is identified, methylprednisolone should be given at an initial dose of 30 mg/kg intravenous bolus followed by a continuous infusion of 5.4 mg/kg/hr. The infusion should be for 23 hours if it is started within 3 hours of injury. If beyond 3 hours but still within 8 hours, then methylprednisolone should be given for 48 hours. The efficacy of methylprednisolone in TSCI from penetrating causes has not been demonstrated, so this therapy is reserved only for closed compartment injury. This is the only indication for steroid use in TSCI. At this time, the decision for surgical intervention should be made, based on the stability of the vertebral column.

SPINAL CORD SYNDROMES

There are three main spinal cord syndromes: Brown-Séquard (hemisection), central cord, and anterior cord. Anterior cord syndrome is associated with deficits referable to bilateral anterior and lateral spinal cord columns. There is loss of touch, pain, and temperature sensations and motor function below the level of the lesion. The posterior column functions of proprioception and vibratory sensation remain intact. In Brown-Séquard syndrome, the deficits are caused by injury

to a lateral half of the cord. There is functional loss of ipsilateral motor function, touch, proprioception, and vibration sensations, and contralateral pain and temperature sensations. Central cord or “man in a barrel” syndrome manifests as motor paralysis of both upper extremities while the lower extremities are spared. Weakness is greater proximally than distally. Pain and temperature sensations are generally reduced, but proprioception and vibration are spared.

SPINAL SHOCK

After acute injury, spinal shock may occur, causing a temporary loss of spinal reflexes below the level of injury. Neurologic examination will reveal loss of deep tendon reflexes, bulbocavernosus reflex, and the anal wink. In high cervical injuries, the lower reflexes (bulbocavernosus and anal wink) may be preserved. There may also be the “Schiff-Sherrington” phenomenon, in which reflexes are affected above the level of injury. In addition, there will likely be loss of autonomic reflexes, leading to neurogenic shock, bowel ileus, and urinary retention.

OTHER TRAUMATIC SPINAL CORD INJURY MANAGEMENT ISSUES

In the intensive care unit, the patient will need continued treatment. Once methylprednisolone therapy has been completed, there is no need for further steroid use. TSCI patients require close cardiovascular and ventilatory care. Other issues are genitourinary, bowel, infectious disease, nutrition, skin and prophylaxis against skin ulcers, and DVT formation.

Patients with spinal cord injury are at risk for neurogenic shock and dysautonomia, which lead to peripheral vasodilation and hypotension. If the lesion is at T3 or above, then sympathetic tone to the heart is compromised. In this setting, hypotension is accompanied by bradycardia: the classic neurogenic shock triad of bradycardia, hypotension, and peripheral vasodilation.

Therapy for dysautonomia begins by ensuring adequate circulating volume. The goal is to administer fluids to restore a euvoletic state. Blood should be transfused if the patient is anemic—that is, if the hematocrit is less than 30. If blood is not required, then either colloid (e.g., albumin solutions) or crystalloid (e.g., normal saline) may be used to maintain a central venous pressure (CVP) of 4 to 6 mm Hg. Hypervolemia should be avoided, as this will exacerbate peripheral edema. Once an adequate circulating volume has been achieved, a vasopressive agent such as phenylephrine, norepinephrine, or dopamine can be used. The goal MAP is 85 mm Hg or greater. Symptomatic bradycardia can be treated with atropine.

Spinal cord patients are at risk for ventilatory compromise. Patients whose injuries are at C5 or higher typically require mechanical ventilation with an appropriate tidal volume (6 to 10 ml/kg) and F_{iO_2} and mandatory machine-driven rate. The F_{iO_2} should be set at a value that gives a P_{O_2} of 80 to 100 mm Hg. The rate should be set to give a P_{CO_2} of 40 mm Hg. Positive end-expiratory pressure (PEEP) should also be used to minimize atelectasis. If the patient does not show signs of ventilatory recovery within 2 weeks of intubation, a tracheostomy should be considered.

Lesions below C5 may also be associated with inadequate spontaneous ventilation. Midcervical lesions may be associated with intact but compromised diaphragm function. If suspected, a “sniff” test under fluoroscopy can be performed to determine if both hemidiaphragms are functioning properly. If not, intubation and tracheostomy with volume-controlled ventilation may be needed. If function is intact, then pressure support (PS) ventilation may be sufficient. The amount of PS to administer is dependent on patient requirements and should be sufficient to lead to an appropriate tidal volume. F_{iO_2} and PEEP should be set as described previously.

Patients with cervical lesions at C6 and below, including the thoracic cord, are generally not mechanical ventilator-dependent. However, their ventilatory effort may be inadequate, as the thoracic cord innervates intercostal muscles, which are accessory muscles of respiration. Such patients have decreased cough and inability to increase ventilation when needed. This leads to atelectasis and compromised ability to clear secretions, which may lead to pneumonia. These patients may benefit from chest physical therapy.

Thromboembolic disease often complicates TSCI and is a leading cause of morbidity and mortality in these patients, as up to 80% will develop DVT without proper prophylaxis. Therefore all patients with TSCI should receive both anticoagulation and leg mechanical compression devices. As soon as possible, sequential compression devices (SCDs) or compression stockings should be placed on patients. Then, as soon as hemostasis is ensured, low-molecular-weight heparin (LMWH) should be initiated. Unfractionated heparin may also be used in conjunction with SCD, but LMWH is preferred. An inferior vena cava filter may be placed in those patients in whom anticoagulation therapy is contraindicated but should not be the primary means of preventing DVT.

Mid to low thoracic spinal cord injury can lead to ileus. A nasogastric tube should be placed to decompress the stomach. Parenteral nutrition should be started as soon as possible. Enteral feeding should be delayed until gastrointestinal motility returns. This normally takes about 2 to 3 weeks. The pharmacologic agents metoclopramide, erythromycin, and cisapride may promote gastrointestinal motility.

Gastric ulcer prophylaxis needs to be administered: H_2 -receptor antagonists, proton pump inhibitors, antacids, or sucralfate. Pancreatitis and trauma-related perforated bowel are potential problems. Loss of abdominal muscle tone and visceral sensation may mask clinical signs such as pain, guarding, or rigidity. Bladder tone may be lost because of spinal shock. A Foley catheter should be placed and maintained for a minimum of 5 to 7 days to help drain the bladder and to evaluate circulatory volume and renal function. After spinal shock has resolved, autonomic dysreflexia may occur from bladder distention. Clinical signs such as sweating, skin flushing, and hypertension may be present. Clinical examination using palpation and percussion will reveal a distended bladder, which can be treated with bladder training or intermittent catheterization. Phenoxybenzamine may be helpful in this condition.

Until enteral feeding can begin, parenteral nutrition should be used. A caloric level of 80% of the Harris-Benedict prediction, which approximates a patient’s total daily energy

expenditures, should be used for quadriplegic patients. This is an approximation of a patient's total daily energy expenditure and is based on the patient's basal metabolic rate and activity level. The full Harris-Benedict predicted amount should be used for patients with thoracic spine injuries and below.

There is a propensity for decubitus ulcers from pressure to develop in patients with TSCI. Mechanical kinetic beds, regular log rolling (every 2 hours), and padded orthotics are all useful in minimizing this complication.

Orthotics, physical therapy, and occupational therapy (for cervical cord injury) are also important. Therapy should begin as soon as the spine is stabilized. This will serve to minimize contractures and to begin the rehabilitation process. It should be remembered that once therapy begins, energy expenditures will increase, and consequently additional nutrition will be needed. Also, as intermittent compression devices will need to be removed during therapy, the heparin dose may need to be increased.

Prognosis

TRAUMATIC BRAIN INJURY

The most useful prognostic indicator after TBI is the neurologic examination at presentation. Clearly, the better the neurologic examination findings, the higher the likelihood of improved recovery. The initial GCS is a very reliable

Table 125-3 American Spinal Injury Association Impairment Scale

Grade	Injury Type	Definition
A	Complete	No motor or sensory function below the lesion
B	Incomplete	Sensory but no motor function
C	Incomplete	Some motor strength (<3)
D	Incomplete	Motor strength >3
E	None	Sensory and motor function normal

prognostic indicator. The lower the initial GCS, the less likely a patient will have meaningful neurologic or functional recovery.

TRAUMATIC SPINAL CORD INJURY

For TSCI, the completeness of the injury is the most useful prognosticator. The American Spinal Injury Association Impairment Scale grades spinal cord injury on the basis of completeness (Table 125-3). A grade A or complete motor and sensory deficit below the lesion is associated with the most ominous prognosis. If this status persists for longer than 24 hours, there is little reasonable likelihood of meaningful recovery. On the other hand, partial injuries, even severe, have substantial probability of recovery.

Prospectus for the Future

Traumatic brain injury (TBI) and traumatic spinal cord injury (TSCI) prevention remains the most effective way of reducing the incidence of these disorders. Practice guidelines have contributed to improved outcome after TBI and TSCI. However, morbidity remains high. Medical management is largely confined to supportive efforts primarily directed toward minimizing secondary injury, optimizing perfusion and oxygenation, and preventing nonneurologic morbidity. Surgical intervention

helps restore structural stability, minimize further injury, and reduce lesion size. However, neither medicine nor surgical treatment reverses neuronal death nor fully prevents secondary injury processes. Research is needed to improve our understanding of the pathogenesis of these injuries and find ways to mitigate it. As new pharmacologic, medical, and surgical approaches are introduced, there will be increasing opportunities to improve the still-poor prognosis of many patients.

Epilepsy

Michel J. Berg

Definition

Epileptic (or electrical) seizures are caused by abnormal highly synchronous discharges of neurons. They are a common sign of brain dysfunction. A wide variety of symptoms can occur depending on the location in the brain affected, including involuntary movements, sensations, and impaired consciousness.

Seizures often occur during the course of medical or neurologic illnesses in which brain function is temporarily deranged (symptomatic seizures) (Table 126-1). The most common secondary causes are childhood febrile seizures, metabolic derangements (such as hypoglycemia or hyponatremia), intoxications (alcohol, cocaine), acute head traumas, and hypoxic-ischemic conditions (syncope, embolic stroke). Symptomatic seizures are usually self-limited, and recurrent seizures do not occur after the underlying disorder has been corrected. Therefore symptomatic seizures do not indicate epilepsy.

Epilepsy is a chronic disorder defined as a condition with recurrent seizures not produced directly by a secondary cause. There are many different epileptic syndromes (the epilepsies). Classification of the epilepsy syndrome depends on a number of factors including the seizure type, cause, genetic factors, neuroimaging, and response to therapy. The phrase *seizure disorder* is synonymous with the word *epilepsy*.

A single seizure may occur as an unprovoked event with no discoverable reason. By definition, two separate seizures are required to make the diagnosis of epilepsy; that is, a single seizure does not constitute epilepsy.

Individuals with epilepsy have increased seizure susceptibility (lowered seizure threshold). Genetic factors and prior brain injury (from a multitude of causes) are the major contributors to such susceptibility.

Most seizures in someone with epilepsy occur in an unpredictable fashion. It is this unpredictable timing that results in the major negative impact on quality of life. If functionally impairing seizures occur during waking hours (*diurnal seizures*), then activity restrictions are required including restriction from driving, operating heavy machin-

ery, heights, and unobserved swimming or bathing (showering with a good drain is recommended). These activity restrictions lead to loss of independence. The psychological impact of having intermittent involuntary loss of body control and the dependant status imposed by the activity restrictions are major contributors to the substantial increased incidence of comorbid depression in people with epilepsy (up to 50%).

In many people with epilepsy there is a higher seizure frequency during sleep because of increased synchronization of neuronal activity. Seizures that occur exclusively in sleep constitute *nocturnal epilepsy*. In women with epilepsy (WWE), seizures sometimes occur more often during the week around menses or at ovulation (*catamenial epilepsy*). Sleep deprivation, alcohol consumption, infectious illness, certain medications, and severe emotional stressors can further lower the seizure threshold and are associated with more seizures in people with epilepsy (see Table 126-1).

Incidence and Etiology

Seizures can occur at any time. Ten percent of people in developed countries have a seizure at some time during their lives. In contrast, 0.7% to 1% have current epilepsy (prevalence), and 3% to 4% have epilepsy at some time during their lives (lifetime prevalence). In the United States, there are approximately 125,000 new cases of epilepsy diagnosed each year (incidence). The incidence and prevalence are biphasic, with epilepsy being more common in childhood (primarily resulting from perinatal injury, infections, and genetic factors) and in old age (from stroke, tumors, and dementia) (Fig. 126-1). In developing countries the frequency of epilepsy is higher because of a variety of factors including increased brain infections with organisms such as cysticercosis.

Before the 1990s, in most people with epilepsy the cause was not determined. The advent of magnetic resonance imaging (MRI) and, more recently, genetic analysis has substantially improved our ability to identify the underlying cause of many types of epilepsy. About 70% of adults and

Tramadol, lidocaine, meperidine (in renal insufficiency)
Tricyclic antidepressants
Cyclosporine
Cocaine (crack), phencyclidine, amphetamines
Alcohol and benzodiazepine withdrawal
Central nervous system disease
Hypertensive encephalopathy, eclampsia
Hepatic and uremic encephalopathy
Sickle cell disease, thrombotic thrombocytopenic purpura
Systemic lupus erythematosus
Meningitis, encephalitis, brain abscess
Acute head trauma, stroke, brain tumor

*The metabolic derangements and drugs listed in Table 126-1 also lower the seizure threshold in people with epilepsy.

40% of children with new-onset epilepsy have partial (focal) seizures. In many it is not possible to identify a specific cause, although focal seizures imply a cerebral injury or lesion. The most common specific lesions are hippocampal sclerosis, neuronal and glial tumors, vascular malformations, neuronal migration disorders (e.g., cortical dysplasia), hamartomas, encephalitis, cerebral trauma, embolic stroke, and hemorrhage. Not all patients with cerebral lesions develop epilepsy; how or why a particular lesion becomes epileptogenic is poorly understood.

Hereditary influences have long been associated with epilepsy. During the past decade, a number of gene mutations have been associated with specific epilepsy syndromes.

At least 10 of the genetic epilepsies are known to be channelopathies; that is, a specific channel in a population of neurons, such as one isoform of the sodium channel, is mutated. Although still rare, new channelopathies are being identified, and it is likely that channel dysfunction will contribute to many of the epilepsies. An example of a channelopathy is *Dravet syndrome*, also known as *severe myoclonic epilepsy of infancy* (SMEI). Dravet syndrome is caused by a complete loss of function mutation in the voltage-gated sodium channel gene, *SCN1A*. Dravet syndrome typically manifests at about 6 months of age with prolonged hemi-clonic seizures associated with fever. Most cases of supposed vaccine (DPT)-associated encephalopathy are now known to result from Dravet syndrome first manifesting with the minor febrile reaction to the pertussis vaccine. Adults with Dravet syndrome are typically mentally retarded with spasticity or ataxia, gait dysfunction, and occasional nocturnal clonic seizures as well as other seizure types. Dravet syndrome is a more common cause of mental retardation with epilepsy than previously appreciated. Recognition of Dravet

Figure 126-1 Causes of epilepsy according to age in all newly diagnosed cases in Rochester, Minnesota, 1935 to 1984. (Modified from Hauser WA, Annegers JF, Kurland LT: Incidence of epilepsy and unprovoked seizures in Rochester, Minnesota: 1935-1984. *Epilepsia* 1994;34:453.)

syndrome is important because certain antiepileptic drugs (AEDs) worsen it (lamotrigine, phenytoin), whereas others are particularly beneficial (topiramate, levetiracetam, valproate, benzodiazepines).

Neuronal migration disorders (see Chapter 123) identified by MRI are another cause of epilepsy that is being increasingly recognized.

Classification and Clinical Manifestations

Seizures are classified by their clinical symptoms and signs. The manifestations of a seizure depend on whether its onset involves most or only a part of the cerebral cortex, on the functions of the cortical areas, and on the subsequent pattern of spread within the brain. Seizures are of two broad types: (1) those with onset limited to part of the cerebral hemisphere (*partial* or *focal seizures*) and (2) those with onset that involves the cerebral cortex diffusely (*generalized seizures*). Seizures are dynamic and evolve; a patient's seizure pattern varies depending on the extent and manner of spread of the electrical discharge. Thus simple partial seizures (SPSs) can evolve into complex partial seizures (CPSs), and partial seizures can evolve into secondarily generalized tonic-clonic (GTC) seizures.

In an individual, seizures are typically stereotyped, although a person can have more than one seizure type and

a specific seizure type can have varying intensities. The behaviors that occur during the seizure are termed the *semiology*. The seizure itself is referred to as the *ictus*, and the period of time during which the seizure occurs is termed the *ictal phase*. The time after the seizure, until the patient is fully recovered, is the *postictal phase*, and the time between seizures (which can be years) is the *interictal phase*.

The epileptic syndromes can be divided into three major categories: *partial epilepsy*, *primary (idiopathic) generalized epilepsy*, and *symptomatic generalized epilepsy*. This classification is based on the widely used scheme of the International League against Epilepsy. Specific seizure types occur in each of these groups.

PARTIAL SEIZURES

Simple Partial Seizures

In *partial seizures* (also known as *localization-related* or *focal seizures*), a localized region of the brain has abnormal neurons that intermittently fire hypersynchronously, recruiting the surrounding, otherwise normal neurons, generating a seizure. If the abnormal neuronal firing is confined, there may be no clinical manifestation, and the event, which can be detected only with electroencephalography (EEG), is termed a *subclinical* or *electrical seizure*. If the electrical discharge involves a slightly larger area, an SPS occurs and manifests as a symptom *without* impairment of consciousness. The symptom may be a sensation, autonomic function (e.g., nausea or another epigastric sensation), abnormal thought (e.g., fear, déjà vu), or involuntary movement. An SPS is commonly called an *aura* and can serve as a warning that a more intense seizure is about to occur. Auras occur in about 60% of patients with partial epilepsy.

During an SPS the patient can interact normally with the environment except for limitations imposed by the seizure itself on specific localized brain functions. SPSs are divided into *SPS without impairment*, which do not interfere with function (e.g., just an internal sensation) and *SPSs with impairment*, which can interfere with function (e.g., a jerking limb that would disrupt the ability to drive safely).

SPSs with motor signs manifest as *clonic* (rhythmic jerking) or *tonic* (stiffening) movements of a discrete body part. When the seizure begins in the primary motor cortex and spreads to involve adjacent areas of the precentral gyrus, clonic movements progress in an orderly sequence (*Jacksonian march*) that reflects the motor cortex homunculus topographic organization (e.g., mouth to hand to arm to leg).

Complex Partial Seizures

A CPS is a focal-onset seizure *with* impairment of consciousness. The degree of consciousness impairment spans from minimal to complete unresponsiveness. Almost always the patient's eyes are open during the ictus, indicating an awake state (albeit impaired). The eyes may close after the seizure ends, and the patient typically experiences some degree of postictal confusion, fatigue, and sometimes headache (with the head pain usually ipsilateral to the seizure focus). A CPS typically lasts 1 to 3 minutes, with a postictal state of a few minutes to hours.

The specific signs and symptoms that occur during a partial seizure characteristically reflect the location of seizure

Table 126-2 Ictal Manifestations: Localization of Seizures by Signs and Symptoms

Locus	Manifestation
Temporal lobe	
Uncus or amygdala	Foul odor
Middle or inferior temporal gyrus	Visual changes: micropsia, macropsia
Parahippocampal-hippocampal area	Déjà vu; jamais vu
Parahippocampal-septal area	Fear, pleasure, anger, dreamy sensation
Auditory association cortex	Voices, music
Insular, anterior temporal cortex	Lip smacking, drooling, abdominal symptoms, cardiac arrhythmia
Frontal lobe	
Motor cortex	Contralateral clonic movements of face, fingers, hand, foot
Premotor cortex	Contralateral arm extension; fencing posture
Language areas	Speech arrest, aphasia
Lateral cortex	Contralateral eye deviation
Bifrontal	Absence-like
Parietal lobe	Sensory symptoms
Occipital lobe	Visual hallucinations (often in color), teichopsias, metamorphopsias

onset (Table 126-2). The location of the focus is important as it predicts the nature of the pathology and directs diagnostic testing. Both medical and surgical treatments are determined, in part, by focus location.

Psychomotor, *temporal lobe*, and *limbic seizures* are all terms that have been used in the past to describe a variety of the ictal behaviors now classified as CPSs, but they are not synonymous. Not all CPSs arise from the temporal lobe, nor do all involve the limbic system. Similarly, certain temporal lobe and limbic phenomena may not be associated with the alteration in awareness that is required to designate it a CPS.

Medial temporal lobe seizures involve the hippocampal and amygdalar areas. An epigastric sensation or a vague cephalic sensation is the most common aura symptom. Less frequently, the classical symptom of a foul smell, déjà vu, or other odd thinking occurs. Olfactory auras are referred to as *uncinate seizures* because of their origin in or near the uncus of the medial temporal lobe. In lateral temporal seizures (neocortical), language impairment (dominant hemisphere) or formed visual or auditory hallucinations occur. As a temporal lobe seizure spreads to involve the dominant temporal lobe or bilateral temporal lobe structures including the limbic system, the seizure becomes complex. A blank stare is often described by witnesses. Automatic motor behaviors, termed *automatisms*, are common in seizures that involve the limbic system (usually in the temporal lobe). Automatisms include oroalimentary signs (e.g., lip-smacking, repetitive swallowing) and repetitive hand movements (manual automatisms). Other temporal lobe seizure signs include speech arrest (dominant hemisphere), recurring vocalizations (nondominant hemisphere), and eye blinking.

Frontal lobe seizures have at least four different semiologic patterns, as follows:

1. *Supplementary motor seizures* (superior frontal gyri, posterior aspect) consist of contraversive posturing of the head and arms such that a fencing posture is assumed; the contralateral arm is extended, the head is turned strongly to that side, and the ipsilateral arm is flexed and held either up above the head or across the chest.
2. *Lateral frontal seizures* manifest as contralateral head and eye deviation.
3. *Hypermotor seizures* (frontal, poorly localized) can be dramatic, consist of wild asynchronous movements, and are often confused with psychogenic non-epileptic attacks (PNEAs); thus they are sometimes termed *pseudo-pseudoseizures*. Almost all hypermotor seizures last less than 40 seconds and typically occur one to five times a night during sleep and less often during waking. Obscene verbal explicatives are commonly uttered loudly during hypermotor seizures.
4. *Frontal absence seizures* are rare and caused by diffuse, bisynchronous epileptic activity. These consist of staring and mimic typical or atypical absence seizures (see later).

Parietal lobe seizures consist of somatosensory sensations or higher cognitive function disruption. The somatosensory sensations can have a “Jacksonian march.” *Occipital lobe seizures* involve unformed or poorly formed visual hallucinations that are often in color (in contrast to the visual aura of migraine, which is black, gray, and white). Forced eye deviation can occur with occipital seizures. Occipital seizures can have a prolonged discharge lasting tens of minutes that is subclinical or minimally clinical before propagating. Parietal and occipital seizures do not become complex until propagating to the temporal lobes or limbic system.

Reflex seizures are precipitated by a specific stimulus, such as touch, a musical tune, a particular movement, reading, stroboscopic lights, or certain complex visual images. Reflex seizures arise in the parietal or occipital lobes, as these mediate sensory functions. Reflex seizures are uncommon, with the exception of the photosensitive response in juvenile myoclonic epilepsy (JME).

Secondarily Generalized Convulsive Seizures

A focal-onset seizure that spreads throughout the brain results in a *secondarily generalized seizure*. Typically there is a tonic phase that consists of extensor posturing lasting 20 to 60 seconds, followed by progressively longer periods of inhibition manifesting as a clonic phase that lasts up to another minute—hence the descriptive name *generalized tonic-clonic seizure*. The terms *convulsion*, *generalized tonic-clonic*, *grand-mal*, and *major-motor seizure* are often used interchangeably, although *generalized tonic-clonic* is a specific phenomenologic description of the behavior. In some patients, a few clonic jerks precede the tonic-clonic sequence; in others, only a tonic or clonic phase is present.

As a partial seizure transitions into a secondarily generalized convulsion, the arm contralateral to the seizure focus may extend first while the ipsilateral arm is flexed at the elbow. This is termed the “*figure-4 sign*” and is useful for lateralizing the seizure focus. A loud, “*tonic cry*” may occur at the onset of a convulsion as air is forcibly expelled through tightly contracted vocal cords. The eyes are open and commonly described to roll back. During a convulsion,

breathing does not occur and cyanosis becomes evident. Foaming at the mouth may be present. Oral trauma, especially involving the tongue, is typical. Urinary incontinence is common. Fecal incontinence is rare. First aid involves turning the patient onto a side as the seizure ends to allow the saliva to drool from the mouth, decreasing the likelihood of aspiration. Witnesses commonly describe a GTC as lasting 5 to 10 minutes or longer; however, the GTC phase rarely lasts longer than 2 minutes.

The postictal phase is marked by transient deep stupor, followed in 15 to 30 minutes by a lethargic, confused state, sometimes with automatic behaviors. As recovery progresses, many patients complain of headache, muscle soreness, mental dulling, lack of energy, or mood changes lasting for hours to days.

Convulsions result in a number of striking but transient physiologic changes, including hypoxemia, lactic acidosis, elevated catecholamine levels, and increased serum concentrations of creatine kinase, prolactin, corticotropin, and cortisol. Complications include oral trauma, vertebral compression fractures, shoulder dislocation, aspiration pneumonia, and very rarely sudden death, which may be related to acute pulmonary edema, cardiac arrhythmia, or suffocation.

Partial seizures (of all intensities) may be followed by a transient neurologic abnormality reflecting postictal depression of the epileptogenic cortical area. Therefore focal weakness may follow a partial motor seizure, or numbness a sensory seizure. These reversible neurologic deficits are referred to as *Todd paralysis* and last minutes to hours, rarely more than 48 hours. Examination of a patient immediately after a seizure may show transient focal abnormalities that indicate the site or at least the side of seizure origin.

PARTIAL EPILEPSY

The classification of the epilepsy syndromes closely follows the classification of the seizures, but epilepsy is the condition with recurrent seizures. *Partial* (localization-related, focal) *epilepsy* is characterized by recurrent partial seizures. It is divided into two main groups, idiopathic and symptomatic.

Idiopathic Partial Epilepsy

The idiopathic partial epilepsies are thought to result from a subtle genetic developmental abnormality. The most common type is *benign epilepsy with central midtemporal spikes* (BECTS), also known as *benign rolandic epilepsy* (BRE). This common epilepsy syndrome of childhood represents about 15% of all pediatric epilepsies. Seizures usually begin between the ages of 3 and 13 years in an otherwise normal child. The seizures consist of brief simple partial hemifacial motor or sensory events. There is typically twitching of one side of the face, speech arrest, drooling, and paresthesias of the face, gums, tongue, or inner cheeks. These signs may be so minor that they escape notice, although the affected child often points to his face and goes to a parent and holds on until it is over; the child then quickly resumes normal activity. Seizures may progress to include hemiclonic movements or hemitonic posturing. Secondarily GTC seizures occasionally occur, usually during sleep. The parents may report only the convulsions; the focal signature can be

missed unless the child is carefully questioned. The electroencephalogram reveals distinctive, stereotyped epileptiform discharges over the central and midtemporal regions that are dramatically activated by sleep with a normal underlying background. Prognosis is invariably good; the seizures disappear and the electroencephalogram normalizes by mid to late adolescence. Outcome is not affected by treatment, but AEDs prevent recurrent attacks.

Symptomatic Partial Epilepsy

The symptomatic partial epilepsies are the most common type of epilepsy and are classified based on the cerebral lobe involved during the initial phase of the seizure. Temporal lobe epilepsy (TLE) is the most frequent, followed by frontal, with rarer cases of parietal and occipital. Although often not identified in life, all cases of symptomatic partial epilepsy have an underlying focal abnormality in the cerebral cortex such as a scar, malformation, growth, or abnormal gene expression. An individual patient with symptomatic partial epilepsy usually has a single focus. However, the focus can involve a large, multilobar circuit. Some patients have multiple foci, each with different seizure manifestations.

TLE is the most common epilepsy syndrome of adults, accounting for at least 40% of epilepsy cases. Habitual seizures begin in late childhood or adolescence. There is often a history of childhood febrile seizures. Virtually all patients have CPSs, some of which secondarily generalize. Most TLE arises from medial temporal limbic structures, typically associated with gliosis in the hippocampus (*hippocampal sclerosis; mesial temporal sclerosis*). In a quarter of cases, TLE is caused by another structural lesion such as a cavernous malformation, hamartoma, cortical dysplasia, glial tumor, or scar related to previous head injury or encephalitis. When a lesion is present in addition to hippocampal sclerosis, the condition is termed *dual pathology*.

Post-Traumatic Epilepsy

The likelihood of developing post-traumatic epilepsy relates directly to the severity of the head injury. The relative risk

for developing epilepsy after a penetrating wound to the brain (e.g., bullet or shrapnel) is up to 600 times that in the general population; such wounds lead to epilepsy in most cases. Severe closed head injuries result in epilepsy 20% of the time. Severe closed head injuries are defined by the presence of an intracranial hemorrhage (subdural, epidural, subarachnoid, or cerebral contusion), unconsciousness or amnesia lasting more than 24 hours, or persistent abnormalities on neurologic examination, such as hemiparesis or aphasia. Although the majority of the patients with a severe head injury who develop seizures do so within 1 to 2 years, new-onset epilepsy may appear after 20 years or longer. Mild closed head injuries (uncomplicated brief loss of consciousness, no skull fracture, absence of focal neurologic signs, and no contusion or hematoma) may minimally increase the risk of seizures. Post-traumatic epilepsy is always partial, although only convulsions may be clinically evident, especially with multifocal injury. Early seizures within a week of the head injury do not necessarily signify future epilepsy.

PRIMARY GENERALIZED SEIZURES

Primary generalized seizures begin diffusely and involve both cerebral hemispheres simultaneously from the outset. They lack focal clinical and electroencephalographic features. Primary generalized seizures must be distinguished from partial seizures; in some cases they have similar clinical features.

Absence seizures (petit mal) occur mainly in children and are characterized by sudden, momentary lapses in awareness with staring. Sometimes rhythmic blinking occurs with a slight loss of neck tone. Most absence seizures last less than 10 seconds. If the absence lasts longer than 20 seconds, automatisms (see earlier) are usually present. The electroencephalogram has a characteristic pattern of three-per-second spike and slow waves (Figure 126-2) during an absence seizure. Behavior and awareness return to normal immediately after the seizure ends, although brief confusion may be present if the surroundings changed during the seizure.

Figure 126-2 Absence (*petit mal*) epilepsy. The electroencephalogram shows the typical pattern of generalized 3-Hz spike-wave complexes associated with a clinical absence seizure.

There is no postictal period and usually no recollection that a seizure occurred.

Myoclonic seizures manifest as rapid, recurrent, brief muscle jerks that can occur bilaterally, synchronously or asynchronously, or unilaterally without loss of consciousness. The myoclonic jerks range from small movements of the face or hands to massive bilateral spasms that simultaneously affect the head, limbs, and trunk. Repeated myoclonic seizures may crescendo and evolve to a GTC seizure. Although they can occur at any time, myoclonic seizures often cluster shortly after waking.

Primary GTC seizures may begin with a few myoclonic jerks or abruptly with a tonic phase lasting 20 to 60 seconds, followed by up to 1 minute of a clonic phase, followed by a postictal state (as described earlier). Although there are usually no focal features, sometimes head turning occurs; this movement does not suggest a specific localization.

IDIOPATHIC (PRIMARY) GENERALIZED EPILEPSY

The idiopathic generalized epilepsies (IGEs) are likely polygenic, resulting from a combination of mutations and polymorphisms in genes involved in thalamocortical circuitry. Different members of the same family may have dissimilar phenotypes. However, no specific IGE genes have been identified. A person with IGE has a 10% chance of passing the condition to a child. Most people with IGE have normal intelligence.

Childhood absence epilepsy (CAE; pyknolepsy, petit mal epilepsy) is the most common type of childhood epilepsy. It begins at 3 to 12 years of age with a peak at 7 years. Children with CAE have frequent absences (often hundreds per day) and are sometimes initially thought to have attention problems or to be daydreamers. Parents tend to report more absences at mealtimes, but that is because of closer observation; the absences are usually present throughout the day. One half of children with CAE have occasional GTC seizures. CAE is self-limited, and seizures and the electroencephalographic abnormalities resolve by young adulthood. The absence seizures of CAE are typically provoked by hyperventilation, a useful procedure in the office setting and during EEG.

JME begins between ages 8 and 20 years. It is characterized by clusters of myoclonic seizures in the morning, starting shortly after waking. The clusters typically persist for 10 to 30 minutes. The jerks are predominantly in the arms and last less than one second. Consciousness is preserved. An affected teenager often fails to mention the morning jerks unless specifically asked. Sometimes there is a history of throwing breakfast utensils or toothbrushes because of the jerks. JME is often diagnosed after a morning GTC seizure. In JME, GTC seizures are particularly common after sleep deprivation or alcohol consumption during the prior night. People with JME are usually photic sensitive—that is, the seizures and electroencephalographic discharges are activated by flickering lights at 5 to 20 Hz (*photic-paroxysmal* or *photic-convulsive* response). This is a type of reflex seizure (see earlier). Some people with JME also have absence seizures. The electroencephalogram is similar to that seen in CAE, but the generalized spike and slow wave discharges are slightly faster (3 to 4 Hz) and often have polyspike components. In contrast to CAE, the seizures in JME persist

into adulthood and can be lifelong, although they lessen with age.

Less common IGE phenotypes include *juvenile absence epilepsy* (JAE) and *GTC seizures alone* (GTCA). In JAE the predominant seizure type is absence and, like JME, the condition persists into adulthood. In GTCA the predominant seizure type is a convulsion, sometimes with a predilection for the morning. Less frequent absences or myoclonic seizures can occur in GTCA. Although onset of JME, JAE, and GTCA is typically during the teen years, cases of IGE with onset in elder age have been reported.

SYMPTOMATIC SECONDARY GENERALIZED EPILEPSY

Symptomatic generalized epilepsy occurs in people with multifocal or diffuse brain dysfunction from early in life. There is usually an associated encephalopathy with some degree of mental retardation. In addition to all of the seizure types that occur in partial epilepsy and IGE, people with symptomatic generalized epilepsies have tonic and atonic drop seizures and atypical absence seizures.

Drop seizures can be tonic and/or atonic. “Drop” implies that if the patient is upright, he or she falls, with no protective reflexes. Patients with drop seizures often experience head injuries and should wear a helmet except when they are directly attended by a care provider, in a secure chair, or lying down. During a *tonic seizure*, the arms abruptly thrust forward at a 90-degree angle to the body and the entire body stiffens. Classically the fall is backward. During an *atonic seizure*, tone is abruptly lost in the postural muscles and the patient falls forward.

Atypical absence seizures manifest as staring or mental slowing associated with a slow generalized spike and slow wave discharge (2.5 Hz or less) on the electroencephalogram. They may last minutes or even hours. Fluctuating levels of awareness and gradual onset and offset are described with atypical absences.

Lennox-Gastaut Syndrome

The *Lennox-Gastaut syndrome* (LGS) is a common form of symptomatic generalized epilepsy caused by diffuse or multifocal brain dysfunction. LGS manifests at 2 to 10 years of age. Sixty percent of patients have preexisting encephalopathy and developmental delay, and 20% had infantile spasms (see later). LGS is responsible for 5% to 10% of childhood epilepsy. It is characterized by the combination of tonic and atonic seizures, myoclonic seizures, and atypical absences with the characteristic electroencephalographic pattern of 2.5 Hz or slower generalized spike and slow waves. During sleep there are bursts of diffuse fast rhythms on the electroencephalogram indicative of tonic-atonic seizures, often with minimal clinical expression. Tonic-clonic and partial seizures may also occur.

Almost all people with LGS have mental retardation with associated behavioral disorders. LGS is a chronic condition requiring supervision; many patients ultimately live in group homes. If drop seizures are present, a helmet should be prescribed for protection.

Infantile Spasms

Infantile spasms are often a precursor of LGS, although not formally classified as a symptomatic generalized epilepsy. By

definition, infantile spasms begin during the first year of life. They affect approximately 1 in 5000 children. The epileptic spasms manifest as flexor or extensor tonus, myoclonus, or a mixed pattern. The spasms last 1 to 20 seconds each and occur in clusters for up to 20 minutes. *West syndrome* is the combination of epileptic spasms, hypsarrhythmia (a chaotic, disorganized epileptiform electroencephalographic pattern), and mental retardation. It is common for the term *infantile spasms* to be used synonymously with *West syndrome*. Infantile spasms have a poor prognosis, with over 90% of patients developing mental retardation and most progressing to symptomatic generalized epilepsy; only a small percent of patients with cryptogenic cases recover. There are many causes of infantile spasms, including perinatal insults, cerebral malformations, central nervous system (CNS) infections, tuberous sclerosis, and inborn errors of metabolism.

OTHER SEIZURE CONDITIONS

Febrile Seizures

Febrile seizures affect between 3% and 5% of children younger than the age of 6 years. About 30% of children have more than one attack; the likelihood of recurrence is greater if the first seizure occurs before 1 year of age or there is a family history of febrile seizures. Although most affected children have no long-term consequences, febrile seizures increase the risk of developing epilepsy later in life. This risk is low for most children (2% to 3%) but is 10% to 15% in those who had prolonged or focal febrile seizures, a family history of nonfebrile seizures, or neurologic abnormalities before the first febrile seizure.

Diagnosis

Accurate diagnosis is the cornerstone of epilepsy treatment. The diagnostic evaluation has three objectives: (1) to determine that the events are epileptic seizures; (2) to identify a specific underlying cause; and (3) to establish if the seizures are symptomatic and isolated or if epilepsy is present and, if so, to determine the specific epilepsy syndrome.

HISTORY AND EXAMINATION

The patient's and witnesses' descriptions of the events are central to making the diagnosis. Extra attention should be given to exploring details of the behavior during the seizure. The setting of the seizure can suggest acute causes such as drug withdrawal, CNS infection, trauma, or stroke. A history of recent-onset seizures in an adult suggests a new intracranial lesion, and a more chronically sustained or remote history of attacks suggests chronic epilepsy. Any focal feature before, during, or after the seizure suggests a structural brain lesion requiring appropriate investigation. The pattern of the seizures and the patient's age are often important clues to the seizure and epilepsy type.

The physical examination findings are normal in most patients with epilepsy. Physical findings that should be sought include overt or subtle focal neurologic signs, including slight unilateral lower facial paresis, clumsy fine finger movements, and mild hyperreflexia, as these can be present in partial epilepsy with a contralateral seizure focus. Careful skin examination is indicated to detect features of neurocu-

taneous syndromes such as a facial port-wine stain involving the upper eyelid in Sturge-Weber syndrome; hypopigmented macules (ash-leaf spots), shagreen patch, and facial angiofibromas in tuberous sclerosis; and café-au-lait spots and axillary freckling in neurofibromatosis. Asymmetry in the size of the hands, feet, or face signifies a long-standing abnormality of the cerebral hemisphere contralateral to the smaller side. Absence seizures can be triggered in untreated children with hyperventilation for 2 to 3 minutes.

LABORATORY TESTS

EEG is the most important diagnostic test for seizures and epilepsy. Electroencephalographic findings are useful and sometimes essential for establishing the diagnosis, classifying the seizures correctly, identifying the epilepsy syndrome, and making therapeutic decisions. In combination with suitable clinical findings, *epileptiform* electroencephalographic discharges, termed *spikes* or *sharp waves*, strongly support a diagnosis of epilepsy.

In patients with recurrent seizures, focal epileptiform discharges are consistent with focal epilepsy, whereas generalized epileptiform activity usually indicates a generalized form of epilepsy. However, most electroencephalograms are obtained between seizures, and interictal abnormalities alone cannot prove or disprove a diagnosis of epilepsy.

Forty percent to 50% of patients with epilepsy show epileptiform abnormalities on the initial electroencephalogram. The chance of capturing epileptiform activity is enhanced by sleep deprivation the night before the test so that the patient sleeps during a portion of the electroencephalographic recording. Serial electroencephalograms increase the yield of positive tracings. A small proportion of patients with epilepsy have normal interictal electroencephalograms despite all efforts to record an abnormality.

The interpretation of the interictal electroencephalogram is confounded by two factors. One is that epileptiform discharges occur in about 2% of normal people; many of these are thought to be asymptomatic markers of a genetic trait, especially in children. Second is that the interpretation of the electroencephalogram is subjective and there are normal benign variant waveforms and artifacts that can be misinterpreted as epileptiform activity and erroneously considered to be evidence of seizure susceptibility.

Epilepsy can be definitively established by recording a characteristic ictal discharge during a representative clinical attack. This is uncommon during routine electroencephalographic recordings but can be accomplished with *inpatient video-EEG long-term monitoring* (LTM) performed at many epilepsy centers throughout the world. Inpatient video-EEG monitoring is indicated in people who have ongoing seizures despite being treated with appropriate AEDs. About one third of patients admitted for LTM are found to not have epilepsy; the majority of these patients have PNEAs (see later). In the 25% to 30% of people with partial epilepsy who continue to have disabling seizures despite trials with multiple AEDs, inpatient video-EEG monitoring is a critical test for determining candidacy for resective epilepsy surgery.

NEUROIMAGING

Brain MRI complements electroencephalographic findings by identifying structural pathology that may be causally

related to the development of epilepsy. MRI is the best test to detect epileptogenic cerebral lesions including hippocampal sclerosis, neuronal migration disorders, tumors, focal atrophy, arteriovenous malformations, and cavernous malformations. It is important to obtain a complete imaging study that includes T1-weighted, T2-weighted, and inversion-recovery sequences in coronal and axial planes with and without contrast. Imaging in the coronal plane perpendicular to the long axis of the hippocampus has improved detection of hippocampal atrophy and hippocampal high T2 signal, findings that correlate with the pathologic finding of mesial temporal sclerosis and an epileptogenic temporal lobe. Additional sequences that should be routine include T2-weighted gradient-echo (GRE), to detect hemosiderin indicating old hemorrhage associated with vascular malformations or trauma, and diffusion-weighted images (DWI) for cytotoxic edema present with acute cerebral injury including the effects from prolonged seizures.

An MRI should be obtained in all patients suspected of having epilepsy except those with definite benign epilepsy with centro-temporal spikes (BRE) or definite IGE (e.g., CAE and JME). Computed tomography (CT) scan with contrast is an alternate study for those who cannot have MRI but is not as good at detecting small lesions. CT scan can complement MRI because it is better for detecting calcium and a more practical test for acute bleeding. Any patient with seizures and abnormal neurologic findings or focal slow-wave abnormalities on EEG should have neuroimaging. If there is an unexplained change in seizure pattern, repeat neuroimaging should be considered, to evaluate for a new lesion.

Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) provide information about brain function. These techniques use physiologically active, radiolabeled tracers to image the brain's metabolic activity (PET) or blood flow (SPECT). Typically these studies are reserved for select patients undergoing evaluation for epilepsy surgery. About 70% to 85% of patients with TLE have temporal lobe hypometabolism on interictal PET corresponding to the seizure focus. SPECT is most useful when an ictal and interictal study are combined to identify an extratemporal seizure focus. Abnormalities on PET or SPECT are often present even when brain structure on MRI is normal.

OTHER TESTS

Routine blood tests rarely offer diagnostic assistance in otherwise healthy patients with epilepsy. Serum electrolytes, liver function tests, and complete blood count are useful as baseline studies before AED therapy is started. Blood tests are necessary in older patients with acute or chronic systemic disease. Adolescents and young adults with unexplained seizures should be screened for substance abuse (especially cocaine) with blood or urine studies.

Lumbar puncture is indicated only if there is a suspicion of meningitis, encephalitis, or a CNS glucose transporter abnormality; it is otherwise unnecessary. Repeated generalized seizures and status epilepticus can increase cerebrospinal fluid protein content slightly and produce a pleocytosis for 24 to 48 hours; cerebrospinal fluid pleocytosis should be

Table 126-3 Non-Epileptic Episodic Disorders That May Resemble Seizures

Movement disorders: myoclonus, paroxysmal choreoathetosis, episodic ataxias, hyperreflexia (startle disease)
Migraine: confusional, vertebrobasilar, visual auras
Syncope
Behavioral and psychiatric: psychogenic non-epileptic attacks (pseudoseizures), hyperventilation syndrome, panic or anxiety disorder, dissociative states
Cataplexy (usually associated with narcolepsy)
Transient ischemic attack
Alcoholic blackouts
Hypoglycemia

attributed to seizures only in retrospect after an intracranial inflammatory process has been excluded.

An electrocardiogram (ECG) should be obtained in any young person with a first generalized seizure if there is a family history of arrhythmia, sudden unexplained death, or episodic unconsciousness. An ECG should also be obtained in any patient with a personal history of cardiac arrhythmia or valvular disease.

Differential Diagnosis

Not every paroxysmal event is a seizure, and misidentification of other conditions as epilepsy leads to ineffective, unnecessary, and potentially harmful treatment. Misdiagnosis accounts for a substantial portion of patients who have not responded to AED treatment. A variety of conditions can be confused with epilepsy, depending on the age of the patient and the nature and circumstances of the attacks (Table 126-3). Non-epileptic paroxysmal disorders that are confused with epileptic seizures have sudden, discrete abnormal behaviors, variable responsiveness, changes in muscle tone, and various postures or movements.

PNEAs (*pseudoseizures*, *psychogenic non-electrical attacks*) frequently cause intractable “epilepsy” in adults. PNEAs result when the unconscious mind converts emotional conflicts or stressors into a physical state that mimics a seizure (see Chapter 117). Some patients with psychogenic seizures also have epilepsy. Definitive diagnosis requires video-EEG documentation, although a history of atypical and non-stereotyped attacks, emotional or psychological precipitants, psychiatric illness, lack of response to AEDs, and repeatedly normal interictal electroencephalograms suggests the possibility of psychogenic attacks. About 80% of patients with PNEA have been the victims of physical or sexual abuse. PNEAs are more common in females.

Panic attacks (anxiety attacks) with hyperventilation can superficially resemble partial seizures with affective, autonomic, or special sensory symptoms. Hyperventilation typically causes perioral and finger tingling. Prolonged hyperventilation results in muscle twitching or spasms (tetany); affected patients may faint.

Syncope (see Chapter 121) refers to the symptom complex that results when there is a transient, global reduction in

cerebral perfusion. Loss of consciousness lasts only a few seconds, uncommonly a minute or more, and recovery is usually rapid. If the cerebral ischemia is sufficiently severe, the syncopal episode may include tonic posturing of the trunk or clonic jerks of the arms and legs and incontinence (*convulsive syncope*).

Some forms of *migraine* can be mistaken for seizures, especially if the headache is atypical or mild. The visual aura, present in some migraineurs, is typically black, gray, and white; a color aura almost always indicates an epileptic seizure. Basilar artery migraine, a variant noted most often in children and young adults, can include lethargy, mood changes, confusion, disorientation, vertigo, bilateral visual disturbances, and loss of consciousness.

Treatment

If the cause of symptomatic seizures is corrected, AEDs are usually not necessary. Adults with a single, unprovoked seizure and normal clinical and laboratory findings frequently do not have subsequent seizures; antiepileptic treatment is usually not indicated if only one seizure has occurred. However, patients with focal neurologic findings on clinical, radiologic, or electroencephalographic examinations are more likely to have repeated seizures. In individual patients, social considerations may dictate treatment after a single seizure.

If seizures are recurrent, the goal of treatment is complete seizure freedom. There is no perfect AED. They all have potential toxic side-effects and idiosyncratic reactions. For more than half of people with epilepsy, any of the appropriate AEDs for their particular type of seizures can be completely effective and well tolerated. However, for about one quarter of people with epilepsy, no AED or combination of AEDs is completely effective. Once the seizure type and epilepsy syndrome have been determined an initial and, if needed, subsequent AED should be chosen based on both the anticipated efficacy and toxicity profile. All AEDs can cause sedation, cognitive dysfunction, and incoordination in some patients, especially at high levels. Various rare, sometimes life-threatening reactions may occur with all of the AEDs. Commonly encountered situations are as follows:

1. IGE (CAE, JME, others)
 - a. In all IGEs, valproate or lamotrigine is the first line agent and results in complete control in 85% to 90% of patients.
 - i. Valproate tends to cause weight gain and has been associated with the development of polycystic ovary syndrome, particularly in adolescent girls. It results in hair loss in about 5%. It has an increased risk of teratogenicity.
 - ii. Lamotrigine has a small but significant risk of a severe rash (toxic epidermal necrolysis—Stevens-Johnson syndrome) for about the first 2 months after the medication is started. A slow dose escalation substantially reduces this risk. Lamotrigine metabolism is dramatically inhibited by valproate, so in combination, much lower doses of lamotrigine are required. Occasionally lamotrigine worsens myoclonus, but it is effective in most cases of JME.
 - b. Second-line options include topiramate, levetiracetam, and zonisamide.
 - c. In CAE with exclusively absence seizures, ethosuximide is an appropriate first choice. If any convulsions have occurred, valproate or lamotrigine should be used.
 - d. If there is a history of more than 5 minutes of crescendo in absences or myoclonus (often described as a “foggy” state”) culminating in a convulsion, then oral benzodiazepines (lorazepam or diazepam) can abort the absence cluster and prevent a convulsion.
 - e. Absences and myoclonus can be exacerbated by carbamazepine, oxcarbazepine, and GABAergic compounds including gabapentin, pregabalin, and tiagabine. These AEDs should be avoided in IGE.
2. Partial epilepsy
 - a. Almost all of the AEDs (except ethosuximide) can be effective in partial epilepsy. The choice of the first AED should be guided by side effect concerns and pharmacokinetics.
 - b. Phenytoin is the most commonly used AED in partial epilepsy in developed countries. It is typically loaded in the emergency room after the initial seizures and subsequently continued. However, phenytoin has substantial short- and long-term toxicity, and its levels are difficult to regulate because of saturation kinetics and multiple drug interactions. Its toxicities include hirsutism, coarsening of features, and gingival hyperplasia, especially in children and adolescents. Long-term toxicities include osteomalacia, peripheral neuropathy, and cerebellar degeneration with permanent incoordination. Peak level toxicities include nystagmus, gait instability, ataxia, and, if the level rises above 50, acute cerebellar degeneration and cardiac arrhythmias.
 - c. Carbamazepine, oxcarbazepine, topiramate, levetiracetam, lamotrigine, and zonisamide are currently used as first-line therapy for partial seizures. Carbamazepine and oxcarbazepine can cause hyponatremia. Topiramate can lead to weight loss (often desired) but has cognitive side effects. Levetiracetam can cause severe mood changes and marked sedation but is usually well tolerated. Lamotrigine needs to be titrated slowly because of the rash risk. Zonisamide has a long half-life (48 to 72 hours), so it is a good option for intermittently noncompliant patients.
 - d. Patients with Asian ancestry should be tested for the HLA-B*1502 allele before treatment with carbamazepine is initiated. Patients with this allele (which is present only in the Asian population) are at substantial risk for Stevens-Johnson syndrome and toxic epidermal necrolysis when exposed to carbamazepine.
 - e. Adjunctive treatment for partial seizures includes valproate, pregabalin, lacosamide, gabapentin, tiagabine, and primidone. The proportion of gabapentin absorbed decreases with increasing dose, which limits its effectiveness. For most patients, pregabalin is a better choice. Primidone is rapidly converted to phenobarbital by some people, limiting its use.
 - f. Phenobarbital is the most widely used AED in the world because of its low cost. However, it causes sedation and cognitive impairment and it should be

avoided except in difficult-to-control epilepsy. The exception is neonatal seizures, for which it is the most commonly accepted AED.

3. Symptomatic generalized epilepsy (LGS, others)
 - a. All AEDs have a role in the treatment of symptomatic generalized epilepsy, but seizure freedom is rarely achieved. At a minimum, control of the more severe seizures including drop seizures and convulsions should be the target of therapy. Polytherapy is usually required.
 - b. Valproate is commonly the initial medication instituted.
 - c. Added efficacy can be achieved with lamotrigine, topiramate, levetiracetam, and zonisamide.
 - d. Felbamate may be effective, but its use should be limited to epileptologists because of the significant risk of fatal aplastic anemia and liver failure.
 - e. The vagus nerve stimulator (VNS; see later) has a specific role in reducing the severity of seizures in this condition.
 - f. Dravet syndrome and possibly the related syndrome of generalized epilepsy with febrile seizures plus (GEFS+) respond best to topiramate, levetiracetam, and benzodiazepines. Some drugs, including lamotrigine and probably phenytoin, worsen Dravet syndrome.

Determining the dose of AEDs must be done with care. Only a few of the AEDs are safe to load or start at a full therapeutic dose. Most should be started with a gradual dose escalation. Management guidelines are as follows:

1. The type of seizures and epilepsy should be defined, and the preferred medication should be given in usual doses and then increased until seizure control is complete or side effects occur (Table 126-4).
2. If seizures persist at toxic levels, or if major side effects occur, another agent should be tried.
3. Do not stop one agent until another has been added. Otherwise, status epilepticus may result.

4. If seizures persist after two agents have been given to toxic levels, consider referral to a specialized epilepsy center for complex combination therapy and video-EEG LTM.
5. Toxic levels of some AEDs (particularly phenytoin and carbamazepine) can cause seizures.
6. Extended-release and longer-acting AEDs are preferred for most patients.
7. Patients should be counseled repeatedly to adhere to the medication regimen. Pill boxes should be encouraged. Medication noncompliance is the leading cause of breakthrough seizures.

EPILEPSY SURGERY

In the majority of patients, epilepsy is controlled with medication. When seizures cannot be controlled by adequate trials of two appropriate single agents or by the combination of two agents, the epilepsy is termed *medically intractable* (or *refractory*), a situation encountered in approximately 25% of patients with symptomatic partial epilepsy. Such patients are at risk for the consequences of seizures: inability to drive; stigmatization by schools, employers, and families; and threats to personal educational and occupational goals. In appropriately selected cases, epilepsy surgery can abolish seizures with restoration of normal neurologic function. The accurate localization of a small, resectable seizure focus requires intensive investigation at a specialized center.

KETOGENIC DIET

The ketogenic diet is a very high-fat diet with restricted carbohydrates and protein carefully designed to cause a ketotic state mimicking starvation, but supplying adequate nutrition. It is mainly used in children with severe symptomatic generalized epilepsy. The ketogenic diet can be effective in this most refractory form of epilepsy, resulting in seizure freedom in 15% to 20%. However, the diet is hard to maintain and requires a dedicated, cooperative caregiver (usually the patient's mother) and a specially trained dietician.

Table 126-4 Frequently Prescribed Antiepileptic Drugs

Drug	Adult Total Dose per day	Dose Frequency (hr)	"Therapeutic" Concentrations
Carbamazepine	400-1600 mg	6-8 (12 for sustained release)	6-12 µg/mL
Ethosuximide	500-1500 mg	8-12	40-100 µg/mL
Gabapentin	900-3600 mg	6-8	Uncertain
Lacosamide	200-400 mg	12	Uncertain
Lamotrigine*	100-800 mg	12	2-15 µg/mL
Levetiracetam	500-3000 mg	12	15-40 µg/mL
Oxcarbazepine	600-2400 mg	8-12	15-40 µg/mL
Phenobarbital	60-240 mg	24	15-40 µg/mL
Phenytoin	200-400 mg	24	10-20 µg/mL
Pregabalin	100-600 mg	8-12	Uncertain
Rufinamide	1600-3200 mg	8-12	Uncertain
Topiramate	100-600 mg	12	2-20 µg/mL
Valproate	500-6000 mg	8	50-120 µg/mL
Zonisamide	100-600 mg	24	Uncertain

*Slow initial dose titration mandatory for lamotrigine and often indicated for other agents.

VAGUS NERVE STIMULATOR (VNS)

The VNS is an implanted device similar in appearance to a cardiac pacemaker. It is placed into contact with the left vagus nerve in the neck. Typically it is programmed to stimulate the nerve for 30 seconds every 3 to 5 minutes, although there are many other options. Swiping a magnet over the device can give an extra stimulation and sometimes abort a seizure. In up to two thirds of patients, partial seizures are reduced by 50% or more and seizure intensity decreases. The VNS rarely results in seizure freedom. The VNS may have a role in symptomatic generalized epilepsy, improving drop seizures and overall seizure severity. Once a VNS has been implanted, the patient cannot have an MRI of the neck and certain other body regions. MRIs of the head with standard field strengths are permitted, but not with higher field strengths, above 2 Tesla.

STATUS EPILEPTICUS

Status epilepticus can occur with partial or generalized epilepsy and is defined as prolonged or rapidly recurring seizures without full intervening recovery. Various durations have been specified including longer than the patient's typical seizures or seizures ongoing for more than 10 to 30 minutes. *Acute repetitive seizures* are defined as a cluster of seizures over minutes to hours with intervening recovery.

Convulsive status epilepticus (grand mal, major-motor) is a medical emergency. Continuous generalized epileptic activity can damage the brain permanently. The most frequent cause is abrupt withdrawal of AEDs (e.g., noncompliance) in a person with known epilepsy. Other precipitants include withdrawal from alcohol or drugs in a habitual user, cerebral infection, trauma, hemorrhage, and brain tumor.

Complex partial status epilepticus manifests as a sustained state of confusion often associated with motor and automatic automatisms. Some attacks produce bizarre behavior, whereas others are marked by a stuporous state. Patients may resist assistance because of their abnormal state, which can last for hours or even days. The electroencephalogram usually shows nearly continuous discharging activity predominating in one or both temporal regions.

Absence status epilepticus (petit mal status) resembles complex partial status and consists of a confused state with some automatic behaviors. The electroencephalogram is characteristic, with continuous runs of generalized 3- to 4-Hz spike and slow wave activity. The condition occurs in children to young adults with known absence epilepsy. Rarely, absence status occurs as the first manifestation of epilepsy in older persons with no history of seizures. *Atypical absence status* with fluctuating confusion lasting for hours or longer occurs in patients with symptomatic generalized epilepsy (e.g., LGS) and is accompanied by a generalized spike-slow wave pattern of 2.5 Hz or slower on the electroencephalogram.

Partial motor status, also known as *epilepsy partialis continua*, ranges from highly focal, clonic movements of the face or hand to jerks that involve most of the limb or half the body. The clonus frequency can vary from one every 3 seconds to 3 per second. It is relatively uncommon. Its causes include stroke, trauma, neoplasms, and encephalitis; sometimes the cause never becomes clear. Epilepsy partialis

continua often resists all efforts at treatment, and neurosurgical removal of the causative lesion is sometimes required.

Physicians infrequently witness seizures; most of the time they learn about the semiology while taking the history. Merely observing a patient in the midst of a seizure does not indicate that the patient should be treated for status epilepticus. However, once status epilepticus is diagnosed, the need for treatment is urgent.

The longer status epilepticus lasts, the more difficult it is to terminate and the more likely it is to cause brain damage. Aggressive therapy is mandatory for convulsive status epilepticus (Table 126-5). If initial therapy is not rapidly effective, anesthetic agents requiring intubation and ventilation should be used within an hour of onset. Complex partial status can also result in permanent neuronal injury and should similarly be treated aggressively, although therapeutic decisions are often made to try to stop complex partial status with agents that do not cause respiratory suppression to avoid intubation. Absence status is unlikely to result in permanent sequelae and usually responds promptly to benzodiazepine treatment.

Investigation of the cause of the status epilepticus should be undertaken during the treatment and continued after the seizures stop. Severe hyperglycemia can produce refractory partial motor and complex partial status; seizures stop once hyperglycemia is corrected.

Postanoxic status myoclonus, although it can last for weeks and is accompanied by generalized polyspike epileptiform discharges on the electroencephalogram, is usually not treated as status epilepticus. It typically indicates an irreversible condition caused by severe brain injury with a very poor prognosis.

Genetic Counseling and Pregnancy

HEREDITY

Patients with epilepsy should be advised about the hereditary risks for their offspring, although in most people with epilepsy it does not influence their decision about having children. The idiopathic epilepsies have complex inheritance, with about 10% of children of an affected parent developing seizures. There are over 200 Mendelian-inherited syndromes with epilepsy, but these are all rare.

TERATOGENICITY

Children of mothers taking antiepileptic medication have a birth defect rate of 6% to 9%, which is 2 to 3 times that of the general population. Convulsions, however, pose a substantial risk to the mother and fetus. Therefore AEDs should not be stopped during pregnancy. Two AEDs, valproate and carbamazepine, have been incriminated in neural tube closure defects. Because the neural tube closes by 28 days of fetal development, this defect will develop before the mother is aware she is pregnant. Phenytoin, phenobarbital, and primidone have been associated with a spectrum of neurodevelopmental abnormalities. All five of these older AEDs are classified as pregnancy category D by the U.S. Food and Drug Administration (FDA) and should be avoided if

Table 126-5 Treatment of Convulsive Status Epilepticus in Adults

Time (min)	Steps
0-5 (ABCs)	Give oxygen; ensure adequate ventilation. Monitor: vital signs, ECG, oximetry. Establish intravenous access; obtain blood samples for glucose level, complete blood cell count, electrolytes, Ca, Mg, toxins, and AED levels.
6-9 (glucose) (benzodiazepine)	Give glucose if blood glucose level is low or unavailable. In adults give 100 mg of thiamine, as well. Intravenously administer 1-2 mg of lorazepam or 5-10 mg of diazepam as initial therapy. Alternatively use rectal diazepam gel 0.2 mg/kg.
10-20	If the initial dose of benzodiazepine is not effective, then continue to intravenously administer either lorazepam at 2 mg/min up to a total dose of 0.1 mg/kg (maximum 10 mg) or diazepam at 5 mg/min up to a total dose of 0.2 mg/kg (maximum 30 mg). If diazepam is used and the status epilepticus stops, phenytoin (or another AED) should be administered promptly to prevent recurrence of seizures, as diazepam's duration of action may be less than 30 minutes.
21-40 (phenytoin)	If status persists, administer 15-20 mg/kg of fosphenytoin* intravenously no faster than 3 mg/kg/min up to 150 mg/min in adults. (Alternatively use phenytoin 15-20 mg/kg at maximum infusion rate of 1 mg/kg/min up to 50 mg/min in adults via a proximal IV site.) Monitor carefully for hypotension, arrhythmia, local extravasation.
>40 (phenobarbital) (intubate)	If status does not stop after fosphenytoin or phenytoin, give 10-20 mg/kg of phenobarbital intravenously at a maximum of 100 mg/min. When phenobarbital is given after a benzodiazepine, ventilatory assistance is usually required.
(general anesthesia)	If status persists, give general anesthesia (e.g., pentobarbital, propofol, midazolam, or lorazepam IV drip) to induce a burst suppression pattern (electroencephalographic monitoring, if available, should be instituted). Vasopressors or fluid volume are usually necessary.
(alternatives)	Alternative or additional treatments include IV valproate (30 mg/kg) load and levetiracetam.

*Always dosed in phenytoin-equivalents (PE).
AED, antiepileptic drug; ECG, electrocardiogram; IV, intravenous.

possible. Large registries suggest that the newer AEDs have less teratogenicity, but the data are incomplete. Use of two or more AEDs (polytherapy) increases the teratogenic risk.

Pregnancies in WWE should be planned. During the year before conception, an attempt should be made to minimize the teratogenic potential of the AEDs by changing to a newer AED, changing to monotherapy from polytherapy, or tapering off the AEDs, but only if there are clear reasons to believe that seizures will not recur (see later). The lowest effective dose of the AEDs should be used, but this must be balanced with the risk of a breakthrough seizure.

Folic acid deficiency is a well-established factor in neural tube closure defects in the general population. There is little evidence that additional folic acid in a well-nourished woman with epilepsy decreases the AED effects on neural tube closure. However, it is common practice to place WWE of childbearing age on supplemental folic acid (1 mg) as prophylaxis against a neural tube closure defect. Once pregnancy is planned or recognized, the dose of folic acid is commonly increased to 4 mg per day.

MANAGEMENT DURING AND AFTER PREGNANCY

WWE have a 1.5- to 3-fold increased rate of complications of pregnancy, including bleeding, toxemia, abruptio placentae, and premature labor. They should be managed as having high-risk pregnancies. High-quality (focused or type 2) ultrasound, maternal serum alpha-fetoprotein level (elevated in neural tube closure defects), and amniocentesis for chromosomal analysis are used to identify fetal malformations.

During pregnancy, AED concentrations decrease because of increased hepatic and renal clearance and increased plasma volume. The free fraction of highly protein-bound AEDs (e.g., phenytoin and valproate) increase because of decreased albumin concentration and increased competition

for binding sites by sex steroids. Therefore it is essential to monitor drug levels (free levels for highly protein-bound AEDs) before conception and at regular intervals throughout pregnancy. Hepatic induction of glucuronidation can dramatically reduce lamotrigine levels, sometimes requiring doubling or tripling of the lamotrigine dose to maintain pre-pregnancy levels. Lamotrigine levels should be measured at least every month throughout pregnancy. Similarly, oxcarbazepine levels fall by about a third beginning in the first trimester, and thus the dose should be increased and followed at least each trimester.

Emesis, a common problem during early pregnancy, can result in missed and partial doses of AEDs. The expectant mother should have specific instructions to retake a full or partial dose of her AEDs if vomiting occurs shortly after medications have been taken.

After the child is born, the dose of AEDs should be tapered to the pre-pregnancy amount within days to weeks. The AED levels can be checked 1 to 2 weeks after the taper is completed, to confirm they are at the patient's baseline.

In general, breastfeeding is not contraindicated in women taking AEDs.

During the postpartum period the mother with epilepsy may be at increased risk for seizures, especially if her seizures are activated by lack of sleep. To decrease this risk, a support person should perform at least one of the nighttime feedings. Patients whose seizure semiology would put the infant at risk (e.g., dropping or excessively clutching the baby) may require child care modification or supervision.

Psychosocial Concerns

Ongoing epileptic seizures often result in major emotional consequences for the patient and family. Comorbid depression is present in up to 50% of patients with refractory

epilepsy and 20% of patients with controlled epilepsy. Anxiety disorders are similarly common. Both are often unrecognized and untreated. In people with epilepsy, quality-of-life impairment is better correlated with depression than seizure frequency. The unpredictable nature of seizures and the necessary activity restrictions cause dependence, decreased self-worth, embarrassment, underemployment, and helplessness. Reduced libido and hyposexuality are common in patients with epilepsy and often unrecognized.

Family dynamics are often disrupted by the presence of epilepsy. Both families and patients often fear seizures (seizure phobia). It is common for family members to perceive that their loved one is dying when he or she has a convulsion, especially for the first time.

Patients with epilepsy are helped most by complete seizure control, but reassurance and optimistic social guidance aid immeasurably. Once seizure control has been achieved, affected persons should be encouraged to live a normal life, using common sense as their guide. Although activity restrictions may eventually be lifted, patients with past epilepsy should be advised to avoid head-contact sports, high alpine climbing, scuba diving, and professions requiring work at heights, large amounts of driving, or weapon use (with the exception of CAE or BECTS, which may completely remit).

All states grant automobile driver's licenses to patients with epilepsy, provided that no seizures have occurred for specified periods. Life-and-health insurance policies can generally be obtained. The Epilepsy Foundation of America and local social service organizations can assist with patients' social-vocational considerations.

Prognosis

Sixty percent to 70% of people with epilepsy achieve a 5-year remission of seizures within 10 years of diagnosis. About half of these patients are eventually seizure-free without AEDs. Factors favoring remission include an idiopathic form of epilepsy, a normal neurologic examination, and onset in early to middle childhood (excluding neonatal seizures).

Approximately 30% of patients continue to have seizures and never achieve a permanent remission with medications. In the United States, the prevalence of intractable epilepsy

cases is 1 to 2 per 1000 population. Such patients should be evaluated at an epilepsy center.

Injuries resulting from seizures are common. Advising patients not to cook, or to use back burners or microwave ovens, can prevent some serious burns. A helmet is advisable for those with drop seizures.

Sudden unexplained death in epilepsy (SUDEP) occurs in 1 per 1000 patients per year, taking all forms of epilepsy together. In the most refractory epilepsies, the SUDEP rate is greater than 1 per 200 patients per year. SUDEP is believed to result from excessive autonomic nervous system sympathetic tone during an unwitnessed seizure with resultant cardiac arrhythmia or pulmonary edema. Suffocation can occur after an unwitnessed convulsion if the patient ends up face down in a pillow. Accidental deaths related to seizures (e.g., motor vehicle collisions) further increase the death rate. Aspiration with convulsions is common but can be prevented by turning the head to one side as the convulsion ends.

Discontinuing Antiepileptic Drugs

Many patients with epilepsy become seizure-free on medication for an extended period of time. Some patients can discontinue AEDs without a relapse. Successful drug withdrawal is most likely if initial seizure control was readily achieved using monotherapy, there were relatively few seizures before remission, and the electroencephalogram and neurologic examination findings are normal just before drugs are tapered off. A seizure-free interval of at least 2 years is important to reduce the likelihood of relapse; some advocate that seizure freedom should be for at least 5 years unless the epilepsy syndrome is known to remit (e.g., CAE or BECTS). Conversely, risk of relapse is high if seizure control was difficult to establish and required polytherapy, if there were frequent convulsions before control was achieved, if a focal abnormality is present on neurologic examination, or if the electroencephalogram demonstrates focal disturbances of background activity or epileptiform activity at the time drug withdrawal is considered.

Prospectus for the Future

- For the past eight decades, new drugs have been developed for epilepsy. This trend should continue, and one to three new AEDs with differing mechanisms of action should become available every 5 years.
- The molecular pathogenesis of some genetic epilepsies has been defined. These still rare disorders will provide insights and targets for novel antiepileptic treatments that correct neuronal dysfunction. The molecular causes of the common epilepsies will be defined.
- Improved imaging techniques will further facilitate cortical localization and selective ablation of the epileptic focus, resulting in more patients becoming seizure-free and returning to normal life.
- Chronically implanted electrodes located at the seizure foci attached to implanted computers will allow direct monitoring of seizures, and treatments (e.g., electrical stimulation, drugs, cooling) delivered directly to the seizure focus without the need for removal of a portion of the brain.

Central Nervous System Tumors

Lisa R. Rogers and Jennifer J. Griggs

Central nervous system (CNS) tumors can produce devastating effects and are often associated with high mortality rates. Even histologically benign tumors may be unresectable and thus incurable because of their location. Some benign tumors transform into higher grade (malignant) tumors over time. Malignant tumors in the brain or spinal cord have the potential for rapid recurrence.

Brain tumors are the second most common cancers in children. The incidence of brain tumors is low in young adults but increases with advancing age and reaches a plateau between the ages of 65 and 79 years. There may be a recent rise in the incidence of primary brain tumors among elderly patients, but such an increase may reflect better detection rather than increasing incidence. The incidence of primary CNS lymphoma is increasing in all age groups, accounted for only in part by lymphoma that occurs in the acquired immunodeficiency syndrome (AIDS).

The cause of most CNS tumors is unknown. With the exception of gliomas associated with vinyl chloride and tumors that occur after CNS irradiation, no environmental agents are known to be causative. There is no definite evidence supporting a viral origin of CNS tumors. Hereditary syndromes associated with an increased risk of CNS tumors, including von Hippel-Lindau disease, tuberous sclerosis, Li-Fraumeni syndrome, and neurofibromatosis, account for less than 1% of primary CNS tumors. Although the chromosomal abnormality associated with many of these syndromes is known, the specific mechanisms leading to CNS neoplasia have not been defined.

Classification

The World Health Organization has classified primary CNS tumors on the basis of cell of origin. Most primary CNS tumors are of neuroepithelial origin and result from neoplastic transformation of astrocytes, ependymocytes, or oligodendrocytes. Astrocytomas are the most common. Overall, brain metastases occurring from a systemic cancer are the most common CNS tumor, but these tumors are often not

resected and are thus under-represented in incidence figures that rely on surgical pathology registries. In a patient with a known systemic malignant disease, metastasis to the CNS is more likely than a primary CNS tumor.

Clinical Manifestations

In general, symptoms caused by intracranial tumors result from one or more of the following: compression of the brain by tumor, vasogenic edema associated with the tumor or tumor cell infiltration, and destruction of brain parenchyma. Because of the uncompromising rigidity of the cranial vault, both histologically benign and malignant tumors may cause symptoms even when they are small. Symptoms caused by primary brain tumors tend to be slowly progressive rather than acute. In contrast, metastatic tumors are more likely to produce acute symptoms because they grow more rapidly and are associated with more edema. Moreover, hemorrhage into metastatic tumors, particularly renal cell cancer, melanoma, lung tumors, and choriocarcinomas, may cause acute neurologic symptoms.

The majority of pediatric brain tumors arise in the posterior fossa, whereas the majority of adult brain tumors arise in the cerebral hemispheres. Therefore the symptoms of brain tumors are very different in these patient populations. Patients with cerebral hemisphere or posterior fossa tumors may have generalized symptoms that arise from increased intracranial pressure or with focal symptoms resulting from specific areas of compromise. Headache is a common generalized neurologic sign of brain tumor and occurs in up to two thirds of patients as a presenting sign. There are no characteristics unique to the headache resulting from a brain tumor, but useful clinical clues are the new onset of headache, a progressively worsening headache, a headache of a different characteristic from prior chronic headaches, or a headache accompanied by new neurologic symptoms or signs. The pain may localize to the side of the tumor in patients with supratentorial tumors; patients with infratentorial tumors frequently describe pain in the retro-orbital,

retroauricular, or occipital region. Other generalized symptoms include changes in mood or personality, a decrease in appetite, and nausea. Projectile vomiting, common in children, is rare in adults. The frequency of seizures depends on the type and location of brain tumor, and seizures occur in 20% to 80% of patients. The occurrence of the first seizure in an adult should prompt an evaluation for a brain tumor.

A careful history and neurologic examination helps in localizing the site of a suspected brain tumor. The focal symptoms depend on the location of the tumor. *Tumors of the frontal lobe* may grow to a massive proportion before symptoms prompt the patient or the patient's family to seek medical help. Progressive difficulty with concentration and memory, personality changes, hemiparesis, and lack of spontaneity may also occur with a frontal lobe tumor. Aphasia (language disturbance) may occur from involvement of the dominant frontal lobe. Urinary incontinence and gait disorder may also appear if the tumor involves both frontal lobes, such as the "butterfly glioma," which crosses the corpus callosum, or multicentric tumors such as lymphoma, or multiple brain metastases. Neurologic examination may show speech, cognitive, or motor abnormalities, and primitive reflexes may be present.

Involvement of the *temporal lobes* by tumor can lead to memory loss, personality changes, auditory hallucinations, and upper quadrantanopia. Speech may also be affected if the involved temporal lobe is in the dominant hemisphere. If tumors are large enough, they can cause herniation of the uncus through the tentorial notch (*uncal herniation*).

Parietal lobe tumors may cause subtle signs or more dramatic findings such as hemianesthesia and hemianopia, typically upper quadrant. Tumors of the right parietal lobe may also manifest with spatial disorientation. *Occipital lobe tumors* may cause a homonymous hemianopia.

Tumors that arise in the posterior *fossa*, such as pediatric medulloblastoma, ependymoma, brainstem glioma, or cerebellar astrocytoma, can cause gait ataxia and cranial nerve dysfunction.

Metastatic spread of primary CNS tumors to sites outside the CNS is exceedingly rare. Spread along the neuraxis to the meninges and spinal cord; however, can occur with a variety of malignant CNS tumors.

Evaluation of the Patient

RADIOGRAPHIC EVALUATION

All patients suspected of having a brain tumor should undergo a contrast-enhanced computed tomography (CT) scan or magnetic resonance imaging (MRI) brain scan. Brain MRI is the preferred test because it is more useful in imaging the temporal and posterior fossae and because it is more sensitive in detecting the extent of parenchymal involvement by tumor. It is important to obtain both fluid-attenuated inversion recovery (FLAIR) and contrast-enhanced MRI sequences. CT scans done without contrast enhancement are not adequate for evaluation of either primary or metastatic tumors. Although there are exceptions, most low-grade brain tumors do not demonstrate enhancement after intravenous contrast injection. Vasogenic edema can accompany any type of brain tumor and is easily visible on FLAIR MRI

sequences. Cerebral angiography is indicated only when an understanding of tumor blood supply is deemed necessary before surgical resection, for example, in patients with a highly vascularized meningioma. 2-fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET), scanning reveals regions of increased glucose metabolism in many malignant tumors. PET scans are also useful in assessing response to treatment and in distinguishing recurrent tumor from radiation necrosis in tumors treated with brain radiation. Research is currently being conducted with advanced MRI sequences, including magnetic resonance spectroscopy and diffusion-weighted MRI, for the diagnosis and monitoring of brain tumors.

HISTOLOGIC DIAGNOSIS

Biopsy, or removal when possible, of a suspected brain tumor is essential in making an accurate tumor histologic diagnosis or in detecting non-neoplastic disease that can mimic a brain tumor, such as a brain abscess. Exceptions to tissue diagnosis include brainstem tumors that show MRI characteristics of a glioma, because there is significant risk associated with biopsy of the brainstem. Tumor tissue may be obtained by open craniotomy or with MRI- or CT-guided stereotactic techniques. Because the histologic features of the tumor may be mixed, small biopsy specimens can be misleading. When the suspicion of a primary brain tumor is high, the tissue diagnosis can be made at the time of surgical resection. This approach yields the greatest amount of tissue for pathologic examination. In up to 10% of patients with brain metastatic tumors, the primary systemic tumor site is not evident and brain biopsy or resection can be helpful in identifying the most likely primary site.

OTHER DIAGNOSTIC TESTS

Lumbar puncture for CSF examination is helpful if the patient is suspected of having leptomeningeal involvement with tumor, as can occur in patients harboring a lymphoma or medulloblastoma. CSF examination may also be indicated if the diagnosis of a brain tumor is in doubt and CNS infection or another condition needs to be excluded. Lumbar puncture is contraindicated when there is significant mass effect from an intracranial lesion, because removing fluid may lead to brain herniation. Electroencephalography is not routinely performed in patients with brain tumors, even if seizures are part of the clinical presentation.

Treatment

SURGICAL RESECTION

Surgical resection is attempted in most patients with primary brain tumors and in many patients with a single brain metastasis. Even when a surgical cure is unlikely, resection of a large portion of the tumor may relieve symptoms. Such "debulking" of primary and metastatic brain tumors also leads to improvement in survival. Extensive tumor resection is not possible in most patients with tumors arising in areas that are critical for neurologic function, such as the brainstem, language or sensorimotor cortex, basal ganglia, or

corpus callosum because of the risk of permanent and debilitating neurologic dysfunction. Newer methods of mapping cortical areas of language, sensory, and motor function during surgery have improved the results of radical resection in some patients. Surgical resection is not recommended for primary CNS lymphoma because these tumors are often multifocal.

ACUTE TREATMENT OF INCREASED INTRACRANIAL PRESSURE

Most patients with parenchymal CNS tumors have vasogenic edema caused by disruption of the blood-brain barrier. This disruption is a result of the invasion of brain vessels by the tumor or to tumor angiogenesis, the vessels of which are embryonic and lack a tight barrier. Such patients usually benefit from the use of glucocorticoids, which reduce edema possibly by stabilization of this barrier. Dexamethasone is the preferred glucocorticoid because of its long half-life. Patients with symptoms related to vasogenic edema often improve within 48 hours of dexamethasone administration. Doses used for treatment of tumor-related edema are typically 4 to 24 mg per day given in divided doses (2 to 4 times daily). Dexamethasone can be given orally because it is well absorbed from the gastrointestinal tract. Because steroids can be associated with a variety of adverse effects, the lowest dose and duration of administration should be sought.

In patients with severe neurologic signs related to brain edema, an intravenous bolus of 10 to 20 mg dexamethasone should be considered. If the neurologic signs are life threatening, including signs of brain herniation, mannitol should be given at a dose of 0.5 to 2.0 g/kg intravenously to reduce intracranial pressure, and dexamethasone should be given concurrently. Neurosurgical consultation should be obtained to determine if emergency surgery is indicated.

ANTICONVULSANTS

Brain tumors can result in focal or generalized seizures at any time in the clinical course. It is routine to administer anticonvulsants to patients before they undergo biopsy or resection of a brain tumor. Aside from the immediate preoperative and postoperative periods, however, prophylactic anticonvulsants are not indicated for those patients who do not have seizures. Chronic administration of anticonvulsants is indicated in any brain tumor patient suspected or proven to have a seizure. There are important interactions between anticonvulsants and other medications often used by brain tumor patients, such as steroids and chemotherapy, and these interactions must be considered when selecting an anticonvulsant.

RADIATION THERAPY

Brain radiation therapy is commonly delivered by one of three methods: external beam (conventional) radiation therapy, brachytherapy, or radiosurgery. *External beam radiation therapy* uses x-ray beams directed either at the whole brain or to the focal area involved by tumor. Such treatments are typically given over 2 to 6 weeks, depending on the type of tumor. *Brachytherapy* involves the implantation of either permanent or temporary radiation seeds within the tumor.

This approach allows higher than standard doses of radiation therapy to be delivered to the tumor while the surrounding normal tissue is protected. The third approach, *radiosurgery*, involves convergence of multiple radiation beams on a small, well-defined target, the brain tumor. With radiosurgery the dose of radiation to normal brain is minimal. Radiosurgery is typically used for treating small tumors that are not surgically accessible and is ideal for acoustic neuromas and other small tumors that arise adjacent to critical brain structures.

CHEMOTHERAPY

Chemotherapy is rarely used as the sole therapy for primary CNS neoplasms. Exceptions are primary CNS lymphoma, for which high-dose chemotherapy has recently been proven to be very effective, and brain tumors in very young children, in whom chemotherapy is given and brain and spinal radiation is delayed or not given. In other tumors, chemotherapy is typically administered during or after CNS radiation. The major obstacle to the effective use of chemotherapy in most tumors is the blood-brain barrier, which limits the passage of many drugs. Although the barrier is often disrupted by the tumor, the surrounding intact barrier, which often harbors microscopic tumor, limits penetration of the chemotherapy. This leads to tumor regrowth at the margins of the tumor. Attempts to overcome the blood-brain barrier by giving intra-arterial chemotherapy have not shown an advantage over standard intravenous administration. In addition, CNS tumors can be drug resistant, limiting the effectiveness of chemotherapy. Temozolomide, an oral agent, has been shown to be effective in patients with malignant gliomas and is well tolerated. Anaplastic oligodendrogliomas, an uncommon type of malignant glioma, are often unusually sensitive to chemotherapy.

Specific Tumors

MALIGNANT GLIOMA

The term *malignant glioma* refers to a group of heterogeneous tumors and includes glioblastoma multiforme, anaplastic astrocytoma, and anaplastic oligodendroglioma. Some gliomas have histologic features of both astrocytoma and oligodendroglioma (mixed glioma). Of the malignant gliomas, *glioblastoma multiforme* has the worst prognosis; survival beyond 2 years is unusual. Surgical resection, radiation therapy, and chemotherapy are combined to improve symptoms and quality of life. A number of clinical factors, including patient age, the degree of surgical resection, and performance status affect survival. When disease relapse occurs, additional surgical resection, a change of chemotherapy, or use of molecularly targeted agents may be of short-term benefit.

In contrast, *anaplastic astrocytomas* and *anaplastic oligodendrogliomas* are associated with more favorable median survival times. Patients with anaplastic oligodendrogliomas typically benefit the most from chemotherapy or radiation. An important biologic correlate in the anaplastic oligodendroglioma is the status of the 1p and 19q chromosomes within the tumor tissue.

LOW-GRADE GLIOMA

Low-grade gliomas include *astrocytoma*, *oligodendroglioma*, and *ependymoma*. These tumors are more common in young patients, and the outcome is more favorable than in the malignant gliomas.

PRIMITIVE NEUROECTODERMAL TUMOR

Medulloblastoma is the most common form of a primitive neuroectodermal tumor. It typically arises in the midline of the cerebellum in children. It can be difficult to diagnose on clinical grounds because a child cannot describe the symptoms resulting from posterior fossa mass effect. Treatment involves surgical resection, radiation, and chemotherapy.

MENINGIOMA

Meningiomas arise from the meningeal lining surrounding the brain or spinal cord and generally grow slowly; they may also be found incidentally during the evaluation of unrelated neurologic symptoms. They often arise along the dorsal surface of the brain, falx cerebri, sphenoid ridge, or base of the skull or within the lateral ventricles. Most meningiomas are histologically benign.

Complete resection of meningiomas should be attempted, as the risk of recurrent disease is proportionate to the extent of resection. For example, the risk of recurrent disease in the subsequent two decades is close to 20% in patients who do not have complete resection or coagulation of dural attachments. In these patients, and in those who have only partial resection of the tumor itself, postoperative radiation therapy may be considered. In the patient with malignant meningioma, radiation therapy should be recommended regardless of the extent of resection. There is no definitive role for chemotherapy in the treatment of meningiomas.

CENTRAL NERVOUS SYSTEM LYMPHOMA

Primary CNS lymphomas are increasing in incidence among both immunocompromised and immunocompetent people. By definition, a patient with primary CNS lymphoma has no evidence of lymphoma outside the CNS. These tumors most often arise deep within the brain and are therefore less likely to manifest with seizures than are other primary or metastatic CNS neoplasms. Headache, personality changes, and focal symptoms corresponding to the location of the tumor are the usual presenting complaints. Lymphoma is multifocal at the time of diagnosis in 40% of immunocompetent patients and close to 100% of patients with AIDS. Many patients have neoplastic involvement of the leptomeninges, but such involvement is rarely symptomatic. Up to 20% of patients will also have lymphomatous involvement of the eye, and a small percentage of these patients develop eye involvement before the diagnosis of the brain tumor.

Treatment of primary CNS lymphomas requires first that the correct diagnosis be made. Because the disease is often multifocal, it may be confused with metastatic disease from a solid tumor. Symptoms often improve with corticosteroids because of the cytotoxic effects of steroids on lymphoma

cells. However, administration of steroids before brain biopsy should be discouraged, as the prompt resolution of tumor reduces the yield of tissue biopsy. Surgical biopsy, but not resection, is the recommended method for diagnosis. The treatment for this tumor is currently evolving as new treatments emerge. It responds well to whole brain radiation as well as to high-dose chemotherapy, in particular methotrexate. Specific treatment should be based on patient age, performance status, and other variables.

METASTATIC TUMORS TO THE BRAIN

Most brain tumors are metastatic from cancer elsewhere in the body; typically those arising in the lung, breast, colon, or skin (melanoma), but nearly any solid tumor can metastasize to the CNS. Patients have headache, seizures, and focal symptoms reflecting the areas of involvement. Brain metastases are usually multiple. Single lesions are termed *solitary* if there is no other site of active disease in the body.

Treatment of metastases usually begins with corticosteroids to reduce edema and thus improve neurologic symptoms. Surgical resection is indicated for selected patients with a single brain metastasis when it is resectable, when the systemic cancer is well controlled, and when the patient is functioning well physically. In addition, resection or at least biopsy is indicated if there is no known site of systemic cancer and a brain metastasis is suspected. Most surgical patients are also treated with whole brain radiation therapy, as are those patients with multiple brain metastases. Because most chemotherapeutic agents do not cross the blood-brain barrier, the CNS is considered a sanctuary site for the development of metastasis when systemic cancer is treated. When CNS metastases grow and disrupt the blood-brain barrier, however, the chemotherapy may be more effective, and a variety of agents are currently being studied. Stereotactic radiosurgery is also an option for some patients with a limited number of brain metastases.

SPINAL CORD TUMORS

Much less common than tumors of the brain, spinal cord tumors are described as *extradural* (outside of the dural sac) or *intradural*. Most extradural tumors result from extension of vertebral metastasis from other sites, typically lung, breast, and prostate cancers. Intradural tumors are further described as either *extramedullary* (arising outside the spinal cord) or *intramedullary* (arising within the spinal cord). Examples of intradural extramedullary tumors are schwannomas and meningiomas. Ependymomas and astrocytomas are the most common intramedullary tumors. The most common location for spinal tumors is the thoracic region.

Patients with extradural or intradural extramedullary spinal cord tumors develop symptoms as a result of compression of normal structures by the tumor or impairment of the vascular supply, rather than by tumor invasion of the spinal cord parenchyma. Back pain and distal paresthesias in the legs are among the earliest symptoms, followed by loss of sensation and weakness below the level of the tumor and loss of bowel and bladder control.

MRI is the most useful test to evaluate the patient with suspected spinal cord tumor. Unless there is a contraindication to MRI, it has replaced myelography in most cases.

In patients with progressing deficits, urgent evaluation and treatment are indicated. High doses of intravenous corticosteroids are indicated to reduce spinal cord edema. Surgical resection of extradural tumor followed by local radiation therapy or radiation therapy alone are the treatments of choice, depending on a variety of clinical factors. Surgery for biopsy is indicated if there is no known cancer.

Treatment of intradural intramedullary or extramedullary primary spinal tumors is with surgical resection, when possible. In many patients, however, resection carries an unacceptable risk of neurologic damage, and biopsy alone is performed to establish the diagnosis. Most patients require spinal radiation for definitive treatment.

Prospectus for the Future

For patients with high-grade gliomas, such as glioblastoma, there is recent promising evidence that agents that target tumor growth factors, such as vascular endothelial growth factor, may play an important role in therapy. Clinical trials of these agents with standard radiation and chemotherapy are ongoing. In many cancers, including brain tumors, a molecular “signature” can now be obtained from the tumor tissue resected at surgery (Cancer Genome Atlas project). This signature predicts which therapies, including chemotherapies and agents targeting growth factors, will be most effective.

An exciting new concept in our understanding of cancer is that a population of tumor stem cells may be responsible for tumor initiation and self-renewal. These cells are typically not damaged by radiation or chemotherapy. Research is ongoing to determine if these tumor stem cells underlie the failure to eradicate tumors with current therapies. The pathways underlying tumor stem cell growth have been identified in high-grade gliomas and in medulloblastomas. Drugs targeting the tumor stem cell population in these tumors are in early clinical trials.

Infectious Diseases of the Nervous System

Avindra Nath

This chapter focuses on central nervous system (CNS) infections that manifest as abscesses within the parenchyma itself or as parameningeal infections. A category of infections with clinical signs confined to the brain and spinal cord—prion diseases—is also discussed.

Brain Abscess

Brain abscesses produce symptoms and findings similar to those of other space-occupying lesions, such as brain tumors, but often progress more rapidly and affect meningeal structures more frequently than tumors. They originate or extend from extracerebral locations, resulting from (1) blood-borne metastases from unknown sources, lungs, or heart, and (2) direct extension from parameningeal sites of infection (otitis, cranial osteomyelitis, and sinusitis), sites of recent or remote head trauma or neurosurgical procedures, and infections associated with cyanotic congenital heart disease. Commonly isolated pathogens are aerobic and microaerobic streptococci and gram-negative anaerobes, such as *Bacteroides* and *Prevotella*. Less common are gram-negative aerobes and *Staphylococcus*. *Actinomyces*, *Nocardia*, and *Candida* are less frequently found. Infection may be polymicrobial. Culture-negative abscesses from surgical specimens occur in 30% of antibiotic-treated patients and in 5% of patients undergoing surgery before antibiotic administration.

DIAGNOSIS

The classical clinical picture is composed of a triad of elements: those reflecting the infectious nature of the lesion (e.g., fever), those related to focal brain involvement, and those caused by increasing intracranial mass effect. Elements of one or two categories are often absent in a given case, particularly early in the course. For example, nearly one half of patients may not have a fever or leukocytosis. Recent onset of a headache is the most common symptom; headache may increase in severity and may be associated with

focal signs related to the location of the abscess (e.g., hemiparesis or aphasia, followed by obtundation and coma). Seizures precede diagnosis in 30%. Toxoplasma abscesses are often associated with movement disorders because of their propensity for the basal ganglia. The period of evolution may be as brief as hours or as long as days to weeks with more indolent organisms. Cerebrospinal fluid (CSF) examination should be avoided. It is seldom diagnostic, and CSF can be normal. Lumbar puncture in the setting of a mass lesion carries the risk of aggravating an impending transtentorial herniation.

Magnetic resonance imaging (MRI) provides better soft tissue contrast than computed tomography (CT) and is particularly useful for detecting multiple and posterior fossa abscesses, with intravenous gadolinium contrast, or for demonstrating cerebritis, the extent of mass effect, associated venous thrombosis, and the response to therapy. In the early cerebritis stage, although CT scans may be normal, the fluid-attenuated inversion recovery (FLAIR) sequence of MRI is very sensitive for visualization of brain edema. On T1-weighted images, the area of cerebritis is seen initially as a low-signal intensity, ill-defined area. Later stages of infection are noted by the formation of a rim of slightly high signal intensity on T1-weighted images and central necrosis. This area of central necrosis appears bright on diffusion-weighted images (DWI) and dark on apparent diffusion coefficient (ADC) images, which helps differentiate it from tumors, which show the opposite features (Fig. 128-1). That distinction (i.e., brain abscess from tumor) is important for the stereotactic approach to ring-enhancing lesions before biopsy or surgical excision. An abscess is best drained centrally, whereas a tumor is best biopsied along its rim. Other neuroimaging techniques, such as perfusion imaging, MR spectroscopy, and positron emission tomography have limited use in differentiation of brain abscesses from tumors.

TREATMENT

A suspected brain abscess requires urgent intervention. Unless the surgical procedure poses a substantial risk,

Figure 128-1 Magnetic resonance imaging features of a brain abscess. **A**, Contrast-enhanced scan shows ring-enhancing lesion in the left frontal lobe. **B**, The diffusion-weighted image shows restricted diffusion in the cavity resulting from viscous pus and cellular material. **C**, Corresponding apparent diffusion coefficient map shows dark viscous material in the cavity and surrounding edema.

aspiration of the lesion is needed for microbial diagnosis. If antiedema measures are necessary, intravenous dexamethasone in high dosages may be used (16 to 24 mg/day in four divided dosages) for short periods of time until surgical intervention is possible, because it may retard the formation of the capsule and also cause immunosuppression. Proper control of seizures is critical because the tonic phase of a generalized seizure may increase intracranial pressure. In a patient with a large abscess, seizures may trigger a brain herniation. Therefore seizure prophylaxis should be initiated in all patients with cortical or temporal lobe abscesses. Anticonvulsants that can be administered intravenously are the drugs of choice.

Successful antibiotic management of brain abscess is based on knowledge of proved or suspected pathogens together with familiarity with the properties of the antibiotic armamentarium. CNS drug penetration capabilities as well as antibiotic spectrum of activity are important considerations. Empirical antibiotic therapy without surgical intervention may be used if the primary source of infection outside of the CNS is identified or in patients with cerebritis without capsule formation and those with multiple small abscesses or abscesses in basal ganglia or brainstem. If the organism is unknown, empirical therapy may include vancomycin, metronidazole, and a third-generation cephalosporin. In brainstem abscesses, the possibility of *Listeria* infection should be considered and treatment should include intravenous ampicillin. In human immunodeficiency virus (HIV)-infected patients with multiple ring-enhancing lesions, empirical therapy for toxoplasmosis should be initiated even if the patient is seronegative for toxoplasma. Whenever empirical therapy is undertaken, the patient needs to be followed by repeat CT or MRI scanning. Those patients who fail to respond should undergo surgical intervention. An important aspect of the management strategy is the

eradication of the predisposing condition or cause of the brain abscess such as an oral, ear, cardiac, or pulmonary infection.

Parameningeal infections include those that produce supuration in potential spaces covering the brain and spinal cord (epidural abscess and subdural empyema) and those that produce occlusion of the contiguous venous sinuses and cerebral veins (cerebral venous sinus thrombosis).

Subdural Empyema

Subdural empyema refers to infection in the space separating the dura and arachnoid. Two thirds of subdural empyemas originate from the frontal or ethmoid sinuses, 20% from inner ear infections, and the rest from trauma or neurosurgical procedures. The empyema results from direct or indirect extension from infected paranasal sinuses through a retrograde thrombophlebitis. Unilateral empyema is most common because the falx prevents passage across the midline, but bilateral or multiple empyemas can occur. Cortical venous thrombosis or brain abscess develops in about one fourth of patients. In some patients the subdural empyema may be associated with an epidural abscess or meningitis. These infections occur more often in children than in adults.

Initial symptoms are caused by chronic otitis or sinusitis, on which lateralized headache, fever, and obtundation become superimposed. Vomiting, meningeal signs, and focal neurologic abnormalities (hemiparesis or seizures) follow. If untreated, obtundation progresses and the septic mass and swollen underlying brain lead to venous thrombosis or death from herniation. The major differential diagnosis is that of meningitis. Nuchal rigidity and obtundation occur in both, but papilledema and lateralizing deficits are

Figure 128-2 Epidural abscess caused by staphylococcus in the cervical spine in a patient with human immunodeficiency virus (HIV) infection. **A**, Noncontrast T1-weighted image shows an extensive lesion in the epidural space extending from C2 to C7. Note also straightening of the cervical spine. **B**, After laminectomy from C2 to T1 with fusion, this short T1 inversion recovery (STIR) image shows fluid collection in the epidural space as a high-signal intensity lesion. Normal curvature of the spine is seen.

more common in empyema. Lumbar puncture should be avoided in patients with subdural empyema to prevent cerebral herniation. Contrast-enhanced CT or MRI can be diagnostic of empyema, showing an extra-axial, crescent-shaped mass with an enhancing rim lying just below the inner table of the skull over the cerebral convexities or in the interhemispheric fissures. On MRI, subdural empyemas have decreased signal on T1-weighted imaging and increased signal on T2-weighted scans. Similar to brain abscess, subdural empyema has a high signal intensity on DWI and a low signal intensity on ADC maps. Treatment requires both prompt surgical drainage of the empyema cavity and high-dose intravenous antibiotics directed toward organisms found at the time of craniotomy.

Malignant External Otitis

Malignant (necrotizing) external otitis occurs commonly in older patients with diabetes or in any immunosuppressed patient. It is often caused by *Pseudomonas aeruginosa*. It progresses rapidly, with ear pain, facial swelling, osteomyelitis of the base of the skull, dural sinus thrombosis, and purulent meningitis. Multiple cranial nerve palsies, most often facial and auditory, occur because of their proximity to the external ear canal. CT scan may identify bony erosion, and MRI scan shows soft tissue changes and dural enhancement. Urgent treatment is essential: an antipseudomonal penicillin or a third-generation cephalosporin combined with an aminoglycoside or ciprofloxacin, as well as surgical débridement and drainage. If the condition is untreated, the mortality rate is high. Patients with an inadequate response to antibiotic therapy should undergo biopsy for investigation of possible malignancy.

Spinal Epidural Abscess

Infection within the epidural space around the spinal cord can cause paralysis and death. Its incidence is 0.5 to 1.0 per 10,000 hospital admissions in the United States; the frequency is increased in intravenous drug users. The classical triad of fever, spinal pain, and neurologic deficits may not be present in all patients, leading to a delay in diagnosis. Patients are usually febrile and have acute or subacute neck or back pain, with focal percussion tenderness being a prominent sign; stiff neck and headache are common. The pain can be mistaken for sciatica, a visceral abdominal process, chest wall pain, or cervical disk disease. If the infection goes unrecognized at this stage, the symptoms can rapidly evolve, over a few hours to a few days, to produce weakness and finally paralysis distal to the spinal level of the infection. In this clinical setting, spinal epidural abscess should be assumed, systemic antibiotics begun, and urgent neuroradiologic imaging pursued. The differential diagnosis includes compressive and inflammatory processes involving the spinal cord (transverse myelitis, intervertebral disk herniation, epidural hemorrhage, and metastatic tumor), which can usually be detected by MRI (Fig. 128-2). Epidural abscess may be accompanied by diskitis or osteomyelitis of the vertebral bodies.

PATHOPHYSIOLOGIC FACTORS

Infections of the epidural space originate from contiguous spread or through hematogenous routes from a distant source. Cutaneous infection is the most common remote source, especially in intravenous drug users. Abdominal, respiratory tract, and urinary sources are also common. As the use of epidural catheters is increasing for pain

management, epidural abscess and hematoma are also being increasingly reported. The anatomy of the epidural space dictates the location of the abscess. Because the size of the intravertebral canal remains relatively constant whereas the circumference of the spinal cord changes, abscess formation is maximal in the thoracic and lumbar regions and minimal at the cervical spine enlargement.

BACTERIOLOGIC FACTORS

Causative organisms can be identified by culture or Gram stain from pus obtained at exploration (90% of patients), blood cultures (60% to 90% of patients), or CSF (20% of patients). *Staphylococcus aureus* is most common, followed by streptococci and gram-negative anaerobes. Tuberculous abscesses represent as many as 25% of patients in high-risk populations.

TREATMENT

Unless culture and sensitivities dictate otherwise, penicillinase-resistant penicillin should be started empirically as antistaphylococcal treatment for presumed bacterial infection. If methicillin resistance is suspected, vancomycin should be used. Considering the severity of the disease, additional gram-negative coverage with a third-generation cephalosporin or a quinolone may be needed. Surgical decompression was considered mandatory; now, early diagnosis by MRI allows for effective medical therapy alone if started before the occurrence of neurologic complications. Affected patients should be monitored closely; if signs of neurologic deterioration emerge, surgical intervention may be necessary.

Septic Cavernous Sinus Thrombosis

Septic cavernous sinus thrombosis usually occurs as a result of spread of infection from facial structures via facial veins or from the sphenoid or ethmoid sinuses. Symptoms include headache or lateralized facial pain, followed in a few days to weeks by fever and involvement of the orbit, which produces proptosis and chemosis secondary to obstruction of the ophthalmic vein. Paralysis of oculomotor nerves follows rapidly. In some instances, sensory dysfunction occurs in the first and second divisions of the trigeminal nerve and a decrease develops in the corneal reflex. Further involvement of the contiguous orbital contents follows, with mild papilledema and decreased visual acuity, sometimes progressing to blindness. Extension to the opposite cavernous sinus or to other intracranial sinuses with cerebral infarction or increased intracranial pressure secondary to impaired venous drainage can result in stupor, coma, and death. The CSF is abnormal if there is accompanying meningitis or parameningeal infection. The most common causative organism is *S. aureus*, followed by streptococci and pneumococci; anaerobic infection may occur. Diagnosis of cavernous sinus thrombosis is usually made with MRI scan with venogram. Radiologic evaluation includes imaging of the sphenoidal and ethmoidal sinuses, which if infected may require drainage. Empirical antimicrobial therapy should

include an antistaphylococcal agent. Empirical combination therapy with parenteral metronidazole, vancomycin, and ceftriaxone will achieve reasonable CSF and brain penetration and is likely to be active against *S. aureus* as well as the usual sinus pathogens. Parenteral flucloxacillin or dicloxacillin can be added if *S. aureus* infection is strongly suspected, as penicillins have better bactericidal effects than vancomycin for methicillin-susceptible strains of *S. aureus*.

Lateral Sinus Thrombosis

Septic thrombosis of the lateral sinus results from acute or chronic infections of the middle ear and spreads via emissary veins that connect the mastoid with the lateral venous sinus. It may spread to involve the sigmoid sinus. The symptoms include ear pain followed over several weeks by fever, headache, nausea, vomiting, and vertigo. Mastoid swelling may be seen. Sixth cranial nerve palsies and papilledema can occur, but other focal neurologic signs are rare. The diagnosis can be established by MR angiography. Treatment includes empirical broad-spectrum intravenous antibiotics to cover staphylococci and anaerobes (nafcillin or oxacillin with penicillin or metronidazole), but surgical drainage (mastoidectomy) may be required.

Septic Sagittal Sinus Thrombosis

Septic sagittal sinus thrombosis is uncommon and occurs as a consequence of purulent meningitis, infections of the ethmoidal or maxillary sinuses spreading through venous channels, infected compound skull fractures, or, rarely, neurosurgical wound infections. Symptoms include manifestations of elevated intracranial pressure (headache, nausea, and vomiting) that evolve rapidly to stupor and coma. Diagnosis and treatment are similar to those for lateral venous sinus thrombosis, described earlier.

Neurologic Complications of Infectious Endocarditis

Neurologic complications occur in one third of patients with bacterial endocarditis and triple the mortality rate of the disease. Most of these complications derive from valvular vegetations. Cerebral (but not systemic) emboli are increasingly common from mitral valve endocarditis. Most emboli, regardless of the bacterial cause of the infection, occur before or early in the course of treatment. By 2 weeks of therapy, the risk of embolization decreases dramatically. Cerebral emboli are distributed in the brain in proportion to cerebral blood flow. Therefore most emboli lodge in the branches of the middle cerebral artery peripherally, with resultant hemiparesis. Focal seizures may result.

Mycotic aneurysms complicate endocarditis in 2% to 10% of patients and are more common in acute than subacute disease. The middle cerebral artery is most commonly involved, with the aneurysms being located distally in the vessel, differentiating them from congenital berry aneurysms. Multidetector CT angiography may be necessary

to diagnose these aneurysms. Small brain abscesses may complicate the course of endocarditis, but macroscopic abscesses are rare, with most occurring in the setting of acute, rather than subacute, endocarditis. Multiple microabscesses, however, can result in a diffuse encephalopathy similar to that seen in sepsis. Such lesions may escape detection on CT scan and are not amenable to surgical drainage. Antibiotic treatment of the primary disease is indicated. The CSF is abnormal in 70% of patients and simulates that seen in purulent meningitis (polymorphonuclear predominance, elevated protein level, and low glucose level) or a parameningeal infection (lymphocytic predominance, modest protein elevation, and normal glucose level). Endovascular treatment of infectious aneurysms is possible, but endovascular coiling may not prevent hemorrhage associated with panvasculitic rupture of a new aneurysm. Patients with infectious endocarditis who do not respond to conservative medical therapy can have prompt valve surgery after endovascular treatment despite the presence of intracerebral hemorrhage.

Prion Diseases

Several human diseases have been attributed to a unique infectious protein—the prion. The infectious form of prion protein is rich in beta-sheets and is detergent-insoluble, multimeric, and resistant to proteinase K treatment. Prion illnesses (transmissible spongiform encephalopathies) can be classified as sporadic, hereditary, or acquired. The most common form is sporadic Creutzfeldt-Jakob disease (CJD). Familial forms include Gerstmann-Sträussler-Scheinker syndrome, and familial fatal insomnia. Acquired forms are caused by the transmission of abnormal prion protein (PrP) from human to human or from cattle to human. Accidental transmission of CJD from human to human appears to have

occurred with cadaveric dura mater grafts, corneal transplantation, receipt of human growth hormone or pituitary gonadotropin, contaminated electroencephalogram (EEG) electrodes, and contaminated surgical instruments. The appearance of variant CJD in Great Britain, in association with the outbreak of bovine spongiform encephalopathy and the contamination of beef, has greatly increased interest in this group of illnesses. Kuru is another transmissible spongiform encephalopathy that was spread in New Guinea by cannibalism, the practice of which ceased in the 1950s. This disease is now nearly extinct.

SPORADIC CREUTZFELDT-JAKOB DISEASE

Illness from CJD is seen worldwide, with an incidence of 0.5 to 1.0 cases per 1 million population per year. CJD is frequently diagnosed incorrectly initially. Prodromal symptoms include altered sleep patterns and appetite, weight loss, changes in sexual drive, and impaired memory and concentration. Disorientation, hallucinations, depression, and emotional lability are early signs, followed by a rapidly progressive dementia associated with myoclonus (approximately 90% of patients). Myoclonus is generally provoked by tactile, auditory, or visual startle stimuli. CJD has an abrupt onset in 10% to 15% of patients. Other distinctive presentations include seizures, autonomic dysfunction, and lower motor neuron disease suggesting amyotrophic lateral sclerosis. Cerebellar ataxia occurs in one third of patients. Atypical presentations, such as with pure ataxia or visual phenomena (the so-called Heidenhain variant), may go initially undiagnosed.

The clinical tetrad supporting the diagnosis of CJD consists of a subacute progressive dementia, myoclonus, typical periodic complexes on EEG, and normal CSF. FLAIR imaging sequences on MRI show extensive curvilinear

Figure 128-3 Magnetic resonance imaging (MRI) scan of a patient with pathologically proven Creutzfeldt-Jakob disease. **A**, An axial fluid-attenuated inversion recovery (FLAIR) image is relatively normal, but corresponding **(B)** diffusion-weighted scan shows high signal intensity in the cortical ribbon, most prominent in the frontal regions as well as the caudate nucleus.

hyperintensity along the neocortex, termed *cortical ribboning*, affecting frontal, parietal, and temporal lobes, in decreasing order of frequency. Nearly 90% of CJD FLAIR sequences show cortical ribboning to some extent, with a clear majority of cases also showing involvement of the limbic cortex, striatum, and thalamus. The pattern of extensive increased neocortical and/or striatal FLAIR signal and DWI abnormality has a diagnostic accuracy for CJD approaching 95% (Fig. 128-3). A characteristic “pulvinar sign” has been described, denoting a “hockey stick” distribution of hyperintensity in the posteromedial thalamus. Bilateral presence of this sign reliably allows diagnosis of vCJD. Routine CSF study is generally normal. A CSF test for the protein 14-3-3, in the appropriate clinical context, is highly specific and sensitive

for CJD. No effective therapy has been developed. The disease is inexorably progressive. The median time to death from onset is 5 months, and 90% of patients with sporadic CJD die within 1 year. The pathogenic isoform of prion protein can be demonstrated in brain by immunocytochemical staining and by Western-blot analysis.

Although the illness is not communicable in the conventional sense, a risk exists in handling materials contaminated with the prion protein. Gloves should be worn during handling of blood, CSF, and other body fluids. Instruments must be disinfected by steam autoclaving for 1 hour at 132° C, by steam autoclaving for 4.5 hours at 121° C (1.5 psi), or by immersion in 1 N sodium hydroxide for 1 hour at room temperature.

Prospectus for the Future

Major progress continues to be made in magnetic resonance imaging with seven tesla magnets now being available for human imaging and new sequence techniques that are capable of differentiating between blood, necrosis, and pyogenic lesions with great precision and sensitivity. These techniques are expected to greatly advance the diagnosis of CNS infections and the monitoring of treatment. Molecular biological techniques currently lack the sensitivity in detection of non-viral

pathogens in CSF. Hence, further research is needed to advance these diagnostic methods. Advances in surgical techniques, such as minimally invasive laparoscopic techniques are expected to help in evacuation of deep-seated abscesses. However, substantial effort is necessary to develop new antimicrobial agents that penetrate the CNS. Similarly, there are no available drugs for treatment of many viral pathogens and prions, which requires investment of resources for drug development.

Demyelinating and Inflammatory Disorders

Joanne Lynn

Demyelination is a process of injury to myelin of the central nervous system (CNS) or the peripheral nervous system. Diseases of peripheral nervous system myelin are discussed in Chapter 130. Demyelinating diseases of the CNS include acquired and hereditary (referred to as *dysmyelinating*) disorders. The acquired inflammatory demyelinating disorders of the CNS include multiple sclerosis (MS), neuromyelitis optica (NMO), transverse myelitis (TM), optic neuritis, and acute disseminated encephalomyelitis. Table 129-1 lists common disorders of CNS myelin.

Multiple Sclerosis

MS is the most common acquired inflammatory demyelinating disease of the CNS and affects 2.5 million people worldwide with a predominance in women (female:male ratio is 2:1). The prevalence generally increases with distance from the equator and varies from 5 to 119 per 100,000 people in the United States. Onset commonly occurs from age 15 to 50 years. The course is highly variable but for 85% of patients begins with discrete episodes of neurologic dysfunction termed *relapses* that are initially largely reversible and separated by periods of stability or remission. This course is termed *relapsing-remitting*. In many patients the course eventually advances to a steady irreversible progression termed *secondary progressive MS*. Approximately 10% to 15% of patients have a *primary progressive* course, with progressive myelopathy or ataxia without discrete relapses (PPMS). Patients who experience a single episode of CNS demyelination are said to have a clinically isolated syndrome (CIS), and a subset at particularly high risk to subsequently develop MS may be identified by the presence of asymptomatic white matter lesions on brain magnetic resonance imaging (MRI).

ETIOLOGY

The cause remains unknown. Although evidence suggests that MS is an autoimmune disease triggered by environmen-

tal factors, a specific auto-antigen has not been identified. Genetic risk factors have been implicated by familial aggregation and high prevalence in some ethnic populations. MS is a complex genetic disease, with the interaction of genetic and environmental factors contributing to susceptibility and expression. Latitude-based differences in prevalence suggest that the disorder may be the result of a variety of possible factors including immune dysregulation incited by a regional pathogen in a susceptible population, relative lack of sunlight, or decreased vitamin D.

PATHOLOGY

Demyelination in MS occurs in perivenular extensions preferentially in the periventricular areas, termed “Dawson’s fingers.” Entry of immune cells from the vasculature into the brain is facilitated by the specific interaction of lymphocytic molecule VLA-4 with its vascular endothelium ligand, VCAM. After diapedesis through the endothelium and dissolution of the basement membrane, these mononuclear cells migrate to the brain parenchyma. The majority of cells are macrophages and resident microglia, but there are also T, B, and natural killer (NK) cells. T cells, particularly Th1 and Th17 lymphocytes and their cytokines, are considered pivotal in the induction of inflammation that precedes all acute exacerbations of MS and causes demyelination and irreversible axonal injury. After repeated attacks, loss of brain parenchyma and brain atrophy occur. CD8 cells are present in MS lesions, but their role in mediating injury is only beginning to be understood. B cells present in well-formed lymphoid follicles in the brain and meninges secrete immunoglobulins, which may be important in antibody- and complement-mediated injury and are also responsible for the presence of the oligoclonal bands in the CSF. Th2 cells are anti-inflammatory and probably abrogate inflammation and induce clinical remissions. Accordingly, immunomodulatory therapies attempt to modify the immune response from a Th1 state to the more desirable Th2 state.

Table 129-1 Demyelinating Disorders

Multiple sclerosis (MS)
Neuromyelitis optica (Devic disease, NMO)
Clinically isolated syndromes
Optic neuritis
Acute transverse myelitis (TM)
Brainstem demyelination
Acute disseminated encephalomyelitis
Viral infections
Human immunodeficiency virus 1 (HIV-1)-associated myelopathy
Progressive multifocal leukoencephalopathy
Subacute sclerosing panencephalitis
Toxic demyelination
Chemotherapy-related leukoencephalopathy
Radiation leukoencephalopathy
Nutritional or metabolic disorders
Subacute combined degeneration (vitamin B ₁₂ deficiency)
Demyelination of the corpus callosum (Marchiafava-Bignami disease)
Central pontine myelinolysis
Vascular or ischemic disorders
Leukodystrophies

CLINICAL AND LABORATORY DIAGNOSIS

Relapses are manifested as the subacute development of one or often multiple symptoms or signs of neurologic dysfunction referable to the CNS (Table 129-2). The diagnosis is based on the demonstration of dissemination of disease in time (multiple clinical events) and space (multiple sites of involvement) and the exclusion of other neurologic disorders. The 2005 revision of the McDonald Criteria (Table 129-3) for diagnosis of relapsing-remitting MS uses the clinical history, neurologic examination, MRI, evoked responses, and abnormalities in the cerebrospinal fluid to establish the occurrence of lesions in the brain disseminated in time and space.

Magnetic Resonance Imaging

MRI generates image contrast based on the spin resonance properties of protons and is the single best laboratory technique to demonstrate demyelination in the CNS because of its ability to show the contrast between normal myelin and MS lesions. The most abundant source of protons in the brain is water, and water content of an area of demyelination is always higher than that of normal myelin, which is hydrophobic because of its high lipid content.

Lesions of MS are best seen on T2 and T2-FLAIR (fluid-attenuated inversion recovery) sequences. Lesions often assume an ovoid shape and preferentially occur at right angles to the lateral walls of the lateral ventricles and the corpus callosum. Although T1 sequences detect fewer lesions than T2, the presence of hypointensities on T1 images (“black holes”) indicates underlying axonal loss and greater severity of disease. Enhancement after intravenous administration of gadolinium is helpful in detection of lesions where a breach of the blood-brain barrier has occurred within the previous 6 weeks because of active disease (Fig. 129-1).

Table 129-2 Common Symptoms and Signs of Multiple Sclerosis

Symptoms
Numbness, paresthesias
Weakness
Muscle spasms and tightness
Fatigue
Monocular visual impairment
Diplopia
Decreased balance
Vertigo
Urinary dysfunction
Depression
Cognitive impairment
Signs
Sensory deficits
Spasticity
Extensor plantar responses
Optic atrophy
Deafferent papillary defect
Visual field defects
Internuclear ophthalmoplegia
Nystagmus
Tremor
Abnormal affect
Absent abdominal reflexes
Sensory deficits, paresthesias
Weakness
Monocular central scotoma, optic atrophy, afferent papillary defect
Lhermitte phenomenon
Eye movements: diplopia, internuclear ophthalmoplegia, nystagmus
Vertigo
Ataxia, dysmetria or intention tremor, dysarthria
Fatigue
Neurogenic bladder and bowel dysfunction
Sexual dysfunction
Depression
Cognitive impairment
Uhthoff phenomenon: neurologic deficits worsened by fever, heat neuropathic pain

Cerebrospinal Fluid

Cerebrospinal fluid cell count, total protein, and glucose are usually normal. A slight mononuclear pleocytosis or elevation in protein may occur rarely during exacerbations. The typical CSF abnormality in MS is evidence of increased intrathecal synthesis of immunoglobulin G (IgG), indicated by an elevated IgG index (calculated from CSF and serum IgG and albumin) or the presence of oligoclonal IgG bands on isoelectric focusing (Fig. 129-2).

Visual Evoked Potentials

Evoked potentials have been useful in detecting subclinical demyelination in the brainstem using auditory stimuli (auditory evoked potential) or the spinal cord and brain using sensory stimuli (somatosensory evoked potential). The visual evoked potential (VEP) is the most sensitive and the only evoked potential used by the McDonald criteria for diagnosis of MS.

The differential diagnosis of MS is broad and includes diseases that can mimic discrete attacks and gradual progression of neurologic deficits (Table 129-4).

Table 129-3 McDonald Multiple Sclerosis Diagnostic Criteria*

Clinical (Attacks)	Objective Lesions	Additional Requirements to Make Diagnosis
2 or more	2 or more	None Clinical evidence alone will suffice Additional evidence desirable but must be consistent with MS
2 or more	1	Dissemination in space by MRI or two or more MRI lesions consistent with MS plus positive CSF or await further clinical attack implicating other site
1	2 or more	Dissemination in time by MRI or second clinical attack
1	1	Dissemination in space by MRI or two or more MRI lesions consistent with MS plus positive CSF and dissemination in time by MRI or second clinical attack
0 (progression from onset)	1 or more	Disease progression for 1 yr (retrospective or prospective) and two out of three of the following: <ul style="list-style-type: none"> • Positive brain MRI (nine T2 lesions or four or more T2 lesions with positive VEP) • Positive spinal cord MRI (two or more focal T2 lesions) • Positive CSF
Paraclinical Evidence in MS Diagnosis		
What is a positive MRI?		Three out of four of the following: <ul style="list-style-type: none"> • 1 Gd-enhancing brain or cord lesion or 9 T2 hyperintense brain and/or cord lesions if there is no Gd-enhancing lesion • 1 or more brain infratentorial or cord lesions • 1 or more juxtacortical lesions • 3 or more periventricular lesions
What provides MRI evidence of dissemination in time?		<ul style="list-style-type: none"> • A Gd-enhanced lesion detected in scan at least 3 months after onset of initial clinical event at a site different from initial event • A new T2 lesion detected in a scan done at any time compared with a reference scan done at least 30 days after initial clinical event
What is positive CSF?		Oligoclonal IgG bands in CSF (and not serum) or elevated IgG index
What is positive VEP?		Delayed but well-preserved wave form

Individual cord lesions can contribute, along with individual brain lesions, to reaching required number of T2 lesions.

*These diagnostic criteria were developed through the consensus of the International Panel on the Diagnosis of MS and data from Polman CH, Reingold SC, Edan G, et al: Diagnostic criteria for multiple sclerosis: 2005 revisions to the "McDonald Criteria". *Ann Neurol* 58:840-846, 2005; Barkhof F, Filippi M, Miller DH, et al: Comparison of MRI criteria at first presentation to predict conversion to clinically definite multiple sclerosis. *Brain* 120:2059-2069, 1997; and Tintoré M, Rovira A, Martínez MJ, et al: Isolated demyelinating syndromes: comparison of different MR imaging criteria to predict conversion to clinically definite multiple sclerosis. *AJNR Am J Neuroradiol* 21:702-706, 2000.

CSF, cerebrospinal fluid; Gd, gadolinium; IgG, immunoglobulin G; MRI, magnetic resonance imaging; MS, multiple sclerosis; VEP, visual evoked potential.

TREATMENT

The treatment of patients with MS consists of management of acute relapses, disease-modifying therapies (DMTs) aimed at reduction of the severity and frequency of acute relapses or slowing of progressive disease, and symptomatic therapies (Table 129-5). Treatment for a major relapse is intravenous (IV) methylprednisolone at a dose of 500 to 1000 mg daily for 3 to 5 days, sometimes followed by a taper of oral prednisone. A small randomized study demonstrated efficacy for plasmapheresis for steroid-refractory fulminant attacks of demyelination.

Various DMTs are available for MS, and selection is dependent on disease course and severity, drug efficacy, and patient comorbidities and preferences. Studies have shown that early treatment of patients with CIS at high risk for the development of MS with interferon- β or glatiramer acetate (GA) can delay progression to clinically definite MS. The six currently approved DMTs for relapsing-remitting MS are interferon- β -1b (Betaseron), two forms of interferon- β -1a (Avonex and Rebif), and GA (Copaxone), as well as second-line agents natalizumab (Tysabri) and mitoxantrone (Novantrone). Three formulations of interferon- β have been approved for treatment of relapsing forms of MS. Binding of interferon- β to its receptor induces multiple immuno-

modulatory effects including enhancement of Th2 activity, downregulation of antigen presentation, reduction of inflammatory cytokines, and decreased lymphocyte trafficking into the CNS. Adverse events include injection site reactions for subcutaneous formulations, flulike symptoms, and headache. GA is a synthetic polypeptide designed to simulate myelin basic protein and is administered as a daily subcutaneous injection. The exact mechanism of action is not completely understood, but GA competes with myelin-derived antigens for binding with MHC molecules and causes a shift in GA-reactive lymphocyte populations from a Th1 to a Th2 state. GA therapy is well tolerated; adverse events include local injection site reactions and a sporadic postinjection transient reaction of flushing and dyspnea.

Natalizumab is a humanized monoclonal antibody that binds α_4 integrins present on leukocytes and blocks their interaction with vascular endothelial cell adhesions molecules, thereby inhibiting the migration of leukocytes across the blood-brain barrier. It is administered by monthly IV infusion and causes a potent reduction in relapse rate and new and enhancing MRI lesions. Treatment with natalizumab has been associated with the development of progressive multifocal leukoencephalopathy. Mitoxantrone is an anthracenedione chemotherapeutic agent that is U.S. Food

Figure 129-1 A, Axial fluid-attenuated inversion recovery (FLAIR) image of the brain from a patient with MS revealing classical multiple periventricular and deep white matter high-signal lesions. B, Axial T1-weighted image with gadolinium contrast from the same patient shows that two of the lesions are actively inflamed and enhanced with contrast. C, Sagittal FLAIR image of the brain from a patient with MS demonstrating classical periventricular lesions radiating outward from the ventricles. D, Axial T1-weighted image showing areas of T1 low signal (“black holes”).

Figure 129-2 Isoelectric focusing gel of cerebrospinal fluid (CSF) and serum of a patient with multiple sclerosis. The CSF (*upper lane*) shows oligoclonal bands cathodal to (to the right of) pH 8.0, which are not seen in the serum (*lower lane*).

Table 129-4 Differential Diagnosis of Multiple Sclerosis

Relapsing-Remitting

Vascular disease: strokes, vasculitis, CADASIL
 Inflammatory: neuromyelitis optica, acute TM, acute disseminated encephalomyelitis, paraneoplastic syndromes
 Rheumatologic disease: systemic lupus erythematosus, Sjögren syndrome, sarcoidosis, Behçet syndrome, antiphospholipid antibody syndrome
 Spinal cord disease: compression, abscess, spinal arteriovenous malformation

Progressive Syndromes

Degenerative: spinocerebellar ataxias, spine disease, hereditary spastic paraparesis, syrinx
 Infections: HTLV-1, HIV-related, epidural abscess
 Neoplastic: epidural tumor, lymphoma
 Metabolic: adrenomyeloleukodystrophy; vitamin B₁₂, vitamin E, or copper deficiency
 Vascular: spinal arteriovenous malformation; dural venous fistula

CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; HIV, human immunodeficiency virus; HTLV-1, human T-cell lymphotropic virus type 1; TM, transverse myelitis.

Table 129-5 Treatment of Multiple Sclerosis**Acute Exacerbations**

Intravenous methylprednisolone, 500-1000 mg/day for 3-5 days, variably followed by oral prednisone taper
Plasma exchange (very severe exacerbations)

Disease-Modifying Therapies

Interferon- β -1a
Interferon- β -1b (two formulations)
Glatiramer acetate
Natalizumab
Mitoxantrone

Symptomatic Therapies

Weakness: physical therapy, assistive devices, exercise
Spasticity: stretching, baclofen (oral and intrathecal), tizanidine, benzodiazepines, dantrolene, botulinum toxin
Fatigue: amantadine, modafinil, energy conservation strategies
Neuropathic pain: carbamazepine, gabapentin, pregabalin, amitriptyline, narcotics
Bladder dysfunction: anticholinergic medications for failure to store, intermittent self-catheterization or chronic catheterization, sacral neuromodulation therapy
Depression: antidepressants, psychotherapy
Antipyretics for intercurrent infection

and Drug Administration (FDA) approved for treatment of aggressive relapsing and secondary progressive disease. It is administered intravenously every 3 months as the most common dosing interval. The cumulative dosage is limited to 140 mg/m² because of dose-related cardiotoxicity; there is also a risk of treatment-related acute leukemia. Various other immunosuppressive agents such as cyclophosphamide are in wide use as well. At the present time, there are no FDA-approved therapies available for PPMS.

Neuromyelitis Optica (Devic Disease)

Once regarded as a variant of MS, NMO is now recognized as a distinct relapsing, inflammatory demyelinating disease that preferentially affects the spinal cord and optic nerves. Brain MRI is typically normal early on, but nonspecific white matter abnormalities often develop that do not meet MS radiologic diagnostic criteria. A role for humoral immunopathogenesis is supported by the presence of the NMO-IgG autoantibody, which binds to aquaporin-4, a water transport protein in the CNS. Multiple clinical features distinguish NMO from MS. Whereas MS preferentially affects persons of Northern European white ancestry, NMO accounts for a substantial proportion of CNS demyelinating disease in nonwhite populations including Asians, Hispanics, and African Americans. NMO-associated myelitis differs from MS myelitis in that the clinical impairment is often more severe and MRI typically reveals a longitudinally extensive involvement of the cord (extending three or more vertebral segments, whereas MS lesions rarely exceed one or two segments in length). CSF may show pleocytosis with a predominance of neutrophils. Oligoclonal bands are found in the CSF in only 20% to 30% of NMO cases. NMO attacks are initially treated with IV methylprednisolone but often fail to

respond. Plasmapheresis has been shown to be helpful in some cases as a rescue therapy. Maintenance immunosuppressive therapy is generally recommended to decrease the frequency of relapses. Anecdotal reports suggest benefit from azathioprine, rituximab, and other agents; however, optimal treatment regimens are yet to be defined, as no controlled treatment trials have been conducted.

Optic Neuritis

Optic neuritis is an inflammation of the optic nerve that may occur in isolation or in association with a variety of autoimmune disorders including MS and NMO. The clinical presentation consists of visual loss that is more often monocular than binocular, diminished perception of colors, especially red hues, and pain on eye movement. Symptoms progress over a period of hours to 1 week. Examination reveals variable impairments of visual acuity and color vision, visual field loss, and an afferent papillary defect. The optic disc appears normal in the approximately two thirds of patients who have retrobulbar optic neuritis affecting the posterior two thirds of the optic nerve. Papillitis or swelling of the optic disc may be present in patients with inflammation in the anterior portion of the optic nerve. Visual function usually improves to some degree. The differential diagnosis includes optic neuropathy from anterior ischemic optic neuropathy, tobacco-nutritional amblyopia, vasculitis, optic nerve compression, pernicious anemia, Leber hereditary optic neuropathy, infections, and systemic autoimmune inflammatory diseases such as systemic lupus erythematosus (SLE) and Behçet disease. Treatment with intravenous methylprednisolone (500 to 1000 mg) for 3 days followed by a short prednisone taper hastens recovery and is generally administered for moderately severe or bilateral visual loss; however, a significant benefit to long-term visual outcome has not been demonstrated.

Gadolinium-enhanced MRI of the brain should be performed to assess the risk of subsequent development of MS in patients with isolated optic neuritis and other forms of CIS (TM, brainstem syndromes). Patients with characteristic but asymptomatic brain demyelinating lesions are at high risk for eventual development of clinically definite MS; benefit has been shown for initiation of MS DMTs for this subgroup with CIS.

Acute Transverse Myelitis

Acute TM is a focal inflammatory disorder of the spinal cord manifested as sensory, motor, and/or autonomic dysfunction that develops over hours to 3 weeks. Other causes of acute myelopathy including compression, infarction, and infection must be ruled out by clinical presentation, MRI, and other investigations. Acute TM occurs with a yearly incidence of one to four new cases per million people. Severity and recovery are variable. The potential causes of this syndrome include TM; MS; NMO; and post-infectious, postvaccinal, and other systemic inflammatory disorders, such as SLE, sarcoid, Behçet disease, and Sjögren syndrome. Many cases are idiopathic. Inflammation within the cord should be demonstrated as abnormal signal on MRI or be suggested

by CSF pleocytosis or elevated IgG index. Treatment of the acute presentation is 1000 mg methylprednisolone daily for 5 days. Cases secondary to inflammatory conditions require consideration of chronic immunosuppression.

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is typically a monophasic immune-mediated inflammatory demyelinating disorder that primarily affects the brain and spinal cord. It occurs more commonly in children but can occur at any age. Symptoms typically begin 2 days to 6 weeks after an

antigenic challenge such as a vaccination or antecedent infection; however, there are many cases without history of either. Prodromal features of fever, headache, myalgias, and malaise are followed by the rapid development of meningeal signs, declining mental status, weakness, ataxia, cranial nerve palsies, visual loss and seizures. MRI shows multiple large and asymmetrical white matter lesions with variable gadolinium enhancement. Oligoclonal bands may be present transiently in approximately one third of cases. There may be occasional relapsing courses that render differentiation from MS difficult. Acute hemorrhagic leukoencephalitis is a rare, rapidly progressive and fulminant variant of ADEM that is usually triggered by an upper respiratory tract infection and is often fatal. Treatment of ADEM with intravenous methylprednisolone often hastens recovery.

Prospectus for the Future

The cause of multiple sclerosis (MS) remains unknown. However, recent progress in the understanding of its pathogenesis is stimulating the development of many therapeutic strategies.

The development of treatments that reduce central nervous system injury in MS without compromising patient safety is the current challenge.

Neuromuscular Diseases: Disorders of the Motor Neuron and Plexus and Peripheral Nerve Disease

Carlayne E. Jackson

Neuromuscular diseases are classified into four groups, according to which portion of the motor unit is involved (Table 130-1). Motor neuron and peripheral nerve diseases are considered in this chapter; myopathies are considered in Chapter 131, and neuromuscular junction diseases are considered in Chapter 132. The symptoms and signs of the neuromuscular diseases are at times indistinguishable. However, some useful general rules apply to assist with localization based on the distribution of weakness, presence or absence of sensory symptoms, reflex abnormalities, and specific associated clinical features (Table 130-2).

Electromyography and Nerve Conduction Studies

Electromyography (EMG) and nerve conduction studies can also be useful diagnostic tools in localizing the lesion in a patient with a suspected neuromuscular disease. The measurement of electrical activity arising from muscle fibers is performed by inserting a needle electrode percutaneously into a muscle. Normal muscle is electrically silent at rest. Spontaneous activity during complete relaxation occurs in myotonic disorders, in inflammatory myopathies, and in denervated muscles. Spontaneous activity of a single muscle fiber is called a *fibrillation*, and such activity of part of or an entire motor unit is called a *fasciculation*. In myotonia, repeated muscle depolarization and contraction occur despite voluntary relaxation. Abnormalities in motor unit potentials occur during the course of denervation; with the development of reinnervation, the remaining motor units increase in amplitude and become longer in duration and

polyphasic (**Web Figure 130-1**). Conversely, in muscle diseases such as the muscular dystrophies and other diseases that destroy scattered fibers within a motor unit, the motor unit action potentials are of lower amplitude and shorter duration and are polyphasic. A reduced recruitment (interference) pattern from maximum voluntary effort occurs in denervation. Conversely, in patients with primary muscle disease, submaximal voluntary effort produces a full recruitment pattern despite marked weakness.

Nerve conduction is studied by stimulating a peripheral nerve (e.g., the ulnar) with surface electrodes placed over the nerve. The resulting action potential is recorded by electrodes placed over the nerve more proximally in the case of large sensory nerve fibers and over the muscle distally in the case of motor nerve fibers in a mixed motor sensory nerve. For sensory nerves, the sensory nerve action potential (SNAP) is quantitated, and for motor nerves, the compound muscle action potential (CMAP) is quantitated.

Diseases of the Motor Neuron (Anterior Horn Cell)

AMYOTROPHIC LATERAL SCLEROSIS

The most common *acquired* motor neuron disease, amyotrophic lateral sclerosis (ALS), is a progressive, typically fatal disorder resulting from degeneration of the cortical motor neurons originating in layer five of the motor cortex and descending via the pyramidal tract (resulting in upper motor neuron signs and symptoms) and from degeneration of the anterior horn cells in the spinal cord and their brainstem homologues innervating bulbar muscles (resulting in lower

motor neuron signs and symptoms) (Table 130-3). The incidence is approximately 2 per 100,000 population, and there is a slight male predominance. The peak age of onset is in the sixth decade, although the disease can occur at any time throughout adulthood. Epidemiologic studies have incriminated risk factors for ALS including exposure to insecticides, smoking, participation in varsity athletics, and military service in the Gulf War. Mean survival from onset of symptoms is 2 to 5 years, with 10% of patients surviving beyond 10 years. The majority of deaths are related to respiratory muscle failure and aspiration pneumonia. The cause of ALS is largely unknown, with 95% of cases considered “sporadic,” and 5% related to an autosomal dominant disease (familial ALS [FALS]). FALS is an adult-onset disease that is clinically and pathologically indistinguishable from sporadic ALS. FALS is caused by missense mutations in the superox-

ide dismutase gene (*SOD1*) in 20% of patients. Other genetic causes are also being identified (see **Web Table 130-1**).

Clinical symptoms relating to the upper motor neuron degeneration include loss of dexterity, slowed movements, muscle weakness, stiffness, and emotional lability. Signs on neurologic examination that confirm an upper motor neuron lesion include pathologic hyperreflexia, spasticity, and extensor plantar responses (Babinski sign). Lower motor neuron signs and symptoms caused by anterior horn cell degeneration include weakness, muscle atrophy, fasciculations, and cramps. Fasciculations in the absence of associated muscle atrophy or weakness are usually benign and may be aggravated by sleep deprivation, stress, and excessive caffeine ingestion. Muscle weakness in patients with ALS usually begins distally and asymmetrically and may manifest as a monoparesis, hemiparesis, paraparesis, or quadriparesis. It may also be limited initially to the bulbar region, resulting in difficulty with chewing, swallowing, speech, and movements of the face and tongue. For unclear reasons, ocular motility is spared until the very late stages of the illness. Bowel and bladder function and sensation remain spared throughout the course of the disease. Degeneration of the corticobulbar projections innervating the brainstem can lead to involuntary emotional expression disorder (IEED), causing difficulty controlling laughter and/or tearfulness (also called *pseudobulbar affect*). Up to 50% of patients with ALS may also have a component of frontotemporal dementia characterized by executive dysfunction, poor insight, personality changes (disinhibition, impulsivity, apathy), abnormal eating habits, poor hygiene, and language dysfunction.

The diagnosis of ALS remains one of “exclusion,” in which other potential causes must be ruled out through a variety of neuroimaging, laboratory, and electrodiagnostic investigations (**Web Table 130-2**). For example, compression of the cervical spinal cord or cervicomedullary junction from tumors or cervical spondylosis can produce weakness, atrophy, and fasciculations in the upper extremities and spasticity in the lower extremities, closely resembling ALS.

The only current U.S. Food and Drug Administration (FDA)–approved therapy for ALS is riluzole 50 mg twice per day, which in clinical trials prolonged survival by 2 to 3 months. The mechanism of this effect is not known with certainty; however, riluzole may reduce excitotoxicity by diminishing presynaptic glutamate release. Initiation of

Table 130-1 Classification of Neuromuscular Diseases

Site of Involvement	Typical Examples
Anterior Horn Cell	
Without upper motor neuron involvement	Spinal muscular atrophy Progressive muscular atrophy Bulbospinal muscular atrophy Poliomyelitis West Nile virus
With upper motor neuron involvement	Amyotrophic lateral sclerosis Primary lateral sclerosis
Peripheral Nerve	
Mononeuropathy	Carpal tunnel syndrome Ulnar palsy Meralgia paresthetica
Multiple mononeuropathies	Mononeuritis multiplex (e.g., polyarteritis nodosa), leprosy, sarcoidosis, amyloidosis
Polyneuropathies	Diabetic neuropathy Charcot-Marie-Tooth disease Guillain-Barré syndrome
Neuromuscular Junction	Myasthenia gravis Eaton-Lambert syndrome
Muscle	Duchenne muscular dystrophy Dermatomyositis

Table 130-2 Clinical Features of the Neuromuscular Diseases

Clinical Feature	Anterior Horn Cell	Peripheral Nerve	Neuromuscular Junction	Muscle
Distribution of weakness	Asymmetrical limb or bulbar	Symmetrical, usually distal	Extraocular, bulbar, proximal limb	Symmetrical, proximal limb
Atrophy	Marked and early	Mild, distal	None (or very late)	Slight early; marked later
Sensory Involvement	None	Dysesthesias, loss of sensation	None	None
Reflexes	Variable (depending on degree of upper motor neuron involvement)	Decreased out of proportion to weakness	Normal in myasthenia gravis, depressed in Lambert-Eaton syndrome	Decreased in proportion to weakness
Characteristic features	Fasciculations, cramps	Combined sensory and motor abnormalities	Fatigability	Usually painless

Table 130-3 Symptoms and Signs Associated with Amyotrophic Lateral Sclerosis

Symptoms	Signs
Upper Motor Neuron Degeneration	
Loss of dexterity	Pathologic hyperreflexia
Slowed movements	Babinski response
Weakness	Hoffman response
Stiffness	Jaw jerk
Emotional lability	Spasticity
Lower Motor Neuron Degeneration	
Weakness	Muscle atrophy
Fasciculations	Fibrillation potentials on electromyography
Cramps	Neurogenic atrophy on muscle biopsy

noninvasive positive pressure ventilation (NPPV) on a spontaneous timed mode has also been shown to prolong survival up to 20 months and to improve quality of life. NPPV should be initiated when the forced vital capacity (FVC) is less than 50% or when patients report symptoms that suggest nocturnal hypoventilation (daytime fatigue, frequent arousals, supine dyspnea, morning headaches). A cough-assist device can be used to assist with clearing upper airway secretions and has been shown to minimize the risk of pneumonia in clinical trials. A percutaneous gastrostomy (PEG) tube should be recommended before the FVC drops below 50% or when patients are unable to maintain weight with oral intake alone. Symptomatic therapy for spasticity, emotional lability, muscle cramping, and drooling is also essential in maintaining patient dignity and quality of life (Table 130-4). Augmentative speech devices can be prescribed to assist patients with communication and computer access.

OTHER ACQUIRED MOTOR NEURON DISEASES

Other motor neuron diseases involve only particular subsets of motor neurons (Table 130-5). Progressive muscular atrophy (PMA) is a pure lower motor neuron disease that accounts for 8% to 10% of patients with motor neuron disease. Weakness is typically distal and asymmetrical, and bulbar involvement is rare. Patients with PMA generally have a better prognosis than those with ALS, with a survival of 3 to 14 years. Primary lateral sclerosis (PLS) is a pure upper motor neuron syndrome in which patients demonstrate either a slowly progressive spastic paralysis or dysarthria. This is a rare disorder, accounting for 2% of all motor neuron cases. Survival is generally years to decades.

SPINAL MUSCULAR ATROPHY

Spinal muscular atrophy (SMA) is a hereditary form of motor neuron disease in which only the lower motor neuron is affected. The SMAs may begin in utero, in infancy, in childhood, or in adult life and represent the first class of neurologic disorders in which a developmental defect in neuronal apoptosis most likely produces the disease. Two genes are involved in SMA types 1 to 3: the neuronal

apoptosis inhibitor protein (*NAIP*) and survival motor neuron (*SMN*) genes.

Bulbosplinal muscular atrophy (BSMA) or Kennedy disease is an X-linked recessive disorder in which the mean age at onset is 30 years; the range is from 15 to 60 years. BSMA is a trinucleotide repeat disorder with a CAG expansion encoding for a polyglutamine tract in the first exon of the androgen receptor gene, on chromosome Xq11-12. The mechanism by which disruption of the androgen receptor gene alters the function of bulbar and spinal motor neurons is not known. An inverse correlation exists between the

number of CAG repeats and the age of onset of the disease. Affected individuals exhibit chin fasciculations, midline furrowing and atrophy of the tongue, and proximal weakness. Dysphagia and dysarthria are common, and up to 90% of patients demonstrate gynecomastia and infertility. Two findings distinguishing this disorder from ALS are the absence of upper motor neuron signs and in some patients the presence of a subtle sensory neuropathy.

Disorders of the Brachial and Lumbosacral Plexus

The roots within the cervical, lumbar, and sacral regions organize into the cervical, lumbar, and sacral plexuses before giving rise to individual peripheral nerves. Diseases of these plexuses (plexopathies) tend to be *focal* in symptoms and signs, whereas many diseases of the peripheral nerves and muscles are *generalized*.

BRACHIAL PLEXOPATHY

The brachial plexus is constituted by mixed nerve roots from C5 to T1 that fuse into upper, middle, and lower trunks above the level of the clavicle and redistribute into lateral, posterior, and medial cords below that landmark (Web Fig. 130-2). Symptoms include weakness, pain, and sensory loss in the shoulders or arms. Upper trunk lesions may be due to trauma and idiopathic brachial plexitis (see later). Lower trunk lesions may result from malignant tumor invasion, thoracic outlet syndrome, or as a complication of sternotomy. If the entire plexus is involved, radiation injury, trauma, and late metastatic disease are the most common causes.

ACUTE AUTOIMMUNE BRACHIAL NEURITIS

Acute autoimmune brachial neuritis is characterized by the abrupt onset of severe pain, usually over the lateral shoulder, but at times extending into the neck or entire arm. The acute pain generally subsides after a few days to a week; by this time, weakness of the proximal arm becomes apparent. The serratus anterior, deltoid, and supraspinatus are the most commonly affected muscles, but other muscles of the shoulder girdle may also be affected. In rare cases, most of the patient's arm and even the ipsilateral diaphragm are involved. Sensory loss is usually slight and generally involves the axillary nerve distribution. Weakness may last weeks to months and be accompanied by severe atrophy of the shoulder girdle. No therapy has been shown to alter or shorten the clinical course, although steroids and analgesics may reduce pain. Most patients recover within several months to 3 years. The disorder frequently follows an upper respiratory infection or an immunization, but in many instances no antecedent illness occurs. It is bilateral in one third of cases but is always asymmetrical; it may recur in 5% of patients. Recurrent brachial plexopathies that are painless may be related to an autosomal dominant disorder, hereditary neuropathy with liability to pressure palsies (HNPP), caused by a deletion or point mutation of PMP-22 protein (chromosome 17p).

LUMBOSACRAL PLEXOPATHY

The lumbosacral plexus is formed from the ventral rami of spinal nerves T12 to S4. These divide within the plexus into ventral and dorsal branches that form the femoral, sciatic, and obturator nerves. The plexus is located within the substance of the psoas major muscle. Clinical features include proximal pain and weakness in anterior thigh muscles (femoral) or posterior thigh muscles and the buttocks. Bowel and bladder dysfunction may also occur. Diabetes, malignant invasion, radiation therapy, infection (herpes zoster), psoas abscess, trauma, and retroperitoneal hemorrhage are common causes. An autoimmune form is much less frequent than brachial neuritis.

Disorders of the Peripheral Nerves

Peripheral neuropathy refers to a large group of disorders that can produce focal (mononeuropathy or multiple mononeuropathies) or generalized nerve dysfunction (polyneuropathies) (Table 130-6). Peripheral neuropathies are among the most prevalent neurologic conditions, affecting 2% to 8% of adults, with the incidence increasing with age. They range in severity from mild sensory abnormalities, found in up to 70% of patients with long-standing diabetes, to fulminant, life-threatening paralytic disorders such as Guillain-Barré syndrome (GBS).

MONONEUROPATHY AND MULTIPLE MONONEUROPATHIES

Mononeuropathies are disorders in which only a single peripheral nerve is affected. The most common cause is

Table 130-6 Classification and Causes of Peripheral Neuropathy

Type of Neuropathy	Examples
Mononeuropathies	
Compressive	Carpal tunnel syndrome, ulnar palsy
Hereditary	Hereditary neuropathy with predisposition to pressure palsies
Inflammatory	Bell palsy
Multiple mononeuropathies	Vasculitis (mononeuritis multiplex), diabetes, leprosy, sarcoidosis, amyloidosis
Polyneuropathies	
Hereditary	Charcot-Marie-Tooth disease
Endocrine	Diabetes, hypothyroidism
Metabolic	Uremia, liver failure
Infections	Leprosy, diphtheria, human immunodeficiency virus, Lyme disease
Immune-mediated	Guillain-Barré syndrome, chronic inflammatory demyelinating polyneuropathy
Toxic	Lead-, arsenic-, alcohol-, drug-induced
Paraneoplastic	Lung cancer

Table 130-7 Common Mononeuropathies

	Precipitating Factors	Motor Signs and Symptoms	Sensory Signs and Symptoms	Treatment
Median Nerve				
Entrapment at the wrist (carpal tunnel syndrome)	Repetitive wrist flexion or sleep	Weakness in the thenar muscle; inability to make a circle with the thumb and index fingers	Numbness, tingling, and/or pain in thumb, index finger, middle finger, and medial half of ring finger. Tinel and Phalen signs	Neutral wrist splint, carpal tunnel injections or surgery
Ulnar Nerve				
Entrapment at the elbow	External compression in condylar groove, fracture of humerus	Weakness or atrophy of the interossei and thumb adductor	Sensory loss in the little finger and contiguous half of the ring finger	Elbow pads; ulnar nerve transposition or decompression of cubital tunnel
Radial Nerve				
Entrapment at the spiral groove	Prolonged sleeping on arm after drinking excessive amounts of alcohol: "Saturday night palsy"	Wrist drop with sparing of elbow extension; weakness of finger and thumb extensors	Sensory loss on dorsum of hand	Spontaneous recovery; wrist splint
Femoral Nerve				
	Abdominal hysterectomy, hematoma, prolonged lithotomy position, diabetes	Weakness and atrophy of quadriceps	Sensory loss in anterior thigh and medial calf	Physical therapy
Lateral Femoral Cutaneous Nerve				
Meralgia paresthetica	Obesity, pregnancy, diabetes, constrictive belts	None	Sensory loss, pain, or tingling over anterolateral thigh	Weight loss; spontaneous recovery
Peroneal Nerve				
Entrapment at the fibular head	Habitual leg crossing, knee casts, prolonged squatting, profound weight loss	Weakness of ankle dorsiflexors or evertors and toe extensors	Sensory loss in anterolateral leg and dorsum of foot	Ankle-foot orthosis; remove source of compression
Sciatic Nerve				
	Injection injury, fracture or dislocation of hip	Weakness of hamstrings, ankle plantar flexors or dorsiflexors	Sensory loss in buttock, lateral calf and foot	Ankle-foot orthosis; physical therapy
Tibial Nerve				
Entrapment in tarsal tunnel	External compression from tight shoes, trauma, tenosynovitis	None	Sensory loss and tingling in sole of foot	Tarsal tunnel injection, eliminate source of compression, medial arch support

nerve entrapment such as median nerve compression resulting in carpal tunnel syndrome or peroneal nerve injury causing foot drop (Table 130-7). When more than one peripheral nerve is involved, the term *mononeuropathy multiplex* or *multiple mononeuropathies* is often used. Multiple mononeuropathies are most commonly seen in diabetes mellitus and vasculitis but have also been reported in leprosy, sarcoidosis, hereditary neuropathy with predisposition to pressure palsies, and amyloidosis.

Polyneuropathies

Polyneuropathy refers to a group of disorders affecting the motor, sensory, and autonomic nerves. These disorders may predominantly affect the nerve axon (axonal neuropathies), myelin sheath (demyelinating neuropathies), or the small- to medium-sized blood vessels supplying the nerves (vasculitic neuropathies). The clinical features of the polyneuropathies reflect the pathology of the underlying process.

AXONAL NEUROPATHIES

In the symmetrical polyneuropathies, the underlying pathology is usually a slowly evolving type of axonal degeneration that involves the ends of long nerve fibers first and preferentially. With time, the degenerative process involves more proximal regions of long fibers, and shorter fibers are affected. This pattern of distal axonal degeneration or *dying back* of nerve fibers results from a wide variety of metabolic, toxic, and endocrinologic causes. The resulting clinical picture of an axonal polyneuropathy includes early loss of

AXONAL NEUROPATHIES

In the symmetrical polyneuropathies, the underlying pathology is usually a slowly evolving type of axonal degeneration that involves the ends of long nerve fibers first and preferentially. With time, the degenerative process involves more proximal regions of long fibers, and shorter fibers are affected. This pattern of distal axonal degeneration or *dying back* of nerve fibers results from a wide variety of metabolic, toxic, and endocrinologic causes. The resulting clinical picture of an axonal polyneuropathy includes early loss of

muscle stretch reflexes at the ankle and weakness that initially involves the intrinsic muscles of the feet, the extensors of the toes, and the dorsiflexors at the ankle. The motor signs are usually mild in contrast to the sensory abnormalities, which may include numbness, tingling, and burning sensations (dysesthesias). The sensory symptoms usually begin symmetrically in the toes and feet and then ascend proximally to the legs in a “stocking” distribution. When the sensory abnormalities reach the level of the knees, the symptoms begin in the hands, in a “glove” distribution. Truncal and abdominal dysesthesias may develop once the sensory abnormalities ascend to the level of the elbows. Peripheral neuropathies caused by axonal degeneration are generally progressive unless the underlying cause can be identified and treated. Recovery from axonal degeneration requires nerve regeneration, a process that often requires 2 to 3 years.

DEMYELINATING NEUROPATHIES

Demyelination of a peripheral nerve at even a single site can block conduction, resulting in a functional deficit identical to that seen after axonal degeneration. In contrast to repair by regeneration, however, repair by remyelination can be rapid. Autoimmune attack on the myelin sheath occurs in the inflammatory demyelinating neuropathies (GBS and chronic inflammatory demyelinating polyneuropathy [CIDP]) and some neuropathies associated with paraproteinemias (see later). Inherited disorders of myelin such as Charcot-Marie-Tooth (CMT) disease comprise the other major category of demyelinating neuropathies. Other causes include toxic, mechanical, and physical injuries to nerves. Although these examples have nearly pure demyelination, many neuropathies have both axonal degeneration and demyelination. This mixed pathologic abnormality reflects the mutual interdependency of the axons and the myelin-forming Schwann cells. The prominent clinical feature of an acquired demyelinating polyneuropathy is weakness that affects not only the distal muscles, but also the proximal and facial muscles. Unlike in an axonal neuropathy, sensory loss is rarely the presenting symptom. Patients generally have diffuse hyporeflexia or areflexia.

VASCULITIC NEUROPATHIES

Vasculitic neuropathies occur as a result of disease of the small or medium-sized blood vessels that leads to ischemia

and infarction of isolated peripheral nerves. The term *mononeuritis multiplex* is also used to describe this clinical situation, in which there is multifocal involvement of individual nerves leading to asymmetrical, predominantly distal weakness and sensory loss associated with severe pain. Causes include systemic vasculitis (rheumatoid arthritis, systemic lupus erythematosus, Wegener granulomatosis, Churg-Strauss syndrome, polyarteritis nodosa) and primary peripheral system vasculitis (25% of cases). Therapy with corticosteroids in addition to a cytotoxic agent can stabilize and in some cases improve the neuropathy.

Etiology of Neuropathies

Neuropathic disorders can be broadly divided into those that are acquired and those that are hereditary (Table 130-8). Acquired disorders are the more common and have many causes: metabolic or endocrine disorders (diabetes mellitus, renal failure, porphyria); immune-mediated disorders (GBS, CIDP, multifocal motor neuropathy, anti-myelin-associated glycoprotein neuropathy); infectious causes (human immunodeficiency virus [HIV], Lyme disease, cytomegalovirus [CMV], syphilis, leprosy, diphtheria); medications (HIV drugs, chemotherapies); environmental toxins (heavy metals); or paraneoplastic processes. Diabetes mellitus and alcoholism are the most common causes of polyneuropathy in developed countries. As many as one third of acquired neuropathies are idiopathic.

Clinical Approach to the Patient with Suspected Polyneuropathy

Because of the many causes, it is important to approach the patient with neuropathy systematically, beginning with the patient's history and physical examination. It is essential to determine which nerves are involved (motor, sensory, or autonomic) and in what specific combination (Table 130-9). Small-fiber neuropathies often manifest with unpleasant or abnormal sensations such as a burning pain, electric shock–like sensations, cramping, tingling, pins and needles, or prickly feelings such as the limb “feeling asleep.” Large-fiber neuropathies can manifest as numbness,

Table 130-8 Hereditary Neuropathic Disorders

	Inheritance Pattern	Genetic Defect	Clinical Features
Hereditary sensorimotor neuropathies	AR, AD, or X-linked	See Web Table 130-4	Pes cavus, distal atrophy and weakness, hammer toes
Familial amyloid polyneuropathy	AD	Transthyretin Gelsolin Apolipoprotein A1	Pain, autonomic dysfunction
Fabry disease	X-linked	α -Galactosidase	Cardiac ischemia, renal disease, stroke, cutaneous angiokeratomas
Tangier disease	AR	Apolipoprotein A	Low HDL levels, orange tonsils
Refsum disease	AR	Phytanic acid oxidase	Retinitis pigmentosa, cardiomyopathy, deafness, ichthyosis

AD, autosomal dominant; AR, autosomal recessive; HDL, high-density lipoprotein.

Table 130-9 Differential Diagnosis of Neuropathic Disorders Based on Symptoms

Motor Symptoms Only	Sensory Symptoms Only	Autonomic Symptoms
Porphyria	Cryptogenic sensory polyneuropathy	Amyloid neuropathy
Charcot-Marie-Tooth	Metabolic, drug-related, or toxic neuropathy	Diabetic neuropathy
Chronic inflammatory demyelinating polyneuropathy	Paraneoplastic sensory neuropathy	Fabry disease
Guillain-Barré syndrome		Guillain-Barré syndrome
Lead neuropathy		Hereditary sensory or autonomic neuropathy
Motor neuron disease		Porphyria

tingling, or as gait ataxia. Symptoms suggesting motor nerve involvement include muscle weakness that typically involves the distal foot muscles. Autonomic nerve involvement is suggested by symptoms of orthostatic hypotension, impotence, cardiac arrhythmia, or bladder dysfunction.

The distribution of muscle weakness is important. In axonal neuropathies the weakness predominantly involves the distal lower extremity muscles, and in demyelinating neuropathies the weakness can involve both proximal and distal muscles as well as facial muscles. Most neuropathies result in *symmetrical* weakness. If asymmetry is present, motor neuron disease, radiculopathy, plexopathy, compressive mononeuropathies, or mononeuritis multiplex should be considered. The intensity and distribution of painful dysesthesias can be informative. Although many axonal neuropathies are associated with a burning sensation in the feet, pain as the chief complaint suggests specific causes of neuropathy (Table 130-10). A neuropathy that manifests with acute, asymmetrical weakness and severe pain suggests vasculitis.

In patients with severe, asymmetrical proprioceptive deficits, with sparing of motor function, the site of the lesion is usually the sensory neuron. This specific syndrome has a relatively limited differential diagnosis, including paraneoplastic process, Sjögren syndrome, cisplatin toxicity, vitamin B₆ toxicity, and HIV infection.

Most neuropathies are relatively insidious in onset, particularly those associated with metabolic or endocrine disorders. Acute neuropathies may be caused by a vasculitic process, toxin exposure, porphyria, or GBS. GBS is commonly preceded by a viral illness, immunization, or a surgical procedure. The neurologic history must thoroughly explore potential toxic exposures such as prior medications and alcohol use (**Web Table 130-3**).

Because many neuropathies are hereditary, it is essential to obtain a detailed family history, specifically inquiring about a history of gait instability, use of adaptive equipment, or skeletal deformities of the feet. Hereditary neuropathies

Table 130-10 Neuropathies Associated with Pain

Alcoholic neuropathy
Amyloidosis
Cryptogenic sensorimotor neuropathy
Diabetic neuropathy
Fabry disease

HIV, human immunodeficiency virus.

may be autosomal recessive, autosomal dominant, or X-linked. In some situations it may be helpful to actually examine family members because the severity of disease may vary considerably from one generation to the next. The most common hereditary neuropathy is CMT disease (see later).

A complete neurologic examination should always be performed in a patient complaining of numbness. If the patient shows evidence of upper motor neuron involvement in addition to the sensory loss, vitamin B₁₂ or copper deficiency should be considered, even in the absence of apparent anemia. An elevated methylmalonic acid or homocystine level can also help confirm this diagnosis in patients with borderline B₁₂ levels. The presence of weakness and upper motor neuron signs without associated sensory loss suggests ALS.

If the neuropathy is associated with mental status abnormalities, then pyridoxine intoxication or deficiencies of thiamine, niacin (“dementia, diarrhea, dermatitis”), and vitamin B₁₂ should be considered in the differential diagnosis. Lyme disease (see Chapter 97) may result in both peripheral nervous system symptoms (facial nerve palsies, paresthesias, weakness) and central nervous system symptoms (dementia, headache). Acquired immunodeficiency syndrome (AIDS) can also affect both the central and the peripheral nervous systems. GBS and CIDP usually occur at the time of HIV seroconversion, whereas sensory neuropathy, mononeuritis multiplex, and CMV polyradiculopathy generally occur in the context of low CD4 counts in the terminal stages of the disease.

Laboratory Approach to the Patient with Suspected Neuropathy

Once a preliminary differential diagnosis is developed based on the history and neurologic examination findings, laboratory studies can confirm the diagnosis. Laboratory tests to identify potentially treatable causes of neuropathy are included in Table 130-11. Additional studies can be ordered based on the suspected diagnosis. An impaired glucose tolerance test is found in more than half of patients with idiopathic sensory neuropathy and is more sensitive than tests

Table 130-11 Peripheral Neuropathy Laboratory Studies

Standard Tests	Tests Indicated in Selected Cases
B ₁₂	Anti-Hu antibody
Complete blood count (CBC)	ESR, ANA, RF, SS-A, SS-B
Glucose tolerance test	Genetic studies for Charcot-Marie-Tooth
RPR	Human immunodeficiency virus (HIV)
Sequential multi-channel analysis (SMA) 20	Lyme antibody
Serum protein electrophoresis (SPEP) and immunofixation electrophoresis (IFE)	Phytanic acid
Thyroid function tests	24-hr urine for heavy metals
Nerve conduction studies or electromyogram (EMG)	Quantitative sensory testing Lumbar puncture Nerve biopsy Skin biopsy Tilt table testing

of fasting glucose or hemoglobin A_{1c} (HbA_{1c}). In a patient with acute, asymmetrical weakness and sensory loss, screening for an inflammatory process (ESR, ANA, RA, SS-A, SS-B) is appropriate. In addition, genetic testing is now available for most patients with CMT disease. If a monoclonal protein is identified on serum protein electrophoresis, a skeletal survey, urine immunofixation electrophoresis, and bone marrow biopsy should be ordered to rule out an underlying lymphoproliferative disorder. If the patient has a monoclonal protein associated with autonomic dysfunction, congestive heart failure, or renal insufficiency, a biopsy (rectal, abdominal fat, or sural nerve) is essential to exclude a diagnosis of amyloidosis. CIDP can be associated with a monoclonal gammopathy, and in this situation patients should be treated with immunosuppressive therapy. Monoclonal gammopathies observed in patients with an axonal peripheral neuropathy are frequently benign (monoclonal gammopathy of unknown significance) and do not necessarily warrant therapy.

A lumbar puncture is indicated only if an acquired demyelinating neuropathy such as GBS or CIDP is being considered. In these cases one would expect to find an “albuminocytologic dissociation” with an elevation in cerebrospinal fluid (CSF) protein and a relatively normal white blood cell (WBC) count. If the CSF WBC count is >50, Lyme disease, HIV-associated disease, or a paraneoplastic process must be considered.

Electrodiagnostic studies consisting of nerve conduction testing and EMG can be a helpful extension of the physical examination. These studies are useful in defining whether the neuropathic process is caused by a primarily axonal or demyelinating process. In general, axonal degeneration decreases the amplitude of the CMAP out of proportion to the degree of reduction in peripheral nerve conduction velocity, whereas demyelination produces prominent reduction in conduction velocities. Nerve conduction testing can help determine, in the case of a demyelinating neuropathy, whether the process has an acquired or hereditary cause.

Table 130-12 Symptomatic Treatment for Neuropathic Pain

Tricyclic Antidepressants
Amitriptyline 10-150 mg qhs
Nortriptyline 10-150 mg qhs
Imipramine 10-150 mg qhs
Desipramine 10-150 mg qhs
Anticonvulsants
Lamotrigine 200-400 mg qd
Gabapentin 300-1200 mg tid
Carbamazepine 100-200 mg tid
Topiramate 150-200 mg bid
Oxcarbazepine 1200-2400 mg qd
Pregabalin 150-600 mg qd
Alternative Treatments
Tramadol 50-100 mg qid
Mexiletine 150 mg bid-tid
Lidoderm patches
Capsaicin cream
Transcutaneous nerve stimulation
Acupuncture

A uniform slowing of nerve conduction usually suggests a hereditary cause. Electrodiagnostic studies can identify subclinical neuropathy (in patients receiving potentially neurotoxic medications) and can quantitate the extent of axon loss. Finally, these studies can localize the lesion in the case of radiculopathies, plexopathies, and multiple mononeuropathies.

Sensory nerve biopsies are necessary in the diagnosis of a vasculitic neuropathy because treatment involves potentially toxic medications. Performing a muscle biopsy in addition to the nerve biopsy may improve the diagnostic yield and should be considered because the inflammation is random and focal and easily missed. Nerve biopsies are not indicated in “cryptogenic” neuropathies, diabetic neuropathy, or motor neuron disease.

Treatment Strategies in Peripheral Neuropathy

Despite a very thorough history, examination, and laboratory studies, as many as one third of patients remain undiagnosed. In this situation, the focus of management is pain control. Patients with neuropathy frequently report a burning, searing, and aching sensation in their feet and hands that interferes with sleep. Neuropathic pain is difficult to treat but may respond to various medications having different mechanisms of action (Table 130-12). It is important to “start low and taper slow” and to treat for a minimum of 4 weeks before concluding that an agent is ineffective.

Common Mononeuropathies

(see Table 130-7)

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome results from compression of the median nerve at the wrist as it passes beneath the flexor

retinaculum. Symptoms usually begin in the dominant hand but commonly involve both hands over time. Patients typically report numbness, tingling, and burning sensations in the palm and in the fingers supplied by the median nerve: the thumb, index finger, middle finger, and medial one half of the ring finger. Some patients report that all fingers become numb. Pain and paresthesias are most prominent at night and often interrupt sleep. The pain is prominent at the wrist but may radiate to the forearm and occasionally to the shoulder. Shaking the hand relieves both pain and paresthesias. Percussion of the median nerve at the wrist provokes paresthesias in a median nerve distribution in 60% of patients (Tinel sign), and flexion of the wrist for 30 to 60 seconds provokes pain or paresthesias in 75% of cases (Phalen sign). Precipitating factors include activities that require repetitive wrist movements: mechanical work, gardening, house painting, and typing. Predisposing causes include pregnancy, diabetes, acromegaly, rheumatoid arthritis, chronic renal failure, thyroid disorders, and primary amyloidosis.

The diagnosis is based on clinical symptoms and signs. Electrodiagnostic studies may demonstrate prolongation of the sensory or motor latencies across the wrist in up to 85% of patients. In more severe cases, EMG may demonstrate evidence of denervation in the abductor pollicis brevis. Treatment initially includes avoidance of repetitive wrist activities and the use of a neutral wrist splint. If these conservative measures fail, injections of lidocaine and methylprednisolone can be given into the carpal tunnel or surgical treatment by section of the transverse carpal ligament can effectively decompress the nerve. Indicators that have been shown to predict failure with conservative management include age >50, disease duration >10 months, constant paresthesias, and a positive Phalen sign in <10 seconds.

ULNAR PALSY

The ulnar nerve may become entrapped at the elbow because of external compression in the condylar groove. Injury may also occur years after a malunited supracondylar fracture of the humerus with bony overgrowth. Contrary to the findings in carpal tunnel syndrome, muscle weakness and atrophy characteristically predominate over sensory symptoms and signs. Patients notice atrophy of the first dorsal interosseous muscle and difficulty performing fine manipulations of the fingers. Numbness of the little finger, the contiguous one half of the ring finger, and the ulnar border of the hand may be present. Ulnar nerve compression can be confirmed with electrodiagnostic studies demonstrating slowed motor conduction velocity across the elbow. Treatment includes the use of elbow pads to avoid compression or surgical procedures including transposition of the ulnar nerve or decompression of the cubital tunnel.

PERONEAL NEUROPATHY

The peroneal nerve can become compressed as it wraps around the fibular head and passes into the fibular tunnel between the peroneus longus muscle and the fibula. Compression may occur as a result of habitual leg crossing, prolonged bed rest, knee casts, prolonged squatting, anesthesia,

or profound weight loss. The nerve can also be compressed as a result of Baker cysts, fibular fractures, blunt trauma, tumors, or hematomas at the knee. Symptoms include “foot drop” with selective weakness of the ankle dorsiflexors and evertors as well as the toe extensors. Reflexes remain normal, and sensory loss generally involves the anterolateral leg and dorsum of the foot. Electrodiagnostic studies demonstrate slowing of the peroneal conduction velocity across the fibular head and may demonstrate denervation if axonal injury is present. Compressive injuries usually resolve spontaneously within weeks to months. Magnetic resonance imaging (MRI) and surgical exploration should be considered if symptoms are progressive.

Specific Acquired Polyneuropathies

GUILLAIN-BARRÉ SYNDROME: ACUTE INFLAMMATORY DEMYELINATING POLYNEUROPATHY

Since the advent of polio vaccination, GBS has become the most frequent cause of acute flaccid paralysis throughout the world. GBS is an immune-mediated disorder that follows an identifiable infectious disorder in approximately 60% of patients. The best-documented antecedents include infection with *Campylobacter jejuni*, infectious mononucleosis, CMV, herpesvirus, and mycoplasma. *C. jejuni* is often associated with more severe axonal cases.

The initial symptoms of GBS often consist of tingling and pins-and-needles sensations in the feet and may be associated with dull low-back pain. By the time of presentation, which occurs hours to 1 to 2 days after the first symptoms, weakness has usually developed. The weakness is usually most prominent in the legs, but the arms or cranial musculature may be involved first. Muscle stretch reflexes are lost early, even in regions where strength is retained. Cutaneous sensory deficits (loss of pain and temperature) are relatively mild; however, large fiber function (vibration and proprioception) are more severely impaired. Other clinical features include pain (20%), paresthesias (50%), autonomic symptoms (20%), facial weakness (50%), ophthalmoparesis (9%), bulbar weakness, and respiratory failure (25%). Symptoms associated with GBS typically evolve over a 2- to 4-week period, with approximately 90% of patients showing no evidence of progression beyond 4 weeks. For this reason, patients who are seen within several weeks from onset continue to require hospitalization for close observation. Respiratory muscle strength should be monitored with bedside measurements of the FVC. Intubation should be initiated when the FVC falls below 15 mL/kg.

Treatment may include either intravenous gammaglobulin (0.4 g/kg/day \times 5 days) or plasmapheresis—the exchange of the patient’s plasma for albumin (200 mL/kg over 7 to 10 days). Clinical studies have confirmed equal efficacy between these two therapies, with no additional benefit conferred with combination therapy. Corticosteroids are not effective in GBS. Indications for therapy include inability to ambulate independently, impaired respiratory function, or rapidly progressive weakness. Clinical features predicting a poor

prognosis or prolonged recovery time include rapidly progressive weakness, need for mechanical ventilation, and low-amplitude CMAPs. The mortality rate remains 5% to 10%, usually because of respiratory complications, cardiac arrhythmia, or pulmonary embolism. With appropriate supportive care and rehabilitation, 80% to 90% of patients recover with little or no disability.

CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

CIDP has been considered the “chronic form” of GBS, because by definition the symptoms must progress for at least 8 weeks. The clinical features include proximal and distal weakness, areflexia, and distal sensory loss. Autonomic dysfunction, respiratory insufficiency, and cranial nerve involvement can occur but are much less common than in GBS. Treatment for CIDP includes the use of oral immunosuppressive agents such as prednisone, cyclosporine, mycophenolate mofetil, and azathioprine. Intravenous immune globulin and plasmapheresis are also indicated for severe or refractory cases.

DIABETIC NEUROPATHY

Diabetes mellitus is the most frequent cause of peripheral neuropathy worldwide. The diabetic neuropathies take many clinical forms, including symmetrical polyneuropathies and a wide variety of individual plexus or nerve disorders.

Diabetes mellitus often causes a slowly progressive, distal, symmetrical sensorimotor polyneuropathy (DSPN). DSPN is uncommon at the time of diagnosis of diabetes, but its prevalence increases with duration of diabetes with a lifetime prevalence of 55% for type 1 and 45% for type 2. The precise pathogenesis is not defined, but, similar to the ocular and renal complications, diabetic neuropathy can be reduced in incidence and in severity by maintaining blood glucose levels close to normal. Initial symptoms may consist of numbness, tingling, burning, or prickling sensations affecting the feet and toes. Mild distal weakness and gait instability may subsequently develop. The sensory symptoms can then chronically progress to involve a “stocking-glove pattern.” The small-fiber dysfunction often produces spontaneous neuropathic pain in which unpleasant sensations can be evoked by normally innocuous stimuli, such as the bed sheets on the toes at night. Continuous burning or throbbing pain may occur, and prolonged walking is often distressing. In severe cases, patients may develop foot ulcers in insensitive areas that necessitate amputation. Autonomic dysfunction is also frequently associated with DSPN including impotence, nocturnal diarrhea, sweating abnormalities, orthostatic hypotension, and gastroparesis.

Other less common neuropathies associated with diabetes include cranial neuropathies (the sixth, third, and rarely fourth nerves), mononeuropathies, mononeuropathy multiplex, radiculopathies, and plexopathies. Diabetic amyotrophy (also known as *diabetic lumbosacral polyradiculopathy*) is a distinctive disorder characterized by severe thigh pain followed by proximal>distal lower extremity weakness that progresses over a period of months. The onset is invariably

unilateral, but the condition may progress to involve both lower extremities. Physical therapy and effective pain management are essential; treatment with immune modulators is controversial.

TOXIC-INDUCED NEUROPATHIES

Toxic neuropathies constitute a large number of disorders caused by alcohol, drugs, heavy metals, and environmental substances (Web Table 130-3). The majority of toxic neuropathies manifest as a distal sensorimotor axonal neuropathy that chronically progresses over time unless the offending agent is eliminated. Clinical evaluation should focus on the temporal relationship between exposure and the onset of sensory or motor symptoms as well as symptoms of systemic toxicity.

CRITICAL ILLNESS POLYNEUROPATHY

Critical illness polyneuropathy (CIP) is a common cause of failure to wean from a ventilator in a patient with associated sepsis and multi-organ failure. Clinical features include generalized or distal flaccid paralysis, especially involving the lower extremities, depressed or absent reflexes, and distal sensory loss with relative sparing of cranial nerve function. The diagnosis can be confirmed with nerve conduction studies showing evidence of a severe, generalized axonal neuropathy. CSF protein should be normal and, in addition to conduction studies, distinguishes CIP from GBS.

Specific Hereditary Polyneuropathies

CHARCOT-MARIE-TOOTH DISEASE

The eponym Charcot-Marie-Tooth (CMT) identifies a group of heritable disorders of peripheral nerves that share clinical features but differ in their pathologic mechanisms and the specific genetic abnormalities (Web Table 130-4). CMT is the most common heritable neuromuscular disorder, with an incidence of 17 to 40 cases per 100,000.

CMT disease usually manifests during the first to second decades with symptoms related to insidious foot drop: frequent tripping and inability to jump well or run as fast as other children. Over time, distal upper extremity weakness develops, resulting in difficulty with buttoning, handling keys, and opening jars. Examination reveals distal weakness and wasting of the intrinsic muscles of the feet, the peroneal muscles, the anterior tibial muscles, and the calves (inverted champagne bottle legs). A variable degree of impaired large-fiber sensory function is reflected in reduced vibratory sensation at the toes. Muscle stretch reflexes are lost, first at the ankles. Typically, a foot deformity exists, with high arches (pes cavus) and hammer toes, reflecting long-standing muscle imbalance in the feet. Most patients with CMT disease have nearly normal occupational and daily activities, and they have a normal life span. Although no specific treatment has been developed, the foot drop can be treated by

appropriate bracing of the ankle with ankle-foot orthoses. Genetic counseling and education of affected patients and their families are important, both for reassurance and to preclude unnecessary diagnostic evaluation of affected members in future generations.

Demyelinating forms of CMT are classified as CMT1 and axonal forms as CMT2. CMT is usually transmitted as an autosomal dominant trait; however, X-linked dominant transmission is responsible for approximately 10% of cases. Rare autosomal recessive forms are designated CMT4, and these patients tend to have an earlier onset and more severe phenotype. CMT1A is the most common form and accounts for 90% of CMT1 and 50% of all CMT cases. CMT1A is associated with the 17p11.2-p12 duplication in the *PMP22* gene expressed by Schwann cells. A deletion or a point mutation of the *PMP22* gene produces a different phenotype—HNPP, which is characterized by recurrent episodes of focal entrapment with attacks of weakness and numbness in the peroneal, ulnar, radial, and median nerves (in descending order of frequency) or in a brachial plexus distribution. Commercial testing for the *PMP22* duplication or deletion is now widely available.

Familial Amyloid Neuropathies

Amyloid neuropathy is an autosomal dominant disorder caused by extracellular deposition of the fibrillary protein amyloid in peripheral nerve and sensory and autonomic ganglia, as well as around blood vessels in nerves and other tissues. The age of onset varies from 18 to 83 years. In all forms of amyloidosis, the initial and major abnormalities affect the small sensory and autonomic fibers. Involvement of small fibers responsible for pain and temperature sensibilities leads to loss of the ability to perceive mechanical and thermal injuries and to an increased risk of tissue damage. As a result, painless injuries present a major hazard of this disorder; in advanced stages, they can lead to chronic infections or osteomyelitis of the feet or hands and the necessity for amputation. Amyloid deposition in the heart can lead to cardiomyopathy. Mutations in transthyretin, apolipoprotein A1, or gelsolin are responsible. Early recognition is essential, as liver transplantation has been shown to halt disease progression.

Prospectus for the Future

The discovery of the cause of some cases of familial amyotrophic lateral sclerosis (ALS) has not yet translated into treatment strategies, nor has it shed light on potential treatments for the more common, clinically identical sporadic syndrome. Genetic and environmental factors that might alter a patient's predisposition of developing sporadic ALS are also being sought, and with this knowledge comes the hope that novel

treatments will soon be developed. In the meantime, many innovative clinical trials are being conducted. The identification of the molecular cause of many of the hereditary peripheral neuropathies has opened the prospect of genetic approaches to treatment. For the acquired neuropathies, symptomatic treatments continue to be developed and improved.

Muscle Diseases

Robert C. Griggs

Skeletal muscle diseases (myopathies) are disorders in which a primary structural or functional impairment of muscle occurs. Myopathies can be broadly classified into hereditary and acquired disorders. The hereditary disorders include the muscular dystrophies, congenital myopathies, channelopathies, metabolic disorders, and mitochondrial disorders. The acquired include inflammatory disorders, metabolic disorders, endocrine disorders, disorders associated with systemic illness, and drug-induced or toxic disorders.

Organization and Structure of Muscle

Muscle consists of many motor units. The number of muscle fibers innervated by a single motor unit varies from muscle to muscle. Muscles subserving finely coordinated movements, such as an ocular muscle, can have fewer than 10 muscle fibers in a motor unit. Powerful proximal limb muscles have large motor units with 1000 to 2000 fibers innervated by a single motor neuron.

The muscle fibers consist of thick and thin filaments (myofibrils). The myofibrils are surrounded by the sarcolemmal membrane and basal lamina. A large number of muscular dystrophies are now known to be caused by genetic defects in this region (Fig. 131-1). The sarcolemmal components are known as the *dystrophin-glycoprotein complex* (DGC). The DGC is a trans-sarcolemmal complex of proteins and glycoproteins that links the subsarcolemmal cytoskeleton to the extracellular matrix. Dystrophin was the first well-characterized protein in the DGC. Other DGC components include the dystroglycan complex (α and β), the sarcoglycan complex (α , β , γ , and δ), and the syntrophin complex (α , β 1, and β 2). Closely adherent to the extracellular portion of the sarcolemma is the basal lamina, components of which are known as *laminins*.

Assessment

The most important aspect of evaluating a patient with a myopathy is the history. The most common symptom of a

patient with muscle disease is a loss of function caused by weakness. If the weakness is in the legs, then patients report difficulty climbing stairs and rising from a low chair or toilet or from the floor. When the arms are involved, patients notice trouble lifting objects (especially over their heads) and washing or brushing their hair. These symptoms point to proximal weakness, the most common site of weakness in a myopathy. In less common distal myopathies, patients first complain of poor hand grip (difficulty opening jar tops and turning door knobs) or tripping as a result of ankle weakness from muscle weakness. Rarely they may exhibit a change in speech or swallowing, droopy eyelids, and double vision from weakness of cranial nerve–innervated muscles.

The tempo of the disease course is important. Weakness may be present all of the time (fixed) or intermittently (episodic). Myopathies can produce either fixed or episodic symptoms. Muscle disorders can be *acute* (<4 weeks), *subacute* (4 to 8 weeks), or *chronic* (>8 weeks). Examples include (1) acute or subacute inflammatory myopathies (dermatomyositis [DM] and polymyositis [PM]), (2) chronic slow progression over years (most muscular dystrophies), or (3) fixed weakness with little change over decades (congenital myopathies). Patients with channelopathies or metabolic myopathies have recurrent attacks over many years, whereas a patient with acute muscle destruction caused by a toxin such as cocaine may have a single acute episode.

Patients who report a generalized global *weakness* or *fatigue* seldom have a myopathy, particularly if the neurologic examination findings are normal. Fatigue is a complaint of the patient with myasthenia gravis but otherwise is usually a nonspecific symptom. Muscle pain (myalgia) is also a nonspecific complaint that infrequently accompanies some myopathies. Myalgias may be episodic (e.g., metabolic myopathies) or nearly constant (e.g., occasional inflammatory myopathies). However, muscle pain is surprisingly uncommon in most muscle diseases, and limb pain is more likely to be caused by bone or joint disorders. Rarely is a muscle disease responsible for vague aches and discomfort in muscle if strength is normal. The involuntary muscle cramp is localized to a single muscle and lasts from seconds to minutes. In most instances, cramps are benign and normal; they do not reflect myopathy. Cramps occur with dehydration, hyponatremia, azotemia, and myxedema and

Figure 131-1 The dystrophin-glycoprotein complex and related proteins.

in nerve disease such as amyotrophic lateral sclerosis. Muscle contractures are rare and resemble a cramp. They last longer than cramps and occur with exercise in glycolytic enzyme defects. On electromyographic (EMG) examination, contractures are electrically silent, whereas cramps have rapidly firing motor unit discharges. Muscle contracture should not be confused with fixed tendon contracture. Myotonia is the phenomenon of impaired relaxation of muscle after forceful voluntary contraction. Patients report muscle stiffness or persistent contraction in almost any muscle group but particularly the hands. Exercise-induced weakness and myalgias may be accompanied by dark or red urine (myoglobinuria). Myoglobinuria follows rapid muscle destruction.

EXAMINATION

Specific muscle function should be tested. Muscle strength is quantitated by the Medical Research Council of Great Britain (MRC) grading scale of 0 to 5:

- 5: Normal power
- 4: Active movement against gravity and resistance
- 3: Active movement against gravity
- 2: Active movement only with gravity eliminated
- 1: Trace contraction
- 0: No contraction

Muscles should be inspected for atrophy or hypertrophy. Atrophy of proximal limb muscles is usual in longstanding myopathies. Muscles can also become diffusely hypertrophic

in dystrophic or myotonic conditions. In Duchenne and Becker dystrophies, the calves enlarge as a result of pseudo-hypertrophy from replacement with connective tissue and fat. The sensory examination findings should be normal in muscle disease. Reflexes are preserved early in the disease process, but when muscles become extremely weak, reflexes become hypoactive or unelicitable. Evidence of upper motor neuron damage (e.g., spasticity, Babinski signs, clonus) is present in myopathies only if coincidental central nervous system disease exists.

PATTERNS OF WEAKNESS

Six broad patterns of muscle weakness occur in myopathies:

1. The most common is in proximal muscles of the arms and legs: a limb-girdle distribution. Neck flexor and extensor muscles can also be affected. The reason why most myopathies begin in proximal muscles is unknown.
2. Distal weakness may begin in the upper or lower extremities. Such distal weakness is often a feature of neuropathies.
3. Scapulo-peroneal weakness includes weakness of the periscapular muscles and distal lower extremity weakness of the anterior compartment. The scapular muscle weakness is usually accompanied by scapular winging.
4. Distal upper extremity weakness in the distal forearm muscles (wrist and finger flexors), and proximal lower extremity weakness involving the knee extensors

(quadriceps) may occur. This pattern is typical of inclusion body myositis (IBM) and frequent in myotonic dystrophy.

5. Involvement of ocular or pharyngeal muscles may be predominant.
6. Neck extensor weakness (the *dropped head syndrome*) may be prominent.

These six patterns of myopathy are useful in differential diagnosis, but neuromuscular diseases other than myopathies can also exhibit one of these weakness patterns. For example, whereas proximal greater than distal weakness is characteristic of myopathies, patients with acquired demyelinating neuropathies (Guillain-Barré syndrome and chronic inflammatory demyelinating polyneuropathy) often have proximal as well as distal muscle involvement. Such neuropathies are additionally accompanied by sensory and reflex loss. Ocular, pharyngeal, and proximal limb weakness is characteristic of neuromuscular junction transmission disorders such as myasthenia gravis. However, affected patients often have diplopia and weakness that fluctuates, suggesting the correct diagnosis.

MUSCLE BIOPSY

Fixed muscle is of little value for diagnosis. Examination of muscle tissue under light microscopy is primarily performed using frozen specimens. The muscle biopsy can establish if either a neuropathic or a myopathic disorder is present; it can also suggest a specific diagnosis of many hereditary and acquired myopathies.

Muscular Dystrophies

Muscular dystrophies are inherited myopathies characterized by progressive muscle weakness and degeneration and subsequent replacement by fibrous and fatty connective tissue. Historically, muscular dystrophies were categorized by their distribution of weakness, age at onset, and inheritance pattern. Advances in the molecular understanding of the muscular dystrophies have defined the genetic mutation and abnormal gene product for most of these disorders (Table 131-1).

Dystrophinopathies are X-linked disorders resulting from mutations of the large dystrophin gene located at Xp21. Dystrophin is a large subsarcolemmal cytoskeletal protein that, along with the other components of the DGC, provides support to the muscle membrane during contraction. Mutations disrupting the translational reading frame of the gene result in near-total loss of dystrophin (Duchenne dystrophy), whereas in-frame mutations result in the translation of semifunctional dystrophin of abnormal size or amount (Becker dystrophy). The incidence of Duchenne dystrophy is 1 in 3500 male births; one third of the cases result from a new mutation. Duchenne dystrophy manifests as early as age 2 to 3 years as delays in motor milestones and difficulty running. The proximal muscles are the most severely affected, and the course is relentlessly progressive. Patients begin to fall frequently by age 5 to 6, have difficulty climbing stairs by age 8 years, and are usually confined to a wheelchair by age 12. Most patients die of respiratory complications in

their 20s. Congestive heart failure and arrhythmias can occur late in the disease. The smooth muscle of the gastrointestinal tract is involved and may cause intestinal pseudo-obstruction. The average IQ of boys with Duchenne dystrophy is low, reflecting central nervous system involvement. Becker dystrophy is a milder form of dystrophinopathy and varies in severity depending on the gene lesion. It is less common than the Duchenne form, with an incidence of 5 per 100,000.

Myotonic dystrophy occurs in two forms: DM-1 and DM-2. Both dystrophies are autosomal-dominant multisystem disorders that affect skeletal, cardiac, and smooth muscle and other organs, including the eyes, the endocrine system, and the brain. DM-1 is the most prevalent muscular dystrophy, with an incidence of 13.5 per 100,000 live births. DM-1 can occur at any age, with the usual onset of symptoms in the late second or third decade. However, some affected individuals may remain symptom-free their entire lives. A severe form of DM-1 with onset in infancy is known as *congenital myotonic dystrophy*. The severity of DM-1 generally worsens from one generation to the next (anticipation). Typical patients exhibit facial weakness with temporalis muscle wasting, frontal balding, ptosis, and neck flexor weakness. Extremity weakness usually begins distally and progresses slowly to affect the proximal limb-girdle muscles. Percussion myotonia can be elicited on examination in most patients, especially in thenar and wrist extensor muscles.

Associated manifestations in DM-1 include cataracts, testicular atrophy and impotence, intellectual impairment, and hypersomnia associated with both central and obstructive sleep apnea. Respiratory muscle weakness may be severe, with impairment of ventilatory drive. Cardiac conduction defects are common and can produce sudden death. Pacemakers may be necessary, and annual electrocardiographic examinations are recommended. Chronic hypoxia can lead to cor pulmonale. The molecular defect of myotonic dystrophy (DM-1) is an abnormal expansion of CTG repeats in chromosome 19q13.2. The second myotonic dystrophy (DM-2) is caused by an abnormal expansion of a tetranucleotide repeat on chromosome 3q. The precise pathomechanisms of DM-1 and DM-2 are unknown but probably relate to abnormal RNA transcribed by the pathologic repeats. DM-2 resembles DM-1. However, weakness is often proximal; patients may complain of myotonia and myalgias. Patients with DM-2 may have less severe cardiac and other organ involvement than those with DM-1.

Congenital Myopathies

Congenital myopathies are defined by their appearance on biopsy (Table 131-2). They are usually present at birth with hypotonia and subsequent delayed motor development. Most congenital myopathies are relatively nonprogressive and may not be diagnosed until the second or third decade. Clinical findings common in the congenital myopathies are reduced muscle bulk, slender body build, a long, narrow face, skeletal abnormalities (high-arched palate, pectus excavatum, kyphoscoliosis, dislocated hips, and pes cavus), and absent or reduced muscle stretch reflexes. The molecular

genetic defects of most congenital myopathies are now known, and these disorders, as well as the muscular dystrophies, are being reclassified.

Metabolic Myopathies

Metabolic myopathies (Table 131-3) include (1) glucose and glycogen metabolism disorders, (2) lipid metabolism disorders, and (3) mitochondrial disorders.

GLUCOSE AND GLYCOGEN METABOLISM DISORDERS

Glucose, and its storage form glycogen, is essential for the short-term, predominantly anaerobic energy requirements

of muscle. Disorders of glucose and glycogen metabolism (called *glycogenoses*) have two distinct syndromes: (1) dynamic symptoms of exercise intolerance, pain, cramps, and myoglobinuria; and (2) static symptoms of fixed weakness without exercise intolerance or myoglobinuria. Of the

11 glycogenoses, only glucose 6-phosphate (type I) and liver phosphorylase (type VI) deficiencies spare muscle.

Glycogenoses with Exercise Intolerance (Myoglobinuria)

Exercise intolerance (Table 131-4) begins in childhood with exertional muscle pain, cramps, and myoglobinuria appearing in the second or third decade. Many patients note a *second wind* phenomenon after a period of brief rest so that they can continue the exercise at the previous level of activity. Muscle pain is caused by electrically silent contractures. Strength, blood creatine kinase (CK) levels, and EMG findings between attacks are usually normal early in the disease, but they may become abnormal with advancing age. After episodes of severe myoglobinuria, EMG shows myopathic units and fibrillations. EMG performed during a contracture shows electrical silence. In the forearm exercise test, the venous lactate level fails to rise in myophosphorylase, phosphofructokinase, and phosphoglycerate kinase deficiencies and rises subnormally in phosphorylase β kinase, phosphoglucomutase, and lactate dehydrogenase deficiencies. Diagnosis is made by muscle biopsy study of the enzymes or by defining specific genetic mutations.

Glycogenoses with Fixed Weakness and No Exercise Intolerance

Glycogenoses with fixed weakness and no exercise intolerance (see Table 131-3) produce a syndrome of progressive proximal weakness. Diagnosis requires muscle biopsy or genetic mutation definition. Acid maltase deficiency can now be treated with enzyme replacement.

DISORDERS OF FATTY ACID METABOLISM

Lipids are essential for the aerobic energy needs of muscle during sustained exercise. Serum long-chain fatty acids are the primary lipid fuel for muscle metabolism. They are transported into the mitochondria as carnitine esters and

Table 131-3 Metabolic and Mitochondrial Myopathies

Glycogen Metabolism Deficiencies

Type II	$\alpha_{1,4}$ -glucosidase (acid maltase)
Type III	Debranching enzyme
Type IV	Branching enzyme
Type V	Phosphorylase* (McArdle disease)
Type VII	Phosphofructokinase* (Tarui disease)

Mitochondrial depletion syndrome
Leigh disease and neuropathy, ataxia, retinitis pigmentosa (NARP)
Succinate dehydrogenase deficiency*

*Deficiency can produce exercise intolerance and myoglobinuria.

Table 131-4 Channelopathies and Related Disorders

Disorder	Clinical Features	Inheritance	Chromosome	Gene
Chloride Channelopathies				
Myotonia congenita				
Thomsen disease	Myotonia	Autosomal dominant	7q35	<i>CLC-1</i>
Becker disease	Myotonia and weakness	Autosomal recessive	7q35	<i>CLC-1</i>
Sodium Channelopathies				
Paramyotonia congenita	Paramyotonia	Autosomal dominant	17q13.1-13.3	<i>SCNA4A</i>
Hyperkalemic periodic paralysis	Periodic paralysis, myotonia, and paramyotonia	Autosomal dominant	17q13.1-13.3	<i>SCNA4A</i>
Hypokalemic periodic paralysis (<10% of cases)	Periodic paralysis	Autosomal dominant	17q13.1-13.3	<i>SCNA4A</i>
Calcium Channelopathies				
Hypokalemic periodic paralysis	Periodic paralysis (most cases)	Autosomal dominant	1q31-32	Dihydropyridine receptor
Malignant hyperthermia (some cases)	Anesthetic-induced delayed relaxation	Autosomal dominant	19q13.1	Ryanodine receptor
Potassium channelopathy (Andersen-Tawil syndrome)	Periodic paralysis, cardiac arrhythmia, skeletal abnormalities	Autosomal dominant	17q23	<i>KCNJ2</i>
Rippling muscle disease (Web video 131-1)	Muscle mounding or stiffness	Autosomal dominant	1q41	Caveolin-3

are metabolized by means of beta-oxidation. Carnitine palmitoyl transferase (CPT) I converts cytoplasmic acyl coenzyme A (CoA) to acylcarnitine, which is then transported into the mitochondria by carnitine acyltransferase in exchange for carnitine. CPT II on the inner mitochondrial membrane reconstitutes acyl CoA. A deficiency of carnitine, CPT, or the enzymes of beta-oxidation can lead to impaired muscle lipid metabolism.

As with glycogen pathway defects, abnormal fatty acid metabolism causes exercise intolerance with myoglobinuria or static weakness with a lipid storage myopathy. In addition, some disorders of lipid metabolism can produce multi-organ metabolic crises, with hepatic failure and altered mental status. Most lipid disorders are believed to be autosomal recessive (see Table 131-3).

MITOCHONDRIAL MYOPATHIES

Mitochondrial myopathies (see Table 131-3) produce slowly progressive weakness of proximal limbs or external ocular and other cranial muscles and abnormal fatigability on sustained exertion. Some of these myopathies affect multiple organs or systems, in addition to muscle. In mitochondrial myopathies, some muscle fibers contain abnormal mitochondria. These fibers appear *ragged red* on biopsy stains (trichrome) and may fail to react for cytochrome *c* oxidase. Serum lactic acid levels are often elevated at rest in mitochondrial myopathy. Mitochondrial diseases are caused by mutations in either nuclear or mitochondrial DNA. During fertilization, all of the mitochondria are contributed by the mother; thus all mutations of mitochondrial DNA are either maternally transmitted or arise *de novo* in the maternal ovum or in early embryonic life. However, because the majority of mitochondrial proteins (95%) are encoded from nuclear genes, mitochondrial disorders can also have autosomal-dominant or X-linked heredity. Mitochondrial disorders produce biochemical defects proximal to the respiratory chain (involving substrate transport and usage) or within the respiratory chain.

SPECIFIC MITOCHONDRIAL DISORDERS AFFECTING MUSCLE

Progressive External Ophthalmoplegia

Severe ptosis and progressive external ophthalmoplegia (PEO) are clinical hallmarks of mitochondrial disease. Ptosis is often the presenting symptom and can be noted in childhood. Patients and their physicians often overlook both ptosis and PEO (lack of eye movements). Patients often do not complain of double vision. Slight proximal weakness may occur. PEO caused by mitochondrial disease is associated with single or multiple mitochondrial DNA deletions. Patients with single mitochondrial deletions have Kearns-Sayre syndrome, which manifests before age 20 years and includes a wide variety of multisystem abnormalities: retinitis pigmentosa, heart block, hearing loss, short stature, ataxia, delayed puberty, peripheral neuropathy, and impaired ventilatory drive. Kearns-Sayre syndrome is caused by single large mitochondrial deletions; it is sporadic with no family history of the disorder. Patients with PEO who have multiple mitochondrial deletions have an autosomal-dominant

inheritance pattern. Many of the responsible genes have been identified (see Table 131-3).

Myoclonic Epilepsy and Ragged Red Fibers

Patients with myoclonic epilepsy and ragged red fibers (MERRF) have varying symptoms of myoclonus, generalized seizures, ataxia, dementia, sensorineural hearing loss, and optic atrophy, as well as limb-girdle weakness. Some patients also have peripheral neuropathy, cardiomyopathy, and cutaneous lipomas. Ptosis and PEO are usually not present.

Mitochondrial Encephalomyopathy with Lactic Acidosis and Strokelike Episodes

Patients with mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes (MELAS) have normal early development, experience migraine-like headaches and strokes before age 40 years, and have chronic lactic acidosis. Other features can include dementia, hearing loss, and episodic vomiting, ataxia, and coma, as well as diabetes. Ptosis and PEO are uncommon.

Channelopathies (Nondystrophic Myotonias and Periodic Paralyses)

The myotonias are categorized into dystrophic and nondystrophic disorders. The nondystrophic myotonias and the periodic paralyses are caused by mutations of various ion channels in muscle (see Table 131-4). The term *channelopathies* is often used to describe this group of disorders.

CHLORIDE CHANNELOPATHIES

Myotonia congenita is caused by point mutations in the muscle chloride channel gene. Autosomal-dominant and autosomal-recessive forms are allelic. The autosomal-dominant form (Thomsen disease) and the autosomal-recessive form (Becker myotonia congenita) are both benign and are associated with muscle hypertrophy and action, percussion, and electrical myotonia. Cold increases the myotonia, and exercise improves it. The heart or other organs are not involved. Patients with Thomsen disease are not weak, but patients with Becker myotonia congenita have fluctuations in strength and may develop persistent limb-girdle weakness. Many patients do not require treatment, but drugs such as quinine, procainamide, phenytoin, and mexiletine reduce myotonia and may improve strength.

SODIUM CHANNELOPATHIES

Several autosomal-dominant disorders are caused by point mutations in the voltage-dependent sodium channel gene. All of these disorders have symptoms beginning in the first decade. Paramyotonia congenita has paradoxical myotonia in that myotonia *increases* with exercise. Myotonia is worsened by cold temperature. The myotonia can be treated with sodium channel blockers such as mexiletine.

In hyperkalemic periodic paralysis, attacks of weakness last 1 to 2 hours and are precipitated by fasting, by rest after exercise, or by ingesting potassium-rich foods. During attacks, patients are hyporeflexic with normal sensation, and no ocular or respiratory muscle weakness is present. The

serum potassium level may be normal during the attack, and therefore a more appropriate term may be *potassium-sensitive periodic paralysis*. Episodes of weakness rarely necessitate acute therapy; oral carbohydrates or glucose improves weakness. Treatments to prevent attacks include thiazide diuretics, β -agonists, and a low-potassium, high-carbohydrate diet, with avoidance of fasting, strenuous activity, and cold.

In a small proportion of patients, hypokalemic periodic paralysis results from mutations in the sodium channel (see **Web video 131-2**).

CALCIUM CHANNELOPATHIES

The majority of cases of hypokalemic periodic paralysis are caused by mutations in the muscle calcium channel. Attacks begin by adolescence and are triggered by exercise, sleep, stress, or meals rich in carbohydrates and sodium. Attacks last from 3 to 24 hours. A vague prodrome of stiffness or heaviness in the legs can occur, and if the patient performs mild exercise, then a full-blown attack may be aborted. Ocular, bulbar, and respiratory muscles are rarely involved. Early in the disease, patients have relatively normal interattack examinations except for eyelid myotonia (approximately 50%). Later, many patients have proximal weakness. Preventive measures include a low-carbohydrate, low-sodium diet and carbonic anhydrase inhibitors. Acute attacks are treated with oral potassium. Patients with hypokalemic periodic paralysis and mutations in the sodium channel are often worsened by carbonic anhydrase inhibitors.

Thyrotoxic periodic paralysis resembles hypokalemic periodic paralysis and is common in male Asian young adults; β -adrenergic blocking agents reduce the frequency and severity of attacks, but the ultimate treatment is directed against the thyrotoxicosis. A channel defect has not yet been identified.

Malignant hyperthermia is characterized by severe muscle rigidity, fever, tachycardia precipitated by depolarizing muscle relaxants, and inhalational anesthetic agents such as halothane. The symptoms usually occur during surgery but can first be noticed in the postoperative period. Patients may have had previous anesthesia without symptoms. During attacks, the CK level is markedly elevated, and myoglobinuria develops. The disorder is caused by excessive calcium release by the sarcoplasmic reticulum calcium channel, the ryanodine receptor. Some patients have mutations in the ryanodine receptor gene on chromosome 19q13, which is the same gene mutated in central core disease. The symptoms are treated with dantrolene, and at-risk patients should not be given known provocative anesthetic agents. The occurrence of malignant hyperthermia in one member of a family should prompt prompt consideration as to whether other family members might also be at risk.

OTHER FORMS OF MUSCLE STIFFNESS

Neuroleptic malignant syndrome with muscular rigidity, altered mental status, and hyperthermia is caused by central dopaminergic blockade from neuroleptics. The muscle rigidity can produce myoglobinuria.

Stiff-person syndrome is an acquired autoimmune condition that produces severe muscle stiffness of proximal, and

especially paraspinous, muscles. Excess motor unit activity caused by autoantibodies to glutamic acid decarboxylase is present, which is a major enzyme in the synthesis of δ -aminobutyric acid, and this circumstance results in disinhibition in the central nervous system. Some patients also have antibodies to islet cells and develop diabetes mellitus. Symptomatic treatment consists of diazepam; immunosuppressive treatment can improve the condition.

Inflammatory Myopathies

Inflammatory myopathies are acquired, nonhereditary disorders (Table 131-5) that are characterized by muscle weakness and inflammation on muscle biopsy. Most are associated with elevated CK levels, myopathic EMG findings, and a limb-girdle distribution of weakness. Occasionally, inflammatory myopathies have distal, focal, or other selective involvement of particular muscles.

IDIOPATHIC INFLAMMATORY MYOPATHY

The three major categories of idiopathic inflammatory myopathy are DM, PM, and IBM (Table 131-6). PM and DM are both characterized by the onset of symmetrical weakness subacutely over weeks or several months. Myalgias can occur, but muscle pain and tenderness are rarely chief complaints. Patients complaining of myalgia who do not have demonstrable weakness are more likely to have polymyalgia rheumatica or fibromyalgia than PM. Esophageal muscles are affected in up to 30% of both PM and DM cases, leading to dysphagia.

The rash of DM may accompany or precede the onset of muscle weakness. This rash can be a heliotrope rash (purplish discoloration of the eyelids often associated with

Infections

Bacterial (e.g., *Staphylococcus*, *Streptococcus*, gas gangrene, *Clostridium welchii*)
Viral: acute myositis after influenza or other viral infections; retrovirus-related myopathies (HIV, HTLV-1)
Parasitic: toxoplasmosis, trypanosomiasis, cysticercosis, trichinosis
Fungal

HIV, human immunodeficiency virus; HTLV-1, human T-cell leukemia virus type 1.

Table 131-6 Idiopathic Inflammatory Myopathies: Clinical and Laboratory Features

Myopathy	Sex	Typical Age at Onset	Pattern of Weakness	Creatine Kinase	Muscle Biopsy	Response to Immunosuppressive Therapy
Dermatomyositis	Women >men	Childhood and adult	Proximal >distal	Increased (up to 50× normal)	Perifascicular atrophy, MAC, immunoglobulin, complement deposition on vessel	Yes
Polymyositis	Women >men	Adult	Proximal >distal	Increased (up to 50× normal)	Endomysial inflammation	Yes
Inclusion body myositis	Men >women	Elderly (>50 yr)	Proximal and distal; predilection for finger and wrist flexors, knee extensors	Increased (<10× normal)	Endomysial inflammation, rimmed vacuoles; amyloid deposits; electron microscopy: 15- to 18-nm tubulofilaments	No

MAC, membrane attack complex.

periorbital edema); Gottron sign (papular, erythematous, scaly lesions over the knuckles); a macular erythematous, sun-sensitive rash on the face, neck, and anterior chest, shoulders, upper back, elbows, and knees; or periungual erythema caused by dilated capillary loops with thrombi or hemorrhage.

IBM presents as an insidious onset of slowly progressive proximal and distal weakness typically after age 50 years. It is the most common inflammatory myopathy in older adults. Many patients have a distinctive pattern of muscle involvement, with early weakness and atrophy of the quadriceps (knee extensors), volar forearm muscles (wrist and finger flexors), and tibialis anterior (ankle dorsiflexors).

Cardiac involvement, resulting in congestive heart failure and conduction defects, and interstitial lung disease can develop in a minority of patients with PM and DM (but not IBM). Vasculitis of the gastrointestinal tract, kidneys, lungs, and eyes can complicate DM (but not PM), particularly in children. The incidence of malignancy in older adults with DM is increased.

The electromyogram in DM, PM, and IBM demonstrates brief myopathic motor units, increased recruitment, and fibrillation potentials. The serum CK level is usually increased. The erythrocyte sedimentation rate is normal in most patients. An elevated erythrocyte sedimentation rate suggests a different or coincidental disease. A muscle biopsy should be performed in all patients with suspected inflammatory myopathy to support the diagnosis (see Table 131-6).

Histologic features and immunologic studies suggest that DM is a humorally mediated micro-angiopathy. The micro-angiopathy leads to ischemic damage of muscle fibers. PM is likely to be a cell-mediated disorder. The cause of IBM is unknown.

Corticosteroids and other immunotherapies can improve strength and function in patients with DM and PM. In contrast, IBM is usually refractory to immunosuppressive therapy.

INFECTIOUS MYOSITIS

An acute viral myositis can occur in the setting of an influenza viral upper respiratory tract infection. In addition to typical influenza-associated myalgias, affected patients develop proximal weakness, elevated CK levels, and a myopathic electromyogram. The disorder is self-limited, but when severe it is often associated with myoglobinuria and occasionally with renal failure. A similar syndrome can complicate infections with other viruses.

An inflammatory myopathy can occur in the setting of human immunodeficiency virus infection, either in early or in later acquired immunodeficiency syndrome. The clinical presentation is similar to that of patients with PM. Patients' condition may improve with corticosteroid therapy. The disorder must be distinguished from the toxic myopathy caused by zidovudine, which responds to dose reduction.

Myopathies Caused by Endocrine and Systemic Disorders

Excess corticosteroids can result from endogenous Cushing disease or can be caused by exogenous glucocorticoid administration. Iatrogenic corticosteroid myopathy (or atrophy) is the most common endocrine-related myopathy. However, muscle weakness is rarely the presenting manifestation of Cushing disease, and in virtually all instances of corticosteroid myopathy, other factors contributing to weakness are also present. Therapy consists of reducing the corticosteroid dose to the lowest possible level. Exercise and adequate nutrition prevent and may improve weakness.

Patients with hyperthyroidism often have some degree of proximal weakness, but this is rarely the presenting manifestation of thyrotoxicosis. Hypothyroid myopathy is associated with proximal weakness and myalgias, muscle

enlargement, slow relaxation of the reflexes, and marked (up to 100-fold) increase of the serum CK level.

Progressive, painless proximal weakness in a patient with diabetes is seldom the result of diabetes-related myopathy. Chronic inflammatory demyelinating neuropathy should be suspected. Asymmetrical, usually painful, proximal leg weakness can occur from an ischemic radiculoplexopathy. In rare cases, acute muscle infarction can develop in quadriceps or hamstring muscles. Affected patients complain of severe pain, tenderness, and swelling. Magnetic resonance imaging of the thigh shows changes consistent with a muscle infarct. The syndrome resolves spontaneously over weeks.

Toxic Myopathies

Many drugs have been associated with muscle damage; common ones are listed in Table 131-7. Most of these drugs can produce proximal weakness, elevated CK levels, myopathic EMG readings, and abnormalities on muscle biopsy. Symptoms generally improve on stopping the medication. Some drugs can produce acute, rapidly progressive muscle destruction and myoglobinuria, particularly the hypocholesterolemic drugs clofibrate, gemfibrozil, lovastatin, simvastatin, pravastatin, and niacin. An acute necrotizing myopathy associated with myoglobinuria occurs in chronic alcoholics after heavy drinking. Hypokalemia caused by sweating, vomiting, diarrhea, and renal wastage may be causative.

Also known as critical illness myopathy (CIM), acute quadriplegic myopathy develops in a patient in the intensive care setting and is often discovered when a patient is unable to be weaned off a ventilator. The cause of the diffuse weakness is the prolonged daily use of either (often both) high-dose intravenous glucocorticoids (usually methylprednisolone) or nondepolarizing neuromuscular blocking agents (e.g., vecuronium). Patients often have had sepsis and multi-organ failure. The diagnosis of CIM can be confirmed on muscle biopsy, which shows the loss of myosin thick filaments on electron microscopic examination. Treatment is supportive after discontinuation of the offending agents. Strength returns over a period of weeks or months; patients can usually be weaned off the ventilator. Many patients with CIM develop plexopathies that cause focal weakness, with evidence of denervation on EMG studies. These plexopathies may result from compression by swollen muscles; they resolve slowly and often incompletely over many months.

Table 131-7 Toxic Myopathies

Inflammatory: cimetidine, D-penicillamine
Noninflammatory necrotizing or vacuolar: cholesterol-lowering agents, chloroquine, colchicine
Acute muscle necrosis and myoglobinuria: cholesterol-lowering drugs, alcohol, cocaine
Malignant hyperthermia: halothane, ethylene, others; succinylcholine
Mitochondrial: zidovudine
Myosin loss: nondepolarizing neuromuscular blocking agents; glucocorticoids

Myoglobinuria

Acute muscle destruction can produce a brown discoloration of urine by myoglobin. Myoglobin, a 17,000-D molecular-weight protein that contains the heme moiety, is present in high concentration in muscle. The visible discoloration of urine by myoglobin indicates both massive and acute muscle destruction and warns of impending renal damage. The pigment has to be distinguished from hemoglobin. If no hematuria is present, then a positive urine test for blood strongly suggests myoglobinuria.

Muscle pain, swelling, and weakness precede overt myoglobinuria by a few hours. In addition to myoglobin, phosphate, potassium, creatine, and muscle enzymes are released into the circulation. Serum CK levels can be over 1000 times normal. The heme pigment in the glomerular filtrate and casts in the tubules cause proteinuria and tubular necrosis. Renal failure is more likely if hypotension, acidosis, and hypovolemia coexist. With increasing renal insufficiency, hyperphosphatemia, hypocalcemia, tetany, and life-threatening hyperkalemia appear. Death may result from renal or respiratory failure.

Myoglobinuria is caused by massive ischemia of muscle from any cause: crush injuries, prolonged pressure, or persistent contraction and rigidity (such as from status epilepticus, malignant hyperthermia, or neuroleptic malignant syndrome). Infectious causes include viral and bacterial infections. The acute episode is treated by rest, maintenance of adequate urine flow by hydration and diuretics, and alkalization of the urine with sodium bicarbonate. Other measures consist of treating the renal insufficiency as required and removing the offending cause, if possible.

Prospectus for the Future

With the discovery of the molecular defects in nearly all of the inherited muscle diseases, gene therapy strategies are under development. Vectors are available for potential correction of the defects arising from mutations in small genes. The very large dystrophin gene mutated in Duchenne dystrophy poses

technical challenges. Strategies to correct muscle gene abnormalities via arterial administration with viral vectors that target muscle have greater appeal than intramuscular administration into multiple skeletal (and cardiac) muscles.

Neuromuscular Junction Disease

Emma Ciafaloni

Disorders of the neuromuscular junction interfere with the transmission of electrical impulses from peripheral nerve to muscle. They can be acquired or inherited and are associated with weakness and fatigability on exertion (Table 132-1). In each disorder the safety margin of neuromuscular transmission is compromised by one or more specific defects: acetylcholine (ACh) synthesis or packaging of ACh quanta into synaptic vesicles, the release of ACh quanta from the nerve terminal by nerve impulses, and the efficiency of the released ACh quanta to generate a post-synaptic depolarization.

Myasthenia Gravis

Myasthenia gravis (MG) is an acquired autoimmune disorder. Pathogenic autoantibodies induce acetylcholine receptor (AChR) deficiency at the motor end plate. Circulating AChR antibodies are present in 70% to 80% of cases, and immunoglobulin G and complement components are deposited on the postsynaptic membrane. AChR deficiency results from lysis of the junctional folds and destruction of AChRs cross-linked by antibodies that block the binding of ACh to AChR. The incidence is 2 to 5 per year per 1 million population, and the prevalence 13 to 64 per million. The female-to-male ratio is 6:4. The disease may manifest at any age, but the incidence in women peaks in the third decade and that in men in the sixth or seventh decade.

CLINICAL FEATURES

MG can involve either the external ocular muscles selectively (ocular MG) or the general voluntary muscle system (generalized MG). The symptoms usually fluctuate, tending to be worse later in the day (diurnal fluctuation). They are provoked or worsened by exertion, intercurrent infections, menses, and excitement. Ocular muscle involvement is usually bilateral and asymmetrical, and typically is associated with ptosis and diplopia. Weakness of other muscles innervated by cranial nerves results in loss of facial expression, a

smile that resembles a snarl, nasal regurgitation of liquids, choking on foods and secretions, and slurred, nasal speech. Abnormal fatigability of the limb muscles causes difficulty in combing the hair, lifting objects repeatedly, climbing stairs, walking, and running. On examination, fatigue is most reliably demonstrated in the eyes: the *curtain sign* of worsening ptosis with upgaze or asymmetrical nystagmus on extremes of lateral and medial gaze. Proximal limb muscles are affected more than distal ones, but in advanced cases weakness is widespread. Initially, the symptoms are ocular in 40%, are generalized in 40%, involve only the extremities in 10%, and involve only the bulbar or bulbar and eye muscles in another 10%. Ocular muscles are affected in nearly all patients after a year of disease. The symptoms remain ocular in only 15%. When the disease becomes generalized, usually it does so within the first year of onset. Two thirds of patients with MG have thymic hyperplasia, and 10% to 15% have thymoma. In about 10% the MG is associated with another autoimmune disease. Circulating AChR antibodies can be detected in most infants born to myasthenic mothers, but only 12% of such children develop transient neonatal MG, usually during the first few hours of life. The disease is caused by the transfer of AChR antibodies and is self-limited.

DIAGNOSIS

Anticholinesterase Tests (Tensilon Test)

Edrophonium given intravenously acts within a few seconds and lasts for a few minutes. Two milligrams of the drug are injected intravenously over 15 seconds. If no response occurs in 30 to 45 seconds, an additional 8 mg is injected. The evaluation of the response requires objective assessment of one or more signs not easily influenced by motivation, such as degree of ptosis and range of ocular movements. Possible cholinergic side effects of the drug include fasciculations, flushing, lacrimation, abdominal cramps, nausea, vomiting, and diarrhea. The drug must be given cautiously to patients with cardiac disease because it may cause sinus bradycardia,

atrioventricular block, and, rarely, cardiac arrest. Atropine should be available during the test. Edrophonium should not be given to patients having respiratory difficulty.

Diagnostic Testing**Repetitive Nerve Stimulation**

Supramaximal stimulation of a motor nerve at 2 or 3 Hz results in a 10% or greater decrement of the amplitude of the evoked compound muscle action potential from the first to the fifth response. The test is positive in about 75% with generalized MG, provided that two or more distal and two or more proximal muscles are examined. It is less frequently abnormal (approximately 50%) in purely ocular MG.

Single Fiber Electromyography

Single fiber electromyography (SFEMG) is currently the most sensitive method for diagnosis of MG and reveals increased jitter and blocking in 99% of patients with generalized MG and in 97% of those with purely ocular MG when a weak muscle is tested. SFEMG is usually available only in specialized EMG laboratories.

Blood Tests and Radiography

The AChR antibody test measures the binding of antibody to AChR labeled with radioactive α bungarotoxin. The antibody-binding test result is positive in nearly all adults with moderately severe or severe MG, in 80% with mild generalized MG, and in 50% with ocular MG. Some patients without AChR have abnormal antibodies to MuSK, a muscle-specific tyrosine kinase with a role in aggregation of AChR and the end plate. Striated muscle antibodies also occur in MG patients. Their role is unknown, but they are often associated with thymoma. Because of the frequency of thymomas, chest x-ray studies and chest computed tomography (CT) scanning are indicated.

TREATMENT

Anticholinesterases, thymectomy, alternate-day prednisone, azathioprine, cyclosporine, plasmapheresis, and intravenous immunoglobulin are used to treat MG. Anticholinesterases

are useful in all forms of the disease. Pyridostigmine bromide (60-mg tablets) acts for 3 to 4 hours, and neostigmine bromide, 15 mg, acts for 2 to 3 hours. Pyridostigmine bromide has fewer muscarinic side effects and is therefore more widely used. One-half to two tablets are given every 4 hours in the daytime. This medication is also available in 180-mg “time-span” tablets for use at bedtime and as a syrup for children and patients requiring nasogastric feeding. In critically ill patients or postoperatively, neostigmine can be used intramuscularly (1.5 mg is equivalent to 60 mg pyridostigmine) or intravenously (0.5 mg is equivalent to 60 mg of pyridostigmine). Patients who have difficulty with respiration, feeding, or handling secretions and who are not responding to relatively high doses of anticholinesterases are best treated by anticholinesterase withdrawal, tracheal intubation, and ventilator support.

In patients with generalized disease not responding adequately to anticholinesterases, other forms of therapy must be used. Thymectomy has been believed to improve the clinical course of MG, but a controlled clinical trial of the procedure is now in progress. On the other hand, thymoma is an indication for thymectomy because the tumor is often locally invasive. Alternate-day prednisone treatment induces remission or improves the disease in more than half the patients. Azathioprine in doses of 2 to 3 mg/kg/day also induces remissions or improvement in more than half of patients treated. The time required for improvement is 12 to 15 months. Surveillance for side effects (pancytopenia, leukopenia, and hepatocellular injury) must be maintained during therapy. Azathioprine as an adjunct to alternate-day prednisone reduces the maintenance dose of prednisone and is associated with fewer corticosteroid side effects. Mycophenolate mofetil, cyclosporine, and other immunosuppressants are also used. Plasmapheresis is helpful in patients with sudden worsening of MG and is indicated in severe generalized MG refractory to other forms of treatment. A course of five exchanges of 2 L of plasma on alternate days often results in objective improvement and lowers the AChR antibody titer in a few days. Plasmapheresis is expensive and not usually suitable for long-term treatment. Intravenous immunoglobulin, 2 g/kg divided over 2 to 5 days, also improves severe MG and may be more widely available. The mean duration of the response is 9 weeks in patients who are also treated with corticosteroids and 5 weeks in those who are not.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome (LEMS) is a presynaptic neuromuscular junction disorder in which pathogenic autoantibodies against the voltage-sensitive calcium channels at the motor nerve terminal cause a decreased release of acetylcholine. Among patients older than age 40 years, 70% of men and 30% of women have an associated carcinoma, usually a small cell carcinoma of the lung. LEMS may predate tumor detection by up to 3 years. SOX antibodies in patients with LEMS predict the presence of small cell lung cancer. Non-neoplastic LEMS has an association with other autoimmune disorders, HLA-B8 and Drw3 antigens, and organ-specific autoantibodies. Patients with LEMS have weakness

and fatigability of proximal limb and trunk muscles with relative sparing of extraocular and bulbar muscles. The lower limbs are more severely involved than the upper ones. On maximal voluntary contraction, the force produced by a weak muscle increases for a few seconds and then again decreases. Tendon reflexes are usually hypoactive or absent and reappear after short activation of the muscles. Autonomic manifestations (dry mouth, impotence, decreased sweating, orthostatic hypotension, and altered pupillary reflexes) occur in 50% of patients. Nerve conduction studies are always abnormal and show a small compound muscle action potential that facilitates more than 100% after short activation of the muscle. Repetitive stimulation at 2 to 3 Hz induces a further decrement, but stimulation at frequencies higher than 10 Hz or voluntary exercise for a brief period facilitates the response to normal amplitude. Treatment strategies include pyridostigmine, corticosteroids, azathioprine, and intravenous immune globulin. 3, 4-Diaminopyridine is an effective treatment but is not widely available in the United States; it can cause seizures and other side effects.

Botulism

Botulism is a paralytic illness caused by the neurotoxin produced by the anaerobic bacterium *Clostridium botulinum*. Botulinum toxin binds irreversibly to the presynaptic nerve endings, where it inhibits the release of acetylcholine. Types of the disease include foodborne botulism, most commonly caused by home-canned food; wound botulism, with most cases occurring among heroin users; and infant botulism, occurring most commonly in the second month of life because of intestinal colonization. Botulism should be suspected in any infant with poor feeding, constipation, poor sucking and crying, muscle weakness, and respiratory distress. The disease is characterized by symmetrical descending flaccid paralysis starting with blurred vision, dysphagia, and dysarthria. Prompt recognition and treatment with mechanical ventilatory support and early administration of

antitoxin are crucial to reduce mortality. Health Department and Centers for Disease Control and Prevention (CDC) laboratories can confirm the diagnosis by detecting the toxin in serum or stool specimens and can provide the antitoxin. Nerve conduction studies and repetitive nerve stimulation testing can also confirm the diagnosis. Recovery of muscle strength may take several months.

Drug-Induced Myasthenic Syndromes

Aminoglycoside antibiotics, antiarrhythmic agents (procainamide and quinidine), β -adrenergic blockers (propranolol and timolol), phenothiazines, lithium, trimethaphan, methoxyflurane, and magnesium given parenterally or in cathartics reduce the safety margin of neuromuscular transmission. However, overt myasthenic symptoms do not usually appear unless an overdose of the drug is administered or the renal or hepatic elimination of the drug is impaired. The drugs may worsen MG or LEMS.

Succinylcholine, a depolarizing blocking drug, is used to induce muscle relaxation during anesthesia. A single dose of the drug sufficient to cause transient apnea is eliminated by plasma pseudocholinesterase in 10 to 20 minutes. In approximately 1 in 2500 patients receiving the drug, prolonged apnea occurs and persists up to several hours. Most of these patients have an autosomal recessive abnormality of the plasma pseudocholinesterase. Curare and related agents used during surgery and in critically ill patients to induce muscle relaxation produce blockade of the neuromuscular junction. Their use in patients with MG and other myasthenias is associated with profound and prolonged weakness.

Organophosphate insecticides irreversibly inhibit cholinesterases. Ingestion is associated with alterations in sensorium, convulsions, coma, severe muscarinic side effects, cramps, fasciculations, and muscle weakness from a depolarization block.

Prospectus for the Future

A multicenter, randomized, controlled trial of thymectomy in MG began in early 2006. This trial may provide long-needed answers about the value of this procedure. Randomized, con-

trolled trials of other treatments (e.g., mycophenolate mofetil) are also in progress.

The Aging Patient

133 The Aging Patient – HEFLIN * COHEN

The Aging Patient

Mitchell T. Heflin and Harvey Jay Cohen

Over the last century, the number of Americans over the age of 65 years increased from 3 million to over 35 million. During the same period the population over age 85 grew most rapidly, expanding from 100,000 in 1900 to over 4 million by the end of the 20th century. By 2030, the number of adults over age 65 will likely reach 70 million, or just over 20% of the total population. Ten million of those people will be over age 85 (Fig. 133-1). A 2007 report from the National Institute on Aging and the U.S. State Department points out that this phenomenon is not isolated to the United States. Around the globe, the percentage of the population over 65 years of age will increase by 25% to 50% over the next 25 years and by 140% in developing nations.

The aging of the world's population will compel virtually all health care providers to gain competency in geriatrics, the clinical science of assessment, prevention, and treatment of illness in older adults. A basic grasp of geriatrics requires understanding at epidemiologic, biologic, and clinical levels. The provider must appreciate the impact of aging on presentation of and predisposition to certain conditions, identification of goals of care, and selection of treatment strategies. Moreover, care of older adults demands a multifaceted approach, accounting for individual, family, and community resources for caregiving. Finally, the practice of geriatrics requires an appreciation for systems of care that include interprofessional teams working in a variety of settings ranging from home to hospital to long-term care. This chapter will provide an introduction to geriatrics and the essentials of caring for older adults.

Epidemiology of Aging

Most experts believe that the rapid growth of the population of older adults reflects the many health care successes of the twentieth century. Fries, in his landmark paper, attributes the extension of the human life span to “the elimination of premature death, particularly neonatal mortality.” Improvements in other aspects of public health, including adequate nutrition and housing, safe drinking water, immunizations,

and antibiotics, have led to lower rates of mortality throughout childhood and early adulthood, affording an opportunity for more people to survive to late life. Examination of survival curves across the twentieth century demonstrates a marked change in the shape of the overall graph from nearly linear in 1900 to rectangular in the 1990s, with much of the mortality compressed into late life (Fig. 133-2). Although the life expectancy at birth over the same period has risen dramatically from 47 years to nearly 77 years, the maximum life span has remained remarkably stable.

The Biology of Aging

The relatively static nature of the maximum life span reflects the human body's limits at the cellular, tissue, and organ level in dealing with the stresses of aging. Across cell types and organ systems, certain consistent age-related alterations in function exist. Variability in tissue and organ function decreases, as evidenced by less fluctuation in heart rate or hormone secretion. Organ systems also exhibit predictable declines in function over time. These changes are most evident at times of stress, and ultimately these systems are slower to react and recover. The overall result is an impaired ability to deal with any demands beyond a narrow range outside the normal. This progressive narrowing in reserve, often termed “homeostenosis,” can be depicted as a steady tapering in the reserve available in multiple organ systems as time progresses (Fig. 133-3). In this situation an individual may function within the normal range in the absence of crisis, but stress such as acute illness may exceed his or her capacity to restore function and recover health. The result at best may be a decline in health and ability, and at worst, death.

THEORIES OF AGING

Scientific research provides a number of plausible theories of aging, which can be grouped into two major categories. *Error or damage theories* propose that aging occurs because

Figure 133-1 Number of people aged 65 years and older, by age group, for selected years 1900 to 2006 and projected years 2010 to 2050. (From Federal Interagency Forum on Aging-Related Statistics: Older Americans 2008: Key Indicators of Well-Being. Federal Interagency Forum on Aging-Related Statistics. Washington, DC, U.S. Government Printing Office, March 2008.)

Figure 133-2 Percent surviving by age. Death registration by states, 1900 to 1902, and in the United States, 1949 to 1951 and 1999 to 2001. (From U.S. Decennial Life Tables for 1999-2001, United States Life Tables. Natl Vital Stat Rep 57:1-10, 2008.)

of persistent threats from damaging agents and an ever-declining ability to respond to or repair this damage. *Program theories* postulate that genetic and developmental factors most significantly determine the biologic life course and the maximal age of the organism. In actuality, biologic aging may reflect a complex combination of many types of events.

The free radical theory of aging proposes that oxidative metabolism results in an excess of highly reactive byproducts, called *oxygen free radicals*, which damage proteins, DNA, and lipids. Molecular injury leads to cell dysfunction and ultimately to tissue and organ disrepair. Proponents of this hypothesis may argue that organisms with higher

Figure 133-3 Schematic representation of decreased homeostatic reserve or "homeostenosis." (From Fries J, Crapo LM: Vitality and aging: Implications of the rectangular curve. San Francisco, WH Freeman, 1981.)

metabolic rates live shorter lives (presumably because of a more rapid accumulation of byproducts). Although the latter portion of the theory has been called into question, many still contend that limiting the production of oxidants can improve health and possibly extend life. A second theory asserts that the accumulation of glucose-related molecules on proteins contributes to their dysfunction and degradation. These "glycosylated" molecules become more abundant over time and lead to impaired function at the tissue and organ level. Theory proponents point to the many chronic problems that routinely arise in patients with diabetes mellitus as proof of the significance of this phenomenon.

A different line of reasoning asserts that the human life span and aging result from genetic based timing mechanisms. Older theories suggest that evolutionary pressures are biased for traits that promote health and reproduction in

early adulthood, possibly at the expense of health and function in late life. Furthermore, little selective pressure exists against negative traits that emerge in late life, leaving humans prone to the ill effects of aging. Geneticists have identified, among species of fruit flies and certain nematodes, specific genes that result in a significant prolongation in the organism's life span. Work is ongoing to discover similar genetic sequences among mammalian models.

Study of the enzyme telomerase has also generated much interest among theorists on aging. In a process called apoptosis, cells undergo programmed death to be replaced by younger cells. These divisions and replacements are limited by the number of generations intrinsic to a specific cell line (the so-called "Hayflick phenomenon"). With the extension of life expectancy to nearly 80 years over the last century, some scientists postulate that people are outliving their allotted number of cell divisions (replicative aging). DNA in the telomeres at the end of chromosomes marks the inevitable loss of chromosomal material with replication. As telomeres shorten, cell aging and demise eventually occur. The enzyme telomerase prevents telomere shortening and may increase a cell's number of allotted replications and thereby extend the life span of the organ. Of course, this advantage must be weighed against the price of "immortality," namely the increased risk of malignancy.

The most recent development in the biology of aging goes beyond theory to application. Caloric restriction, or the purposeful reduction of food intake, is the only intervention that has been shown to reproducibly extend the maximal life span. In rats, life span increases an average of 20 months with a 40% reduction in calories. Rhesus monkeys enrolled in a trial of caloric restriction appear to have a lower disease burden and mortality than controls after 15 years. The mechanism is not well understood but may be metabolically mediated. In observational studies in humans, those with lower average body temperature, lower insulin levels, and higher dehydroepiandrosterone sulfate (DHEAS) levels (all changes found in calorically restricted monkeys) appeared to survive longer. Current research is focused on reproducing this phenomenon in human subjects and discovering chemical agents that mimic these metabolic effects.

To understand the changes in the individual's ability to cope with physiologic stress with age, one must also examine the changes at the level of the organ system. Table 133-1 provides an overview of these changes by system. As will be evident, although normal aging is not itself a diagnosis, it is, indeed, fertile ground for disease and disability.

THE FRAILTY PHENOTYPE

The concept of "homeostenosis" bridges the biologic changes of aging and the increased vulnerability of humans to illness and functional decline in late life—a state commonly referred to as "frailty." Recent research has established a definition of frailty that moves beyond traditional components of chronologic age, comorbidity, and disability to identify a unique clinical entity with independent predictive capacity. The "cycle of frailty" ties together the individual system-specific changes and identifies key events or clinical presentations that create a specific phenotype (Fig. 133-4). Five key elements form the core of this cycle, including the following:

Table 133-1 Changes in Physiologic Function with Age

Organ System	Age-Related Decline in Function
Special senses	Presbyopia Lens opacification Decreased hearing Decreased taste, smell
Cardiovascular	Impaired intrinsic contractile function Decreased conductivity Decreased ventricular filling Increased systolic blood pressure Impaired baroreceptor function
Respiratory	Decreased lung elasticity Decreased maximal breathing capacity Decreased mucus clearance Decreased arterial PO_2
Gastrointestinal	Decreased esophageal and colonic motility
Renal	Decreased glomerular filtration rate
Immune	Decreased cell-mediated immunity Decreased T-cell number Increased T-suppressor cells Decreased T-helper cells Loss of memory cells Decline in antibody titers to known antigens Increased autoimmunity
Endocrine	Decreased hormonal responses to stimulation Impaired glucose tolerance Decreased androgens and estrogens Impaired norepinephrine responses
Autonomic nervous	Impaired response to fluid deprivation Decline in baroreceptor reflex Increased susceptibility to hypothermia
Neurologic	Decreased vibratory sense Decreased proprioception
Musculoskeletal	Decreased muscle mass

PO_2 , partial pressure of oxygen.

1. Weight loss
2. Weakness
3. Poor endurance
4. Slowness
5. Inactivity

Frailty is defined as the presence of three or more of these conditions. By this definition, frailty independently predicts falls, declines in mobility, loss of ability to perform activities of daily living (ADLs), hospitalization, and death. This definition seems to provide a defined link between aging-related disease and disability and, perhaps, a target for interventions to prevent the onset of functional decline—that is, a means of further compressing comorbidity and disability in late life.

Clinical Care of Older Adults

Caring for older adults requires a strong foundation in the basics of internal medicine integrated with an appreciation for the complexity and heterogeneity of the impact of aging

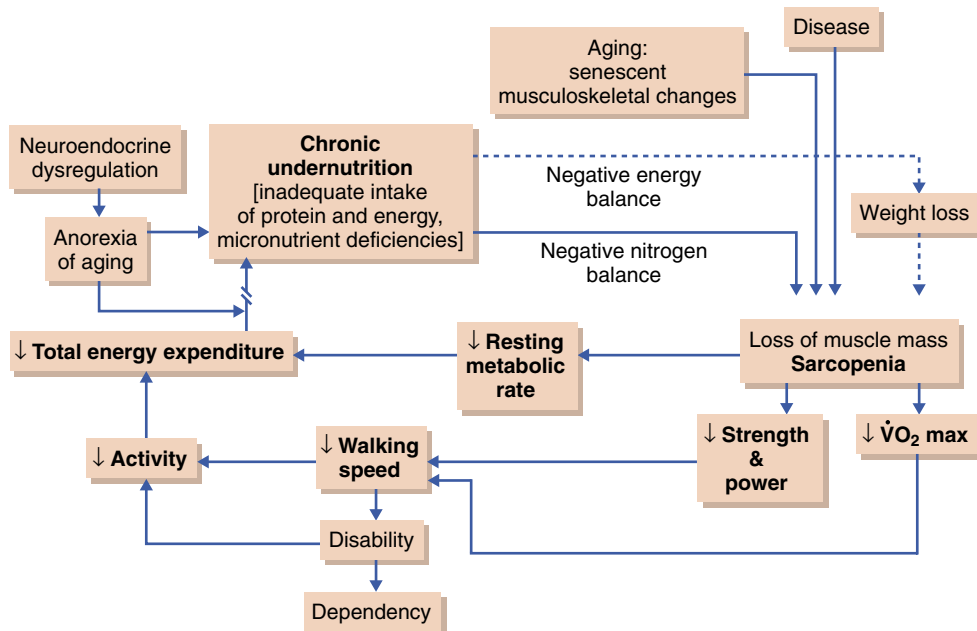

Figure 133-4 Cycle of frailty hypothesized as consistent with demonstrated pairwise associations and clinical signs and symptoms of frailty. (From Fried LP, Walston J: Frailty and failure to thrive. In Hazzard WR, Blass JP, Ettinger WH Jr, et al (eds). *Principles of Geriatric Medicine and Gerontology*, 4th ed. New York, McGraw-Hill, 1998, pp 1387-1402.)

on health and well-being. The clinician must possess strong diagnostic skills, given that older adults may have atypical presentations or multiple comorbid conditions and functional decline. In addition, he or she must monitor for a number of nonspecific conditions, such as problems with mobility, mood, or mentation, that affect self-care capacity and safety. Treatment strategies present unique challenges as well, often requiring a balance of pharmacologic and non-pharmacologic interventions with careful consideration of the individual's goals for care. This section presents the core components of the comprehensive assessment of the older patient.

COMORBID CONDITIONS, FUNCTION, AND LIFE EXPECTANCY

With advancing age and declines in reserve, older adults experience high rates of chronic illness and related functional decline. Eighty percent of those over age 65 years have at least one chronic illness, and 50% have two or more comorbid conditions. Some of these conditions contribute directly to increased rates of mortality, including the leading causes of death among older adults—heart disease, cancer, and stroke. Many common diseases, however, primarily threaten function and result in disability and institutionalization. Arthritis, dementia, hearing loss, and vision impairment are all important problems in this respect. The presence of multiple comorbid conditions may compound the disabling effects of individual diseases and further complicate management. In the era of evidence and guidelines, a provider caring for a patient with several common chronic conditions, such as diabetes mellitus, coronary artery disease, and osteoporosis, may feel compelled to prescribe six or seven medications to remain in compliance with current recommendations. This practice can result in significant cost to the patient and with limited accounting for risks, benefits,

and individual preferences. In addition to considering the discrete management of individual diseases, care of the older adult requires assessment of the overall impact of treatment on symptoms, function, and life expectancy.

Function, defined formally, is “a person’s ability to perform tasks and fulfill social roles across a broad range of complexity”—more succinctly, self-care capacity. Assessing this ability provides the clinician with a means of understanding the impact of illness, assessing quality of life, identifying care needs, and estimating progress and prognosis. Comprehensive assessment of function should include questions about self-care capacity as well as objective measures of cognition and mobility. (The latter two are detailed in separate sections later.) Self-care capacity is most often divided into basic, instrumental, and advanced ADLs. Basic ADLs include those actions that maintain personal health and hygiene, including transferring, bathing, toileting, dressing, and eating. Instrumental ADLs (IADLs) include activities necessary for living independently, specifically driving, cooking, shopping, managing medications and finances, using the telephone (or other communication device), and doing housework. Advanced ADLs include social or occupational functions associated with activities such as hobbies, employment, or caregiving. Approximately 28% of adults over age 65 and 78% of those over age 85 have difficulty with IADLs or one or more basic ADLs. Predictably, as the incidence of disability rises, so does the rate of dependence and nursing home residence. Long-term care in skilled facilities increases from 1.4% among those age 65 to 74 to 20% among those older than age 85. Impairment in ADLs is also associated with an increased risk of falls, depression, and death in the affected elder. Among older adults the assessment of self-care capacity provides key health status information independent of age and comorbid conditions.

For clinicians, navigating the myriad options for management of multiple chronic conditions requires individualized

Figure 133-5 Upper, middle, and lower quartiles of life expectancy for women and men at selected ages. (From Walter LC, Covinsky KE: Cancer screening in elderly patients—a framework for individualized decision making. *JAMA* 285:2750, 2001.)

assessment of risks, benefits, and specific goals of various therapies. Estimates of life expectancy, integrating the impact of age, comorbid illness, and function, have been generated to assist in medical decision making. These estimates assist providers in predicting median survival and thus can help in estimating the potential life remaining in which one might benefit from a given procedure or therapy (Fig. 133-5). For example, the options offered to a frail 85-year-old man with less than 3 years left to live may be quite different from those presented to his healthy counterpart of the same age with a median life expectancy of 5 to 7 years. In addition, any decision should take into account the individual patient's goals and preferences.

ALTERED PRESENTATION OF DISEASE

Competent care of the frail older adult starts with recognition of disease, even in the absence of typical signs and symptoms. Presentation of disease among the elderly may differ dramatically from that expected; manifestations of distress may be subtle or nonspecific, and improvement is less obvious and slower. This phenomenon occurs for a number of reasons. As noted previously, older adults experience high rates of comorbid illness, which may confound the clini-

cian's ability to diagnose a problem accurately. For example, a patient with heart disease and chronic obstructive pulmonary disease who visits the office because of dyspnea may be experiencing a flare of his pulmonary disease or an atypical presentation of ischemic heart disease or both. Reporting of symptoms may also be affected by psychosocial factors, including limited access to the health care system, cognitive problems, or minimization of symptoms as "normal aging." Likewise, health care providers may minimize complaints by older adults with complex medical illness or frail health.

The alert clinician may anticipate atypical presentations for certain conditions (Table 133-2). Hyperthyroidism can manifest with apathy, malaise, depression, and fatigue, while lacking classic symptoms of tremor, tachycardia, or sweating. It can also manifest with heart failure and is highly prevalent among older adults with new-onset atrial fibrillation. Likewise, older patients with hypothyroidism may atypically demonstrate failure to thrive, weight loss, cognitive decline, or depression. In the presence of infection, older adults may not reliably mount fever or experience localized symptoms. Studies have demonstrated that lowering the threshold definition of fever can improve the diagnostic utility of body temperature as a sign of bacterial infection. Although chest pain remains the most common and important symptom of

Table 133-2 Atypical Disease Presentations in Older Adults

Diagnosis	Potential Presenting Symptoms and Signs
Myocardial infarction	Altered mental status Fatigue Fever Functional decline
Infection	Altered mental status Functional decline Hypothermia
Hyperthyroidism	Altered mental status Anorexia Atrial fibrillation Chest pain Constipation Fatigue Weight gain
Depression	Cognitive impairment Failure to thrive Functional decline
Electrolyte disturbance	Altered mental status Falls Fatigue Personality changes
Malignancy	Altered mental status Fever Pathologic fracture
Pulmonary embolus	Altered mental status Fatigue Fever Syncope
Vitamin deficiency	Altered mental status Ataxia Dementia Fatigue
Fecal impaction	Altered mental status Chest pain Diarrhea Urinary incontinence
Aortic stenosis	Altered mental status Fatigue

Note: This table represents only a limited list of select disease processes and presentations; it is not meant to serve as an exhaustive reference for use during patient care activities.

ischemic heart disease, dyspnea in the absence of chest pain is a commonly reported symptom, particularly in older adults and those with multiple comorbidities.

In truth, any medical illness may manifest nonspecifically among older adults, particularly those in frail health. Nonspecific symptoms related to an underlying illness include changes in mentation, difficulty with balance and falls, new urinary incontinence (UI), and a general change in functional ability. A lack of understanding of the phenomenon of altered presentation of disease can lead to delays in diagnosis and treatment and result in worse outcomes for older adults. Research indicates that altered presentation predicts not only suboptimal care, but future functional decline and increased mortality.

MEDICATIONS

Medication-related problems are very common in older adults. In the United States, outpatients over age 65 take, on

average, three to five medications. Although medications may be indicated for specific medical conditions, use of multiple medications increases the risk for drug-drug interactions and associated adverse drug events. Altered pharmacokinetics and pharmacodynamics contribute to adverse drug events, which are a common cause of hospitalization and morbidity in the elderly. Common changes in pharmacokinetics include changes in body composition, with increased fat stores and decreased body water. Fat-soluble medications, such as benzodiazepines, have a prolonged duration of effect because of this phenomenon. Age-related declines in glomerular filtration rates result in decreased clearance of many medications, including such drugs as atenolol, digoxin, and lithium. Accurate calculations of creatinine clearance will inform drug choice and dosing and improve prescribing safety. Pharmacodynamic changes include decreased sensitivity to certain commonly prescribed drugs, such as β blockers, and increased sensitivity to other agents, such as narcotics and warfarin.

Given the risks of medication use in older adults, health care providers and systems should employ strategies to improve both the effectiveness and safety of prescribing. Evidence-based recommendations include the following:

- Maintain an up-to-date medication list, including over-the-counter medications and herbal supplements.
- Comprehensively review medications at least once annually (if not at every visit) and, in particular, at the time of transitions between care settings (e.g., after hospitalization). A clear indication for each medication, and documentation of response to therapy (particularly for chronic conditions), should be included.
- Assess for duplication and drug-drug or drug-disease interactions. Using a drug information database will help with this process.
- Assess adherence and affordability and inquire about the patient's system for administering medications (e.g., a pillbox).
- Assess for specific classes of medications commonly associated with adverse events: warfarin, analgesics (particularly narcotics and nonsteroidal anti-inflammatory drugs [NSAIDs]), antihypertensives (particularly angiotensin-converting enzyme [ACE] inhibitors and diuretics), insulin and hypoglycemic agents, and psychotropics.
- Minimize or avoid use of anticholinergic medications, which present specific risks.

A clear and rational approach to prescribing and ongoing management of medications that accounts for indication, interactions, and adherence may reduce the risk of common adverse events.

COGNITION

Dementia

The prevalence of dementia increases with age, with estimates ranging from 20% to 50% after age 85. The most common forms of dementia include Alzheimer disease, Lewy body dementia, and vascular dementia. The latter is commonly present in combination with Alzheimer disease in a condition termed *mixed etiology dementia*. Dementia is most often characterized by impairment in one or more

cognitive domains severe enough to disrupt function or occupation. Mild cognitive impairment (MCI) is present when an individual has discernible cognitive limitations without apparent functional impact. Patients with MCI develop dementia at a rate of approximately 15% per year. In general, a diagnosis of dementia is associated with a higher risk of falls, functional impairment, institutionalization, and death. Caregivers of demented individuals also face increased rates of stress and health problems. Clinicians diagnose dementia through symptom and functional history (often including the input of caregivers), cognitive assessment, and physical examination. A number of instruments, including the Mini Mental Status Examination (MMSE), clock-drawing test (CDT), and the Mini-Cog, are validated screening tools. The time-tested MMSE offers an assessment of multiple cognitive domains but does not provide adequate measure of executive function and is prone to lack of sensitivity in individuals with high premorbid intelligence and lack of specificity in those with low levels of education. Validated assessments of executive function include the CDT, verbal fluency test, or the Trail B test. Instruments also exist for collecting data regarding patient function from a relative or caregiver. In patients suspected of having dementia, assessments of personal safety with respect to firearms, driving, and the home environment should be performed. A careful medication review and physical examination, including vital signs, complete neurologic assessment, and evaluations of gait and balance, are, of course, essential in dementia to reveal specific findings that point to a specific cause (see Chapter 116).

Delirium

The differential diagnosis for cognitive problems other than dementia is broad and includes delirium, mood disturbance, and drug effects. The differentiation of dementia and delirium may present the most significant challenge, particularly in the hospitalized elderly (Table 133-3). Delirium is characterized by its acuity and alteration in global cognitive function, whereas dementia is chronic and affects specific cognitive domains. Delirium affects more than 2 million

hospitalized persons each year. Its incidence is variably estimated at 25% to 60% among patients in acute care settings and results in extra hospital days and related expenditures. Delirium is also associated with prolonged hospital stay, increased costs, increased readmission rate to the hospital (12% to 65% at 6 months), and higher in-hospital and 1-year mortality. The Confusion Assessment Method (CAM) offers a validated tool to diagnose delirium. Per the CAM, delirium is likely present if the patient has both an acute onset of confusion with fluctuating course and inattention and either disorganized thinking or altered level of consciousness. Key risk factors for delirium include older age, cognitive impairment, comorbid illness, and functional decline. Precipitating factors related to acute illness include hypoxia, electrolyte abnormalities, dehydration, and malnutrition as well as medications and alcohol withdrawal. Although treatment of delirium is difficult and revolves around the underlying medical issues, controlled trials have demonstrated that a multi-modal intervention may be effective in preventing delirium in high-risk patients. The evidence demonstrates that the use of restraints in combative or confused older adults leads to increased morbidity and mortality. Nonpharmacologic management strategies include reorientation and preservation of sleep patterns, family or caregiver presence at the bedside, and early mobilization. The use of pharmacologic agents, specifically neuroleptics or sedative hypnotics such as benzodiazepines, should be reserved for cases in which nonpharmacologic strategies do not help and the patient presents a risk of harm to himself or herself or others.

MOOD

Older adults commonly experience depressive symptoms, with prevalence estimates as high as 15% to 19% among those over age 75. The presence of comorbid illness and grief often confound the presentation of depression. As a result, it can remain undetected despite its significant adverse impact on quality of life, morbidity, and mortality. Suicide rates are almost twice as high in the elderly when compared with the general population, with the rate highest for white men over 85 years of age. Among older adults, depression can manifest atypically with cognitive, functional, or sleep problems as well as complaints of fatigue or low energy. Several instruments have been developed and validated for screening for depression in the elderly. Asking two simple questions about mood and anhedonia (“Over the past 2 weeks have you felt down, depressed, or hopeless?” and “Over the past 2 weeks have you felt little interest or pleasure in doing things?”) may be as effective as using longer instruments. Any positive screening test result should trigger a full diagnostic interview. When screening for depression in the elderly, it is particularly important to have systems in place to provide feedback of screening results, a readily accessible means of making an accurate diagnosis, and a mechanism for providing treatment and careful follow-up. Recent trials indicate that the addition of counseling to pharmacologic therapy confers additional benefit for older, frail patients with depression. Anxiety, like depression, is also common among older adults and may similarly result in physical and cognitive symptoms, insomnia, agitation, psychosis, and isolation. Clinicians should consider a diagnosis of generalized

Table 133-3 Features of Delirium versus Dementia

Feature	Delirium	Dementia
Onset	Acute	Insidious
Course	Fluctuating, lucid at times	Generally stable
Duration	Hours to weeks	Months to years
Alertness	Abnormally low or high	Usually normal
Perception	Illusions and hallucinations common	Usually normal
Memory	Immediate and recent impaired	Recent and remote impaired
Thought	Disorganized	Impoverished
Speech	Incoherent, slow or rapid	Word-finding difficulty
Physical illness or medication causative	Frequently	Usually absent

anxiety, panic, or agoraphobia in older adult patients with any of these symptoms.

MOBILITY

Problems with mobility are particularly common in the elderly. Among those over age 65, 20% of men and 32% of women report difficulty with one or more of five specific physical activities (stooping or kneeling, reaching overhead, writing, lifting 10 pounds, or walking two to three blocks). Among these, respondents cite problems with walking most commonly. Difficulties with balance and gait present significant risks for older adults. Approximately 30% of community-dwelling elders fall each year. The annual incidence of falls approaches 50% in patients over 80 years of age. Five percent of falls in older adults result in fracture or hospitalization. Risk factors for falls include a history of falls, fear of falling, decreased vision, cognitive impairment, medications (particularly anticholinergic, psychotropic, and cardiovascular medications), diseases causing problems with strength and coordination, and environmental factors. Effective interventions for people with a history of falls or who are at risk for falling involve addressing multiple contributing factors. Providers should regularly inquire about recent falls or a fear of falling in older patients. For patients who report falling, the assessment should include review of circumstances of the fall(s), measure of orthostatic vital signs, visual acuity testing, cognitive evaluation, and gait and balance assessment. A brief physical examination maneuver called the “timed get up and go” has the patient arise from a sitting position, walk 10 feet, turn, and return to the chair to sit. A time of more than 16 seconds to complete the process, or observation of postural instability or gait impairment, suggests an increased risk of falling. Gait speed, an additional measure of mobility, has recently received much attention for its predictive ability in older adults. Gait speed is measured over a 10-meter span with the patient walking at a comfortable pace. A speed of less than 0.8 m/sec predicts difficulty navigating outside the home, and a speed of less than 0.6 m/sec predicts a high risk of falls and functional decline. For those found to be at risk for falls, providers should also review all medications for possible causative agents and inquire about home safety. High-risk patients should be evaluated for assistive devices and a supervised exercise program (Table 133-4).

HEARING AND VISION

Problems with vision and hearing are very common among older adults and frequently complicate the management of comorbid conditions and accelerate functional decline. Significant vision loss occurs in 16% to 18% of adults over age 65. Common causes include glaucoma, cataracts, age-related macular degeneration, and retinopathy from hypertension and diabetes. Decreased visual acuity increases fall risk and has been associated with all-cause mortality. Such problems may be detectable with regular testing via bedside tools such as the Snellen or Jaeger eye chart. Given the implications of vision loss for function and safety, a general ophthalmologic examination every 1 to 2 years is recommended for all older adults. Furthermore, ophthalmologic centers have recognized the multifaceted challenges faced by older adults with

vision impairment and have developed specialized low vision clinics offering evaluation by optometrists, occupational therapists, and social workers with a focus on improving quality of life and maintaining independence.

Hearing loss is the third most common ailment in older adults (behind hypertension and arthritis), affecting an estimated 40% to 66% of those over age 75. It is associated with depression, social isolation, poor self-esteem, and functional disability. Pure tone audiometry is the reference standard for screening for hearing loss, but a simple whispered voice test is also highly sensitive and specific. Ideally all older adults would undergo annual hearing screen by questionnaire and handheld audiometry. Unfortunately, the lack of reimbursement for hearing aids under most insurance plans, including Medicare, presents a major barrier for many older adults.

CONTINENCE

UI affects up to 30% of community-dwelling older adults and at least half of those residing in skilled nursing facilities (SNFs). It occurs more frequently in women, but this gender disparity narrows as the rate of UI in men increases after age 85. The impact of UI on health ranges from increased risk of skin irritation, pressure wounds, and falls to social isolation, functional decline, and depression. For caregivers of older adults, UI complicates physical care and can contribute to decisions for placement in SNFs. Common comorbid conditions include diabetes mellitus, heart failure, arthritis, and dementia.

A systematic approach to the investigation of UI can often reveal a cause and potential solution. It is important to first determine if the incontinence is acute or chronic in nature. Acute causes of incontinence are often attributable to specific medical problems, including infection, metabolic disturbance, or medication effects. The mnemonic DIAPERS recalls the various potential acute causes of UI (*D*, delirium; *I*, infection; *A*, atrophic vaginitis; *P*, pharmaceuticals; *E*, excess urine output from congestive heart failure (CHF) or hyperglycemia; *R*, restricted mobility; and *S*, stool impaction). If the UI is chronic, then further history can characterize the nature of the symptom from among four types. Urge incontinence from detrusor overactivity is the most common type. Patients with this problem will complain of urinary frequency, nocturia, and a sudden onset of urge to void. Stress incontinence occurs with incompetence of pelvic musculature or urethral sphincter and is characterized by small amounts of leakage with laughing, sneezing, coughing, or even standing. Overflow incontinence results from urinary retention, often related to prostatic hyperplasia in men or bladder atony in patients with diabetes or spinal cord injury. Patients often have constant dribbling or leakage without a true sense of needing to void. Finally, functional incontinence results from comorbid conditions that limit a patient's ability to act on or interpret the need to void, mobility problems such as arthritis, and weakness or cognitive problems. Table 133-5 describes the various types of incontinence and suggested approaches. Of course, older adults with multiple comorbid conditions often have incontinence that results from a combination of chronic and/or acute causes.

Continence problems are frequently treatable but are often not raised by patients as a concern. A targeted history

Table 133-4 Recommended Components of Clinical Assessment and Management for Older Persons Living in the Community Who Are at Risk for Falling

Assessment and Risk Factor	Management
Circumstances of previous falls*	Change in environment and activity to reduce the likelihood of recurrent falls
Medication use <ul style="list-style-type: none"> • High-risk medications (e.g., benzodiazepines, other sleep medications, neuroleptics, antidepressants, anticonvulsives, or class IA antiarrhythmics)*† • Four or more medications‡ 	Review and reduction of medications
Vision* <ul style="list-style-type: none"> • Acuity <20/60 • Decreased depth perception • Decreased contrast sensitivity • Cataracts 	Ample lighting without glare; avoidance of multifocal glasses while walking; referral to an ophthalmologist
Postural blood pressure (after ≥5 min in a supine position, immediately after standing, and 2 min after standing)‡ <ul style="list-style-type: none"> • ≥20 mm Hg (or ≥20%) drop in systolic pressure, with or without symptoms, either immediately or after 2 min of standing 	Diagnosis and treatment of underlying cause, if possible; review and reduction of medications; modification of salt restriction; adequate hydration; compensatory strategies (e.g., elevating head of bed, rising slowly, or performing dorsiflexion exercises); pressure stockings; pharmacologic therapy if the above strategies fail
Balance and gait†† <ul style="list-style-type: none"> • Patient's report or observation of unsteadiness • Impairment on brief assessment (e.g., the "get up and go" test or performance-oriented assessment of mobility) 	Diagnosis and treatment of underlying cause, if possible; reduction of medications that impair balance; environmental interventions; referral to physical therapist for assistive devices and for gait, balance, and strength training
Targeted neurologic examinations <ul style="list-style-type: none"> • Impaired proprioception* • Impaired cognition* • Decreased muscle strength†† 	Diagnosis and treatment of underlying cause, if possible; increase in proprioceptive input (with an assistive device or appropriate footwear that encases the foot and has a low heel and thin sole); reduction of medications that impair cognition; awareness on the part of caregivers of cognitive deficits; reduction of environmental risk factors; referral to physical therapist for gait, balance, and strength training
Targeted musculoskeletal examinations of legs (joints and range of motion) and examination of feet*	Diagnosis and treatment of underlying cause, if possible; referral to physical therapist for strength, range-of-motion, and gait and balance training, and for assistive devices; use of appropriate footwear; referral to podiatrist
Targeted cardiovascular examination† <ul style="list-style-type: none"> • Syncope • Arrhythmia (if there is known cardiac disease, abnormal electrocardiogram, and syncope) 	Referral to cardiologist; carotid-sinus massage (in case of syncope)
Home-hazard evaluations after hospital discharge††	Removal of loose rugs and use of nightlights, nonslip bathmats, and stair rails; other interventions as necessary

*Recommendation of this assessment is based on observations that the finding is associated with an increased risk of falling.

†Recommendation of this assessment is based on one or more randomized controlled trials of a single intervention.

‡Recommendation of this assessment is based on one or more randomized controlled trials of a multifactorial intervention strategy that included this component.

From Tinetti ME. Preventing falls in elderly persons. *N Engl J Med* 348:42-49, 2003.

Table 133-5 Causes, Types, and Treatment of Urinary Incontinence

Type	Definition	Cause	Treatment
Stress	Leakage associated with increased intra-abdominal pressure (coughing, sneezing)	Hypermobility of the bladder base, frequently caused by lax perineal muscles	Pelvic muscle exercise, timed voiding, α -adrenergic drugs, estrogens, surgery
Urge	Leakage associated with a precipitous urge to void	Detrusor hyperactivity (outflow obstruction, bladder tumor, detrusor instability), idiopathic (poor bladder), compliance (radiation cystitis), hypersensitive bladder	Bladder training, pelvic muscle exercise, bladder-relaxant drugs (anticholinergics, oxybutynin, tolterodine, imipramine)
Overflow	Leakage from a mechanically distended bladder	Outflow obstruction, enlarged prostate, stricture, prolapsed cystocele, acontractile bladder (idiopathic, neurologic [spinal cord injury, stroke, diabetes])	Surgical correction of obstruction, intermittent catheter drainage
Functional	Inability or unwillingness to void	Cognitive impairment, physical impairment, environmental barriers (physical restraints, inaccessible toilets), psychological problems (depression, anger, hostility)	Prompted voiding, garment and padding, external collection devices

and physical examination can often identify the cause of UI and lead to appropriate intervention. We recommend asking about and documenting the presence or absence of UI biannually and determining whether the UI, if present, is bothersome to the patient or caregiver. In addition to a history of acute and chronic causes, a targeted physical examination should include an assessment for fluid overload, genital and rectal examination, and neurologic evaluation. Urine and blood tests are indicated to evaluate for infection, metabolic causes, and renal dysfunction. In addition, in patients suspected of having urinary retention, catheterization or ultrasound can help define the postvoid residual and determine the need for catheter placement and further urologic evaluation. Many institutions now offer more specialized evaluation and care through incontinence clinics, which offer multidisciplinary approaches to management addressing both pharmacologic and nonpharmacologic options. Effective nonpharmacologic options include scheduled toileting, bladder training, and biofeedback. Use of these strategies may avoid the use of medications with common adverse effects, such as anticholinergic medications for detrusor overactivity.

NUTRITION

Older adults experience high rates of malnutrition related to various causes, including medical illness, dental problems, or access issues related to limited mobility, cost, or cognitive problems. Approximately 15% of older outpatients and half of the hospitalized elderly are malnourished and have clearly associated increases in morbidity and mortality. The utility of general laboratory testing is limited, but a combination of serial weight measurements and inquiries about changing appetite can reveal problems with nutritional status in the elderly. Vulnerable elders with an involuntary weight loss of 10% or more in 1 year or less should undergo further evaluation for undernutrition, including assessment of medical or medication-related causes, dental status, problems with acquiring or preparing food, appetite and intake, swallowing ability, and previous directions for dietary restrictions.

Social and Legal Issues

The geriatric social history includes assessments of resources for direct caregiving and financial support available to a patient. These issues become particularly important for frail older adults, given their physical and economic vulnerability.

CAREGIVING

The clinician should always inquire about who is providing care for the older patient. This includes both personal care with ADLs and help with IADLs such as transportation, medications, food preparation, finances, and housekeeping. This list should include both formal caregivers, such as home health professionals or hired aides, and informal caregivers, such as family members, neighbors, or friends. The majority of care provided in the United States is delivered by informal caregivers. Over 34 million people in the United States provide informal care for older adults and, of these, 8.9

million are caring for persons suffering from dementia. The majority of informal caregivers are women and elderly themselves, with an average age of 63 years. The stress and strain of providing daily care can have serious deleterious effects on the caregiver's health. Studies have demonstrated adverse effects on blood pressure and immune function and increased rates of cardiovascular disease and death. In addition, caregivers have alarmingly high rates of psychological illness, with symptoms of depression reported in up to 50%. This problem is particularly prevalent in those providing care for patients with dementia or other cognitive problems. The presence of mental illness further raises the risk of verbal or physical abuse or neglect of the patient. The clinician must recognize caregiver problems early and consider referral to a social worker, patient resource manager, or, when available, a geriatric assessment team. Key risk factors for stress include (1) a frail family caregiver; (2) a patient with cognitive impairment, emotional disturbance, substance abuse, sleep disruption, or behavioral problems; (3) low income or financial strain; and (4) acute illness or hospitalization. Providers should recognize the overt signs and symptoms of physical or mental strain and regularly inquire about caregiver burden with an offer to talk apart from the patient if need be.

A number of resources exist to support caregivers and provide strategies for problem solving and self-care. Community-based programs provide assistance with meals, transportation, or respite care options through volunteer organizations or subsidized programs. Counseling on both the physical and emotional aspects of care has been demonstrated to reduce health risks to the caregiver and delay institutionalization. This includes in-home or institutional respite stays to provide caregivers with precious time off. Studies consistently demonstrate that such services are underused by caregivers.

MISTREATMENT

All too often, caregiver stress and social isolation increase the risk of abuse or neglect of older adults. Elder mistreatment has been reported in 3% to 8% of the older adult population in the United States. A variety of forms of neglect or physical abuse can result in adverse health outcomes for older victims. Victims themselves are unlikely to report instances of abuse, making it difficult to address issues in the clinical setting. Older adults who are noted to have contusions, burns, bite marks, genital or rectal trauma, pressure ulcers, or unexplained weight loss without clinical explanation should be asked about mistreatment or referred to social work services.

FINANCES

The older adult population in the United States varies widely in measures of wealth. Although the overall rate of poverty among adults over age 65 has declined over the last 50 years, 10% of older adults still live at or below the poverty line, and the percentage is higher among African Americans (24%) and Hispanics (21%). Providers should screen for problems with financial resources, as these issues have direct implications for health status and well-being. Older adults with limited means may be more prone to have problems

affording medications, meals, and basic amenities. Referrals to community resource networks can help identify options for help with basic needs, including housing options and congregate meals. Information on agencies and services in specific locales can be identified at www.eldercarelocator.org.

ADVANCE DIRECTIVES

Older patients may experience periods of altered sensorium or cognitive impairment and become unable to participate in their financial or health care decisions. In such situations a surrogate must intervene on behalf of the patient. Powers of attorney, living wills, advance directives, and guardianship documents become important in these situations. A power of attorney lists a surrogate who is authorized to manage a patient's financial affairs. Trust in this representative is important because the surrogate has the right to spend the patient's money and incur debt in the patient's name. A health care power of attorney designates a representative to make health care choices for the patient. For patients who have not created a health care power of attorney, typically the spouse or other first-degree relative is the default surrogate decision maker. The patient's preferences are sometimes detailed in a living will or other more detailed advance directive. This document often addresses situations in which the patient has a terminal illness, persistent vegetative state or progressive neurologic condition and can include explicit directions for care management including withdrawal or withholding of specific measures, including artificial nutrition and hydration. If no surrogate is designated and no next of kin is available, guardianship may be obtained. Guardianship is a legal proceeding whereby the court appoints a surrogate decision maker. For more information on legal issues and the elderly the reader is referred to the National Academy of Elder Law Attorneys at www.naela.org.

High-Risk Circumstances

THE HOSPITALIZED PATIENT

Millions of older adults are hospitalized in the United States each year for a variety of acute illnesses and elective procedures. Fortunately, in the United States, Medicare Part A covers nearly all the costs associated with acute care, including the costs of hospitalization and follow-up rehabilitation. While in the hospital, however, older adults are vulnerable to myriad complications related to both their compromised health state and problems inherent to the acute care environment itself. As noted previously, delirium plagues the hospitalized elderly at a very high rate and increases their risk of prolonged hospital stays, nursing home admission, and death. Hospitalized older adults also experience the effects of immobilization, with loss of muscle strength and deconditioning. Acutely, these factors increase the risk of falls and impair function and ability to provide self-care. In addition, poor oral intake may result in malnutrition, and illness-related fluid losses cause dehydration. As a result, hypotension and protein-calorie malnutrition are common problems. Immobility and malnutrition both predispose the acutely ill patient to the development of pressure wounds, which, in

the right circumstance, can develop in under 2 hours. All these problems worsen in the presence of delirium or depressed mood. Environmental factors also contribute to problems, including tethers such as catheters and intravenous lines, which increase risk of falls, and noisy wards, frequent tests, and procedures that further disrupt diurnal rhythms and sleep. Up to a third of hospitalized older adults experience a decline in their ability to perform ADLs in the course of their hospitalization. Patients who experience declines in function during hospitalization have higher rates of rehospitalization, prolonged institutionalization, and mortality after discharge, and many (41%) never return to their preadmission level of function. To combat these problems, some hospitals have created specialized inpatient geriatric care units, often termed *acute care for elders (ACE) units*. These units incorporate adaptations in the physical environment and specially trained staff to provide safe, patient-centered care designed to maximize restoration of function and prevent common complications of hospitalization. Likewise, geriatric evaluation and management (GEM) units (described later) offer specialized, team-based post-acute care with an emphasis on rehabilitation and return to prior level of function.

CARE TRANSITIONS

As noted previously, older adults experience high rates of complications during acute illness and require prolonged periods of time to recover. For this reason, management in the postacute period represents a critical and complex time in their care. Specifically, older adults with acute illness often find themselves transferred between different care settings and providers. Nearly a quarter of hospitalized older adults are discharged to SNFs, and another 12% are discharged with home health care. Of those discharged to skilled facilities, 19% will return to the hospital within 30 days. Transitions in care represent high-risk episodes, and evidence shows that patients and caregivers frequently experience miscommunication, medication errors, and missed essential laboratory tests or appointments during this period of time. Recent trials have demonstrated a reduction in rehospitalization through a structured discharge and transition plan that includes medication reconciliation before and after discharge, careful planning for laboratory and appointment follow-up, communication with patients and caregivers about expectations and preferences, and specific coaching for caregivers in symptom management and care. More information on care management in transitions is available at www.caretransitions.org.

Systems of Care

AMBULATORY AND HOME CARE

The majority of care for older adults occurs in the outpatient clinic. Much of the cost of this care, including visit fees, laboratory tests, x-ray studies, and vaccinations, is covered under Medicare Part B, for which patients pay a monthly premium. Outpatient visits may occur with the physician, physician's assistant, nurse practitioner, or clinical nurse specialists, depending on the nature of the problem and the

structure of the clinic. Other key members of the care team include social workers, pharmacists, psychologists, and physical and occupational therapists. Most assessments discussed in this chapter can be performed in the clinic, including functional assessments, cognitive and mood screening, gait and balance assessment, medication review, eye and ear examinations and continence evaluations. Interview of a caregiver can augment the information collected. Care in this setting can be complicated, though, by problems with transportation and ineffective or inefficient communication among multiple providers, particularly for patients with multiple specialists.

Over the last several years, home care has re-emerged as a very effective means of providing health care for older adults. As with the outpatient clinic, Medicare Part B will reimburse providers in part for services rendered in the home. In addition, if a rehabilitative or skilled service is needed, Medicare Part A provides coverage. Patients receiving services in the home must be “homebound,” implying that they are significantly functionally impaired and travel with assistance out of the home infrequently and usually for medical purposes. Services rendered in the home include a full range of evaluations by teams of providers from a variety of health professions depending on needs. Social workers often lead these visits and perform case management, assessing financial and other resource needs. Nurses, clinical nurse specialists, and/or nurse practitioners provide skilled services when necessary, including health education, symptom monitoring, or wound care. Physical and occupational therapy can assess mobility and home safety and greatly enhance function and independence. Furthermore, examination of a person’s home environment can reveal much about his or her nutritional habits and can facilitate education or intervention in this area. Physicians may serve as medical directors of such programs but may also perform visits themselves to learn more about a given patient’s health status. If significant concerns exist about a patient’s safety, particularly in the setting of cognitive impairment, a home visit may provide information about the need for more urgent interventions, including referrals to Adult Protective Services. Research has demonstrated that coordinated home care programs can improve management of chronic disease, including dementia, diabetes mellitus, and CHF, and can reduce rehospitalization in CHF.

LONG-TERM CARE

The phrase *long-term care* describes the array of services available to provide care for patients with disability from chronic and acute conditions. This definition includes the services offered in the outpatient and home settings described previously. Most associate the term, however, with the system of living facilities providing personal and medical care for disabled adults of all ages. SNFs provide long-term care for those with permanent disabilities from chronic illness or short rehabilitative stays after acute illness (e.g., stroke) or procedures (e.g., joint replacement). The scope of services may also include end-of-life care in conjunction with a hospice care team. Facility staff includes licensed nurses who give 24-hour supervision, with much of the personal care provided by certified nursing assistants (CNAs). Each facility also has a medical director overseeing various

aspects of medical care. An attending physician, who may or may not be the medical director, performs patient visits every 30 to 60 days. Most SNFs also employ physical, occupational, and speech therapists for rehabilitation care, dietitians, social workers, and recreational therapists. Patients with moderate or severe dementia constitute approximately 60% of patients living in SNFs. Although Medicare Part A provides payment for rehabilitative stays of 100 days or less (with a co-payment for days 21 to 100), it does not finance long-term stays. Patients of this type pay out of pocket, through long-term care insurance, or through Medicaid, a joint federal and state assistance program. Medicaid constitutes 47% of all payment sources for SNF care.

For patients with less complex care needs, assisted living facilities or domiciliary care homes provide an alternative arrangement for long-term care. Although these facilities vary dramatically in their size and structure, most provide nonskilled care for patients who need some assistance with ADLs. Licensed nurses may be present during discrete periods of time, and other professions may visit the facility intermittently to provide specific services such as physical therapy. Facilities do not have medical directors, and patients normally continue to see a primary care provider in the outpatient clinic. Unlicensed staff, including nursing aides, provides most of the personal care and assistance. Medicaid provides some reimbursement for this type of care, but the majority of residents pay out of pocket or through other assistance programs, such as social security.

PACE

In the 1970s a group providing care for older adults in San Francisco developed a model of long-term care centered in the community. Proponents of this model, entitled the Program of All-inclusive Care for the Elderly (PACE), believed that the community (rather than the institution) provided a better location to meet the chronic care needs of older adults. From its start as a community-based effort in California, the PACE model has grown with the support of foundations and now Medicare and Medicaid and offers services for seniors at 42 locations in 22 states. Participants must be over 55 and certified by the state to be eligible for nursing home care. The PACE program then uses resources otherwise slated to pay for the individual’s long-term care to provide care in the community—much of it coordinated through senior centers offering an array of resources and services, including the following:

- Adult day care, offering nursing; physical, occupational, and recreational therapies; meals; nutritional counseling; social work; and personal care
- Medical care provided by a PACE physician familiar with the history, needs, and preferences of each participant
- Home health care and personal care
- All necessary prescription drugs
- Social services
- Medical specialists such as audiology, dentistry, optometry, podiatry, and speech therapy
- Respite care*

*Information from the National PACE Association website at www.npaonline.org.

When necessary, PACE participants are admitted to the hospital or nursing home. These services are provided under the auspices of the PACE program as part of the care package. The benefits of care for older adults, particularly those of limited means, appear to be substantial; questions about cost, generalizability, and sustainability remain.

GERIATRIC CARE

In caring for frail older adults with complex care needs, consultation with a geriatrician or geriatrics-focused team can often provide highly useful information. The geriatrician can assist in the assessment and management of the specific conditions or situations described earlier. He or she can help with difficult decisions regarding treatment options in the context of multiple comorbidities and limited life expectancy and offer advice on appropriate level or setting of care for an older adult. Geriatricians complete a minimum of 1 year of fellowship after residency training in internal medicine or family practice. After training they are eligible for board certification and qualified to work in a number of different settings, including the hospital, long-term care, home care, or outpatient clinics. Comprehensive assessment by a geriatrician or geriatrics team includes components

detailed previously, including evaluation of the patient's medical condition, function, and social support. Normally the consultant will work with an interdisciplinary team (IDT) that may include a nurse case manager, physician's assistant, social worker, physical or occupation therapist, pharmacist, psychologist, or others. The outcome of the geriatric assessment is a comprehensive plan for safely restoring the patient to optimal function with mutually agreeable and realistic goals of care.

In the setting of acute illness, geriatricians also provide important services. As described earlier, acute-care-for-elders (ACE) units can improve patient care and prevent iatrogenic complications. Similarly, once patients are medically stable, transfer to a specialized geriatrics care unit, often termed a geriatric evaluation and management (or GEM) unit, may be possible, to provide a comprehensive medical assessment and plan for transition of care. Early consultation with a geriatrician and an IDT in the acute care setting can help in the management of complex medical illness and with communication with patients and caregivers about posthospitalization options. Subsequent to hospitalization, locating facilities or services that offer comprehensive care by a geriatrician and IDT would be ideal, including a coordinated approach that uses specific strategies to manage transitions of care.

Prospectus for the Future

Over the last quarter century, our understanding of the biology of human aging and chronic disease has expanded dramatically and allowed us to begin to develop novel strategies for more effective prevention and management of the medical ailments of late life. Concurrently with these scientific advances, however, we have also seen an increase in the population of older adults that has outpaced the resources available for care. In facing this challenge, the current generation of physicians and physicians-in-training must recognize the unique principles of care for the older patient and gain competence, if not mastery, in this area. These principles include (1) age-related changes in biology and physiology that make older adults more vulnerable to chronic illness and disability; (2) the presence of comorbid illness and functional decline, which predict health outcomes and life expectancy independent of age; (3) that older adults manifest illness in a number of nonspecific ways, including impairments in mobility, mentation, and mood; (4) effective and optimal

care, which includes careful assessment of health status and social circumstances, in identifying preferred treatment strategies; and 5) novel systems of care that incorporate interprofessional teams providing care across the spectrum of settings. Indeed, it is this last point that most accurately foretells the future of geriatric medicine. In recent years, randomized controlled trials of multifaceted, interdisciplinary interventions accounting for both host and environmental factors have proven highly effective in management of a variety of conditions. Examples include home-based interventions for congestive heart failure, dementia, and depression and specific protocols for prevention and management of falls and delirium in hospitals and nursing homes. In order to continue to meet the challenge of providing care for the oldest members of society, we must support the development and dissemination of these measures that adopt a holistic view of the individual patient's experience across providers and settings.

Section XXI

Palliative Care

134

Palliative Care – HOLLOWAY * QUILL

Palliative Care

Robert G. Holloway and Timothy E. Quill

Palliative care is a philosophy of care. The primary goal of palliative care is to minimize suffering and to support the best possible quality of life for patients and their families. Patients with serious and debilitating illness need and deserve excellent symptom control, assistance with difficult medical decisions, effective communication and collaboration among their providers, alleviation of psychosocial problems, and an empathetic presence that fosters hope and healing relationships. Palliative care affirms life by supporting the patient's goals for the future in light of a full understanding of his or her medical condition, potentially including hopes for cure, life prolongation, relief from suffering, and preparation for death when time is short. This process includes exploring what will be left undone if treatment does not go as hoped, who should make medical decisions for the patient if decision-making capacity is lost, and what, if any, limits might be set on aggressive therapy. Twelve key elements of palliative care have been identified by a National Consensus Process (**Web Table 134-1**).

Palliative care provides an organized, highly structured system for delivering care by an interdisciplinary team, including physicians, nurses, social workers, chaplains, counselors, and other health care professionals. Palliative care should be integrated within various health care settings including the hospital, emergency department, nursing home, home care setting, assisted living facilities, and outpatient settings. Palliative care remains very unevenly available, so many patients and families needlessly suffer, having no, limited, or delayed access to appropriate palliative care.

The integration of palliative care into the experiences of patients and families is designed to meet four objectives. First, to ensure that pain and symptom control, psychosocial distress, spiritual issues, and practical needs are addressed throughout the continuum of care. Second, to make certain that patients and families obtain the information they need in an ongoing and comprehensible manner to understand their prognosis and treatment options. This process incorporates their values and preferences and is sensitive to changes in the patient's condition over time. Third, palliative care seeks to provide seamless care coordination across settings with high-quality communication among providers.

Finally, for those patients who are not going to recover, to the extent possible palliative care prepares patients and families for the dying process and for death, including providing options for hospice care, opportunities for personal growth, and bereavement support.

Common Illness Trajectories and Palliative Care

There are distinct trajectories of functional decline before dying (**Web Fig. 134-1**). These four trajectories have major implications for palliative care and health care delivery. Patients and families likely have different physical, psychological, social, and spiritual needs depending on the trajectory of their illness before they die. Being aware of these trajectories can help providers deliver appropriate care that integrates both disease-directed and palliative treatments.

TRAJECTORY 1: SHORT PERIOD OF EVIDENT DECLINE BEFORE DEATH

Cancer typifies trajectory 1. Function is preserved until rather late, followed by a predictable and precipitous decline over weeks to months. The onset of decline usually suggests metastatic tumor. A more predictable decline in function can assist in anticipating care needs, transitioning away from curative treatments toward a more exclusive emphasis on palliation, and eventually into hospice care. Not all malignancies follow this trajectory (e.g., prostate, breast), and some nonmalignant conditions may follow this course.

TRAJECTORY 2: CHRONIC ILLNESS WITH EXACERBATIONS AND SUDDEN DYING

Congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD), end-stage liver disease, and acquired immunodeficiency syndrome (AIDS) typify trajectory 2.

These organ system diseases represent chronic illnesses with occasional, acute exacerbations (e.g., physiologic stress that overwhelms the body's reserves), often requiring hospital admission. Patients can have a return of function after an exacerbation, but often not to the level of their baseline. They also may die suddenly during an exacerbation, but it is difficult to predict in advance. Prognosticating is very challenging in this trajectory. For example, patients with heart failure who die suddenly also have a 50% chance of living 6 months or longer 1 week before their sudden death. When patients choose to forego or stop aggressive life support, planning for aggressive symptom relief during a future exacerbation is essential.

TRAJECTORY 3: PROLONGED DWINDLING

Dementia and frailty typify trajectory 3. Affected patients have a prolonged course of physical and cognitive decline and slowly dwindle away. Additional diagnoses include other neurodegenerative conditions (e.g., Parkinson's disease, amyotrophic lateral sclerosis) and patients with multiple moderate to severe comorbidities (e.g., arthritis, visual impairment, past mild strokes, diabetes with neuropathy). Gradual decline in function, weight loss, fatigue, and low levels of activity are core features. Caregiver demands are usually immense. Prognosticating survival is difficult, and complications such as pneumonia and fractures may be terminal events. The benefits and burdens of artificial nutrition must be balanced in the late stages.

TRAJECTORY 4: SUDDEN, SEVERE NEUROLOGIC INJURY

Sudden impairment trajectories are those that stem from sudden neurologic injury that can lead to profound cognitive and functional impairment. These include stroke, hypoxic ischemic encephalopathy, and traumatic brain injury. The vast majority of deaths occur either early after the event when treatments are withheld or withdrawn or in the chronic stage in survivors who have accumulating

debility (these events represent the leading cause of adult disability). At the extremes of impairment are persistent vegetative states, minimally conscious states, and locked-in syndrome. But there is a vast spectrum of severe impairments short of these extremes that raise questions about how to manage potentially severe debility with little chance of improvement. This trajectory requires a health system responsive to negotiating goals of treatment with patients and surrogates who may consider these future health states "worse than death."

Communication Skills and Negotiating Goals of Treatment

Excellent communication skills are central to palliative care: communication with patients, family, other physicians, nurses, and other members of the health care team. The overarching aim is to assist the patient and family in establishing the goals of current and future treatment in a process of shared decision making. When negotiating goals of treatment in palliative care, the focus is often to assist with the following decisions: to help decide types and aggressiveness of disease-directed therapies, to ensure optimum palliation of symptoms, to assist in hospice determinations, to discuss withholding or withdrawing therapies, and to facilitate advance care planning and to initiate surrogate decision making if patient lacks capacity. These discussions occur at various time points in the course of advancing illness when new and important information is learned and needs to be communicated to the patient and family. The need to renegotiate goals should also be anticipated when triggers of advancing disease suggest limited life expectancy or excessive suffering. These discussions are almost always variants of "bad news" discussions.

The overall approach to communication and negotiating goals of care in each of these scenarios is similar (Table 134-1). This includes running an effective family meeting with or without the patient present. Initial elements include

Table 134-1 General Strategy for Communicating and Negotiating Goals of Care in Common Palliative Care Settings

Step	Goals of Care
1	Prepare and establish setting Do not have a rigid preset agenda
2	Ask patient and family what they know and understand Provide sufficient time for patients and families to "tell their story" Use active listening skills
3	Find out how much patient and family want to know Acknowledge and explore emotions
4	Discuss prognosis and benefits and burdens of treatment options Be mindful of optimistic and pessimistic predictions Be prepared to make recommendations
5	Respond to emotions and empathetic response Convey honesty, and reframe hope Use "I wish" statements
6	Summarize, establish, and implement plan, follow-up Possible time-limited trial

establishing the proper setting, identifying key stakeholders, and “doing your homework” (i.e., discussing potential plans with people from all relevant subspecialties who may have communicated with the patient and families). When the meeting begins, first find out what the patient and family understand about the medical condition, and ask about what added information they want. Keeping an open mind and trying to hold back on a fixed agenda (e.g., to “get the DNR” or to “stop futile care”) helps clinicians allow patients and families sufficient time to “tell their stories” and provides the context within which effective decision making can occur. In general, the more patients and families speak in the early parts of such meetings, the better.

The provider then needs to share prognostic information and discuss the benefits and burdens of the available treatment options. Alerting the patient or family of impending bad news (“I am afraid I have some difficult news to share with you”) is a useful initial communication strategy. The amount of information should be paced with frequent pauses to allow time for emotional responses. Comprehension should be frequently checked, and questions should be encouraged. The skilled clinician can flexibly assess, probe, and pace the content and depth of the discussions and negotiations in an emotionally responsive (acknowledge, explore, empathize, and legitimize) and culturally competent manner. This includes the ability to understand and respect diverse religious practices and differing preferences about degree of truth telling. When appropriate, the clinician should make recommendations based on scientific knowledge as well as awareness of a patient’s values and preferences and should be prepared to help resolve conflicts among patient, family members, and providers. Finally, providers need to develop strategies to preserve and potentially reframe hope, including ways to “hope for the best” while simultaneously “preparing for the worst.” Commitments to minimize suffering and to not abandon the patient and family are essential. At the end of the discussions, the provider should summarize key aspects of what was reviewed and establish a follow-up plan for future communications and treatments.

Estimating and Communicating Prognosis

A core component of information shared in the palliative care setting is prognosis. Understanding prognosis is central to making decisions about aggressive treatment as well as hospice. Prognosis is a prediction of possible future outcomes of a disease (survival, symptoms, function, quality of life, family impact, and financial considerations) with or without treatment. Most patients and families want to know prognosis; they both hate it and crave it at the same time. Because there are some patients and families who may not want to know prognosis or may want it communicated in a particular way, it is essential to begin by finding out what the patient and family know and want to know.

Inaccurate predictions may lead to poor decision making. Indeed, physicians tend to overestimate survival in patients with advanced cancer by about 30%, and the bias is more pronounced the longer the physician-patient relationship.

Overly optimistic predictions can lead to overuse of ineffective or unwanted disease-directed treatment, delay in hospice referrals, false expectations, unnecessary tests and procedures, and poor symptom control. Therefore accurately estimating and communicating prognosis is central to optimal decision making in advanced illness and at the end of life.

In advanced illnesses, common factors found to be predictive of short-term survival (i.e., less than 3 to 6 months) include performance status, anorexia-cachexia syndrome, delirium, and dyspnea. In addition to physicians’ subjective predictions of survival, there exist models to assist with prognostic estimates, including generic models for particular populations (e.g., hospice enrollees) as well as disease-specific models (e.g., cancers, heart failure, liver disease, stroke, AIDS, spinal cord compression). Hospice eligibility criteria also exist for different diseases. Although not uniformly reliable, they can be useful in formulating estimates when prognosis might be 6 months or less if the disease were allowed to run its natural course (a prognostic criterion for hospice referral).

For an individual patient, however, prognostic uncertainty remains the rule. Therefore it is important to integrate both evidence and experience-based medicine and present the information in formats tailored to the particular patient (verbal descriptions, numerics, frequencies, or graphics). Prognostic estimates should be bounded with ranges to convey realistic uncertainty, being sure to allow for exceptions in both directions. For example, “in my experience, patients with your condition live on average a few weeks to a few months. It could be longer if you are lucky, but it could also be shorter.” For survival-predominant prognoses (e.g., “How long do I have?”), be mindful of overly optimistic prognoses, remembering to think of and convey the lower bound (e.g., “some may live longer, but others may unfortunately live shorter”). For outcome-predominant prognoses (e.g., “What will life be like?”), be mindful of overly pessimistic predictions, remembering the power of adaptation and engendering hope by helping patients and families find new meaning.

Suffering and Symptom Management

In addition to establishing and facilitating goals of treatment, palliative care aims to relieve suffering, defined as severe distress related to events that threaten the stability of personhood or how the physical, psychological, spiritual, and social aspects of self are interconnected. Beginning with simple, open-ended screening questions such as “In what ways are you suffering most?” and then following with more domain-related screening questions (physical, psychological, spiritual, social) may allow for more probing and multidimensional inquiries to better understand the various sources of and contributions to an individual’s suffering.

One of the first steps in the care of any seriously ill patient is to control pain and other forms of physical suffering. There are striking similarities between the burden of symptoms experienced in patients dying of cancer and the symptoms experienced in noncancerous conditions. Although

the profile of symptoms may differ, each disease carries with it troubling symptoms that can potentially be addressed and managed.

PHYSICAL SYMPTOMS

Pain

Uncontrolled pain dominates all other experiences, and most pain can be relieved using basic pain management strategies. These include a detailed history and physical examination, categorizing the likely type(s) (i.e., somatic, visceral, neuropathic) and severity (rated on a 0 to 10 scale) of pain, knowledge about proper opioid dosing strategies, and judicious use of consultations and invasive interventions (e.g., nerve blocks, epidural analgesia). The overarching three-tiered approach is to use nonopioids (e.g., acetaminophen, nonsteroidal anti-inflammatory drugs) for mild pain, weak opioids (e.g., hydrocodone or codeine) for mild to moderate pain, and strong opioids (e.g., morphine, hydromorphone, fentanyl, methadone) for moderate to severe pain.

Most patients with chronic moderate to severe pain should be initially started on around-the-clock administration of a short-acting opioid. Table 134-2 shows the equianalgesic dosing, usual starting doses, half-life, duration, and relative costs for the commonly available opioid agents. Once the total daily dosage has been determined (sum of all scheduled and “as needed” doses), the patient may be switched to a long-acting opioid to cover the baseline requirements. As-needed opioids for breakthrough pain should be approximately 10% of the total daily dose every 1 to 2 hours orally or every 30 to 60 minutes subcutaneously or intravenously. Continuous intravenous (IV) or subcutaneous (SC) infusions of opioids may be needed for rapid control of severe pain. Methadone is useful in palliative care because of its excellent oral bioavailability, lack of active metabolites in renal impairment, low cost, flexible route of administration (oral [PO], IV, SC), and possible effect on both neuropathic and somatic pain. However, it does have a dose-dependent, progressively long half-life and arrhythmogenic potential.

Constipation occurs with all opioids, and it should be anticipated and treated. Other predictable but less common side effects include nausea, myoclonus, urinary retention, pruritus, and delirium. Some of these side effects are time-limited with initiation (e.g., nausea), whereas others can be managed by dose reduction or opioid rotation (e.g., myoclonus, delirium). Major respiratory depression is extremely rare if the opioid dose is appropriate and proportionate to the severity of symptoms. In the absence of a prior history of drug and alcohol abuse, addiction is rare, but physical dependence (i.e., withdrawal symptoms on abrupt cessation) and tolerance (i.e., a decrease in drug effect over time) should be expected. Naloxone should be rarely used unless a clear overdose is suspected or if life-threatening complications occur. Special caution is needed about opioid prescribing in elderly and debilitated patients, and recommended starting doses should be reduced by approximately 50%. There are additional opioid selection recommendations for patients with renal insufficiency (avoid morphine and codeine; use hydromorphone and oxycodone with caution; methadone and fentanyl optimal) and hepatic insufficiency

(cautiously use fentanyl, hydromorphone, oxycodone, or methadone; avoid or decrease dose of morphine).

Other Symptoms

There are numerous physical symptoms not related to pain that can dominate and overwhelm the clinical picture in any given patient. These include dyspnea, nausea and vomiting, constipation, anorexia-cachexia, fatigue, bleeding, agitation, apathy, myoclonus, pruritus, and specific functional deficits. Each symptom requires a structured approach to the history and physical examination, with a full exploration of the potential causes and treatment options, and informed by the prognosis and preferences of the patient and family.

Psychological Pain

Depression, anxiety, and delirium are all common in the palliative care setting. They are frequently underrecognized and under-treated. Appropriate diagnosis and treatment can improve quality of life.

Nearly all patients in palliative care and their families experience sadness, preparatory grief, and transient anxiety as illness advances. Grief or normal sadness is often experienced in waves with retained capacity for pleasure. Depression is more enduring, persistent, and intense and may be associated with hopelessness, helplessness, worthlessness, and guilt. Two screening questions assessing depressed mood and anhedonia include “Are you depressed?” and “Do you have much interest and pleasure in doing things?” One should be cautious using somatic symptoms to diagnose depression (e.g., fatigue, anorexia, sleep disturbance), as they frequently overlap with physiologic changes associated with advanced disease. For depression and anxiety, consider and rule out contributions from physical symptoms (e.g., uncontrolled pain), medical causes (e.g., hypothyroidism, hyperthyroidism), and medications. Effective pharmacologic and nonpharmacologic treatments exist for both depression and anxiety, although treatment selection depends on symptom intensity, patient prognosis, and treatment benefits and burdens. Other members of the interdisciplinary team (social worker, chaplain, and psychologist) often play a critical role in assessment and ongoing management.

Delirium, an acquired and fluctuating disorder of consciousness and cognition, occurs commonly in the palliative care setting. The level of psychomotor activity can vary from hyperactive (“agitated” delirium) to hypoactive (“quiet” delirium). Nearly 80% of the delirium in the palliative care setting is the hypoactive variant. As a result, it is often underdiagnosed, or misdiagnosed as depression and fatigue. The most common causes of delirium in palliative care include medications (e.g., opioids), metabolic disorders caused by progressive organ failure, and infection. Meticulous attention to the history from collateral sources (nurses, caregiver) and a detailed medication history are essential for an accurate diagnosis. Although delirium may reverse if an obvious cause is identified and removed, frequently it represents an important marker of progressive illness, so cognitive improvements may be transient and incomplete. In addition to cause-specific treatment (e.g., change or stop medications, treat infection, administer oxygen, ensure adequate hydration, administer bisphosphonates), environmental interventions are recommended for all patients (e.g., quiet reassurance, gentle reorientation, optimization of sensory

Table 134-2 Equianalgesic Table for Adults with Moderate to Severe Pain

Medication	Equianalgesic Dose (for chronic administration)		Usual Starting Doses Adult > 50 kg: For opioid naive patients (♦ 1/2 dose for elderly, or severe renal or liver disease)	Comments
	IM/IV onset	PO		
Morphine	15-30 min 10 mg	PO onset 30-60 min 30 mg	Parenteral 2.5-5 mg IV q3-4h (♦1.25-2.5 mg) PO 5-15 mg q3-4h (IR or oral solution) (♦2.5-7.5 mg)	Comments IR tablets (15, 30 mg) oral sol. (2 mg/ml, 4 mg/ml) Conc solution (20 mg/ml) can give buccally Morphine ER tablets (15, 30, 60, 100, 200 mg) q 8-12h Kadian ER pellets (10, 20, 30, 50, 60, 100, 200 mg) q 12-24h Avinza ER pellets (30, 60, 90, 120 mg) q 24h Rectal suppositories (5, 10, 20, 30 mg) Not recommended in renal failure OxyIR capsule (5 mg); IR tablet (5, 10, 15, 20, 30 mg); conc solution (20 mg/ml) Oxycontin (10, 15, 30, 30, 60, 80 mg) – due to high cost and potential for abuse, use only if failure or contraindication to morphine ER Not enough literature regarding dosing in renal failure; use caution Tablet (2, 4, 8); oral liquid (1 mg/ml) Use carefully in renal failure
Oxycodone	Not available	20 mg	Parenteral Not available PO 5-10 mg q3-4h (♦2.5 mg)	OxyIR capsule (5 mg); IR tablet (5, 10, 15, 20, 30 mg); conc solution (20 mg/ml) Oxycontin (10, 15, 30, 30, 60, 80 mg) – due to high cost and potential for abuse, use only if failure or contraindication to morphine ER Not enough literature regarding dosing in renal failure; use caution Tablet (2, 4, 8); oral liquid (1 mg/ml) Use carefully in renal failure
Hydromorphone	1.5 mg	7.5 mg	Parenteral 0.2-0.6 mg IV q 2-3h (♦0.2 mg) PO 1-2 mg q3-4h (♦0.5-1 mg)	Tablet (2, 4, 8); oral liquid (1 mg/ml) Use carefully in renal failure
Methadone*	$\frac{1}{2}$ oral dose 2 mg PO methadone = 1 mg parenteral methadone	24 hr. oral morphine <30 mg 31-99 mg 100-299 mg 300-499 mg 500-999 mg 1000-1200 mg >1200 mg Oral morphine: Methadone ratio 2:1 4:1 8:1 12:1 15:1 20:1 Consider consult	Parenteral 1.25-2.5 mg q 8h (♦1.25 mg) PO 2.5-5 mg q 8h (♦1.25-2.5 mg)	Table (5,10 mg);sol (1 mg/ml, 2 mg/ml & concentrated 10 mg/ml) Usually q 12h or q 8h; long variable T $\frac{1}{2}$ Acceptable with renal disease Small dose change makes big difference in blood level Tends to accumulate with higher doses, always advise "hold for sedation" Because of long half life, do not use methadone prn When converting from oral to parenteral, cut dose in half for safety When converting parenteral to oral, keep dose the same
Fentanyl*	100 mcg (single dose) (T1/2 and duration of parenteral doses variable)	24 hr oral MS dose 30-59 mg 60-134 mg 135-224 mg 315-404 mg Initial patch 12.5 mcg/hr 25 mcg/hr 50 mcg/hr 100 mcg/hr	Parenteral 25-50 mcg IM/IV q 1-3h (♦12.5- 25 mcg) PO Transderm patch 12.5 mcg/hr q72h (Use with caution in opioid naive and in unstable patients because of 12 hour delay in onset and offset)	Transdermal patch (12.5, 25, 50, 75, 100 mcg); N.B. Incomplete cross-tolerance already accounted for in conversion to fentanyl; when converting to other opioids from fentanyl, generally reduce the equianalgesic amount by 50% Acceptable with renal disease, monitor carefully if using long term IV: Very short acting; associate with chest wall rigidity Oral lozenge (200 mcg start) and buccal tablet (100 mcg start)—indicated for breakthrough cancer pain only (see PDR and package insert)

*Parenteral methadone and fentanyl are not integrated into the equianalgesic table. See Quill, 2010 for more detail on dosing and prescribing.

input, minimization of night disruptions). Pharmacologic management should be used sparingly and cautiously and may include antipsychotic medications, benzodiazepines, and psychostimulants (for the hypoactive variant).

Spiritual and Existential Pain

Spiritual and existential distress is prevalent in patients and families with serious illness, especially at the end of life. Spirituality is about one's relationship with and responses to transcendent questions that confront one as a human being (i.e., search for meaning and purpose in life). Religion is a set of texts, practices, and beliefs about the transcendence shared by a community. Spirituality is broader than religion. The spiritual issues of seriously ill and dying patients often center on questions of meaning, value, and relationships. Dying patients want to be assured of their value in the face of actual or perceived threats to their intactness as a human being (physical or cognitive declines, altered appearances). Spirituality helps people find hope in despair and can help restore purpose.

One of the goals of palliative care is to relieve spiritual and existential distress. Patients and families often welcome such discussions. Examples of open-ended questions to facilitate this dialogue include “Are you at peace with all of this?” and “Is faith (religion, spirituality) important to you?” Acknowledgment and empathetic listening are the most important responses for most clinicians, not “correct answers.”

Other strategies for fostering hope and meaning include developing caring relationships, setting attainable goals, involving the patient in the decision-making process, affirming the patient's worth, using lighthearted humor (when appropriate), and reminiscing with life review. It is important, however, to know one's professional boundaries and to refer to other members of the care team as appropriate (“Would you like to explore religious matters with someone?”).

The Role and Use of Diagnostic Tests and Invasive Procedures

Several questions should be considered in determining the appropriateness of aggressive medical or palliative interventions near the end of life. What is the goal or expected outcome of the proposed intervention? What is the probable efficacy of the intervention? What are the patient's baseline levels of function and life expectancy? What are the potential side effects and burdens of the intervention? What are the patient's and family's wishes?

The range of medical and palliative options available is huge, so the challenge is to determine what makes sense to enhance the well-being of this patient at this particular stage of illness. Palliative interventions range from simple laboratory tests to more invasive options such as chemotherapy, radiotherapy, surgical or endoscopic interventions, stenting procedures, thoracentesis, paracentesis, pericardiocentesis, home inotropic therapy, noninvasive ventilation, antibiotics, and transfusions. The challenge is to individualize, so that patients can take full advantage of treatments that will

help them meet their goals while not having their experience dominated by near-futile invasive interventions.

The Role of Hospice

Hospice care is a specialized form of palliative care aimed at patients in the terminal stages of illness and their families. In 2007, 1.3 million patients were served by hospice programs in the United States. In order for a patient to qualify for the Medicare Hospice Benefit, two physicians must sign a statement certifying that the patient's prognosis for survival, if the disease were to run its natural course, is more likely than not to be 6 months or less. In addition, patients and families must agree to the hospice philosophy of care, aimed primarily at comfort, and forgo insurance coverage for disease-directed therapies. Hospice criteria exist to assist in making these determinations for most common medical conditions. Hospice care can be delivered in hospitals, patient's homes, nursing homes, or dedicated “hospice houses.” The Medicare Hospice Benefit covers most costs related to terminal care without a deductible, which includes palliative medications, nursing oversight, supplies, and bereavement care. Hospice also covers up to 4 hours of custodial caregiver services per day, but family and/or friends have to provide the remaining care and support if a patient is to stay at home.

Cancer continues to be the most common diagnosis for patients dying in hospice programs. However, the prevalence of noncancer diagnoses is increasing, and patients with noncancerous conditions now represent more than 50% of all hospice admissions. Discussing hospice with patients and families can be challenging. First, it is often initially viewed as a “bad news” discussion, given that patients and families need to confront the fact that disease-directed treatment is no longer effective and that prognosis is likely to be 6 months or less. Second, given the reimbursement restrictions, patients may also need to forgo particular types of treatment that are important to them (e.g., acute hospital or intensive care unit [ICU]-level care, dialysis, chemotherapy, milrinone for heart failure).

Request for Hastened Death—Last Resort Options

The prevalence of suicidal ideation and suicide attempts is higher in patients with advanced life-limiting illness compared with those without serious disease. The prevalence of patients requesting a health care professional to help hasten death is not precisely known, but the situation is not uncommon. The motivation behind such requests may relate to relentless physical suffering, disfigurement, hopelessness, loss of dignity, fear of being a burden, or a “cry for help.” Most enduring requests from patients with progressive medical illnesses, however, arise not from inadequate symptom control, but from a patient's belief about dignity, meaning, and control over the circumstances of death. Although some providers might be uncomfortable with exploring such requests, they need to be approached

systematically with a diligent search to understand the root causes before a response is given.

A careful evaluation includes a precise clarification and exploration of exactly what the patient is asking and why. Is the request based on transient thoughts about ending life (common) or a serious appeal for assistance (relatively rare)? Does the request occur in the context of intense physical suffering, psychological despair, an existential crisis, or a combination of factors? Does the patient have full decision-making capacity, and is the request proportionate to the level of suffering? Evaluating such requests can be emotionally fatiguing and conflicting, and clinicians need self-awareness in distinguishing their emotions from the patient's, including tending to one's own support.

Responding to such a request should first include intensification of potentially reversible contributions to suffering. This will often include treating physical and psychological symptoms, aggressive attempts to foster hope, consulting psychiatrists or spiritual counselors, and creative brainstorming with trusted colleagues and team members. Some requests for hastened death persist despite optimal palliative care. In such circumstances, the clinicians should seek out a second opinion and confront the possibilities. These possibilities include withdrawal of life-sustaining interventions, palliative sedation, voluntary cessation of oral intake, and assisted suicide (illegal in the United States except for the states of Oregon and Washington). Although it is important to support the patient, clinicians must balance this desire with integrity and nonabandonment. This may include drawing specific boundaries regarding what the clinician can and cannot do, while still searching in earnest for a mutually acceptable solution.

Common Ethical Challenges in Palliative Care

INADEQUATE TREATMENT OF PAIN AND THE MYTH THAT PAIN MEDICATION HASTENS DEATH

Evidence abounds that pain is undertreated in many medical settings, including in those patients who are severely and even terminally ill (especially women, the elderly, minorities, and those who are cognitively impaired). Some undertreatment stems from fears about addiction as well as concerns about the possibility of hastening death. When patients with prior addiction problems are excluded, the incidence of new addictive behavior when opioids are used to treat pain in those with well-defined serious illness is probably less than 1%. Similarly, data suggesting that properly prescribed opioids hasten death are virtually nonexistent. In fact, there is some suggestion that opioids might even prolong life in these settings, and they certainly enhance quality of life in those with advanced illness and major pain or dyspnea.

WHEN PATIENTS AND FAMILIES WANT NEAR-FUTILE TREATMENT

The patient autonomy movement in medicine has led to patients and families taking an active role in their own

medical decision making. This is generally a positive development except in two circumstances: (1) when physicians stop taking an active role and using their expertise to guide patients in their decision making, thereby abdicating their professional responsibility of advocating for the best possible treatment based on the patient's medical condition and personal values, and (2) when patients or their families want and even demand near-futile treatment toward the end of life despite physicians' advice that treatment will cause much more burden than benefit. Physicians might try to respond to patients who want "everything" by suggesting that they might want to try everything that is "more likely to help than harm," but avoid any treatment that is most likely to "do more harm than good." But some patients and families will accept no limits on treatment no matter what the burden and the improbability of success. Of course, truly futile treatment should not be offered or provided on request, but absolute futility has been difficult to define in many cases.

FEEDING TUBE QUESTIONS WHEN PATIENTS STOP EATING AND DRINKING

Many patients gradually stop eating and drinking as a natural part of the dying process, but this can be very hard for patients and families to accept in light of fears about "starving to death" and in view of seemingly simple technologies that can potentially combat and even reverse the problem. In fact, with few exceptions, feeding tubes have not been shown to prolong life in most advanced illnesses such as metastatic cancer or advanced Alzheimer disease. It is important to know about the exceptions (e.g., esophageal and oropharyngeal cancers, amyotrophic lateral sclerosis, and perhaps acute stroke) but also to have an open and frank discussion about the naturalness of eating and drinking less and less as many illnesses progress. If there is uncertainty about whether a particular patient might benefit from a feeding tube, and patient and family are clear about wanting to give it a try, the clinician can frame the decision as a "time-limited trial" to see how the patient tolerates tube feeding psychologically as well as physiologically in a specified timeframe. A nasogastric tube has a built-in time limit of about a month before a percutaneous endoscopic gastrostomy (PEG) tube needs to be inserted; this provides a potential framework for such a trial. Explaining to patients and families about the positive aspects of natural feeding, even in small amounts, of real food (smell, taste, enjoyment) may help focus the decision on important quality-of-life issues that may otherwise be ignored, rather than on more technical, physiologic issues.

Last Hours and Days of Living

An integral aspect of palliative care is preparing and guiding the patient and caregivers through the dying process. When prognosis is measured in hours to days, there are typical signs and symptoms that occur. Patients become weak and fatigued and gradually lose mobility. There is also a gradual and predictable decrease in food and fluid intake. Most patients do not experience hunger and thirst, and the

associated mouth dryness that occurs is easily palliated with small sips or sponges of cold water. Caregivers will frequently ask about IV hydration. In rare instances, IV or SC fluids may temporarily improve mental status and energy in the final days of life. Most of the time, however, the benefits are difficult to discern, and the excessive fluids may contribute to end-of-life physiologic conditions (edema, ascites, effusions, and pulmonary secretions) that do not improve longevity and may worsen comfort.

As patients become weaker, there is a predictable decrease in the level of consciousness with increasing periods of somnolence eventually giving way to a comatose state. Education about this process should include associated changes in respiratory patterns and anticipation of progressive periods of apnea, interspersed with episodes of hyperpnea and deep breathing (Cheyne-Stokes respirations). During this process caregivers often feel they are on “a roller-coaster ride,” and gentle guidance on what to expect can allay concerns. As consciousness wanes, swallowing slows and the cough reflex weakens. As a result, saliva pools in the oropharynx and can result in noisy respiration (“death rattle”), which can usually

be palliated with transdermal scopolamine, glycopyrrolate (given via oral [PO], IV, or SC route), or sublingual atropine ophthalmic drops. Families should be reminded that these symptoms are a natural part of the dying process, and that persistent shortness of breath is relatively uncommon but can be treated with opiates and benzodiazepines if needed.

As death approaches, reduced perfusion causes cooling and cyanosis of the extremities and a decrease in and darkening of the urine. Most deaths are relatively peaceful, but a few can be preceded by periods of intense agitation and restlessness (hyperactive terminal delirium). Antipsychotic medications and conventional doses of benzodiazepines can usually treat terminal delirium. Before and when death occurs, families should be encouraged to carry out cultural or religious rituals that are important to them. Providers should express condolences, be available for questions, and be responsive to intense emotional reactions that sometimes occur. A short condolence card or letter is almost always appreciated. If possible, efforts should be made to follow up with family members and caregivers deemed at risk for complicated bereavement and grief.

Prospectus for the Future

Palliative care became an officially recognized subspecialty in the United States in 2006. Physicians from 10 specialties can be board certified in hospice and palliative medicine, including family medicine, internal medicine, emergency medicine, pediatrics, physical medicine and rehabilitation, anesthesiology, psychiatry, neurology, radiology, and surgery. As patients live longer with chronic illness, there will be an increasing need to

fully integrate palliative care providers and programs within hospitals, in nursing homes, and in the outpatient setting. There is a compelling need for research to better define the optimal timing, setting, and delivery of palliative care to improve the quality of life and lessen the suffering of patients and families with advanced illness.

Alcohol and Substance Abuse – LANGE * HILLIS

Alcohol and Substance Abuse

Richard A. Lange and L. David Hillis

Alcohol Dependence and Abuse

Alcohol dependence and abuse are major public health problems. Seventeen million adults in the United States, about 1 in every 12, abuse alcohol or are alcohol-dependent, and 58 million have participated in binge drinking within the past month. In the United States, alcohol use is the third leading preventable cause of death—exceeded only by cigarette smoking and obesity—and claims over 85,000 lives annually. Alcohol-related liver disease, which affects more than 2 million Americans, is responsible for approximately 13,000 deaths per year. Alcohol use contributes to roughly 30% of all fatalities caused by motor vehicle accidents, or approximately 13,000 vehicular deaths annually, and is a major contributor to risky sexual behavior, domestic violence, homicide, and suicide. For the year 1998, the economic cost of alcohol abuse was estimated to be \$185 billion.

Definitions of Alcohol Abuse and Dependence

The American Psychiatric Association has specific criteria for the diagnoses of *alcohol abuse* and *alcohol dependence*; these criteria are described in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, and are listed in Table 135-1. A person can be diagnosed with abuse only if he or she does not fit the criteria for dependence, and a person who meets the criteria for both abuse and dependence is diagnosed with dependence. The so-called *binge drinker* is defined as one who typically consumes five or more drinks on a single occasion. The terms *tolerance* and *dependence* are used to describe a continuum in the adaptation of the central nervous system (CNS) to drug usage. Tolerance may enable the alcoholic to maintain sobriety even in the setting of markedly elevated blood alcohol concentrations. Alcohol dependence is present when the individual has tolerance, withdrawal symptoms, and an uncontrollable urge to consume alcohol (see Table 135-1).

Epidemiologic Factors

Among individuals aged 12 or older, whites are more likely to report current alcohol use than other racial groups (Fig. 135-1), and men are more likely than women to be drinkers (57% versus 46%, respectively). Surveys indicate that approximately 40% of high school seniors and 65% of college students currently use alcohol (Fig. 135-2), and more than one half of all college students admit to heavy episodic drinking. Although the prevalence of ethanol use is highest in individuals younger than 30 years of age, survey data suggest that about two thirds of persons over age 30 consume ethanol.

Pharmacologic and Metabolic Factors

After oral ingestion, alcohol is absorbed predominantly in the small intestine, and its rate of intestinal absorption is accelerated by the simultaneous ingestion of carbohydrates and carbonated beverages. Prolonged retention of alcohol in the stomach, as occurs when food is consumed before drinking, delays alcohol absorption, because absorption in the stomach is considerably slower than in the duodenum. Once in the blood, alcohol equilibrates rapidly across all membranes, including the blood-brain barrier, thereby accounting for the prompt onset of its euphoric effects. Maximal blood alcohol concentrations are reached 45 to 75 minutes after alcohol is ingested.

The liver metabolizes approximately 90% of ethanol to acetaldehyde via the alcohol dehydrogenase pathway; subsequently, acetaldehyde is converted by aldehyde dehydrogenase to acetate, which enters the Krebs cycle. At low or moderate serum concentrations of ethanol, the alcohol dehydrogenase pathway functions almost exclusively in metabolizing ethanol. At high concentrations, the microsomal ethanol oxidizing system contributes to metabolism. Less than 10% of ethanol is excreted unchanged through the skin, kidneys, and lungs. Variability among individuals in

Table 135-1 Criteria for the Diagnosis of Alcohol Abuse and Dependence in a 12-Month Period

Alcohol Abuse (One or More of the Following)	Alcohol Dependence (Three or More of the Following)
Failure to meet obligations at home, school, or work	Alcohol tolerance: increased consumption as a result of decreased effects of alcohol
Inappropriate or recurrent use of alcohol in harmful or hazardous situations	Symptoms or signs of alcohol withdrawal
Evidence of legal problems	Alcohol consumption increases for long periods
Concerns related to alcohol consumption are ignored or minimized	Attempts to quit typically fail
	More time is diverted to obtain, use, and recover from use of alcohol
	Withdrawal from customary social, occupational, and recreational contacts
	Alcohol abuse continues despite knowledge of psychophysical dependence

oxidation of ethanol (in cases of more active alcohol dehydrogenase variants) or slower acetaldehyde oxidation (in cases of less active aldehyde dehydrogenase variants). Acetaldehyde is a toxic substance, the accumulation of which leads to a highly aversive reaction that includes facial flushing, nausea, and tachycardia.

Mechanisms of Alcohol-Induced Organ Damage

The major organs that are susceptible to damage by alcohol are the liver, pancreas, heart, brain, and bone (Table 135-2). Several alcohol-related medical disorders are caused by various nutritional deficiencies; ethanol is deficient in proteins, minerals, and vitamins. Therefore the initial management of the alcoholic must attend to suggested dietary deficiencies (e.g., thiamine) and electrolyte imbalances, including potassium, magnesium, calcium, and zinc.

Alcohol-related liver disease is the leading preventable cause of hepatic failure in the industrialized world. Genetic factors are thought to play a role in susceptibility to this disorder because alcoholic liver disease is more prevalent in whites than in other ethnic groups, despite a similar magnitude of ethanol consumption. The histopathologic features of alcoholic liver disease include fatty infiltration, hepatitis, fibrosis, and end-stage cirrhosis.

Clinical Manifestations of Alcohol Ingestion

ACUTE ALCOHOL INTOXICATION

Mild ethanol intoxication produces slurred speech, ataxia, irregular eye movements, and poor coordination. Signs of

Accidents, trauma, violence, suicide

CNS depression and associated cerebellar or vestibular dysfunction include dysarthria, ataxia, and nystagmus. Although blood alcohol concentrations are not precisely correlated with the degree of intoxication and the clinical effect of ethanol widely varies among individuals, stupor and coma usually develop at blood concentrations approaching 400 mg/dL, and blood levels of 500 mg/dL often are fatal. However, it is important to understand that death may occur even when the blood alcohol concentration is as low as 300 mg/dL.

WITHDRAWAL SYNDROME (CONVULSIONS)

Alcohol withdrawal occurs in three stages. The signs of minor withdrawal usually appear 6 to 12 hours after the discontinuation of ethanol and are caused by central adrenergic hyperexcitability; they consist of anxiety, tremors, sweating, tachycardia, diarrhea, and insomnia. Additional evidence of autonomic nervous system hyperactivity often appears within 12 to 24 hours and includes increased startle response, nightmares, and visual hallucinations. Alcohol withdrawal seizures (so-called *rum fits*) are generalized clonic-tonic convulsions that occur 12 to 48 hours after the discontinuation of ethanol and are estimated to occur in 2% to 5% of alcoholics.

DELIRIUM TREMENS

Delirium tremens (DTs) is characterized by delirium (a confused state with varying levels of consciousness), hallucinations, tremor (caused by marked autonomic nervous system overactivity), and agitation. It occurs in approximately 5% of alcoholics, most often in chronic heavy abusers with underlying neurologic damage. If unrecognized and untreated, the in-hospital mortality rate of DTs approaches 25%.

Management and Treatment

Intervention strategies in alcohol abusers are designed to modify the individual's attitudes, knowledge, and skills to prevent alcohol misuse. In the outpatient setting, increased frequency of contact between the primary care physician and the patient increases the likelihood of detection, intervention, and prevention of heavy alcohol consumption. All scheduled office visits should include alcohol screening, assessment, and possible brief attempts at intervention (one or more discussions lasting 10 to 15 minutes), as studies show that this approach decreases alcohol intake and its consequences. Behavioral or pharmacologic treatment should be considered, because two thirds of treated patients have a reduction in the amount of consumption (by more than 50%) as well as the consequences of consumption (e.g., alcohol-related injury or job loss). A year after treatment, one third of patients are either abstinent or drink moderately without consequences.

SCREENING AND INTERVENTION STRATEGIES

The National Institute on Alcohol Abuse and Alcoholism (NIAAA) provides several web-based guidelines for alcohol screening during routine health examination (see www.niaaa.nih.gov). A four-step plan exists with which physicians can (1) screen patients for alcohol use, (2) assess for the presence of alcohol-related problems, (3) provide advice concerning appropriate action, and (4) monitor the patient's progress. For the current drinker the physician should inquire about the number of drinks consumed per day,

Table 135-3 CAGE: An Alcoholism Screening Test

1. Have you ever felt you should *cut* down on your drinking?
2. Have people *annoyed* you by criticizing your drinking?
3. Have you felt *guilty* about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (i.e., as an *eye-opener*)?

number of days per week on which ethanol is consumed, and total number of drinks consumed per month. Alcohol consumption that exceeds 14 drinks per week or three drinks per day should trigger an in-depth assessment of alcohol-related problems. The physician should ascertain if the individual is at risk for alcohol-related problems, has an existing problem, or may be alcohol-dependent.

The CAGE questionnaire (each of the letters in the acronym refers to one of the questions) (Table 135-3) is a useful screening tool for identifying alcohol-dependent individuals. A positive response to two or more of the four questions is indicative of a potential alcohol problem and should prompt questions regarding the quantity and frequency of consumption. Difficulties with work-related, interpersonal, and family relationships and/or evidence of high-risk behavior despite self-reported low-risk consumption indicate that the individual is at risk for alcohol dependence. To assess for alcohol dependence, the individual should be queried about morning drinking, blackouts, depression, abdominal pain, hypertension, sexual dysfunction, and problems with sleep. If drinking has been associated with legal problems, impaired behavior, feelings of guilt, or trauma, alcohol dependence should be suspected. The patient with alcohol dependence exhibits a compulsion (e.g., a preoccupation) to drink, lack of control once drinking has started, symptoms of withdrawal, drinking to relieve symptoms, and increased tolerance to alcohol. On physical examination, evidence of alcoholic liver disease may be exhibited as jaundice, hepatomegaly, palmar erythema, male gynecomastia, spider angiomas, and ascites. The serum γ -glutamyltransferase concentration typically is elevated in individuals who drink excessively.

LOW-RISK DRINKING

A standard drink contains 12 g of alcohol, an amount similar to that found in one 12-oz bottle of beer or wine cooler, one 5-oz glass of wine, or 1.5 oz of distilled (e.g., 80 proof) spirits. In men older than age 64 and in women, the limit for moderate drinking is one drink per day. For younger men, moderate drinking is defined as no more than two drinks per day. For the same amount of ingested ethanol, women and older adult men achieve a higher blood-ethanol concentration than younger men owing to their smaller volume of body water. A reasonable blood alcohol level should not exceed 50 mg/dL.

A blood-alcohol level as low as 80 mg/dL may exceed the legal definition for driving under the influence (DUI) or driving while intoxicated (DWI). In national surveys the

strategy of the *designated driver* appears to be effective at preventing unsafe driving by drinkers at risk for DWI. Complete abstinence is recommended for people with a history of alcohol dependence, other serious medical conditions (e.g., liver disease), and pregnancy.

NONPHARMACOLOGIC THERAPIES

For the foreseeable future, pharmacologic agents will remain complementary and adjunctive to the traditional approaches of abstinence, group therapy, coping mechanisms, and behavior modification. The most widely employed behavioral approach is the 12-step program administered by Alcoholics Anonymous (AA), with which the recovering alcoholic moves through 12 specific steps aided by his or her attendance at regular meetings within a self-help peer group. Cognitive behavioral therapy is based on the principle that the alcoholic first must identify the internal and external cues to drinking so that he or she can develop effective countermeasures for drinking behavior. Motivation enhancement therapy is a four-session, brief-contact intervention program that encourages self awareness and behavioral changes in the alcoholic. These therapies provide similar efficacy.

CONSIDERATIONS FOR DRUG INTERVENTIONS

If desired, medications can be administered in conjunction with behavioral modification. Disulfiram, naltrexone, and acamprosate have been approved by the U.S. Food and Drug Administration (FDA) for adjunctive therapy.

Disulfiram (Antabuse) inhibits aldehyde dehydrogenase (i.e., the enzyme that converts acetaldehyde to acetate), resulting in a 5- to 10-fold increase in serum acetaldehyde concentrations when alcohol is consumed. This produces uncomfortable symptoms (e.g., facial flushing, tachycardia, nausea, vomiting, and headache), which act to deter alcohol consumption. Because of low medication compliance and limited efficacy, disulfiram is rarely prescribed.

Naltrexone, an opioid antagonist used for the treatment of opiate addiction, is the first medication to be approved by the FDA for the treatment of alcoholism in over 50 years. In clinical trials a combination of naltrexone and psychosocial intervention reduced the number of drinking days, induced a longer period of abstinence from ethanol, and decreased the relapse rate in heavy drinkers when compared with psychosocial intervention alone. Naltrexone is administered in a dose of 50 mg daily for 12 weeks, although larger doses (i.e., 100 to 150 mg daily) and a longer duration of administration may improve its success in preventing relapse. Some recovering alcoholics develop nausea when it is initiated. Because hepatic toxicity may occur at high doses (300 mg), periodic testing of liver function is recommended. Naltrexone is contraindicated in patients receiving opioids, given that opiate withdrawal is an unintended adverse effect of the drug.

Nalmefene, an opiate antagonist, has a mechanism of action similar to that of naltrexone, but the FDA has yet to approve nalmefene for the treatment of alcohol abuse. In placebo-controlled trials, nalmefene was substantially better

than placebo at reducing the rate of relapse in heavy drinkers. In comparison with naltrexone, hepatotoxicity occurs less often.

Acamprosate (Campral) is a structural analog of γ -aminobutyric acid (GABA). It decreases excitatory glutaminergic neurotransmission during alcohol withdrawal. The recommended dosage of Campral is 666 to 1000 mg 3 times a day, and its most common side effects are diarrhea and intestinal cramping. In placebo-controlled trials involving more than 4600 alcoholic patients, acamprosate reduced relapse rates and increased abstinence from ethanol. In comparative trials it did not appear to be as efficacious as naltrexone. Because the liver does not metabolize acamprosate, it is safe in persons with alcoholic liver disease.

Several other drugs have been associated with a reduction in alcohol consumption, including ondansetron (a selective serotonin reuptake inhibitor), topiramate (an anticonvulsant), baclofen (a GABA agonist), and varenicline (a nicotinic acetylcholine-receptor and dopamine partial agonist), but they are not yet approved by the FDA for treatment of alcohol dependence.

FETAL ALCOHOL SPECTRUM DISORDERS

Alcohol freely crosses the placenta and is teratogenic. It is a leading preventable cause of birth defects with mental deficiency, with up to 1 in 100 children in the United States being born with fetal alcohol spectrum disorders (FASDs). The scope of disabilities and malformations varies and depends on the amount of alcohol consumed, the frequency of exposure, the stage of fetal development when alcohol is present, maternal parity, nutrition, and individual variation in maternal and fetal alcohol metabolism.

The term *fetal alcohol spectrum disorders* is used to characterize the full range of prenatal alcohol damage varying from mild to severe and encompassing a broad array of physical defects and cognitive, behavioral, and emotional deficits. It includes conditions such as fetal alcohol syndrome (FAS), alcohol-related neurodevelopmental disorder (ARND), and alcohol-related birth defects (ARBDs).

FAS, the most severe form of FASD, is characterized by growth retardation, neurodevelopmental abnormalities (i.e., microcephaly, hyperactivity, irritability, altered motor skills, learning disabilities, seizure disorders, and mental retardation), and dysmorphic facial features, including short palpebral fissures, flat midface, short nose, smooth philtrum, and a thin upper lip. Children with typical dysmorphic facial features who lack the other features have partial FAS. Children with ARBDs have typical facies associated with FAS and anomalies in other organs (i.e., cardiac, renal, skeletal, auditory) but no growth retardation or neurodevelopmental abnormalities. Children with ARND exhibit behavioral or cognitive abnormalities in the absence of dysmorphic facial features.

Although the damage from prenatal exposure to alcohol cannot be reversed, children with FASDs benefit from early diagnosis and aggressive intervention with physical, occupational, speech and language, and educational therapies. Early recognition can also benefit the impaired mother, resulting in access to alcohol treatment and a better social situation for the entire family.

The diagnosis of FASD is important, but prevention is the answer. Given that no safely established level of alcohol consumption in pregnancy exists, recommendations suggest that pregnant women maintain abstinence. In addition, women who are considering pregnancy or are already pregnant must be counseled about the effects of alcohol on the fetus.

MEDICAL MANAGEMENT OF ALCOHOL WITHDRAWAL AND DELIRIUM TREMENS

For the patient with probable alcohol withdrawal, comorbid conditions that may coexist or mimic the symptoms of withdrawal (e.g., infection, trauma, hepatic encephalopathy, meningitis, drug overdose, metabolic derangements) should be excluded. Once these conditions have been excluded, the patient should be placed in a quiet and protective environment and should receive parenteral thiamine and multivitamins to decrease the risk of Wernicke encephalopathy or Korsakoff amnesic syndrome. Benzodiazepines are the only medications proved to ameliorate symptoms and to decrease the risk of seizures and DTs in patients with alcohol withdrawal. Typically, diazepam (5 to 20 mg), chlordiazepoxide (50 to 100 mg), or lorazepam (1 to 2 mg) is administered intravenously every 5 to 10 minutes until symptoms subside, with the last of these medications preferred in patients with advanced cirrhosis, considering that the liver minimally metabolizes it. Continued administration of a benzodiazepine with a fixed-interval approach (i.e., administered even if symptoms are absent) or a symptom-driven approach typically continues for 24 to 72 hours. All benzodiazepines appear to be similarly efficacious in treating alcohol withdrawal, but long-acting agents may be more effective in preventing withdrawal seizures and are associated with fewer rebound symptoms. Conversely, short-acting agents may offer a lower risk of oversedation. For the patient who is resistant to benzodiazepines, intravenous phenobarbital (130 to 260 mg administered intravenously every 15 minutes) may be given.

Prescription Drug Abuse

According to the National Survey on Drug Use and Health, an estimated 19.9 million Americans aged 12 years or older were current illicit drug users in 2007, meaning they had used prescription drugs for nonmedical purposes or illicit drugs within 1 month of the survey interview (Fig. 135-3). This estimate of current illicit drug users represents 8% of the population aged 12 years or older. Marijuana was the most commonly used illicit drug: 53% of illicit drug users used marijuana only, 27% used drugs other than marijuana (including sedatives, hypnotics, stimulants, hallucinogens, and inhalants), and 19% used both.

SEDATIVES AND HYPNOTICS

Benzodiazepines and barbiturates are the major sedative-hypnotic drugs among the commonly abused drugs that are listed in Table 135-4. The patient with sedative-hypnotic intoxication may have slurred speech, incoordination,

Figure 135-3 Past-month illicit drug use among persons aged 12 or older, according to the National Survey on Drug Use and Health (2007). (From Substance Abuse and Mental Health Services Administration, Office of Applied Studies: Results from the 2007 National Survey on Drug Use and Health: National Findings. NSDUH Series H-34, DHHS Publication No. SMA 08-4343. Rockville, Md, 2008.)

unsteady gait, impaired attention or memory, stupor, and coma. The psychiatric manifestations of intoxication include inappropriate behavior, labile mood, and impaired judgment and social functioning. On physical examination the person may have respiratory depression or even arrest, nystagmus, and hyperreflexia. Although benzodiazepines rarely depress respiration to the extent that barbiturates do (and, as a result, have a much wider margin of safety), the effects of these drugs are additive with those of other CNS depressants, such as ethanol. Chronic use may produce physical and psychological dependence and a potentially dangerous withdrawal syndrome.

Benzodiazepines potentiate the effects of GABA, which inhibits neurotransmission. They are available as short-acting agents (temazepam [Restoril] and triazolam [Halcion]), intermediate-acting agents (alprazolam [Xanax], chlordiazepoxide [Librium], estazolam [ProSom], lorazepam [Ativan], and oxazepam [Serax]), and long-acting agents (clorazepate [Tranxene], clonazepam [Klonopin], diazepam [Valium], flurazepam [Dalmane], halazepam [Paxipam], Prazepam [Centrax], and quazepam [Doral]).

Table 135-4 Commonly Abused Drugs

Substance: Category and Name	Examples of Commercial and Street Names	How Administered*	Intoxication Effects and Potential Health Consequences
Cannabinoids			Euphoria, slowed thinking and reaction time, drowsiness, inattention, confusion, impaired balance and coordination, enhanced perception; cough, frequent respiratory infections; impaired memory and learning; increased heart rate, anxiety; panic attacks; tolerance, addiction
Hashish	Boom, chronic, gangster, hash, hash oil, hemp	Smoked, swallowed	
Marijuana	Blunt, dope, ganja, grass, herb, joints, Mary Jane, pot, reefer, sinsemilla, skunk, weed	Swallowed, smoked	
Sedative-Hypnotics (CNS Depressants)			Reduced pain and anxiety, feeling of well-being, lowered inhibitions, labile mood, impaired judgment, poor concentration, fatigue, confusion, impaired coordination and memory, respiratory depression and arrest, addiction
Benzodiazepines (other than flunitrazepam)	Restoril, Halcion, Xanax, Librium, ProSom, Ativan, Serax, Tranxene, Klonopin, Valium, Dalmane, Doral; candy, downers, sleeping pills, tranks	Swallowed	Sedation, drowsiness, dizziness

Table 135-4 Commonly Abused Drugs—Cont'd

Substance: Category and Name	Examples of Commercial and Street Names	How Administered	Intoxication Effects and Potential Health Consequences
Flunitrazepam [†]	Rohypnol; forget-me pill, Mexican Valium, R2, Roche, roofies, roofinol, rope, rophies	Swallowed, snorted	Visual and gastrointestinal disturbances, urinary retention, amnesia while under drug's effects
Barbiturates	Amytal, Nembutal, Seconal, phenobarbital; barbs, reds, red birds, phennies, tooies, yellows, yellow jackets	Injected, swallowed	Sedation, drowsiness, depression, unusual excitement, fever, irritability, poor judgment, slurred speech, dizziness
GHB [†]	γ -hydroxybutyrate; G, Georgia home boy, grievous bodily harm, liquid ecstasy	Swallowed	Drowsiness, dizziness, nausea and vomiting, headache, loss of consciousness, hallucinations, peripheral vision loss, nystagmus, loss of reflexes, seizures, coma, death
Dissociative Anesthetics			Increased heart rate and blood pressure; impaired function, memory motor loss, numbness, nausea and vomiting
PCP and analogues	Phencyclidine; angel dust, boat, hog, love boat, peace pill	Injected, swallowed, smoked	Possible decrease in blood pressure and heart rate; panic, aggression, violence, suicidal ideation; loss of appetite, depression
Ketamine*	Ketalar SV; cat Valiums, K, Special K, vitamin K	Injected, snorted, smoked	At high doses: delirium, depression, respiratory depression and arrest, amnesia while under drug's effects
Hallucinogens			Altered states of perception and feeling, nausea, chronic mental disorders, persisting perception disorder (flashbacks)
LSD	Lysergic acid diethylamide; acid, blotter, boomers, cubes, microdot, yellow sunshines	Swallowed, absorbed through mouth tissues	Also, for LSD and mescaline: increased body temperature, heart rate, blood pressure; loss of appetite; sleeplessness, numbness, weakness, tremors
Mescaline	Buttons, cactus, mesc, peyote	Swallowed, smoked	
Opioids and Morphine Derivatives			Pain relief, euphoria, drowsiness, respiratory depression and arrest, pinpoint pupils, nausea, confusion, constipation, sedation, unconsciousness, seizures, coma, tolerance, addiction
Codeine or oxycodone	Empirin with Codeine, Fiorinal with Codeine, Robitussin A-C, Tylenol with Codeine, OxyContin, Roxicodone, Vicodin; Captain Cody, Cody, schoolboy (with glutethimide), doors and fours, loads, pancakes and syrup	Injected, swallowed	Less analgesia, sedation, and respiratory depression than morphine

Table 135-4 Commonly Abused Drugs—Cont'd

Substance: Category and Name	Examples of Commercial and Street Names	How Administered	Intoxication Effects and Potential Health Consequences
Fentanyl	Actiq, Duragesic, Sublimaze; Apache, China girl, China white, dance fever, friend, goodfella, jackpot, murder 8, TNT, Tango and Cash	Injected, smoked, snorted	
Heroin	Diacetylmorphine; brown sugar, dope, H, horse, junk, skag, skunk, smack, white horse	Injected, smoked, snorted	Staggering gait
Morphine or meperidine	Roxanol, Duramorph, Demerol; M, Miss Emma, monkey, white stuff	Injected, swallowed, smoked	
Opium	Laudanum, paregoric; big O, black stuff, block, gum, hop	Swallowed, smoked	
Stimulants			Increased heart rate, blood pressure, metabolism; feelings of exhilaration, energy, increased mental alertness, rapid or irregular heart beat; reduced appetite, weight loss, heart failure, seizures, coma
Amphetamine	Adderall, Biphentamine, Dexedrine; bennies, black beauties, crosses, hearts, LA turnaround, speed, truck drivers, uppers	Injected, swallowed, smoked, snorted	Rapid breathing, paranoia, hallucinations, tremors, loss of coordination, irritability, anxiety, restlessness, delirium, panic, impulsive behavior, aggressiveness, Parkinson disease, tolerance, addiction
Methamphetamine	Desoxyn; chalk, crank, crystal, fire, glass, go fast, ice, meth, speed	Injected, smoked, snorted	Aggression, violence, psychotic behavior, memory loss, cardiac and neurologic damage, impaired memory and learning, tolerance, addiction
Methylphenidate	Ritalin; JIF, MPH, R-ball, Skippy, the smart drug, vitamin R	Injected, swallowed, snorted	Increase or decrease in blood pressure, psychotic episodes, digestive problems, loss of appetite, weight loss
Cocaine	Cocaine hydrochloride; blow, bump, C, candy, Charlie, coke, crack, flake, rock, snow, toot	Injected, smoked, snorted	Increased temperature, chest pain, respiratory failure, nausea, abdominal pain, stroke, seizures, malnutrition
MDMA [†] (methylenedioxymethamphetamine)	DOB, DOM, MBDB, MDA; Adam, clarity, ecstasy, Eve, lover's speed, peace, Methyl-J, Eden, STP, X, XTC	Swallowed	Mild hallucinogenic effects, hallucinations, paranoia, increased tactile sensitivity, empathic feelings, nystagmus, ataxia, tremor, hyperthermia, impaired memory and learning

Substance: Category and Name	Examples of Commercial and Street Names	How Administered	Intoxication Effects and Potential Health Consequences
Other Compounds			Stimulation, loss of inhibition, headache, nausea or vomiting, slurred speech, loss of motor coordination, wheezing, unconsciousness, cramps, weight loss, muscle weakness, depression, memory impairment, damage to cardiovascular and nervous systems, sudden death
Inhalants	Solvents (paint thinners, gasoline), glues, gases (butane, propane, aerosol propellants, nitrous oxide), nitrites (isoamyl, isobutyl, cyclohexyl); laughing gas, poppers, snappers, whippets	Inhaled through nose or mouth	

*Taking drugs by injection can increase the risk of infection through needle contamination with staphylococci, human immunodeficiency virus, hepatitis, and other organisms.
[†]Associated with sexual assaults (e.g., date rapes).
 CNS, central nervous system.

Flunitrazepam (Rohypnol, also known as *roach*, *roofies*, *circles*, *Mexican valium*, or *rope*) is a popularly abused benzodiazepine that is not legally available in the United States but is often smuggled here from other countries. Flunitrazepam has been implicated in cases of *date rape* and is known as a *club drug* because adolescents and young adults often use it at nightclubs and bars or during all-night dance parties called *raves*.

In persons with an acute benzodiazepine overdose, respiratory depression is the major danger. Flumazenil (Romazicon), a competitive antagonist of benzodiazepines, can be given intravenously for acute overdose. Although it reverses the sedative effects of benzodiazepines, flumazenil may not completely reverse respiratory depression, and it may cause seizures in patients with physical dependence or concurrent tricyclic antidepressant poisoning.

Benzodiazepine cessation may precipitate withdrawal symptoms, depending on the half-life of the benzodiazepine, the duration of use, and the dose. Such withdrawal is characterized by intense anxiety, insomnia, irritability, perceptual changes, hypersensitivity to light and sound, psychosis, hallucinations, palpitations, hyperthermia, tachypnea, diarrhea, muscle spasms, tremors, and seizures. Withdrawal symptoms usually peak 2 to 4 days after the discontinuation of a short-acting agent and 5 to 6 days after discontinuation of a longer-acting one; however, panic attacks and nightmares may recur for months. In general, agents with shorter half-lives produce more intense withdrawal symptoms compared with agents with longer half-lives. Detoxification requires a change to a longer-acting benzodiazepine (e.g., clonazepam, diazepam) or phenobarbital and a tapering regimen of 7 to 10 days for short-acting agents or 10 to 14

days for longer-acting ones. For hemodynamically unstable patients who require very rapid medication titration to control withdrawal symptoms and for those with severe hepatic failure, short-acting medications are indicated in lieu of phenobarbital. Propranolol can be given to decrease tachycardia, hypertension, and anxiety.

Barbiturates may be short acting (pentobarbital and secobarbital), intermediate acting (amobarbital, aprobarbital, and butobarbital), or long acting (mephobarbital and phenobarbital). The symptoms of acute intoxication with and withdrawal from barbiturates are similar to those of benzodiazepines. For acute barbiturate overdose, oral charcoal and alkalinization of the urine (to a pH >7.5) with forced diuresis are effective in lowering the blood concentration. For patients with hemodynamic compromise refractory to aggressive supportive therapy, barbiturate elimination can be increased by hemodialysis or charcoal hemoperfusion. The effective treatment of withdrawal symptoms requires estimating the daily dose of the abused drug and substituting an equivalent phenobarbital dose to stabilize the patient, after which the dose of phenobarbital is tapered over 4 to 14 days, depending on the half-life of the abused drug. Benzodiazepines may also be used for detoxification, and propranolol and clonidine may help reduce symptoms.

Abuse of γ -hydroxybutyrate (GHB) has increased substantially over the last decade in the United States. This drug is abused for its sedative, euphoric, and bodybuilding effects. GHB is a metabolite of the neurotransmitter GABA, and it also influences the dopaminergic system. It potentiates the effects of endogenous or exogenous opiates. The ingestion of GHB results in immediate drowsiness and dizziness, with the feeling of a *high*. These effects can be potentiated by the

concomitant use of alcohol or benzodiazepines. Similar to flunitrazepam and ketamine, GHB is a popular club drug, and it has been implicated in cases of date rape. Its street names include *G*, *liquid E*, *liquid X*, *fantasy*, *Georgia home boy*, and *grievous bodily harm*. Adverse effects that may occur within 15 to 60 minutes of its ingestion include headache, nausea, vomiting, hallucinations, loss of peripheral vision, nystagmus, hypoventilation, cardiac dysrhythmias, seizures, and coma. In rare instances these adverse effects have led to death. The withdrawal from GHB becomes clinically apparent within 12 hours and may last up to 12 days.

OPIOIDS

Opioids include the natural and semisynthetic alkaloid derivatives of opium, as well as the purely synthetic drugs that mimic heroin. They bind to opioid receptors in the brain, spinal cord, and gastrointestinal tract; in addition, they act on several other CNS neurotransmitter systems, including dopamine, GABA, and glutamate, to produce analgesia, CNS depression, and euphoria. With continued opioid use, tolerance and physical dependence develop. As a result, the user must use larger amounts of the drug to obtain the desired effect, and withdrawal symptoms may occur if use is discontinued. The commonly abused opioids include heroin, morphine, codeine, oxycodone (OxyContin or Roxicodone), meperidine (Demerol), propoxyphene (Darvon), hydrocodone (Vicodin), hydromorphone (Dilaudid), buprenorphine (Temgesic) and fentanyl (Sublimaze). Intravenous heroin use, particularly when combined with cocaine (a so-called *speedball*), is increasing in the United States. The controlled-release pain reliever OxyContin was made available for use in 1995. By 2001, OxyContin was the most prescribed brand-name narcotic and was frequently diverted for illicit use, in which it was ingested orally, inhaled, or dissolved in water and administered intravenously to obtain an immediate high. In 2002, buprenorphine (Subutex) was made available in the United States for use in opiate addiction therapy. Unlike methadone, which must be dispensed from a clinic, buprenorphine can simply be prescribed by a physician. As a result, its illicit use has increased substantially.

Acute opioid overdose produces pulmonary congestion, with resultant cyanosis and respiratory distress, and changes in mental status that may progress to coma. Other manifestations include fever, pinpoint pupils, and seizures. Unsterile intravenous practices can lead to skin abscesses, cellulitis, thrombophlebitis, wound botulism, meningitis, rhabdomyolysis, endocarditis, hepatitis, or human immunodeficiency virus (HIV) infection. Neurologic complications from intravenous heroin use include transverse myelitis, inflammatory polyneuropathy, and peripheral nerve lesions.

For acute opioid overdose, the patient's respiratory status must be assessed and supported. Naloxone should be administered intravenously and repeated at 2- to 3-minute intervals, often in escalating doses. The patient should respond within minutes with increases in pupil size, respiratory rate, and level of alertness. If no response occurs, opioid overdose is excluded, and other causes of somnolence and respiratory depression must be considered. Naloxone should be titrated carefully because it may precipitate acute withdrawal symptoms in opioid-dependent patients.

Withdrawal symptoms may appear as early as 6 to 10 hours after the last injection of heroin. Initially the individual often has feelings of drug craving, anxiety, restlessness, irritability, rhinorrhea, lacrimation, diaphoresis, and yawning; these signs are followed by dilated pupils, piloerection, anorexia, nausea, vomiting, diarrhea, abdominal cramps, bone pain, myalgias, tremors, muscle spasms, and, in rare cases, seizures. These symptoms and signs peak at 36 to 48 hours and then subside over 5 to 10 days, if untreated. A protracted abstinence syndrome characterized by bradycardia, hypotension, mild anxiety, sleep disturbance, and decreased responsiveness may occur for up to 5 months.

Withdrawal from opioids can be managed with methadone, a long-acting synthetic agonist drug; withdrawal symptoms of methadone develop more slowly and are less severe than those caused by heroin. Methadone can be given twice daily and tapered over 7 to 10 days. Alternatively, levo- α -acetylmethadol (LAAM), a long-acting agonist, or buprenorphine, a partial agonist, can be given. The latter is combined with naloxone in a formulation (Suboxone) developed to decrease the potential for abuse. Clonidine reduces autonomic hyperactivity and is particularly effective if combined with a benzodiazepine.

Patients with repeated relapses can be maintained on methadone or LAAM. Buprenorphine may also be used as maintenance therapy. Naltrexone is a long-acting opioid antagonist that blocks impulsive opioid use. It can be given daily or two to three times weekly, but only after the patient is thoroughly detoxified because it may precipitate withdrawal. Pharmacotherapy must be combined with psychotherapy and structured rehabilitation to achieve an optimal outcome.

AMPHETAMINES

Amphetamines have been used therapeutically for weight reduction and treatment of attention-deficit disorder and narcolepsy. Similar to cocaine, they cause a release of monoamine neurotransmitters (dopamine, norepinephrine, and serotonin) from presynaptic neurons. In addition, however, they have neurotoxic effects on dopaminergic and serotonergic neurons. Their euphoric and reinforcing effects are mediated through dopamine and the mesolimbic system, whereas their cardiovascular effects are caused by the release of norepinephrine. Chronic use leads to neuronal degeneration in dopamine-rich areas of the brain, which may increase the risk for the eventual development of Parkinson disease.

Amphetamines can be abused orally, intranasally, intravenously, or by smoking. The most frequently used drugs are dextroamphetamine (Dexedrine), methamphetamine (Desoxyn), and methylphenidate (Ritalin). Methamphetamine is known on the street as *ice*, *crank*, *meth*, *crystal*, *tina*, *glass*, and *yaa baa*. Recently the illicit use of amphetamines has increased substantially, in part because (1) it is easily and quickly synthesized from ephedrine or pseudoephedrine (Fig. 135-4), and (2) its psychotropic effects persist for up to 24 hours. The anorexiant phenmetrazine and phentermine, which are structurally and pharmacologically similar to amphetamine, also have been used illicitly.

Tolerance to the stimulant effects of amphetamines develops rapidly, and toxic effects can occur with higher doses. Acute amphetamine toxicity is characterized by excessive

Figure 135-4 The chemical structures of amphetamine and methamphetamine, which can be easily manufactured from ephedrine or pseudoephedrine given that they are structurally similar and widely available.

sympathomimetic effects, including tachycardia, hypertension, hyperthermia, cardiac arrhythmias, tremors, seizures, and coma. The patient may experience irritability, hyper-vigilance, paranoia, stereotyped compulsive behavior, and tactile, visual, or auditory hallucinations. The clinical picture may simulate an acute schizophrenic psychosis. The symptoms of withdrawal are similar to those seen with cocaine (described in the next section), but the acute psychosis and paranoia are often significantly pronounced.

The treatment of amphetamine abuse centers on a quiet environment, benzodiazepines for anxiety, and sodium nitroprusside for severe hypertension. Antipsychotics, such as haloperidol, can reduce the agitation and psychosis by blocking dopamine's effects on the CNS receptor. Urine acidification with ammonium chloride accelerates amphetamine excretion.

Illicit Drug Abuse

COCAINE

Cocaine use has increased dramatically among adolescents and young adults. Among individuals 12 years old or older in 2007, 2.1 million had used cocaine within the previous month and 906,000 had used it for the first time within the previous 12 months, which averages to about 2500 initiates per day. It is a frequent cause of drug-related visits to emergency rooms. Cocaine can be taken orally or intravenously; alternatively, because it is well absorbed through all mucous membranes, abusers may achieve a high blood concentration after intranasal, sublingual, vaginal, or rectal administration. Its freebase form—called *crack* because of the popping sound it makes when heated—is heat stable so that it can be smoked. Crack cocaine is considered to be the most potent and addictive form of the drug. Euphoria occurs within seconds after crack cocaine is smoked and is short lived. Compared with smoking of crack cocaine or the intravenous injection of the drug, mucosal administration results in a slower onset of action, a later peak effect, and a longer duration of action. The blood half-life is approximately

1 hour. The drug's major metabolite is benzoylecgonine, which can be detected in the urine for 2 to 3 days after a single dose.

An intense, pleasurable reaction lasting 20 to 30 minutes occurs after cocaine use, after which rebound depression, agitation, insomnia, and anorexia occur, which are then followed by fatigue, hypersomnolence, and hyperphagia (the *crash*). This crash usually lasts 9 to 12 hours but occasionally may last up to 4 days. Users often ingest the drug repetitively at relatively short intervals to recapture the euphoric state and to avoid the crash. On occasion, sedatives or alcohol are ingested concomitantly to reduce the intensity of anxiety and irritability associated with the crash. The combination of cocaine and intravenously administered heroin (so-called *speedball*, *snowball*, *Belushi*, or *dynamite*) is frequently used so that the abuser can experience the cocaine-induced euphoria and then *float* down on the opiate. Unfortunately, this combination has been reported to cause sudden death. People who use cocaine in temporal proximity to the ingestion of ethanol produce the metabolite cocaethylene, which has also been implicated in cocaine-related deaths.

Cocaine blocks the presynaptic reuptake of norepinephrine and dopamine, producing an excess of these neurotransmitters at the site of the postsynaptic receptor. Thus cocaine acts as a powerful sympathomimetic agent, resulting in tachycardia, hypertension, tachypnea, hyperthermia, agitation, pupillary dilation, peripheral vasoconstriction, and seizures. Cocaine causes potent vasoconstriction of cerebral arteries and therefore may result in a stroke. It is associated with myocardial ischemia and arrhythmias and, in rare cases, with myocardial infarction in young persons with normal or nearly normal coronary arteries. The principal mechanisms of ischemia and infarction are coronary arterial vasoconstriction, thrombosis, platelet aggregation, tissue plasminogen activator inhibition, increased myocardial oxygen demand, and accelerated atherosclerosis (Fig. 135-5).

For patients with cocaine-induced hypertension or tachycardia, labetalol and benzodiazepines are usually effective in lowering systemic arterial pressure and heart rate. Patients with acute myocardial infarction should receive aspirin, heparin, nitroglycerin, and, if indicated, reperfusion therapy (with a thrombolytic agent or primary coronary intervention). The use of β -adrenergic blockers should be avoided because ischemia may be worsened by unopposed α -adrenergically mediated coronary arterial vasoconstriction. Patients with a normal electrocardiogram or nonspecific changes can be managed safely with observation.

The immediate treatment of acute cocaine intoxication includes obtaining vascular and airway access, if needed, and careful electrocardiographic monitoring. Benzodiazepines can be given to control CNS agitation, and haloperidol or risperidone can be used in the severely agitated patient. A supportive environment is needed, but detoxification is not required, given that few physical signs of true dependence are present.

Most chronic cocaine abusers have psychological dependence and an intense craving for cocaine. Personal and group therapies are important adjuncts to pharmacologic treatment, but relapse is common and is difficult to manage. Although no medication is FDA approved for treatment of cocaine addiction, disulfiram, modafinil, anticonvulsants

Figure 135-5 The mechanisms by which cocaine may induce myocardial ischemia or infarction. Cocaine may cause increases in the determinants of myocardial oxygen demand when oxygen supply is limited (*top*), when intense vasoconstriction of the coronary arteries occurs (*middle*), or when accelerated atherosclerosis and thrombosis are present (*bottom*).

(e.g., topiramate and tiagabine), serotonin reuptake inhibitors (e.g., citalopram), serotonin receptor antagonists (e.g., ondansetron), and GABA receptor agonists (e.g., baclofen) have shown some promise in promoting cocaine abstinence. More recent research is focused on so-called *vaccine strategies*, whereby protein-conjugated analogues of cocaine would be administered to produce anti-cocaine antibodies that bind cocaine, thereby preventing its passage across the blood-brain barrier.

CANNABIS

The cannabinoid drugs include marijuana (the dried flowering tops and stems of the hemp plant) and hashish (a resinous extract of the hemp plant). Marijuana is the illicit drug with the highest rate of dependence or abuse. Of the 6.9 million persons in the United States with dependence on or abuse of illicit drugs in 2007, 3.9 million were dependent on or abused marijuana or hashish (representing 1.6% of the total population aged 12 years old or older). Marijuana and hashish are among the drugs most commonly used by adolescents, with approximately one half of 12th graders admitting use at least once and 20% reporting that they are current users. Most of their pharmacologic effects come from metabolites of δ -9-tetrahydrocannabinol, which bind to specific cannabinoid receptors located in the CNS, spinal cord, and peripheral nervous system. The primary mode of use is smoking, with mood-altering

and intoxicating effects noted within 3 minutes and peak effects in approximately 1 hour. The acute physiologic effects are dose related and often include increased heart rate, conjunctival congestion, dry mouth, fine tremor, muscle weakness, and ataxia. Psychoactive effects include euphoria, enhanced perception of colors and sounds, drowsiness, inattentiveness, and inability to learn new facts. Tolerance and physical dependence occur, and chronic users may experience mild withdrawal symptoms of irritability, restlessness, anorexia, insomnia, or mild hyperthermia. Rarely, acute psychosis with panic reactions occurs. The treatment of withdrawal is supportive and includes reassurance; benzodiazepines may be used in severely agitated patients. Cannabinoids have been used as antiemetic agents in patients with cancer receiving chemotherapy, for weight stimulation (in patients with cancer or HIV infection), and in the treatment of glaucoma.

HALLUCINOGENS AND DISSOCIATIVE DRUGS

Hallucinogens (drugs that cause hallucinations) include lysergic acid diethylamide (LSD), mescaline, psilocybin, and ibogaine. *Dissociative drugs* distort perceptions of sight and sound and produce feelings of detachment—dissociation—without causing hallucinations. They include phencyclidine (PCP), ketamine, and dextromethorphan (a widely available cough suppressant).

LSD is the most potent of the hallucinogenic drugs. Although it is known to interact with serotonin receptors in the cerebral cortex and *locus ceruleus*, the precise psychoactive mechanism is unknown. Within 30 minutes of its oral ingestion, sympathomimetic effects appear, including mydriasis, hyperthermia, tachycardia, elevated blood pressure, diaphoresis, dry mouth, increased alertness, tremors, and nausea. Within 2 hours, the psychoactive effects become apparent, with heightened perceptions (highly intensified colors, smells, sounds, and other sensations), body distortions, mood variations, and visual hallucinations. An acute panic reaction may occur, sometimes leading to self-injury or suicide. After approximately 12 hours, the syndrome begins to subside, but fatigue and tension may persist for another day. Flashbacks (brief recurrences of the hallucinations) may occur days or even weeks after the last dose but tend to disappear without treatment. Acute panic reactions are best treated in a supportive environment; benzodiazepines can be given to severely agitated patients.

PCP is a potent addictive hallucinogen that produces a prompt stimulant effect similar to that of amphetamines, with feelings of euphoria, power, and invincibility. Patients may have hypertension, tachycardia, hyperthermia, bidirectional nystagmus, slurred speech, ataxia, hallucinations, extreme agitation, and rhabdomyolysis. With more severe reactions, patients may be brought to medical attention in a coma-like state, with open eyes and pupils that are partially dilated, a decreased pain response, brief periods of excitation, and muscle rigidity. On occasion, patients may have hypertensive urgency, seizures, and bizarre (often violent) behavior, which lead to suicide or extreme violence toward others. Tolerance and mild withdrawal symptoms have been seen in daily users, but the major problem is drug craving. Treatment entails a quiet environment, sedation with benzodiazepines, hydration, haloperidol for terrifying hallucinations, and suicide precautions. Continuous gastric suction and acidification of the urine with intravenous ammonium chloride or ascorbic acid may aid in the drug's excretion, but acidification may increase the risk of renal failure if rhabdomyolysis is present.

Ketamine is a rapidly acting general anesthetic; unlike most anesthetics, it produces only mild respiratory depression and appears to stimulate the cardiovascular system. Adverse effects, including delirium and hallucinations, limit the use of ketamine as a general anesthetic in humans. Similar to PCP, ketamine is a dissociative anesthetic. In addition, it has both analgesic and amnesic properties and is associated with less confusion, irrationality, and violent behavior than PCP. Ketamine is one of the club drugs that has been implicated in date rape.

INHALANTS

The inhalants may be classified as (1) *organic solvents*, including toluene (airplane glue and spray paint), paint thinners, kerosene, gasoline, carbon tetrachloride, shoe polish, acetone (nail polish removers and Liquid Paper), xylene (permanent markers), and degreasers (dry cleaning fluids); (2) *gases*, such as butane, propane, aerosol propellants, and anesthetics (ether, chloroform, halothane, and nitrous oxide); and (3) *nitrites*, such as cyclohexyl nitrite, amyl nitrite, and

butyl nitrite (room deodorizer). These drugs are most often inhaled by children or young adolescents, after which they produce dizziness and intoxication within minutes. Prolonged exposure or daily use may lead to hearing loss, bone marrow depression, cardiac arrhythmias, cerebral degeneration, peripheral neuropathies, and damage to the liver, kidneys, or lungs. A characteristic “glue sniffer’s rash” around the nose and mouth is sometimes seen after prolonged use. In rare instances death may occur, most likely from hypoxemia, cardiac arrhythmias, pneumonia, or aspiration of vomit while unconscious. Detoxification is rarely required for the patient who has abused these substances, but psychiatric treatment may be needed to prevent relapse.

DESIGNER DRUGS

The term *designer drugs* refers to illicit synthetic drugs, many of which have increased potency in comparison with their parent compounds. The most common designer drugs include analogs of fentanyl, meperidine, piperazine, and methamphetamines. The best-known fentanyl derivatives are α -methyl fentanyl (*China white*), parafluorofentanyl, and 3-methyl fentanyl. Because these drugs are approximately 1000 times as potent as heroin, the fact that fatal overdoses from respiratory depression have been reported is not surprising.

The major meperidine derivatives are 1-methyl-4-phenyl-4-propionoxypiperidene (MPPP) and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). These drugs produce euphoria similar to that caused by heroin. In some users, MPTP causes neuronal degeneration in the substantia nigra, which produces an irreversible form of Parkinson disease.

Piperazines, a new class of designer drugs of abuse, are commonly sold as party pills in the form of tablets, capsules, or powders on the drug black market and in so-called “head shops” or over the internet. 1-Benzylpiperazine (BZP) is the most prevalent of these compounds. Aside from BZP and 1-(3,4-methylenedioxybenzyl)piperazine (MDBP), the phenylpiperazine derivatives 1-(3-trifluoromethylphenyl) piperazine (TFMPP), 1-(3-chloro phenyl) piperazine (mCPP), and 1-(4-methoxyphenyl)piperazine (MeOPP) are often abused. Because piperazines and amphetamines cause similar pharmacologic symptoms, piperazine poisoning can easily be wrongly diagnosed as amphetamine poisoning. Furthermore, piperazines are not detected by routinely used immunochemical screening procedures for drugs of abuse, but they require an appropriate toxicologic analysis (e.g., by gas chromatography–mass spectrometry). The methylenedioxy synthetic derivatives of amphetamine and methamphetamine are generally referred to as *ecstasy* and include 3,4-methylenedioxy methamphetamine (MDMA, also known as *Adam*); 3,4-methylenedioxyethylamphetamine (MDEA, also known as *Eve*); and *N*-methyl-1-(3,4-methylenedioxyphenyl)-2-butanamine (MBDB, also known as *Methyl-J* or *Eden*). These drugs have CNS stimulant and hallucinogenic properties. They produce elevated mood and increased self-esteem and may cause acute panic, anxiety, paranoia, hallucinations, tachycardia, nystagmus, ataxia, and tremor. Deaths in some users have been attributed to cardiac arrhythmias, hyperthermia with seizures, and intracranial hemorrhage.

Prospectus for the Future

The elucidation of ligands to psychotropic drugs is being used to provide molecular clues for the derivation of structural analogs that have therapeutic benefits. For example, recent studies have identified the receptors to which tetrahydrocannabinoid binds to mediate its effects. In the brain, activation of the cannabinoid-1 receptor causes the psychotropic effects associated with marijuana use. Cannabinoid-1 receptors also are found in adipose tissue and the gastrointestinal tract, where they regulate food intake and glycemic control. A cannabinoid-1 receptor antagonist, rimonabant, has been

shown to be effective in suppressing the reinforcing and rewarding properties of different agents that are often abused (e.g., cocaine, nicotine, alcohol) and reducing food intake and body weight. This agent appears to be effective in treating drug addiction and obesity-related disorders, although its high rate of adverse psychiatric effects (i.e., depression, anxiety, and suicidal ideation) have halted its clinical development. The identification of other receptors and signaling pathways may permit the development of other agonists or antagonists that will serve as effective pharmacotherapeutic agents.
