Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Sabre Foundation

Dedication

Thomas E. Andreoli

When Dr. Thomas Andreoli died of a cerebral hemorrhage on April 14, 2009, he had nearly completed the editorial oversight of this, the eighth edition of the textbook he co-founded in 1986. In many ways this textbook epitomizes his career as an educator, clinical scientist, and international leader of the medical profession.

As an outstanding, life-long investigator in his chosen field of nephrology, Dr. Andreoli served as president of both national and international medical societies and was recognized by honorary doctoral degrees from both European and American universities.

As a dedicated bedside clinician and teacher, Dr. Andreoli served as an outstanding chair of medicine, and endowed chairs in his name were established at both the University of Alabama School of Medicine and the University of Arkansas College of Medicine. His superlative teaching was recognized by his receiving, inter alia, the Louis Pasteur Award from the University Louis Pasteur, Mastership of the American College of Physicians, and the Robert H. Williams Distinguished Chair of Medicine Award from the Association of Professors of Medicine.

Perhaps Dr. Andreoli's most distinguished contribution was his lifelong Oslerian devotion to translating medical science from bench to bedside. Despite his major national and international commitments, he continued throughout his career to hold morning resident teaching rounds five times weekly, maintaining a broad knowledge of all aspects of internal medicine and genuinely and gently transmitting that knowledge to two generations of medical students. He was uniquely qualified for, and committed to, imparting his wisdom and skill as a physician, which provided the basis for his serving as a founding editor of *Essentials of Medicine*, and editor-in-chief of its last three editions. We feel immensely privileged to have been his co-editors and friends, and we dedicate this text to Dr. Thomas Andreoli.

Charles C. J. Carpenter, MD, MACP

*Professor of Medicine
Brown Medical School
Director, Brown University AIDS Center
Providence, Rhode Island*

Clementine M. Whitman

No tribute to Dr. Andreoli's accomplishments would be complete without acknowledging the contributions of Clementine Whitman, his personal assistant of 40 years, who moved with him from Alabama to Texas and to Arkansas. Clementine was the hub of Dr. Andreoli's professional and personal life, meticulously handling every detail. Dr. Andreoli, a man as demanding of others as of himself, was indeed blessed and fortunate to have such a talented, dedicated, loyal, and hard-working person by his side.

Sudhir V. Shah, MD, FACP

*Professor of Medicine
Director, Division of Nephrology
University of Arkansas College of Medicine
Little Rock, Arkansas
Chief, Renal Section, Medicine Service
John L. McClellan Memorial Veterans Hospital
Little Rock, Arkansas*

Preface

This is the eighth edition of *Andreoli and Carpenter's Cecil Essentials of Medicine*. *Essentials VIII*, like its predecessors, is intended to be comprehensive but concise. *Essentials VIII* therefore provides an exacting and thoroughly updated treatise on internal medicine, without excessive length, for students of medicine at all levels of their careers.

We welcome with enthusiasm a new editor, Edward J. Wing, MD, Frank L. Day Professor of Biology, and Dean of Medicine and Biological Sciences at Brown University Warren Alpert Medical School.

Essentials VIII has three cardinal components. First, at the beginning of each section—kidney, for example—we provide a brief but rigorous summary of the fundamental biology of the kidney and/or the cardinal signs and symptoms of diseases of the kidney. The same format has been used in all the sections of the book. Second, the main body of each section contains a detailed, but again, concise description of the diseases of the various organ systems, together with their pathophysiology and their treatment.

Finally, *Essentials* relies heavily on the Internet. *Essentials VIII* is published entirely on a Web site on the Internet. In the online version of *Essentials VIII*, we provide a substantial amount of supplemental material, indicated in the hard copy text by boldface symbols (for example, **Web Fig. 1**) and

denoted by an arrow icon shown in the margin of this page. This icon is present throughout the hard copy of the book as well as in the Internet version and directs the reader to a series of illustrations, tables, or videos in the Internet version of *Essentials*. This material is clearly crucial to understanding modern medicine, but we hope that, in this manner, the supplemental material will enrich *Essentials VIII* without having enlarged the book significantly.

As in prior editions, we make abundant use of 4-color illustrations. And as in prior editions, each section has been reviewed by one or another of the editors, and finally by the editor-in-chief.

We thank James T. Merritt, Senior Acquisitions Editor, Medical Education, of Elsevier, Inc., and especially Rebecca Gruliow, Managing Editor for Global Medicine, Elsevier, Inc. Both Jim Merritt and Rebecca Gruliow contributed heartily to the preparation of this eighth edition of *Essentials*. Lastly, we thank our very able secretarial staff, Ms. Clementine M. Whitman (Little Rock); Ms. Barbara S. Bottone (Providence); Ms. Shirley E. Thomas (Rochester); Ms. Jennifer F. Schroff (Salt Lake City); and Ms. Jean M. Drinan, and Ms. Catarina A. Santos (Providence).

Introduction to Molecular Medicine

1 Molecular Basis of Human Disease – BENJAMIN

Molecular Basis of Human Disease

Ivor J. Benjamin

Medicine has evolved dramatically during the past century from a healing art in which standards of practice were established on the basis of personal experience, passed on from one practitioner to the next, to a rigorous intellectual discipline steeped in the scientific method. The scientific method, a process that tests the validity of a hypothesis or prediction through experimentation, has led to major advances in the fields of physiology, microbiology, biochemistry, and pharmacology. These advances served as the basis for the diagnostic and therapeutic approaches to illness in common use by physicians through most of the 20th century. Since the 1980s, the understanding of the molecular basis of genetics has expanded dramatically, and advances in this field have identified new and exciting dimensions for defining the basis of *conventional* genetic diseases (e.g., sickle cell disease) as well as the basis of complex genetic traits (e.g., hypertension). The molecular basis for the interaction between genes and environment has also begun to be defined. Armed with a variety of sensitive and specific molecular techniques, contemporary physicians can now begin not only to understand the molecular underpinning of complex pathobiologic processes but also to identify individuals at risk for common diseases. Understanding modern medicine, therefore, requires an understanding of molecular genetics and the molecular basis of disease. This introductory chapter offers an overview of this complex and rapidly evolving topic and attempts to summarize the principles of molecular medicine that will be highlighted in specific sections throughout this text.

Deoxyribonucleic Acid and the Genome

All organisms possess a scheme to transmit the essential information containing the genetic make-up of the species through successive generations. In human cells, 23 pairs of chromosomes are present, each pair of which contains a

unique sequence and therefore unique genetic information. In the human genome, about 6×10^9 nucleotides, or 3×10^9 pairs of nucleotides, associate in the double helix. All the specificity of DNA is determined by the base sequence, and this sequence is stored in complementary form in the double-helical structure, which facilitates correction of sequence errors and provides a mechanistic basis for replication of the information during cell division. Each DNA strand serves as a template for replication, which is accomplished by the action of DNA-dependent polymerases that unwind the double-helical DNA and copy each single strand with remarkable fidelity.

All cell types except for gametocytes contain this duplicate, diploid number of genetic units, one half of which is referred to as a *haploid number*. The genetic information contained in chromosomes is separated into discrete functional elements known as *genes*. A gene is defined as a unit of base sequence that usually, but with rare exceptions, encodes a specific polypeptide sequence. New evidence suggests that small, noncoding RNAs play critical roles in expression of this essential information. An estimated 30,000 genes are present in the human haploid genome, and these are interspersed among regions of sequence that do not code for protein and whose function is as yet unknown. For example, noncoding RNAs (e.g., transfer RNA [tRNA], ribosomal RNA [rRNA], and other small RNAs) act as components of enzyme complexes such as the ribosome and spliceosome. The average chromosome contains 3000 to 5000 genes, and these range in size from about 1 kilobase (kb) to 2 megabases (Mb).

Ribonucleic Acid Synthesis

Transcription, or RNA synthesis, is the process for transferring information contained in nuclear DNA to an intermediate molecular species known as messenger RNA (mRNA).

Figure 1-1 Transcription. Genomic DNA is shown with enhancer and silencer sites located 5' upstream of the promoter region, to which RNA polymerase is bound. The transcription start site is shown downstream of the promoter region, and this site is followed by exonic sequences interrupted by intronic sequences. The former sequences are transcribed *ad seriatim* (i.e., one after another) by the RNA polymerase.

Two biochemical differences distinguish RNA from DNA: (1) the polymeric backbone is made up of ribose rather than deoxyribose sugars linked by phosphodiester bonds, and (2) the base composition is different in that uracil is substituted for thymine. RNA synthesis from a DNA template is performed by three types of DNA-dependent RNA polymerases, each a multi-subunit complex with distinct nuclear location and substrate specificity. RNA polymerase I, located in the nucleolus, directs the transcription of genes encoding the 18S, 5.8S, and 28S ribosomal RNAs, forming a molecular scaffold with both catalytic and structural functions within the ribosome. RNA polymerase II, located in the nucleoplasm instead of the nucleoli, primarily transcribes precursor mRNA transcripts and small RNA molecules. The carboxyl-terminus of RNA polymerase II is uniquely modified with a 220-kD protein domain, the site of enzymatic regulation by protein phosphorylation of critical serine and threonine residues. All tRNA precursors and other rRNA molecules are synthesized by RNA polymerase III in the nucleoplasm.

RNA polymerases are synthesized from precursor transcripts that must first be cleaved into subunits before further processing and assembling with ribosomal proteins into macromolecular complexes. Ribosomal architectural and structural integrity are derived from the secondary and tertiary structures of rRNA, which assume a series of folding patterns containing short duplex regions. Precursors of tRNA in the nucleus undergo the removal of the 5' leader region, splicing of an internal intron sequences, and modification of terminal residues.

Precursors of mRNA are produced in the nucleus by the action of DNA-dependent RNA polymerase II, which copies the *antisense* strand of the DNA double helix to synthesize a single strand of mRNA that is identical to the *sense* strand of the DNA double helix in a process called *transcription* (Fig. 1-1). The initial, immature mRNA first undergoes modification at both the 5' and 3' ends. A special nucleotide structure called the *cap* is added to the 5' end, which functions to increase binding to the ribosome and enhance translational efficiency. The 3' end undergoes modification by nuclease cleavage of about 20 nucleotides, followed by the addition of a length of polynucleotide sequence containing a uniform stretch of adenine bases, the so-called poly A tail that stabilizes the mRNA.

In addition to these changes that uniformly occur in all mRNAs, other, more selective modifications can also occur.

Figure 1-2 Translation. The open reading frame of a mature messenger RNA is shown with its series of codons. Transfer RNA molecules are shown with their corresponding anticodons, charged with their specific amino acid. A short, growing polypeptide chain is depicted. A, adenine; C, cytosine; CYS, cysteine; G, guanine; MET, methionine; PRO, proline; THR, threonine; U, uracil.

Because each gene contains both exonic and intronic sequences and the precursor mRNA is transcribed without regard for exon-intron boundaries, this immature message must be edited in such a way that splices all exons together in appropriate sequence. The process of splicing, or removing intronic sequences to produce the mature mRNA, is an exquisitely choreographed event that involves the intermediate formation of a spliceosome, a large complex consisting of small nuclear RNAs and specific proteins, which contains a loop or lariat-like structure that includes the intron targeted for removal. Only after splicing, a catalytic process requiring adenosine triphosphate hydrolysis, has concluded is the mature mRNA able to transit from the nucleus into the cytoplasm, where the encoded information is translated into protein.

Alternative splicing is a process for efficiently generating multiple gene products often dictated by tissue specificity, developmental expression, and pathologic state. Gene splicing allows the expression of multiple isoforms by expanding the repertoire for molecular diversity. An estimated 30% of genetic diseases in humans arise from defects in splicing. The resulting mature mRNA then exits the nucleus to begin the process of *translation* or conversion of the base code to polypeptide (Fig. 1-2). Alternative splicing pathways (i.e., alternative exonic assembly pathways) for specific genes also serve at the level of transcriptional regulation. The discovery of catalytic RNA, the capacity for self-directed internal

Figure 1-3 Secondary structure of transfer RNA (tRNA). The structure of each tRNA serves as an adapter molecule that recognizes a specific codon for the amino acid to be added to the polypeptide chain. About one half the hydrogen-bonded bases of the single chain of ribonucleotides are shown paired in double helices like a cloverleaf. The 5' terminus is phosphorylated, and the 3' terminus contains the hydroxyl group on an attached amino acid. The anticodon loop is typically located in the middle of the tRNA molecule. C, cytosine; DHU, dihydroxyuridine; G, guanine; UH₂, dihydrouridine; ψ , pseudouridine; T, ribothymidine; U, uracil. (Data from Berg JM, Tymoczko JL, Strayer JL: Berg, Tymoczko and Stryer's Biochemistry, 5th ed. New York, WH Freeman, 2006.)

excision and repair, has advanced the current view that RNA per se serves both as a template for translation of the genetic code and, simultaneously, as an enzyme (see "Transcriptional Regulation" later in this chapter).

Protein synthesis, or translation of the mRNA code, occurs on ribosomes, which are macromolecular complexes of proteins and rRNA located in the cytoplasm. Translation involves the conversion of the linear code of a triplet of bases (i.e., the codon) into the corresponding amino acid. A four-base code generates 64 possible triplet combinations ($4 \times 4 \times 4$), and these correspond to 20 different amino acids, many of which are encoded by more than one base triplet. To decode mRNA, an adapter molecule (tRNA) recognizes the codon in mRNA through complementary base pairing with a three-base anticodon that it bears; in addition, each tRNA is charged with a unique amino acid that corresponds to the anticodon (Fig. 1-3).

Translation on the mRNA template proceeds without punctuation of the non-overlapping code with the aid of rRNA on an assembly machine, termed *ribosomes*—essen-

tially a polypeptide polymerase. At least one tRNA molecule exists for each 20 amino acids, although degeneracy in the code expands the number of available tRNA molecules, mitigates the chances of premature chain termination, and ameliorates the potential deleterious consequences of single-base mutations. The enzymatic activity of the ribosome then links amino acids through the synthesis of a peptide bond, releasing the tRNA in the process.

Consecutive linkage of amino acids in the growing polypeptide chain represents the terminal event in the conversion of information contained within the nuclear DNA sequence into mature protein (DNA \rightarrow RNA \rightarrow protein). Proteins are directly responsible for the form and function of an organism. Thus, abnormalities in protein structure or function brought about by changes in primary amino acid sequence are the immediate precedent cause of changes in phenotype, adverse forms of which define a disease state.

Inhibition of RNA synthesis is a well-recognized mechanism of specific toxins and antibiotics. Toxicity from the ingestion of the poisonous mushroom (*Amanita phalloides*), for example, leads to the release of the toxin α -amanitin, a cyclic octapeptide that inhibits the RNA Pol II and blocks elongation of RNA synthesis. The antibiotic actinomycin D binds with high affinity to double-helical DNA and intercalates between base pairs, precluding access of DNA-dependent RNA polymerases and the selective inhibition of transcription. Several major antibiotics function through inhibition of translation. For example, the aminoglycoside antibiotics function through the disruption of the mRNA-tRNA codon-anticodon interaction, whereas erythromycin and chloramphenicol inhibit peptide bond formation.

Control of Gene Expression

OVERVIEW

The timing, duration, localization, and magnitude of gene expression are all important elements in the complex tapestry of cell form and function governed by the genome. Gene expression represents the flow of information from the DNA template into mRNA transcripts and the process of translation into mature protein.

Four levels of organization involving transcription factors, RNAs, chromatin structure, and epigenetic factors are increasingly recognized to orchestrate gene expression in the mammalian genome. Transcriptional regulators bind to specific DNA motifs that positively or negatively control the expression of neighboring genes. The information contained in the genome must be transformed into functional units of either RNA or protein products. How DNA is packed and modified represents additional modes of gene regulation by disrupting the access of transcription factors from DNA-binding motifs. In the postgenomic era, the challenge is to understand the architecture by which the genome is organized, controlled, and modulated.

Transcription factors, chromatin architecture, and modifications of nucleosomal organization make up the major mechanisms of gene regulation in the genome.

TRANSCRIPTIONAL REGULATION

The principal regulatory step in gene expression occurs at the level of gene transcription. A specific DNA-dependent RNA polymerase performs the transcription of information contained in genomic DNA into mRNA transcripts. Transcription begins at a proximal (i.e., toward the 5' end of the gene) transcription start site, containing nucleotide sequences that influence the rate and extent of the process (see Fig. 1-1). This region is known as the *promoter region* of the gene and often includes an element of sequence rich in adenine and thymine (the TATA box) along with other sequence motifs within about 100 bases of the start site. These regions of DNA that regulate transcription are known as *cis*-acting regulatory elements. Some of these regulatory regions of promoter sequence bind proteins known as *trans*-acting factors, or transcription factors, which are themselves encoded by other genes. The *cis*-acting regulatory sequences to which transcription factors bind are often referred to as *response elements*. Families of transcription factors have been identified and are often described by unique aspects of their predicted protein secondary structure, including helix-turn-helix motifs, zinc-finger motifs, and leucine-zipper motifs. Transcription factors make up an estimated 3% to 5% of the protein-coding products of the genome.

In addition to gene-promoter regions, enhancer sites are distinct from promoter sites in that they can exist at distances quite remote from the start site, either upstream or downstream (i.e., beyond the 3' end of the gene), and without clear orientation requirements. *Trans*-acting factors bind to these enhancer sites and are believed to alter the tertiary structure or conformation of the DNA in a manner that facilitates the binding and assembly of the transcription-initiation complex at the promoter region, perhaps in some cases by forming a broad loop of DNA in the process. Biochemical modification of select promoter or enhancer sequences, such as methylation of CpG-rich sequences (cytosine-phosphate-guanine), can also modulate transcription; methylation typically suppresses transcription. The terms *silencer* and *suppressor* elements refer to *cis*-acting nucleotide sequences that reduce or shut off gene transcription and do so through association with *trans*-acting factors that recognize these specific sequences.

Regulation of transcription is a complex process that occurs at several levels; importantly, the expression of many genes is regulated to maintain high basal levels, which are known as *housekeeping* or *constitutively expressed* genes. They typically yield protein products that are essential for normal cell function or survival and thus must be maintained at a specific steady-state concentration under all circumstances. Many other genes, in contrast, are not expressed or are only modestly expressed under basal conditions; however, with the imposition of some stress or exposure of the cell to an agonist that elicits a cellular response distinct from that of the basal state, the expression of these genes is induced or enhanced. For example, the heat shock protein genes encoding *stress proteins* are rapidly induced in response to diverse pathophysiologic stimuli (e.g., oxidative stress, heavy metals, inflammation) in most cells and organisms. The increased heat shock protein expression is complementary to the basal level of heat shock proteins whose functions as molecular chaperones play key roles during protein synthesis to prevent protein misfolding, increase protein translocation, and

accelerate protein degradation. These adaptive responses often mediate changes in phenotype that are homeostatically protective to the cell or organism.

MICRORNAS AND GENE REGULATION

Less is currently known about the determinants of translational regulation than is known about transcriptional regulation. The recent discovery and identification of small RNAs (21 to 24 mer), termed *microRNAs* (miRNAs), adds further complexity to the regulation of gene expression within the eukaryotic genome. First discovered in worms more than 10 years ago, miRNAs are conserved noncoding strands of RNA that bind to the 3'-untranslated regions of target mRNAs, enabling gene silencing of protein expression at the translational level. Gene-encoding miRNAs exhibit tissue-specific expression and are interspersed in regions of the genome unrelated to known genes.

Transcription of miRNAs proceeds in multiple steps from sites under the control of an mRNA promoter. RNA polymerase II transcribes the precursor miRNA, termed *primary miRNA* (pri-miRNA), containing 5' caps and 3' poly (A) tails. In the nucleus, the larger pri-miRNAs of 70 nucleotides form an internal hairpin loop, embedding the miRNA portion that undergoes recognition and subsequent excision by double-stranded RNA-specific ribonuclease, termed *Drosha*. Gene expression is silenced by the effect of miRNA on nascent RNA molecules targeted for degradation.

Because translation occurs at a fairly invariant rate among all mRNA species, the stability or half-life of a specific mRNA also serves as another point of regulation of gene expression. The 3'-untranslated region of mRNAs contains regions of sequence that dictate the susceptibility of the message to nuclease cleavage and degradation. Stability appears to be sequence specific and, in some cases, dependent on *trans*-acting factors that bind to the mRNA. The mature mRNA contains elements of untranslated sequence at both the 5' and 3' ends that can regulate translation.

Beginning in the organism's early development, miRNAs may facilitate much more intricate ways for the regulation of gene expression, as have been shown for germline production, cell differentiation, proliferation, and organogenesis. Because recent studies have implicated the expression of miRNAs in brain development, cardiac organogenesis, colonic adenocarcinoma, and viral replication, this novel mechanism for gene silencing has potential therapeutic roles for congenital heart defects, viral disease, neurodegeneration, and cancer.

CHROMATIN REMODELING AND GENE REGULATION

Both the size and complexity of the human genome with 23 chromosomes, ranging in size between 50 and 250 Mb, pose formidable challenges for transcription factors to exert the specificity of DNA-binding properties in gene regulation. Control of gene expression also takes place in diverse types of cells, often with exquisite temporal and spatial specificity throughout the life span of the organism. In eukaryotic cells, the genome is highly organized into densely packed nucleic acid DNA- and RNA-protein structures, termed *chromatin*.

Figure 1-4 Schematic representation of a nucleosome. Rectangular blocks represent the DNA strand wrapped around the core that consists of eight histone proteins. Each histone has a protruding tail that can be modified to repress or activate transcription. (Adapted from Berg JM, Tymoczko JL, Strayer JL: Berg, Tymoczko and Stryer's Biochemistry, 5th ed. New York, WH Freeman, 2006.)

The building blocks of chromatin are called *histones*, a family of small basic proteins that occupy one half of the mass of the chromosome. Histones derive their basic properties from the high content of basic amino acids, arginine, and lysine. Five major types of histones—H1, H2A, H2B, H3, and H4—have evolved to form complexes with the DNA of the genome. Two pairs each of the four types of histones form a protein core, the histone octamer, which is wrapped by 200 base pairs of DNA to form the nucleosome (Fig. 1-4). The core proteins within the nucleosomes have protruding amino-terminal ends, exposing critical lysine and arginine residues for covalent modification. Further DNA condensation is achieved as higher-order structure is imparted on the chromosomes. The nucleosomes are further compacted in layered stacks with a left-handed superhelix resulting in negative supercoils that provide the energy for DNA strand separation during replication.

Condensation of DNA in chromatin precludes the access of regulatory molecules such as transcription factors. Reversal of chromatin condensation, on the other hand, typically occurs in response to environmental and other developmental signals in a tissue-dependent manner. Promoter sites undergoing active transcription, as well as relaxation of chromatin structure, that become susceptible to enzymatic cleavage by nonspecific DNAase I are called *hypersensitive sites*. Transcription factors on promoter sites may gain access by protein-protein interactions to enhancer elements containing tissue-specific proteins at remote sites, several thousand bases away, resulting in transcription activation or repression.

EPIGENETIC CONTROL OF GENE EXPRESSION

Complex regulatory networks revolve around transcription factors, nucleosomes, chromatin structure, and epigenetic markings. *Epigenetics* refers to heritable changes in gene

expression without changes in the DNA sequence. Such examples include DNA methylation, gene silencing, chromatin remodeling, and X-chromosome inactivation. This form of inheritance involves the alterations in gene function without changes in DNA sequence. Chemical marking of DNA methylation is both cell specific and developmentally regulated. Methylation of the 5' CpG dinucleotide by specific methyl transferases, which occurs in 70% of the mammalian genome, is another mechanism of gene regulation. Steric hindrance from the bulky methyl group of 5' methylcytosine precludes occupancy by transcription factors that stimulate or attenuate gene expression. Most genes are found in CpG islands, reflecting sites of gene activity across the genome.

In an analogous manner, modifications of histone by phosphorylation, methylation, ubiquitination, and acetylation are transmitted and reestablished in an inheritable manner. It is conceivable that other epigenetic mechanisms do not involve genomic modifications of DNA. For example, modification of the gene encoding the estrogen receptor α has been implicated in gene silencing at ^{5m}C sites of multiple downstream targets in breast cancer cells. Powerful new approaches are being developed to examine feedback and feed-forward loops in transmission of epigenetic markings.

The concept that dynamic modifications (e.g., DNA methylation and acetylation) of histones or epigenesis contribute, in part, to tumorigenic potential for progression has already been translated into current therapies. Histone acetyltransferases (HATs) and histone deacetyltransferases (HDACs) play antagonistic roles in the addition and removal of acetylation in the genome. Furthermore, genome-wide analysis of HATs and HDACs is beginning to provide important insights into complex modes of gene regulation. Several inhibitors of histone deacetylases, with a range of biochemical and biologic activities, are being developed and tested as anticancer agents in clinical trial. Phase I clinical trials have suggested these drugs are well tolerated. In general, the inhibition of deacetylase remodels chromatin assembly and reactivates transcription of the genome. Because the mechanisms of actions of HDACs extend to apoptosis, cell cycle control, and cellular differentiation, current clinical trials are seeking to determine the efficacy of these novel reagents in the drug compendium for human cancers.

Genetic Sequence Variation, Population Diversity, and Genetic Polymorphisms

A stable, heritable change in DNA is defined as a *mutation*. This strict contemporary definition does not depend on the functional relevance of the sequence alteration and implicates a change in primary DNA sequence. Considered in historical context, mutations were first defined on the basis of identifiable changes in the heritable phenotype of an organism. As biochemical phenotyping became more precise in the mid-20th century, investigators demonstrated that many proteins exist in more than one form in a population, and these forms were viewed as a consequence of variations

in the gene coding for that protein (i.e., allelic variation). With advances in DNA-sequencing methods, the concept of mutation evolved from one that could be appreciated only by identifying differences in phenotype to one that could precisely be defined at the level of changes in the structure of DNA. Although most mutations are stably transmitted from parents to offspring, some are genetically lethal and thus cannot be passed on. In addition, the discovery of regions of the genome that contain sequences that repeat in tandem a highly variable number of times (tandem repeats) suggests that some mutations are less stable than others. These tandem repeats are further described later in this section.

The molecular nature of mutations is varied (Table 1-1). A mutation can involve the deletion, insertion, or substitution of a single base, all of which are referred to as *point mutations*. Substitutions can be further classified as *silent* when the amino acid encoded by the mutated triplet does not change, as *missense* when the amino acid encoded by the mutated triplet changes, and as *nonsense* when the mutation leads to premature termination of translation (stop codon). On occasion, point mutations can alter the processing of precursor mRNA by producing alternate splice sites or eliminating a splice site. When a single- or double-base deletion or insertion occurs in an exon, a frameshift mutation results, usually leading to premature termination of translation at a now in-frame stop codon. The other end of the spectrum of mutations includes large deletions of an entire gene or a set of contiguous genes; deletion, duplication, and translocation of a segment of one chromosome to another; or duplication or deletion of an entire chromosome. Such chromosomal mutations play a large role in the development of many cancers.

Each individual possesses two alleles for any given gene locus, one from each parent. Identical alleles define homozy-

gosity and nonidentical alleles define heterozygosity for any gene locus. The heritability of these alleles follows typical mendelian rules. With a clearer understanding of the molecular basis of mutations and of allelic variation, their distribution in populations can now be analyzed precisely by following specific DNA sequences. Differences in DNA sequences studied within the context of a population are referred to as *genetic polymorphisms*, and these polymorphisms underlie the diversity observed within a given species and among species.

Despite the high prevalence of benign polymorphisms in a population, the occurrence of harmful mutations is comparatively rare because of selective pressures that eliminate the most harmful mutations from the population (lethality) and the variability within the genomic sequence to polymorphic change. Some portions of the genome are remarkably stable and free of polymorphic variation, whereas other portions are highly polymorphic, the persistence of variation within which is a consequence of the functional benignity of the sequence change. In other words, polymorphic differences in DNA sequence between individuals can be divided into those producing no effect on phenotype, those causing benign differences in phenotype (i.e., normal genetic variation), and those producing adverse consequences in phenotype (i.e., mutations). The last group can be further subdivided into the polymorphic mutations that alone are able to produce a functionally abnormal phenotype such as monogenic disease (e.g., sickle cell anemia) and those that alone are unable to do so but in conjunction with other mutations can produce a functionally abnormal phenotype (complex disease traits [e.g., essential hypertension]).

Polymorphisms are more common in noncoding regions of the genome than they are in coding regions, and one common type of these involves the tandem repetition of short DNA sequences a variable number of times. If these tandem repeats are long, they are termed *variable number tandem repeats*; if these repeats are short, they are termed *short tandem repeats* (STRs). During mitosis, the number of tandem repeats can change, and the frequency of this kind of replication error is high enough to make alternative lengths of the tandem repeats common in a population. However, the rate of change in length of the tandem repeats is low enough to make the size of the polymorphism useful as a stable genotypic trait in families. In view of these features, polymorphic tandem repeats are useful in determining the familial heritability of specific genomic loci. Polymorphic tandem repeats are sufficiently prevalent along the entire genomic sequence, enabling them to serve as genetic markers for specific genes of interest through an analysis of their linkage to those genes during crossover and recombination events. Analyses of multiple genetic polymorphisms in the human genome reveal that a remarkable variation exists among individuals at the level of the sequence of genomic DNA (genotyping). Single-nucleotide polymorphism (SNP), the most common variant, differs by a single base between chromosomes on any given stretch of DNA sequence (Fig. 1-5). From genotyping of the world's representative population, 10 million variants (one site per 300 bases) are estimated to make up 90% of the common SNP variants in the population, with the rare variants making up the remaining 10%. With each generation of a species, the frequency of polymorphic changes in a gene is 10^{-4} to 10^{-7} .

Table 1-1 Molecular Basis of Mutations

Type	Examples
Point Mutations	
Deletion	α -Thalassemia, polycystic kidney disease
Substitution	
Silent	Cystic fibrosis
Missense	Sickle cell anemia, polycystic kidney disease, congenital long QT syndrome
Nonsense	Cystic fibrosis, polycystic kidney disease
Large Mutations (Gene or Gene Cluster)	
Deletion	Duchenne muscular dystrophy
Insertion	Factor VIII deficiency (hemophilia A)
Duplication	Duchenne muscular dystrophy
Inversion	Factor VIII deficiency
Expanding triplet	Huntington disease
Very Large Mutation (Chromosomal Segment or Chromosome)	
Deletion	Turner syndrome (45,X)
Duplication	Trisomy 21
Translocation	XX male [46,X; t(X;Y)]*

*Translocation onto an X chromosome of a segment of a Y chromosome that bears the locus for testicular differentiation.

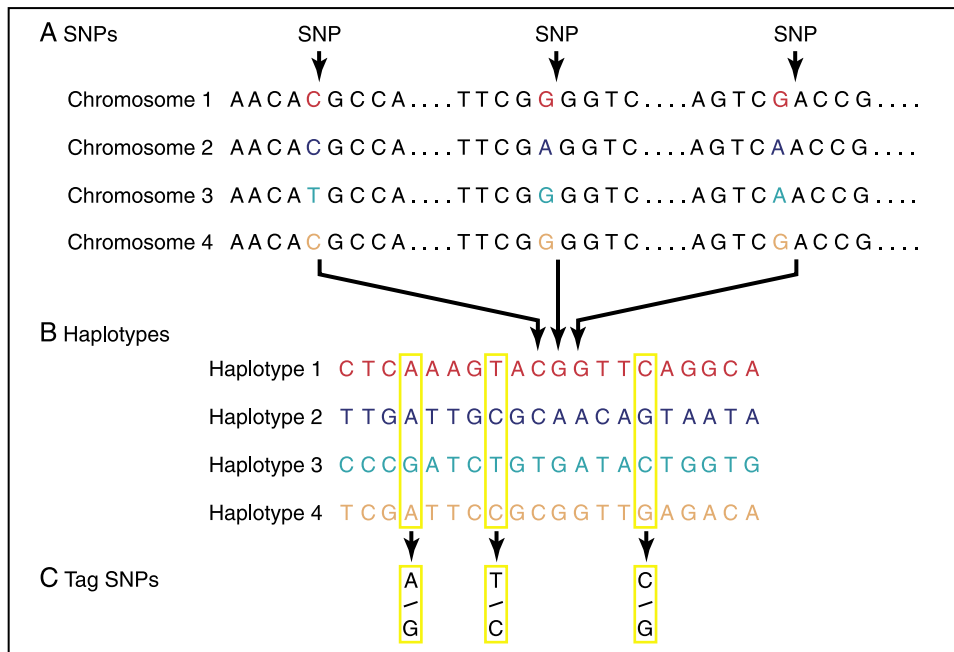

Figure 1-5 Single nucleotide polymorphisms (SNPs), haplotypes, and tag SNPs. A stretch of mostly identical DNA on the same chromosome is shown from four different individuals. SNP refers to the variation of the three bases shown in DNA region. The combination of nearby SNPs defines a haplotype. Tag SNPs are useful tools shown (C) for genotyping four unique haplotypes from the 20 haplotypes (B). (Adapted from International HapMap Consortium: The International HapMap Project. *Nature* 426: 789-796, 2003.)

Thus, in view of the number of genes in the human genome, between 0.5% and 1.0% of the base sequence of the human genome is polymorphic. In this context, the new variant can be traced historically to the surrounding alleles on the chromosomal background present at the time of the mutational event. A haplotype is a specific set or combination of alleles on a chromosome or part of a chromosome (see Fig. 1-5). When parental chromosomes undergo crossover, new *mosaic* haplotypes, containing additional mutations, are created from such recombinations. SNP alleles within haplotypes can be co-inherited in association with other alleles in the population, termed *linkage disequilibrium* (LD). The association between two SNPs will decline with increasing distance, enabling patterns of LD to be decided from the proximity of nearby SNPs. Conversely, a few well-selected SNPs are often sufficient to predict the location of other common variants in the region.

Haplotypes associated with a mutation are expected to become common by recombination in the general population over thousands of generations. In contrast, genetic mapping with LD departs from traditional mendelian genetics by using the entire human population as a large family tree without an established pedigree. Of the possible 10 million variants, the International HapMap Project and the Perlegen private venture have deposited more than 8 million variants comprising the public human SNP map from more than 341 people representing different population samples. The SNPs distributed across the genome of unrelated individuals provide a sufficiently robust sample set for statistical associations to be drawn between genotypes and modest phenotypes. A mutation can now be defined as a specific type of allelic polymorphism that causes a functional defect in a cell or organism.

The causal relationship between monogenic diseases with well-defined phenotypes that co-segregate with the disease requires only a small number of affected individuals compared with unaffected control individuals. In contrast, complex disorders (e.g., diabetes, hypertension, cancer) will necessitate the combinatorial effects of environmental factors and genes with subtle effects. Only through searching for variations in genetic frequency between patients and the general population can the causation of disease be discerned. In the postgenomic era, gene mapping entails the statistical association with the use of LD and high-density genetic maps that span thousands to 100,000 base pairs. To enable comprehensive association studies to become routine in clinical practice, inexpensive genotyping assays and denser maps with all common polymorphisms must be linked to all possible manifestations of the disease. Longitudinal studies of the HapMap and Perlegen cohorts will determine the effects of diet, exercise, environmental factors, and family history on future clinical events. Without similar approaches on securing adequate sample sizes and datasets, the promise of genetic population theory will not overcome the inherent limitations of linking human sequence variation with complex disease traits.

Gene Mapping and the Human Genome Project

The process of gene mapping involves identifying the relative order and distance of specific loci along the genome. Maps can be of two types: genetic and physical. Genetic maps identify the genomic location of specific genetic loci by a statistical analysis based on the frequency of recombina-

Figure 1-6 Crossing over and recombination. **A**, Two haploid chromosomes are shown, one from each parent (*red* and *blue*) with two genomic loci denoted by the circles and squares. **B**, Crossing over of one haploid chromosome from each parent. **C**, Resulting recombination of chromosomal segments now redistributes one haploid locus (*squares*) from one diploid pair to another.

tion events of the locus of interest with other known loci. Physical maps identify the genomic location of specific genetic loci by a direct measurement of the distance along the genome at which the locus of interest is located in relation to one or more defined markers. The precise location of genes on a chromosome is important for defining the likelihood that a portion of one chromosome will interchange, or cross over, with the corresponding portion of its complementary chromosome when genetic recombination occurs during meiosis (Fig. 1-6).

During meiotic recombination, genetic loci or alleles that have been acquired from one parent interchange with those acquired from the other parent to produce new combinations of alleles, and the likelihood that alleles will recombine during meiosis varies as a function of their linear distance from one another in the chromosomal sequence. This recombination probability or distance is commonly quantitated in centimorgans (cM): 1 cM is defined as the chromosomal distance over which there is a 1% chance that two alleles will undergo a crossover event during meiosis. Crossover events serve as the basis for mixing parental base sequences during development and, thereby, promoting genetic diversity among offspring. Analysis of the tendency

for specific alleles to be inherited together indicates that the recombination distance in the human genome is about 3000 cM.

Identifying the gene or genes responsible for a specific polygenic disease phenotype requires an understanding of the topographic anatomy of the human genome, which is inextricably linked to interactions with the environment. The Human Genome Project, first proposed in 1985, represented an international effort to determine the complete nucleotide sequence of the human genome, including the construction of its detailed genetic, physical, and transcript maps, with identification and characterization of all genes. This foray into *large-scale biology* was championed by Nobel Laureate James Watson as the defining moment in his lifetime for witnessing the path from the double helix to the sequencing of 3 billion bases of the human genome, paving the way for understanding human evolution and harnessing the benefits for human health.

Among the earliest achievements of the Human Genome Project were the development of 1-cM resolution maps, each containing 3000 markers, and the identification of 52,000 sequenced tagged sites. For functional analysis on a genome-wide scale, major technologic advances were made, including as high-throughput oligonucleotide synthesis, normalized and subtracted complementary DNA (cDNA) libraries, and DNA micro-arrays. In 1998, the Celera private venture proposed a similar goal as the Human Genome Project using a revolutionary approach, termed *shotgun sequencing*, to determine the sequence of the human genome (**Web Movie 1-1**). The shotgun sequencing method was designed for random large-scale sequencing and subsequent alignment of sequenced segments using computational and mathematic modeling. In the end, the Human Genome Project, in collaboration with the Celera private venture, produced a refined map of the entire human genome in 2001.

Because of the differences in genomic sequence that arise as a consequence of normal biologic variations or sequence polymorphisms, the resulting restriction fragment length polymorphisms (RFLPs) differ among individuals and are inherited according to mendelian principles. These polymorphisms can serve as genetic markers for specific loci in the genome. One of the most useful types of RFLP for localization of genetic loci within the genome is that produced by tandem repeats of sequence. Tandem repeats arise through *slippage* or stuttering of the DNA polymerase during replication in the case of STRs; longer variations arise through unequal crossover events. STRs are distributed throughout the genome and are highly polymorphic. Of importance is that these markers have two different alleles at each locus that are derived from each parent; thus, the origins of the two chromosomes can be discerned through this analysis.

The use of highly polymorphic tandem repeats that occur throughout the genome as genomic markers has provided a basis for mapping specific gene loci through establishing the association or linkage with select markers. Linkage analysis is predicated on a simple principle: the likelihood that a crossover event will occur during meiosis decreases the closer the locus of interest is to a given marker. The extent of genetic linkage can be ascertained for any group of loci, one of which may contain a disease-producing mutation (Fig. 1-7).

Figure 1-7 Linkage analysis. Analysis of the association (genomic contiguity) of a mutation (M) and a polymorphic allelic marker (A) shows close linkage in that the mutation segregates with the A allele, whereas the wild-type gene locus (WT) associates with the B allele.

Identifying Mutant Genes

Deducing the identity of a specific gene sequence believed to cause a specific human disease requires that mutations in the gene of interest be identified. If the gene believed to be responsible for the disease phenotype is known, its sequence can be determined by conventional cloning and sequencing strategies, and the mutation can be identified. A variety of techniques are currently available for detecting mutations. Mutations that involve insertion or deletion of large segments of DNA can be detected by Southern blot, in which the isolated DNA is annealed to a radioactively labeled fragment of cDNA sequence. Prior incubation of the DNA with a specific restriction endonuclease cleaves the DNA sequence of interest at specific sites to produce smaller fragments that can be monitored by agarose gel electrophoresis. Shifts in mobility on the gel in comparison with wild-type sequence become apparent as a function of changes in the molecular size of the fragment. Alternatively, the polymerase chain reaction (PCR) can be used to identify mutations (**Web Movie 1-2**).

In this approach, small oligonucleotides (20 to 40 bases in length), which are complementary to regions of DNA that bracket the sequence of interest and are complementary to each strand of the double-stranded DNA, are synthesized and serve as primers for the amplification of the DNA sequence of interest. These primers are added to the DNA solution. The temperature of the solution is increased to dissociate the individual DNA strands and is then reduced to permit annealing of the primers to their complementary template target sites. A thermostable DNA polymerase is included in the reaction to synthesize new DNA in the 5'-to-3' direction from the primer annealing sites. The temperature is then increased to dissociate duplex structures, after which it is reduced, enabling another cycle of DNA synthesis to occur. Several temperature cycles (usually up to 40) are used to amplify progressively the concentration of the

sequence of interest, which can be identified as a PCR product by agarose gel electrophoresis with a fluorescent dye. The product can be isolated and sequenced to identify the suggested mutation.

If the gene is large and the site of the mutation is unknown (especially if it is a point mutation), other methods can be used to identify the likely mutated site in the exonic sequence. One commonly used approach involves scanning the gene sequence for mutations that alter the structural conformation of short complexes between parent DNA and PCR products, leading to a shift in mobility on a non-denaturing agarose gel (i.e., single-strand conformational polymorphism). A single-base substitution or deletion can change the conformation of the complex in comparison with wild-type complexes and yield a shift in mobility. Sequencing this comparatively small region of the gene then facilitates precise identification of the mutation.

When the gene believed to cause the disease phenotype is unknown, when its likely position on the genome has not been identified, or when only limited mapping information is available, a candidate gene approach can be used to identify the mutated gene. In this strategy, potential candidate genes are identified on the basis of analogy to animal models or by analysis of known genes that map to the region of the genome for which limited information is available. The candidate gene is then analyzed for potential mutations. Regardless of the approach used, mutations identified in candidate genes should always be correlated with functional changes in the gene product because some mutations could be functionally silent, representing a polymorphism without phenotypic consequences. Functional changes in the gene product can be evaluated through the use of cell-culture systems to assess protein function by expressing the mutant protein through transiently transfecting the cells with a vector that carries the cDNA coding for the gene of interest and incorporating the mutation of interest. Alternatively, unique animal models can be developed in which the mutant gene is incorporated in the male pronucleus of oocytes taken from a super-ovulating impregnated female. This union produces an animal that overexpresses the mutant gene; that is, it produces a transgenic animal, an animal with more than the usual number of copies of a given gene, or an animal in which the gene of interest is disrupted and the gene product is not synthesized (i.e., a gene *knockout* animal or an animal with one half [heterozygote] or none [homozygote] of the usual number of a given gene).

MOLECULAR DIAGNOSTICS

The power of molecular techniques extends beyond their use in defining the precise molecular basis of an inherited disease. By exploiting the exquisite sensitivity of PCR to amplify rare nucleic acid sequences, it is possible to diagnose rapidly a range of infectious diseases for which unique sequences are available. In particular, infections caused by fastidious or slow-growing organisms can now be rapidly diagnosed, similar to the case for *Mycobacterium tuberculosis*. The presence of genes conferring resistance to specific antibiotics in microorganisms can also be verified by PCR techniques. The sequencing of the entire genome of organisms such as *Escherichia coli*, *M. tuberculosis*, and *Treponema pallidum* now offers unparalleled opportunities to monitor

the epidemiologic structures of infections, follow the course of acquired mutations, tailor antibiotic therapies, and develop unique gene-based therapies (see later) for infectious agents for which conventional antibiotic therapies are ineffective or marginally effective.

The application of molecular methods to human genetics has clearly revolutionized the field. Through the use of approaches that incorporate linkage analysis and PCR, simple point mutations can be precisely localized and characterized. At the other end of the spectrum of genetic changes that underlie disease, chromosomal translocations, deletions, or duplications can be identified by conventional cytogenetic methods. Large deletions that can incorporate many kilobase pairs and many genes can now be visualized with fluorescent in situ hybridization (FISH), a technique in which a segment of cloned DNA is labeled with a fluorescent tag and hybridized to chromosomal DNA. With the deletion of the segment of interest from the genome, the chromosomal DNA fails to fluoresce in the corresponding chromosomal location.

Advances in molecular medicine have also revolutionized the approach to the diagnosis and treatment of neoplastic diseases, as well as the understanding of the mechanisms of carcinogenesis. According to current views, a neoplasm arises from the clonal proliferation of a single cell that is transformed from a regulated, quiescent state into an unregulated growth phase. DNA damage accumulates in the parental tumor cell as a result of either exogenous factors (e.g., radiation exposure) or heritable determinants. In early phases of carcinogenesis, certain genomic changes may impart intrinsic genetic instability that increases the likelihood of additional damage. One class of genes that becomes activated during carcinogenesis is oncogenes, which are primordial genes that normally exist in the mammalian genome in an inactive (proto-oncogene) state but, when activated, promote unregulated cell proliferation through activation of specific intracellular signaling pathways.

Molecular methods based on the acquisition of specific tumor markers and unique DNA sequences that result from oncogenetic markers of larger chromosomal abnormalities (i.e., translocations or deletions that promote oncogenesis) are now broadly applied to the diagnosis of malignancies. These methods can be used to establish the presence of specific tumor markers and oncogenes in biopsy specimens, to monitor the presence or persistence of circulating malignant cells after completion of a course of chemotherapy, and to identify the development of genetic resistance to specific chemotherapeutic agents. In addition, through the use of conventional linkage analysis and candidate gene approaches, future studies will enable the identification of individuals with a heritable predisposition to malignant transformation. Many of these specific topics are discussed in later chapters.

The advent of *gene chip* technologies or expression arrays has revolutionized molecular diagnostics and has begun to clarify the pathobiologic structures of complex diseases. These methods involve labeling the cDNA generated from the entire pool of mRNA isolated from a cell or tissue specimen with a radioactive or fluorescent marker and annealing this heterogeneous population of polynucleotides to a solid-phase substrate to which many different polynucleotides of known sequence are attached. The signals from the

labeled cDNA strands bound to specific locations on the array are monitored, and the relative abundance of particular sequences is compared with that from a reference specimen. Using this approach, micro-array patterns can be used as molecular fingerprints to diagnose a particular disease (i.e., type of malignancy and its susceptibility to treatment and prognosis) as well as to identify the genes whose expression increases or decreases in a specific disease state (i.e., identification of disease-modifying genes).

Of course, many other applications of molecular medicine techniques are available, in addition to these applications in infectious diseases and oncology. Molecular methods can be used to sort out genetic differences in metabolism that may modulate pharmacologic responses in a population of individuals (*pharmacogenomics*), address specific forensic issues such as paternity or criminal culpability, and approach epidemiologic analysis on a precise genetic basis.

GENES AND HUMAN DISEASE

Human genetic diseases can be divided into three broad categories: (1) those that are caused by a mutation in a single gene (e.g., monogenic disorders, mendelian traits); (2) those that are caused by mutations in more than one gene (e.g., polygenic disorders, complex disease traits); and (3) those that are chromosomal in nature (Table 1-2). In all three groups of disorders, environmental factors can contribute to the phenotypic expression of the disease by modulating gene expression or unmasking a biochemical abnormality that has no functional consequences in the absence of a stimulus or stress. Classic monogenic disorders include sickle cell anemia, familial hypercholesterolemia, and cystic fibrosis. Importantly, these genetic diseases can be exclusively produced by a single specific mutation (e.g., sickle cell anemia) or by any one of several mutations (e.g., familial hypercholesterolemia, cystic fibrosis) in a given family (Pauling paradigm). Interestingly, some of these disorders evolved to protect the host. For example, sickle cell anemia evolved as protection against falciparum malaria, and cystic fibrosis developed as protection against cholera. Examples of polygenic disorders or complex disease traits include type 1 (insulin-dependent) diabetes mellitus, atherosclerotic cardiovascular disease, and essential hypertension. A common

Table 1-2 Molecular Basis of Mutations

Type	Examples
Monogenic Disorders	
Autosomal dominant	Polycystic kidney disease 1, neurofibromatosis 1
Autosomal recessive	β-Thalassemia, Gaucher disease
X-linked	Hemophilia A, Emery-Dreifuss muscular dystrophy
One of multiple mutations	Familial hypercholesterolemia, cystic fibrosis
Polygenic Disorders	
Complex disease traits	Type 1 (insulin-dependent) diabetes, essential hypertension, atherosclerotic disease, cancer

example of a chromosomal disorder is the presence of an extra chromosome 21 (trisomy 21). The overall frequency of monogenic disorders is about 1%. About 60% of these include polygenic disorders, which includes those with a genetic substrate that develops later in life. About 0.5% of monogenic disorders include chromosomal abnormalities. Importantly, chromosomal abnormalities are frequent causes of spontaneous abortion and malformations.

Contrary to the view held by early geneticists, few phenotypes are entirely defined by a single genetic locus. Thus, monogenic disorders are comparatively uncommon; however, they are still useful as a means to understanding some basic principles of heredity. Monogenic disorders are of three types: autosomal dominant, autosomal recessive, and X-linked. *Dominance* and *recessiveness* refer to the nature of the heritability of a genetic trait and correlate with the number of alleles affected at a given locus. If a mutation in a single allele determines the phenotype, the mutation is said to be dominant; that is, the heterozygous state conveys the clinical phenotype to the individual. In contrast, if a mutation is necessary at both alleles to determine the phenotype, the mutation is said to be recessive; that is, only the homozygous state conveys the clinical phenotype to the individual. Dominant or recessive mutations can lead to either a loss or a gain of function of the gene product. If the mutation is present on the X chromosome, it is defined as X-linked (which in males can, by definition, be viewed only as dominant); otherwise, it is autosomal. The importance of identifying a potential genetic disease as inherited by one of these three mechanisms is that, if one of these patterns of inheritance is present, the disease must involve a single genomic abnormality that leads to an abnormality in a single protein. Classically identified genetic diseases are produced by mutations that affect coding (exonic) sequences. However, mutations in intronic and other untranslated regions of the genome occur that may disturb the function or expression of specific genes. Examples of diseases with these types of mutations include myotonic dystrophy and Friedreich ataxia.

An individual with a dominant monogenic disorder typically has one affected parent and a 50% chance of transmitting the mutation to his or her offspring. In addition, men and women are equally likely to be affected and equally likely to transmit the trait to their offspring. The trait cannot be transmitted to offspring by two unaffected parents. In contrast, an individual with a recessive monogenic disorder typically has parents who are clinically normal. Affected parents, each heterozygous for the mutation, have a 25% chance of transmitting the clinical phenotype to their offspring but a 50% chance of transmitting the mutation to their offspring (i.e., producing an unaffected carrier).

Notwithstanding the clear heritability of common monogenic disorders (e.g., sickle cell anemia), the clinical expression of the disease in an individual with a phenotype expected to produce the disease may vary. *Variability in clinical expression* is defined as the range of phenotypic effects observed in individuals carrying a given mutation. *Penetrance* refers to a smaller subset of individuals with variable clinical expression of a mutation and is defined as the proportion of individuals with a given genotype who exhibit any clinical phenotypic features of the disorder.

Three principal determinants of variability in clinical expression or incomplete penetrance of a given genetic disorder can occur: (1) environmental factors, (2) the effects of other genetic loci, and (3) random chance. Environmental factors can modulate disease phenotype by altering gene expression in several ways, including their action on transcription factors (e.g., transcription factors that are sensitive to cell redox state [nuclear factor κ B]) or *cis*-elements in gene promoters (e.g., folate-dependent methylation of CpG-rich regions); or by post-translationally modifying proteins (e.g., lysine oxidation). That other genes can modify the effects of disease-causing mutations is a reflection of the overlay of genetic diversity on primary disease phenotype. Numerous examples exist of the effects of these so-called *disease-modifying genes* producing phenotypic variations among individuals with the identical primary disease-causing mutations (*gene-gene interactions*) and the effects of disease-modifying genes interacting with environmental determinants to alter phenotype further (*gene-environment interactions*). These interactions are clearly important in polygenic diseases; gene-gene and gene-environment interactions can modify the phenotypic expression of the disease. Among patients with sickle cell disease, for example, some patients experience painful crises, whereas others exhibit acute chest syndrome; still other presentations include hemolytic crises.

Genetic disorders affecting a unique pool of DNA, mitochondrial DNA, have been identified. Mitochondrial DNA is unique in that it is inherited only from the mother. In addition, mutations in mitochondrial DNA can vary among mitochondria within a given cell and within a given individual (heteroplasmy). Examples of genetic disorders based in the mitochondrial genome are Kearns-Sayre syndrome and Leber hereditary optic neuropathy. The list of known mitochondrial genomic disorders is growing rapidly, and mitochondrial contributions to a large number of common polygenic disorders may also exist.

MOLECULAR MEDICINE

A principal goal of current molecular strategies is to restore normal gene function to individuals with genetic mutations. Methods to do so are currently primitive, and a number of obstacles must be surmounted for this approach to be successful.

The principal problems are that to deliver a complete gene into a cell is not easy, and persistent expression of the new gene cannot be ensured because of the variability in its incorporation in the genome and the consequent variability in its regulated expression. Many approaches have been used to date, but none has been completely successful. They include the following: (1) packaging the cDNA in a viral vector, such as an attenuated adenovirus, and using the cell's ability to take up the virus as a means for the cDNA to gain access to the cell; (2) delivering the cDNA by means of a calcium phosphate-induced perturbation of the cell membrane; and (3) encapsulating the cDNA in a liposome that can fuse with the cell membrane and thereby deliver the cDNA.

After the cDNA has been successfully delivered to the cell of interest, the magnitude and durability of expression of the gene product are important variables. The magnitude of expression is determined by the number of copies of cDNA

taken up by a cell and the extent of their incorporation in the genome of the cell. The durability of expression appears to be dependent partly on the antigenicity of the sequence and protein product.

Notwithstanding these technical limitations, gene therapy has been used to treat adenosine deaminase deficiency successfully, which suggests that the principle on which the treatment is based is reasonable. Clinical trials of gene therapy have slowed considerably after unexpected deaths were widely reported in both the scientific and lay media. Efforts on other genetic disorders and as a means to induce expression of a therapeutic protein (e.g., vascular endothelial cell growth factor to promote angiogenesis in ischemic tissue) are ongoing.

Understanding the molecular basis of disease leads naturally to the identification of unique disease targets. Recent examples of this principle have led to the development of novel therapies for diseases that have been difficult to treat. Imatinib, a tyrosine kinase inhibitor that is particularly effective at blocking the action of the bcr-abl kinase, is effective for the treatment of chronic-phase chronic myelogenous leukemia. Monoclonal antibody to tumor necrosis factor- α (infliximab) and soluble tumor necrosis factor- α receptor (etanercept) are prime examples of *biologic modifiers* that are effective in the therapy of chronic inflammatory disorders, including inflammatory bowel disease and rheumatoid arthritis. This approach to molecular therapeutics is rapidly expanding and holds great promise for improving the therapeutic armamentarium for a variety of diseases.

Beyond cancer-related categories (e.g., DNA, RNA repair), gene expression arrays have provided additional interactions of regulatory pathways of clinical interest. The limitation of gene expression profile using micro-arrays, which does not account for post-transcriptional and other post-translational modifications of protein-coding products, will likely be overcome by approaches and advances in proteomics. Such processes by signaling networks tend to amplify or attenuate gene expression on time scales lasting seconds to weeks. Much work remains to improve current knowledge about the pathways that initiate and promote tumors. The basic pathways and nodal points of regulation will be identified for rational drug design and target from mechanistic insights gleaned from expression profiling of cultured cell lines, from small animal models of human disease, and from human samples. Although accounting for tissue heterogeneity and variation among different cell types, the new systems' approach for incorporating genomic and computational research appears particularly promising to decipher the pathways that promote tumorigenesis. In turn, biologists and clinicians will use information derived from these tools to understand the events that promote survival, proangiogenesis, and immune escape, all of which may confer metastatic potential and progression.

What potential diagnostic tools are available to establish genetic determinants of drug response? Genome-wide approaches from the Human Genome Project in combination with micro-arrays, proteomic analysis, and bioinformatics will identify multiple genes encoding drug targets (e.g., receptors). Similar high-throughput screening should provide insights into the predisposition to adverse effects of outcomes from treatments that are linked to genetic polymorphisms.

PHARMACOGENETICS

The future of pharmacogenetics is to know all the factors that influence adverse drug effects. In this way, the premature abandonment of special drug classes can be avoided in favor of rational drug design and therapy.

Many hurdles must be overcome for pharmacogenetics to become more widespread and to be integrated into medical practice. Current approaches of trial and error in medical practice are well engrained on the parts of physicians. In addition, the allure for blockbuster drugs by the pharmaceutical industry warrants a new model for approaching individualized doses. New training for physicians in molecular biology and genetics should complement clinical pharmacogenomic studies that determine efficacy in an era of evidence-based medicine. Pharmacogenetic polymorphisms, unlike other clinical variables such as renal function, need only a single test, ideally as a newborn. Polygenic models of therapeutic optimization still face hurdles that reduce the chances for abuse of genetic information and additional costs. On the other hand, SNP haplotyping has the potential to identify genetically similar subgroups of the population and to randomize therapies based on more robust genetic markers. On a population level, genomic variability is much greater within than among distinct racial and ethnic groups.

Both therapeutic efficacy and host toxicity are influenced by the patient's specific disease, age, renal function, nutritional status, and other co-morbid factors. New challenges will be posed for the selection and guide to drug therapy for patients with cancer, hypertension, and diabetes. It is conceivable that treatment of multisystem disorders (e.g., metabolic syndrome) might be derived from novel therapeutics based on individual, interacting, and complementary molecular pathways.

REGENERATIVE MEDICINE

A new era of regenerative biology has emerged with the discovery that adult mammalian cells can be reprogrammed into new cells. Regenerative medicine entails novel applications and approaches to exploit the resident population of progenitor cells for regeneration or repair of damaged tissues. After irreversible damage, transplantation of solid organs such as the heart, kidney, and lungs is a well-established medical-surgical intervention, but the limited availability of organs restricts widespread applications. Manipulation of cultured cells for transplantation heralds an alternative and complementary strategy to solid organ transplantation and offers an expanded platform for regenerative medicine. Although postmitotic, terminally differentiated organs are devoid of significant regenerative capacity, recent evidence for cellular plasticity of adult solid organs, throughout adult life, has challenged this prevailing dogma. This makeover involves approaches either to convert adult into pluripotent stem cells—retaining the ability to differentiate into new cell types—or forced reprogramming of adult cells into mature or progenitor cells.

Embryonic stem (ES) cells share common features of clonogenicity, self-renewal, and multi-potentiality, a prerequisite for differentiation into diverse cell lineages of multicellular adult organism. Both technical and ethical concerns propelled the search for new sources, including

the isolation of ES cells from a single blastomere, which circumvents destruction of the embryo, and the use of post-implantation embryos as ES cell donors. Somatic cell nuclear transplantation (SCNT) or nuclear transfer (NT) is a technique for successful cloning and reprogramming of adult animal cell nuclei from healthy oocyte host cells. SCNT provides a source of stem cells tailored to the donor organism and promises to accelerate the pace for human use. Induced pluripotent stem (iPS) cells share the common features of somatic cell reprogramming but with the aid of four transcription factors by retroviral transduction. Whether symmetrical and asymmetrical cell division promotes the differentiation of pluripotent progenitor cells into distinct lineages of the mature organ awaits future studies. It is conceivable that age, gender, risk factors, and other disease status will have an impact on regenerative

plasticity, proliferation, or cellular functions. Another future hurdle will be to determine whether genetic factors enhance the cellular and molecular properties of ES cells essential for the reconstitution of a well-differentiated organ in vivo.

Might progenitor cells derived from bone marrow or circulating blood be administered safely and efficaciously? Both clinical and translational scientists are being asked to address whether stem cell therapy has efficacy for the current victims of either stroke or heart attack. Beyond the feasibility are questions related to benefits from transplantation of different cells originating from embryonic, fetal, or adult stem cell lineages. Whether priming of endogenous cell-mediated repair mechanisms using genetically engineered cell lines leads to improvement in selected endpoints and clinical outcomes awaits large-scale clinical trials.

Prospectus for the Future

The concept of personalized medicine will be realized from the functional and analytical phenotyping that aids diagnosis and treatment based on the individual's genome and disease profile. An important future challenge will be the extraction of biologically meaningful data of direct clinical relevance to diagnosis, prognosis, therapeutic response, and, ultimately, prevention.

What are the functional consequences of genome occupancy and modification in health and disease? Computational analyses will play an increasing role in understanding cancer pathogenesis and the mechanisms of disease. Information about the hierarchy of cellular functions is being coupled with powerful approaches to derive different yet complementary perspectives about molecular mechanisms. Micro-array analysis has already

provided new classes of hematologic diseases and prognostic factors in breast cancer. Experimental approaches are already underway to reduce tumorigenesis into discrete modules of regulatory networks and biologic processes. A catalog of listed genes that change with tumor type, for example, should not be equated with prognosis, therapeutic response, or adverse outcomes. How to move diagnostic tools using micro-arrays and gene expression profiles into clinical decision making will be the focus of research programs in translational and clinical outcomes.

Specific therapies for many inheritable diseases have lagged substantially behind advances in other fields, but new opportunities appear on the horizon for improving prognosis and clinical outcomes in the era of regenerative medicine.

Evidence-Based Medicine, Quality of Life, and the Cost of Medicine

Sara G. Tariq and Susan S. Beland

The diagnosis and treatment of individual patients involve clinical experience and skills on the part of the physician and knowledge of scientific information obtained through clinical trials. In the past, most of the daily practice was based on informal learning and a tradition of knowledge transferred from experienced clinicians to trainees and colleagues. Increasingly, however, this informal technique is being supplanted by rigorous analysis of the scientific underpinnings of clinical logic. Electronic databases and Internet technology enable collation and dissemination of information to help identify which techniques are supported by clinical trials. *Evidence-based medicine* has evolved during the past decade and uses the best available evidence from published research as the foundation for clinical decision making. This foundation, in addition to clinical expertise and a respect for patient preference, will aid the physician in providing optimal outcomes and a quality of life for the patient. However, the development of new techniques in medicine, often at great cost, can strain the ability of a society to fund and provide such services. Critical appraisal of both new and traditional diagnostic and treatment modalities is thus needed.

Critical Appraisal of the Literature

Being cognizant of the types of evidence is crucial to practice evidence-based medicine. Research studies can be divided into two major categories: primary and secondary (Table 2-1).

Primary studies can have a number of designs. In *randomized controlled studies*, participants in the trial are ran-

domly allocated to one intervention or another. Both groups are followed for a specified period and analyzed in terms of specific outcomes defined at the outset of the study. This type of study allows rigorous assessment of a single variable in a defined patient group, has a prospective design that potentially eradicates bias by comparing two otherwise similar groups, and allows for meta-analysis. However, these studies are expensive and time-consuming. Results of randomized controlled trials can have enormous impact on the practice of medicine, as exemplified by the Women's Health Initiative randomized controlled trial. This study was designed to assess the risks and benefits for postmenopausal hormone use in healthy women. However, the trial was stopped early because of an increased incidence of breast cancer, coronary heart disease, stroke, and thromboembolic disease in the hormone-treated group. *Cohort studies* have two or more groups of participants selected on the basis of differences in their exposure to a particular agent. The participants are prospectively followed to see how many in each group develop a disease or other specific outcome. A well-known example is the Framingham Heart Study that enrolled 5200 participants in 1948 and followed them forward in time to examine the progression and risk factors for heart disease. The data provided from the Framingham Study have helped clinicians understand the development and progression of heart disease and its risk factors. As with randomized trials, cohort studies are time-consuming. *Case-control studies* involve patients with a particular disease or condition who are identified and matched with control patients. The control participants can be patients with another disease or individuals from the general population. The validity of these retrospective studies depends on careful selection of the control group. For example, the impact of risk factors for men and women was recently evaluated in the CARDIO 2000 Study. The authors

Table 2-1 Types of Research Studies

Primary Studies	Secondary Studies
Randomized control	Meta-analyses
Case control	Clinical practice guidelines
Cohort studies	Decision analysis
Cross sectional	Cost-effectiveness analysis
Case series	
Case report	

evaluated 848 hospitalized patients after their first episode of acute coronary syndrome and used 1078 age- and sex-matched controls. The data revealed that women experiencing their first event were significantly older than men. *Case reports* describe the medical history of a single patient. When medical histories of more than one patient with a particular condition are described together to illustrate one aspect of the disease process, the term *case series* is used.

Secondary (integrative) studies attempt to summarize and draw conclusions from primary information. Meta-analyses use statistical techniques to combine and summarize the results of primary studies. By combining the results from many trials, meta-analyses are able to estimate the magnitude of the effect of an intervention or risk factor as well as evaluate previously unanswered questions by performing subgroup analyses. The use of meta-analysis has provoked some controversy. Some investigators believe that meta-analyses may be as reliable as randomized controlled trials, whereas others believe that the technique should be used only as an alternate to randomized trials. However, in the absence of a large randomized controlled study, a meta-analysis of multiple smaller studies may be the best source of information to answer a specific question.

Clinical practice guidelines attempt to summarize diagnostic and treatment strategies for common clinical problems to assist the physician with specific circumstances. They are usually published by medical organizations, such as the American College of Physicians, and government agencies, such as the Agency for Health Care Policy and Research and the United States Preventive Services Task Force. *Decision analysis* uses the results of primary studies to generate probability trees to aid both health professionals and patients in making choices about clinical management. *Cost-effectiveness analysis* evaluates whether a particular course of action is an effective use of resources.

Testing in Medical Practice

Screening tests are performed on asymptomatic healthy people to detect occult disease and should meet the criteria listed in Table 2-2. Screening tests are most useful when a high prevalence of disease is present in the population and the test has adequate sensitivity and specificity parameters. When applied to a disease with low prevalence, a test with low specificity would have an unacceptable number of false-positive results, which would lead to further procedures that are often invasive and expensive.

Table 2-2 Requirements of Screening Tests

- Prevalence of disease must be sufficiently high.
- Disease must have significant morbidity and mortality rates.
- Effective treatment must be available.
- Improved outcomes from early diagnosis and treatment must be present.
- Test should have good sensitivity and specificity parameters.
- Test should carry acceptable risks and be cost-effective.

Diagnostic tests are used to determine the cause of illness in symptomatic persons and can be helpful in *patient management* by evaluating the severity of disease, determining prognosis, detecting disease recurrence, or selecting appropriate medications or other therapies. When considering diagnostic tests, the physician should weigh the potential benefits against the risks and expense.

When comparing the efficacy of a new diagnostic test, the critical issues are the following: (1) Does the new test have something to offer that the currently accepted test does not? (2) Does the new test provide additional information that alters the *post-test probability*, which is the likelihood that a patient who has a positive test has the disease? Comparing the post-test probability with the *pre-test probability* before ordering the test, which is the clinical assessment of diagnostic possibilities, is also important.

Values for some pre-test probabilities have been published, but more often they are derived from the physician's clinical experience and are influenced by the practice setting. For instance, an obese African-American woman from the rural South is experiencing fatigue, blurry vision, and frequent vaginal yeast infections, and she has a strong family history of diabetes. Based on these features, she would have a high pre-test probability for type 2 diabetes mellitus. If a new diagnostic test were available for the diagnosis of diabetes, a comparison could be made on the post-test probabilities expected from the standard test (fasting blood glucose) and the new test. Ideally, the new test would offer greater diagnostic accuracy.

Sensitivity and *specificity* are important parameters to consider when evaluating a diagnostic test. Sensitivity is an index of the diagnostic test's ability to detect the disease when it is present. Specificity is the ability of the diagnostic test to identify correctly the absence of the disease. These parameters are calculated by the use of a 2 × 2 table (Table 2-3). An additional value, the *likelihood ratio*, which uses

Table 2-3 Schematic Outcomes of a Diagnostic Test (2 × 2 Table)

Test Result	Disease Present	Disease Absent
Positive	True positive (a)	False positive (b)
Negative	False negative (c)	True negative (d)

Positive predictive value (true-positive rate) = $a/(a+b)$.
 Negative predictive value (false-positive rate) = $d/(c+d)$.
 Sensitivity = $a/(a+c)$; patients with the disease who have a positive test.
 Specificity = $d/(b+d)$; patients without the disease who have a negative test.

both sensitivity and specificity, gives an even better indication of the test's performance. A high positive likelihood ratio indicates a high likelihood of the presence of disease, whereas a high negative likelihood ratio identifies the absence of disease.

Positive likelihood ratio:

$$= \frac{\text{Sensitivity (probability that test is positive in diseased patients)}}{1 - \text{Specificity (probability that test is positive in nondiseased patients)}}$$

Negative likelihood ratio:

$$= \frac{1 - \text{Sensitivity (probability that test is negative in diseased patients)}}{1 - \text{Specificity (probability that test is negative in nondiseased patients)}}$$

After determining the validity of the diagnostic test, its applicability to the patient in question and whether the test is affordable and accurate in a particular setting should be ascertained. If the diagnostic test requires special devices or skills that are not available in the practice facility, the results provided can be inaccurate. Most importantly, an assessment should be made about whether the test will change the management offered or decrease the need for the use of other tests.

Evaluating Evidence about Treatment

One of the most common problems facing physicians is the need to assess the validity of new treatments being developed as well as validity of traditional treatments that have been used for years. For example, how long after discharge from the hospital should treatment with antimicrobial agents continue for the patient who had been hospitalized for pneumonia? What is the value of plasmapheresis in thrombotic thrombocytopenic purpura? The first step in evaluating prospective treatments is to assess whether the information is derived from a properly conducted randomized controlled study. Every patient who enters the trial must be accounted for at the end of the study. The patients who are lost to follow-up often have different outcomes. If the conclusion of the trial does not change after accounting for the lost patients, then validity is added to the study. Another point to consider is whether patients were analyzed in their original randomized groups even if they did not undergo the intervention in question. This is termed an *intention-to-treat analysis*. A description of whether both groups were treated differently regarding other interventions (e.g., co-interventions) should be included.

Assessing the importance of the data provided is the next step. This includes a number of simple statistical calculations

applied to the available results. The first is *relative risk reduction* (RRR):

$$\text{RRR} = \frac{\text{Incidence of outcome in control group} - \text{Incidence of outcome in study group}}{\text{Incidence of outcome in control group}}$$

For example, the Diabetes Control and Complications Trial investigated the effect of tight control of blood glucose in patients with type 1 diabetes on the development and progression of long-term complications. The study involved more than 1400 patients, with one half randomized to intensive treatment and one half to conventional therapy. In this study, 3.4% of the patients in the conventional group and 2.2% in the intensive group developed microalbuminuria, indicating a 35% decrease in the occurrence of microalbuminuria in the primary prevention group:

$$\text{RRR} = \frac{0.034 - 0.022}{0.034} \times 100 = 35\%$$

The greater the RRR, the more effective the therapy. However, the RRR does not take into account the baseline risk of the patients entering the trial and thus does not differentiate between large and small effects.

The significance of RRR is discussed on the web site (**Web Text 2-1**).

Calculating the *absolute risk reduction* (ARR), which gives the absolute difference in rates between the two groups, is another way of assessing the outcome. The ARR is defined as the number (X) that had the ill effect in the control group minus the number (Y) in the treatment group (i.e., $\text{ARR} = X - Y$). Using the previous example, the ARR for the development of microalbuminuria is $0.034 - 0.022 = 0.012$, or 1.2%. Another valuable calculation is the *number needed to treat*, which represents the number of patients who need to be treated to prevent a single outcome event and is the inverse of the ARR (i.e., $1/[X - Y]$). The lower the number needed to treat, the more clinically relevant is the treatment. Again, using the example, to prevent 1 patient from developing microalbuminuria, 83 patients with diabetes would have to be treated with intensive therapy ($1/[X - Y] = 1/0.012 = 83$). From this example, what seems like a large RRR of 35% actually translates to a relatively small (although significant) number of patients who benefited from intensive treatment.

As before, assessment of the applicability of this information to a particular patient should be made by taking into account whether the patient in question has the same characteristics of the patients included in the study. Evidence of side effects, cause, or value of a particular clinical sign in diagnosis can be assessed along these same lines.

Internet in Clinical Practice

The use of computer systems for disseminating medical information has increased exponentially. Numerous worldwide websites offer high-quality medical news, information

Table 2-4 Worldwide Websites

- Cochrane Collaboration—one of the major organizations involved in evidence-based medicine (<http://www.cochrane.org>)
- MD Consult—comprehensive medical information service (<http://www.mdconsult.com>)
- Centers for Disease Control and Prevention (<http://www.cdc.gov>)
- National Institutes of Health (<http://www.nih.gov>)
- UpToDate—comprehensive clinical information website that is constantly updated (<http://www.uptodate.com>)
- Student Consult—provides access to full standard texts online (<http://www.studentconsult.com>)

about practice guidelines, online textbooks and journals, and information about evidence-based medicine. In addition, many government sites offer up-to-date information (e.g., Centers for Disease Control and Prevention, National Institutes of Health). Table 2-4 lists some of these sites.

Including the Patient in the Decision Process

Searching for the best evidence and applying it have the ultimate goal of providing better patient care. The process should also involve informing the patient of the available options and offering options based on good evidence. Effective communication, geared toward the patient's level of health literacy, is crucial to ensure that the patient makes an informed decision. Using a certain therapy or implementing a diagnostic test may be inconvenient, or the patient may develop a certain side effect that he or she is not willing to accept. Involvement of the patient in the decision-making process requires good communication and adequate resources for patient education.

Quality of Life

Health care in the millennium has changed significantly. An increasing number of patients survive illnesses that used to be fatal, and many patients have multiple co-existing illnesses. Assessing clinical improvement to a given treatment covers only one aspect of the clinician's success. For example, although survival is an important outcome for patients with cancer, overall quality of life is fundamental. A patient can have improvement in disease-free survival without having a significant change in quality of life, and vice versa. Quality of life represents a subjective concept that is defined by the subjective perception of the patient and includes physical, emotional, social, and cognitive functions and the disease symptoms and side effects of a given treatment or intervention. For example, in examining the efficacy of a drug for postchemotherapy anemia, it would not only be important to know whether the hemoglobin rises appropriately but also to know whether the patient subjectively has more energy and is able to perform the normal duties of life.

Quality of life is more commonly becoming a defined outcome measure in clinical trials. An increasing number of studies have been conducted in which health-related quality

of life is either the primary or secondary endpoint. Hopefully, clinicians can then take the information gained from these data and apply it in a holistic manner to optimize patient care.

COST OF MEDICINE

The practice of medicine has significantly changed during the past 30 years. The cost of medicine has risen astronomically, and it is the duty of the physician to be cognizant of this in daily practice. Health care spending is growing much faster than the rest of the economy. Rising hospital expenses reflect many factors, including the demand for new medications and technology as well as the aging population. Physicians can contribute to the reduction of costs by being aware of medication prices and ordering tests appropriately.

The pharmaceutical industry has been accused of contributing to medical inflation. The industry spends more than \$11 billion annually on promotion and marketing, and \$8,000 to \$13,000 per physician each year. They employ 1 drug representative for every 11 physicians in the United States. The average price of drugs rose almost 50% between 1992 and 2000. Literature suggests that the gifts and perks physicians receive from the pharmaceutical representatives have a major influence on their practices and prescribing habits. Caution is recommended when analyzing data from pharmaceutical representatives, taking into account the inherent bias that exists regarding the medication they are marketing. The medical profession is responsible for providing the best care possible for patients, and barriers to this care arise when a gift or amenity accepted from a pharmaceutical representative obscures the judgment of appropriate and cost-effective care. Generic drugs should be prescribed whenever possible. Studies have shown that if physicians substituted generic drugs for brand-name drugs, the potential national savings would be up to 5.9 billion dollars annually. In addition, all medical schools should stress the use of generic drugs to students and residents.

The use of tests is the second area in which physicians must be prudent when it comes to cost. The routine ordering of expensive and unnecessary tests has become part of the medical culture, but they can never take the place of a thorough history and physical examination. Evidence-based medicine is an important tool to use when deciding whether a certain diagnostic test is needed to help in the care of a patient. The risks and benefits of each test that is ordered must be weighed against the costs. For example, asymptomatic patients who are concerned about ovarian cancer may want their physician to order a pelvic ultrasound. The prudent physician will know that the prevalence of ovarian cancer is low in the population and thus the literature does not support the routine use of pelvic ultrasound as a screening tool. Therefore, a pelvic ultrasound is not a cost-effective test for screening ovarian cancer in all female patients.

These are two ways in which physicians can take an active role in helping reduce the cost of medical care in this nation, but the problem is clearly larger than this. Physicians will need to find a balance between being cost-conscious and maintaining high-quality patient care as the medical field continues to expand.

Prospectus for the Future

Challenges to be met:

- Medical schools need to expand the teaching of evidence-based medicine to students and physicians in training.
- Risks and benefits of screening tests need to be better defined (e.g., use of computed tomography in the diagnosis of early lung cancer versus risk for radiation exposure).
- To affect the cost of medicine, the overuse of technology (e.g., computed tomography for every patient with abdominal pain) needs to be addressed from the standpoint of evidence-based medicine.
- Finally, universal health care coverage for all people in the United States is desperately needed.

Structure and Function of the Normal Heart and Blood Vessels

Jack Morshedzadeh, Dean Y. Li, and Ivor J. Benjamin

Gross Anatomy

The heart is composed of four chambers, two atria and two ventricles, which form two separate pumps arranged side by side and in series (Fig. 3-1). The atria are low-pressure capacitance chambers that mainly function to store blood during ventricular contraction (systole) and then fill the ventricles with blood during ventricular relaxation (diastole). The two atria are separated by a thin interatrial septum. The ventricles are high-pressure chambers responsible for pumping blood through the lungs and to the peripheral tissues. Because the pressure generated by the left ventricle is greater than that generated by the right, the left ventricular myocardium is thicker than the right. The two ventricles are separated by the interventricular septum, which is a membranous structure at its superior aspect and a thick, muscular structure at its medial and distal portions.

The atrioventricular (AV) valves separate the atria and ventricles. The mitral valve is a bileaflet valve that separates the left atrium and ventricle. The tricuspid valve is a trileaflet valve and separates the right atrium and ventricle. Strong chords (chordae tendineae) attach the ventricular aspects of these valves to the papillary muscles of their respective ventricles. These papillary muscles are extensions of normal myocardium that project into the ventricular cavities and are important for optimal valve closure. The semilunar valves separate the ventricles from the arterial chambers: the aortic valve separates the left ventricle from the aorta, and the pulmonic valve separates the right ventricle from the pulmonary artery. These valves do not have chordae. Rather, they are fibrous valves whose edges coapt closely, thus allowing for adequate valve closure. Each of the four valves is surrounded by a fibrous ring, or annulus, that forms part of the structural support of the heart. When open, the valves

allow free flow of blood across them and into the adjacent chamber or vessel. When closed, the valves effectively prevent the backflow of blood into the preceding chamber.

The thin, double-layered pericardium surrounds the heart. The visceral pericardium is adherent to the heart and constitutes its outer surface, or *epicardium*. This outer surface is separated from the parietal pericardium by the pericardial space, which normally contains less than 50 mL of fluid. The parietal pericardium has attachments to the sternum, vertebral column, and diaphragm that serve to stabilize the heart in the chest. Normal pericardial fluid lubricates contact surfaces and limits direct tissue-surface contact during myocardial contraction. In addition, the normal pericardium modulates interventricular interactions during the cardiac cycle.

Circulatory Pathway

The circulatory system is composed of two distinct and parallel vascular networks, arterial and venous networks, which interconnect through capillary beds of the distal target organs (see Fig. 3-1). Deoxygenated blood drains from peripheral tissues and enters the right atrium through the superior and inferior venae cavae. Blood draining from the heart enters the right atrium through the coronary sinus. This blood mixes in the right atrium during ventricular systole and then flows across the tricuspid valve and into the right ventricle during ventricular diastole. When the right ventricle contracts, blood is ejected across the pulmonic valve and into the main pulmonary artery, which then bifurcates into the left and right pulmonary arteries as these branches enter their respective lungs. After multiple bifurcations, blood flows into the pulmonary capillaries, where

Figure 3-1 Schematic representation of the systemic and pulmonary circulatory systems. The venous system contains the greatest amount of blood at any one time and is highly distensible, accommodating a wide range of blood volumes (high capacitance). The arterial system is composed of the aorta, arteries, and arterioles. Arterioles are small muscular arteries that regulate blood pressure by changing tone (resistance).

carbon dioxide is exchanged for oxygen across the alveolar-capillary membrane. Oxygenated blood then drains from the lungs into the four pulmonary veins, which empty into the left atrium. During ventricular diastole, the blood flows across the open mitral valve and into the left ventricle. With ventricular contraction, the blood is ejected across the aortic valve and into the aorta and is subsequently delivered to the various organs, where oxygen and nutrients are exchanged for carbon dioxide and metabolic wastes.

The heart receives blood through the left and right coronary arteries (Fig. 3-2). These are the first arterial branches of the aorta and originate in outpouchings of the aortic root called the *sinuses of Valsalva*. The left main coronary artery originates in the left sinus of Valsalva and is a short vessel that bifurcates into the left anterior descending (LAD) and the left circumflex (LCx) coronary arteries. The LAD travels across the surface of the heart in the anterior interventricular groove toward the cardiac apex. It supplies blood to the anterior and anterolateral left ventricle through its diagonal branches and to the anterior two thirds of the interventricular septum through its septal branches. The LCx traverses posteriorly in the left AV groove (between the left atrium and left ventricle), supplying blood to the lateral aspect of the left ventricle through obtuse marginal branches as well as giving off branches to the left atrium. The right coronary artery (RCA) originates in the right sinus of Valsalva and courses down the right AV groove to a point where the left and right AV grooves and the inferior interventricular groove meet, the *crux* of the heart. The RCA gives off atrial branches to the right atrium and acute marginal branches to the right ventricle. The blood supply to the diaphragmatic and posterior aspects of the left ventricle varies. In 85% of individuals, the RCA bifurcates at the crux into the posterior descending coronary artery (PDA), which travels in the inferior interventricular groove to supply blood to the inferior

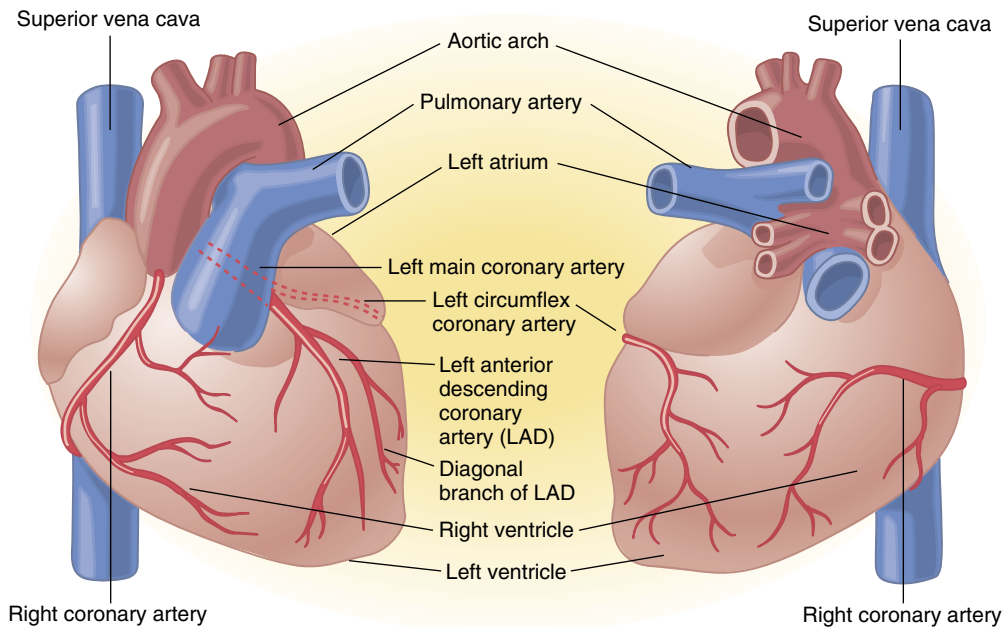

Figure 3-2 Major coronary arteries and their branches.

left ventricular wall and inferior third of the interventricular septum and to the posterior left ventricular (PLV) branches, which supply the posterior left ventricle. This course is termed a *right dominant circulation*. In 10% of individuals, the RCA terminates before reaching the crux, and the LCx supplies the PLV and PDA. This course is termed a *left dominant circulation*. In the remaining individuals, the RCA gives rise to the PDA, and the LCx gives rise to the PLV in a *co-dominant circulation*. An understanding of coronary artery anatomy and distribution of blood supply enables the clinician to define the location of coronary artery disease based on history, physical examination, and noninvasive tests such as electrocardiography (ECG), echocardiography, and radionuclide ventriculography. Small vascular channels, called *collateral vessels*, interconnect the normal coronary arteries. These vessels are nonfunctional in the normal myocardium because no pressure gradient develops across them. However, in the setting of severe stenosis or complete occlusion of a coronary artery, the pressure in the vessel distal to the stenosis decreases, and a gradient develops across the collateral vasculature, resulting in flow through the collateral vessel. The development of collateral vasculature is directly related to the severity of the coronary stenosis and may be stimulated by ischemia, hypoxia, and a variety of growth factors. Over time, these vessels may reach up to 1 mm in luminal diameter and are almost indistinguishable from similarly sized, normal coronary arteries.

Most of the venous drainage from the heart occurs through the coronary sinus, which runs in the AV groove and empties into the right atrium. A small amount of blood from the right side of the heart drains directly into the right atrium through the thebesian veins and small anterior myocardial veins.

Conduction System

The electrical impulse that initiates cardiac contraction originates in the sinoatrial (SA) node, a collection of specialized pacemaker cells measuring 1 to 2 cm in length located high in the right atrium between the superior vena cava and the right atrial appendage (Fig. 3-3). The impulse then spreads through the atrial tissue and through preferential internodal tracts, ultimately reaching the AV node. This structure consists of a meshwork of cells located at the inferior aspect of the right atrium between the coronary sinus and the septal leaflet of the tricuspid valve.

The AV node provides the only normal electrical connection between the atria and ventricles. After an electrical impulse enters the AV node, conduction transiently slows and then proceeds to the ventricles by means of the His-Purkinje system. The bundle of His extends from the AV node down the membranous interventricular septum to the muscular septum, where it divides into the left and right bundle branches. The right bundle branch is a discrete structure that extends along the interventricular septum and enters the moderator band on its way toward the anterolateral papillary muscle of the right ventricle. The left bundle branch is less distinct; it consists of an array of fibers organized into an anterior fascicle, which proceeds toward the anterolateral papillary muscle of the left ventricle, and a posterior fascicle, which proceeds posteriorly in the septum

Figure 3-3 Schematic representation of the cardiac conduction system.

toward the posteromedial papillary muscle. Both the right and the left bundle branches terminate in Purkinje cells, which are large cells with well-developed intercellular connections that allow for the rapid propagation of electrical impulses. These impulse-generating cells then directly stimulate myocytes.

Heart blocks, a form of cardiac arrhythmia, may arise from intrinsic problems of the conduction system or from impaired blood supply (coronary artery disease) to the conduction system. The SA node is supplied by the SA nodal artery, which is a branch of the RCA in about 60% of the population or a branch of the LCx in 40%. The AV node is supplied by the AV nodal artery, which is a branch of the RCA in about 90% of the population or a branch of the LCx in 10%. The right bundle branch receives most of its blood supply from septal perforators that branch off of the LAD. There may also be collateral blood supply from the RCA or LCx. The left anterior fascicle is supplied by septal perforators from the LAD and is particularly susceptible to ischemia and infarction. The proximal portion of the left posterior fascicle is supplied by the AV nodal artery and by septal perforators of the LAD. The distal portion of the posterior fascicle has a dual blood supply from anterior and posterior septal perforators (i.e., the LAD and PDA).

Neural Innervation

The normal myocardium is richly innervated by the autonomic nervous system. The sympathetic supply is from preganglionic neurons located within the superior five to six thoracic segments of the spinal cord, which synapse with second-order neurons in the cervical sympathetic ganglia. Traveling within the cardiac nerves, these fibers end in the SA node, AV node, epicardial vessels, and myocardium. The parasympathetic supply is from preganglionic neurons originating in the dorsal motor nucleus of the medulla and pass as branches of the vagus nerve to the heart. Here the fibers synapse with second-order neurons located in ganglia within the heart. Nerve terminals of the parasympathetic nerves end in the SA node, AV node, epicardial vessels, and myocar-

dium. A supply of vagal afferents from the inferior and posterior aspects of the ventricles mediate important cardiac reflexes, whereas the vagal efferent fibers to the SA and AV nodes are active in modulating impulse initiation and conduction. In general, sympathetic stimulation increases heart rate (HR) and force of myocardial contraction, and parasympathetic stimulation slows HR and reduces the force of contraction.

Myocardium

Cardiac tissue (myocardium) is composed of several cell types that together produce the organized contraction of the heart. Specialized myocardial cells make up the cardiac electrical system (conduction system) and are responsible for the generation of an electrical impulse and organized propagation of that impulse to cardiac muscle fibers (myocytes), which, in turn, respond by mechanical contraction. Atrial and ventricular myocytes are specialized, branching muscle cells connected end to end by intercalated disks. These thickened regions of the cell membrane (sarcolemma) aid in the transmission of mechanical tension between cells. The sarcolemma has functions similar to those of other cell membranes, including maintenance of ionic gradients, propagation of electrical impulses, and provision of receptors for neural and hormonal inputs. In addition, the sarcolemma is intimately involved with the coupling of myocardial excitation and contraction through small transverse tubules (T tubules) that extend from the sarcolemma into the intracellular space. The myocytes contain several other organelles: the nucleus; the multiple mitochondria responsible for generating the energy required for contraction; an extensive network of intracellular tubules called the *sarcoplasmic reticulum*, which functions as the major intracellular storage site for calcium; and the myofibrils, which are the contractile elements of the cell. Each myofibril is made up of repeating units called *sarcomeres*, which are, in turn, composed of overlapping thin actin filaments and thick myosin filaments and their regulatory proteins troponin and tropomyosin (Fig. 3-4).

Muscle Physiology and Contraction

Contraction of myocytes begins with electrical depolarization of the sarcolemma, resulting in an influx of calcium into the cell through channels in the T tubules (Fig. 3-5). This initial calcium entry stimulates the rapid release of large amounts of calcium from the sarcoplasmic reticulum into the cell cytosol. The calcium then binds to the calcium-binding troponin subunit (troponin C) on the actin filaments of the sarcomere, resulting in a conformational change in the troponin-tropomyosin complex. This change facilitates the actin-myosin interaction, which results in cellular contraction. As the wave of depolarization passes, the calcium is rapidly and actively resequestered in the sarcoplasmic reticulum, where it is stored by various proteins, including calsequestrin, until the next wave of depolarization occurs. Calcium is also extruded from the cytosol by

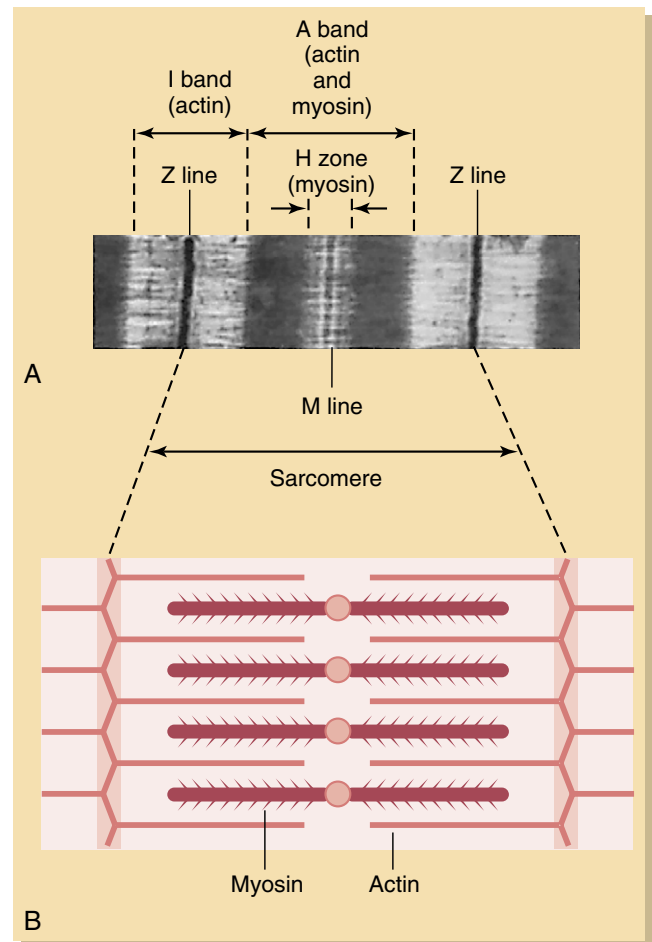

Figure 3-4 **A**, Sarcomere as it appears under the electron microscope. **B**, Schematic of the location and interaction of actin and myosin.

various calcium pumps in the sarcolemma. The force of myocyte contraction can be regulated by the amount of free calcium released into the cell by the sarcoplasmic reticulum. More calcium allows for greater actin-myosin interaction, producing a stronger contraction.

The energy for myocyte contraction is derived from adenosine triphosphate (ATP), which is generated by oxidative phosphorylation of adenosine diphosphate (ADP) in the abundant mitochondria of the cell. ATP is required both for calcium influx and for force generation by actin-myosin interaction. During contraction, ATP promotes dissociation of myosin from actin, thereby permitting the sliding of thick filaments past thin filaments as the sarcomere shortens. Under normal circumstances, fatty acids are the preferred energy source, although glucose can also be used as a substrate. These substrates must be constantly delivered to the heart through the bloodstream because minimal energy is stored in the heart. Myocardial metabolism is aerobic and thus requires a constant supply of oxygen. Under ischemic or hypoxic conditions, glycolysis and lactate may serve as a source of ATP, although in insufficient quantities to sustain the working heart. Ischemic conditions might also promote alterations in both cytosolic and mitochondrial calcium overload, a major terminal event in muscle injury of the heart, termed *myocardial infarction*.

Figure 3-5 Calcium dependence of myocardial contraction. (1) Electrical depolarization of the myocyte results in an influx of Ca^{2+} into the cell through channels in the T tubules. (2) This initial phase of calcium entry stimulates the release of large amounts of Ca^{2+} from the sarcoplasmic reticulum (SR). (3) The Ca^{2+} then binds to the troponin-tropomyosin complex on the actin filaments, resulting in a conformational change that facilitates the binding interaction between actin and myosin. In the presence of adenosine triphosphate (ATP), the actin-myosin association is cyclically dissociated as the thick and thin filaments slide past each other, resulting in contraction. (4) During repolarization, the Ca^{2+} is actively pumped out of the cytosol and sequestered in the SR. M, mitochondrion.

Circulatory Physiology and the Cardiac Cycle

The cardiac cycle is a repeating series of contractile and valvular events during which the valves open and close in response to pressure gradients between different cardiac chambers (Fig. 3-6). This cycle can be divided into *systole*, the period of ventricular contraction, and *diastole*, the period of ventricular relaxation. With the onset of ventricular contraction, the pressure in the ventricles increases and exceeds that in the atria, at which time the AV valves close. Intraventricular pressure continues to rise, initially without a change in ventricular volume (isovolumic contraction), until the intraventricular pressures exceed the pressures in the aorta and pulmonary artery, at which time the semilunar valves open and ventricular ejection of blood occurs. With the onset of ventricular relaxation, the pressure in the ventricles falls until the pressure in the arterial chambers exceeds that

in the ventricles, and the semilunar valves close. Ventricular relaxation continues, initially without a change in ventricular volume (isovolumic relaxation). When the pressure in the ventricles falls below the pressure in the atria, the AV valves open, and a rapid phase of ventricular filling occurs as blood in the atria empties into the ventricles. At the end of diastole, active atrial contraction augments ventricular filling. This augmentation is particularly important in patients with poor ventricular function or stiff ventricles and is lost in patients with atrial fibrillation.

In the absence of valvular disease, no impediment to the flow of blood exists from the ventricles to the arterial beds, and the systolic arterial pressure rises sharply to a peak. During diastole, the arterial pressure gradually falls as blood flows distally, and elastic recoil of the arteries occurs. This response contrasts with the pressure response in the ventricles during diastole, in which pressure gradually increases as blood enters the ventricles from the atria. Atrial pressure can be directly measured in the right atrium, whereas occluding

Figure 3-6 Simultaneous electrocardiogram (ECG) and pressure tracings obtained from the left atrium (LA), left ventricle (LV), and aorta, and the jugular venous pressure during the cardiac cycle. For simplification, right-sided pressures have been omitted. Normal right atrial pressure closely parallels that of the left atrium, and right ventricular and pulmonary artery pressures are timed closely with their corresponding left-sided heart counterparts; they are reduced only in magnitude. The normal mitral and aortic valve closure precedes tricuspid and pulmonic valve closure, respectively, whereas valve opening reverses this order. The jugular venous pulse lags behind the right atrial pulse.

During the course of one cardiac cycle, the electrical events (ECG) initiate and therefore precede the mechanical (pressure) events, and the latter precedes the auscultatory events (heart sounds) they themselves produce. Shortly after the P wave, the atria contract to produce the a wave. The QRS complex initiates ventricular systole, followed shortly by LV contraction and the rapid buildup of LV pressure. Almost immediately, LV pressure exceeds LA pressure, closing the mitral valve and producing the first heart sound. After a brief period of isovolumic contraction, LV pressure exceeds aortic pressure and the aortic valve opens (AVO). When the ventricular pressure once again falls below the aortic pressure, and the aortic valve closes to produce the second heart sound and terminate ventricular ejection. The LV pressure decreases during the period of isovolumic relaxation until it drops below LA pressure, and the mitral valve opens (MVO).

a small pulmonary artery branch and measuring the pressure distally (the pulmonary capillary wedge pressure) is often used to obtain left atrial pressure indirectly. An atrial pressure tracing is shown in Figure 3-6 and is composed of several waves. The a wave represents atrial contraction. As

Table 3-1 Normal Values for Common Hemodynamic Parameters

Heart Rate	60-100 Beats/Minute
Pressures	
Central venous	≤9 mm Hg
Right atrial	≤9 mm Hg
Right ventricular	
Systolic	15-30 mm Hg
End-diastolic	≤9 mm Hg
Pulmonary arterial	
Systolic	15-30 mm Hg
Diastolic	3-12 mm Hg
Pulmonary capillary wedge	≤12 mm Hg
Left atrial	≤12 mm Hg
Left ventricular	
Systolic	100-140 mm Hg
End-diastolic	3-12 mm Hg
Aortic	
Systolic	100-140 mm Hg
Diastolic	60-90 mm Hg
Resistance	
Systemic vascular resistance	800-1500 dynes-sec/cm ⁻⁵
Pulmonary vascular resistance	30-120 dynes-sec/cm ⁻⁵
Cardiac output	4-6 L/min
Cardiac index	2.5-4 L/min

the atria subsequently relax, the atrial pressure falls, and the x descent is noted on the pressure tracing. The x descent is interrupted by a small c wave, which is generated as the AV valve bulges toward the atrium during ventricular systole. As the atria fill from venous return, the v wave is seen, after which the y descent appears as the AV valves open and blood from the atria empties into the ventricles. The normal ranges of pressures in the various cardiac chambers are shown in Table 3-1.

CARDIAC PERFORMANCE

The amount of blood ejected by the heart each minute is referred to as the cardiac output (CO) and is the product of the stroke volume (SV; amount of blood ejected with each ventricular contraction) and the HR:

$$CO = SV \times HR$$

The cardiac index is the CO divided by the body surface area; it is measured in liters per minute per square meter and is a way of normalizing CO to body size. The normal CO at rest is 4 to 6 L/min, although this value can increase fourfold to sixfold during strenuous exercise as a result of increases in HR (chronotropic) and SV (inotropic).

The SV is a measure of the mechanical function of the heart and is affected by preload, afterload, and contractility (Table 3-2). Preload is the volume of blood in the ventricle at the end of diastole and is primarily a reflection of venous return. Within limits, as the preload increases, the ventricle stretches, and the ensuing ventricular contraction becomes more rapid and forceful. This phenomenon is known as the

Table 3-2 Factors Affecting Cardiac Performance

Preload (left ventricular diastolic volume)	Total blood volume Venous (sympathetic) tone Body position Intrathoracic and intrapericardial pressures Atrial contraction Pumping action of skeletal muscle
Afterload (impedance against which the left ventricle must eject blood)	Peripheral vascular resistance Left ventricular volume (preload, wall tension) Physical characteristics of the arterial tree (elasticity of vessels or presence of outflow obstruction)
Contractility (cardiac performance independent of preload or afterload)	Sympathetic nerve impulses Increased contractility Circulating catecholamines Digitalis, calcium, other inotropic agents Increased heart rate or post-extrasystolic augmentation Anoxia, acidosis Decreased contractility Pharmacologic depression Loss of myocardium Intrinsic depression
Heart rate	Autonomic nervous system Temperature, metabolic rate Medications, drugs

Frank-Starling relationship. Because ventricular volume is not easily measured, ventricular filling pressure (ventricular end-diastolic pressure, atrial pressure, or pulmonary capillary wedge pressure) is frequently used as a surrogate measure of preload. Two major means can manipulate the preload in a clinical setting. The first is to modulate volume status: intravenous fluids to increase preload and diuretics to decrease preload. The second is to regulate vascular tone: nitroglycerin to diminish preload.

Afterload is the force against which the ventricles must contract to eject blood. The arterial pressure is often used as a practical measure of afterload; although, in truth, the intraventricular pressure, the size of the ventricular cavity, and the thickness of the ventricular walls (Laplace's law) determine afterload. Thus, afterload is increased in the setting of systemic hypertension or stenosis of the aortic valve but may be equally increased in the setting of ventricular dilation or ventricular hypertrophy. Some antihypertensive drugs, such as angiotensin-converting enzyme (ACE) inhibitors and hydralazine, reduce blood pressure (BP) by reducing afterload.

Contractility, or inotropy, although difficult to define, represents the force of ventricular contraction independent of loading conditions. For example, an increase in contractility results in a stronger ventricular contraction even when

the preload and afterload are kept constant. Direct stimulation from adrenergic nerves in the myocardium and circulating catecholamines released from the adrenal glands can alter contractility under normal conditions. Several medications have important positive inotropic effects that can be exploited clinically, including digoxin and the sympathomimetic amines (e.g., epinephrine, norepinephrine, dopamine). Other medications, many of them antihypertensive medications, (e.g., β blockers, calcium channel antagonists) have negative inotropic effects and can decrease the strength of ventricular contraction.

Overall ventricular systolic function is frequently quantified by the ejection fraction, which is the ratio of the SV to the end-diastolic volume, that is, the fraction of blood in the ventricle ejected with each ventricular contraction. The normal ejection fraction is about 60% and can be measured by invasive (contrast ventriculography) or non-invasive (echocardiography or radionuclide ventriculography) methods.

Clearly, systolic contraction is an important component of ventricular function; however, ventricular diastolic relaxation (lusitropy) also plays an important role in overall cardiac performance. Impaired relaxation (diastolic dysfunction), as occurs with ventricular hypertrophy or ischemia, results in a stiff, noncompliant ventricle, leading to impaired ventricular filling and an increased ventricular pressure for any given diastolic volume.

PHYSIOLOGY OF THE CORONARY CIRCULATION

The heart is an aerobic organ requiring a constant supply of oxygen to maintain normal function. Under normal conditions, the supply of oxygen delivered to the heart is closely matched to the amount of oxygen required by the heart (the myocardial oxygen consumption [MvO_2]). The main determinants of MvO_2 are HR, contractility, and wall stress. The wall stress, as determined by Laplace's law, is directly related to the systolic pressure and the heart size and inversely proportional to wall thickness:

$$\text{Wall stress} = (\text{pressure} \times \text{radius}) / (2 \times \text{wall thickness})$$

Thus, the MvO_2 parallels changes in HR, BP, contractility, and heart size. In general, oxygen delivery to an organ can be augmented by either increasing blood flow or increasing oxygen extraction from the blood. For all practical purposes, the oxygen extraction by the heart is maximal at rest, and thus increases in coronary blood flow must meet increases in MvO_2 .

Because of the compression of intramyocardial blood vessels during systole, most coronary flow occurs during diastole. Therefore, diastolic pressure is the major pressure driving the coronary circulation. An important implication of this fact is that tachycardia, which primarily shortens the duration of diastole, results in reduced time for coronary flow, which occurs despite the increase in MvO_2 associated with increased HR. The systolic pressure has little effect on coronary blood flow except insofar as changes in BP lead to changes in MvO_2 .

Regulation of coronary blood flow occurs primarily through changes in coronary vascular resistance. In response

to a change in M_{vO_2} , the coronary arteries can dilate or constrict to allow for appropriate changes in coronary flow. Additionally, in the range of coronary perfusion pressures of 60 to 130 mm Hg, coronary blood flow is held constant by the process of autoregulation of the coronary arteries. This regulation of arterial resistance occurs at the level of the arterioles and is mediated by several factors. As ATP is metabolized during increased myocardial activity, adenosine is released and acts as a potent vasodilator. Decreased oxygen tension, increased carbon dioxide, acidosis, and hyperkalemia all develop during increased myocardial metabolism and may also mediate coronary vasodilation.

The coronary arteries are innervated by the autonomic nervous system, and activation of sympathetic or parasympathetic neurons alters coronary blood flow by affecting changes in vascular tone. Parasympathetic innervation through the vagus nerve and through the neurotransmitter acetylcholine results in vasodilation. Sympathetic neurons use norepinephrine as a neurotransmitter and may have opposing effects on the coronary vasculature. Stimulation of α receptors results in vasoconstriction, whereas stimulation of β receptors leads to vasodilation.

The ability of the coronary vasculature to mediate changes in blood flow through changes in vascular tone depends in large part on an intact, normally functioning endothelium. The endothelium produces several potent vasodilators, including endothelium-derived relaxing factor (EDRF) and prostacyclin. EDRF is likely to be nitric oxide or a compound containing nitric oxide and is released by the endothelium in response to acetylcholine, thrombin, ADP, serotonin, bradykinin, platelet aggregation, and an increase in shear stress. The latter stimulus accounts for the dilation of the coronary arteries in response to increases in blood flow in the setting of increases in M_{vO_2} (called *flow-dependent vasodilation*).

Vasoconstricting factors, most notably endothelin, are also produced by the endothelium and are likely to play a role in regulating vascular tone. The balance of these vasodilator and vasoconstriction factors may be important in conditions such as coronary vasospasm. In addition to influencing vascular tone, the endothelium has several other functions that have important implications for blood flow and tissue perfusion. These include maintenance of a non-thrombotic surface through inhibition of platelet activity, control of thrombosis and fibrinolysis, and modulation of the inflammatory response of the vasculature. Disturbances in these normal properties of the endothelium (*endothelial dysfunction*) are likely to play an important role in the pathophysiologic conditions of coronary atherosclerosis and thrombosis.

PHYSIOLOGY OF THE SYSTEMIC CIRCULATION

The normal cardiovascular system is capable of providing appropriate blood flow to each of the organs and tissues of the body under a wide range of conditions. This is achieved by maintaining arterial BP within normal limits to meet functional needs from adjustments to the cardiac output and the resistance to blood flow in specific organs and tissues. Arterial pressure is regulated acutely and chronically through various local and systemic, humoral, and neural factors.

Poiseuille's law describes the relationship between pressure and flow. Although not exactly descriptive of blood flow through elastic tapering blood vessels, Poiseuille's law is useful in understanding blood flow. Fluid flow (F) through a tube is proportional (proportionality constant = K) to the pressure (P) difference between the ends of the tube:

$$F = K \times \Delta P$$

The reciprocal of K is the resistance to flow (R); that is $K = 1/R$. When fluid flows through a tube, the resistance to flow is determined by the properties of both the fluid and the tube. In the case of a steady, streamlined flow of fluid through a rigid tube, Poiseuille found that these factors determine resistance:

$$R = 8\eta L / \pi r^4$$

where r is the radius of the tube, L is its length, and η is the viscosity of the fluid. This equation shows that the resistance to blood flow increases proportionately with increases in fluid viscosity or tube length. In contrast, radius changes have a much greater influence because resistance is inversely proportional to the fourth power of the radius. Poiseuille's law incorporates the factors influencing flow, so that:

$$\begin{aligned} F &= \Delta P / R \\ &= \Delta P \pi r^4 / 8\eta L \end{aligned}$$

The most important determinants of blood flow in the cardiovascular system are ΔP and r^4 . Thus, small changes in arterial radius can cause large changes in flow to a tissue or organ. Systemic vascular resistance (SVR) is the total resistance of flow offered by the blood vessels of the systemic circulation. Physiologic changes in SVR are primarily caused by changes in the radius of small arteries and arterioles, the *resistance vessels* of the systemic circulation. The SVR is defined as the pressure drop across the peripheral capillary beds divided by the blood flow across the beds (e.g., $SVR = BP/CO$). In practice, this is calculated as the mean arterial pressure minus the right atrial pressure divided by the cardiac output and is normally in the range of 800 to 1500 dynes sec/cm^5 .

As with the coronary circulation autonomic innervation alters systemic vascular tone through sympathetic and parasympathetic innervation. Local oxygen tension, carbon dioxide levels, pH, and potassium levels have direct effects on vascular tone and blood flow. And finally, a normally functioning endothelium mediates changes in blood flow through potent vasodilatory and vasoconstricting factors (see "Physiology of the Coronary Circulation").

Control of BP through neural regulation occurs by means of tonic and reflexive modulation of autonomic nervous system outflow. Acutely, changes in these outflows influence key determinants of BP, such as cardiac chronotropy, inotropy, and vascular resistance. The primary mechanism by which BP is neurally modulated is through the baroreflexes. The baroreflex loop anatomically originates at the level of the baroreceptor. The baroreceptors are highly specialized stretch-sensitive nerve endings distributed throughout various regions of the cardiovascular systems, such as the

carotid artery, aorta, and the cardiopulmonary region. Baroreceptors located in the carotid artery (e.g., carotid sinus) and aorta are sometimes referred to as *high-pressure baroreceptors* and those in the cardiopulmonary areas as *low-pressure baroreceptors*. After transmission of afferent impulses to the central nervous system, signals are integrated, and the efferent arm of the reflex projects neural signals systemically through the sympathetic and parasympathetic branches of the autonomic nervous system. In general, in response to an increase in systemic BP, there is an increased firing rate of the baroreceptors, efferent sympathetic outflow is inhibited (reducing vascular tone, chronotropy, and inotropy), and parasympathetic outflow is increased (reducing cardiac chronotropy). The opposite occurs when BP decreases.

Cardiac output and systemic BP are controlled not only neurally and by local vasoactive substances through regulation of vascular tone but also by blood volume. A major physiologic control mechanism, which regulates total blood volume, is the *renin-angiotensin-aldosterone system* (RAAS). Renin is an enzyme secreted by the kidneys in response to low renal perfusion, low blood volume, low BP, or low sodium concentration. Renin converts the polypeptide angiotensinogen to angiotensin I in the liver. Angiotensin I circulates in the bloodstream and is converted to angiotensin II by the activity of ACE located primarily in the capillary beds of the lung. Angiotensin II is a powerful vasoconstrictor regulating BP through changes in vascular tone. In addition to its vasoactive properties, angiotensin II activates release of the hormone aldosterone from the adrenal cortex. Aldosterone then acts on the kidneys to retain sodium and thus water. Angiotensin II also acts directly on the posterior pituitary gland, increasing the secretion of vasopressin (e.g., anti-diuretic hormone). Much like angiotensin II, vasopressin is a vasoconstrictor; it also acts on the kidney by retaining water through its action on V2 receptors in the collecting ducts. Although activity of the RAAS is to maintain blood volume, this system has adverse effects in chronic disease states, aggravating conditions such as hypertension and heart failure.

Blood leaves the arterioles and flows into the capillary systems, where oxygen and nutrients are delivered to cells and carbon dioxide and metabolic wastes are removed. The deoxygenated blood then drains into peripheral veins, which contain valves to prevent backflow. These veins have thinner walls than arteries and function as *capacitance vessels*; they are able to accommodate a significantly larger volume of blood than the arterial system. With the aid of the pumping action of skeletal muscles and the respiratory motion of the chest wall, blood returns to the right atrium. This venous return can be altered by constriction or dilation of the peripheral veins. In addition to the venous drainage, a rich system of lymphatic vessels helps drain excess interstitial fluid from the periphery. The various lymphatic vessels drain into the thoracic duct and, subsequently, into the left brachiocephalic vein.

PHYSIOLOGY OF THE PULMONARY CIRCULATION

Similar to the systemic circulation, the pulmonary circulation consists of a branching network of progressively smaller arteries, arterioles, capillaries, and veins. The pulmonary

capillaries are separated from the alveoli by a thin alveolar-capillary membrane through which gas exchange occurs. Carbon dioxide thus diffuses from the capillary blood into the alveoli, and oxygen diffuses from the alveoli into the blood. The flow of blood to various lung segments is regulated by several factors, the most important being the P_{O_2} in the alveoli. In this manner, blood is shunted toward well-ventilated lung segments and away from poorly ventilated segments. As a result of the extensive nature of the pulmonary capillary system and the distensibility of the pulmonary vasculature, the resistance across the pulmonary system (the pulmonary vascular resistance) is about 10% that of the systemic circulation. Owing to these features, the pulmonary system is able to tolerate significant increases in blood flow with little or no rise in pulmonary pressure. Thus, intracardiac shunts (e.g., atrial septal defects) may be associated with normal pulmonary pressure.

The lung receives a dual blood supply. The pulmonary artery accounts for most pulmonary blood flow; however, the lungs also receive oxygenated blood through the bronchial arteries. These vessels supply oxygen to the lung and drain into the bronchial veins. The bronchial veins drain partly into the pulmonary veins; thus, a small amount of deoxygenated blood normally enters the systemic circulation and accounts for a physiologic right-to-left shunt. In the normal setting, this shunt is insignificant, accounting for only 1% of the total systemic blood flow.

Cardiovascular Response to Exercise

The response of the heart to exercise is multifaceted and involves many of the previously discussed mechanisms of circulatory control (Table 3-3). In anticipation of exercise, neural centers in the brain stimulate vagal withdrawal and an increase in sympathetic tone, resulting in an increase

Table 3-3 Physiologic Responses to Exercise

Increased heart rate	Increased sympathetic stimulation
Increased stroke volume	Decreased parasympathetic stimulation
Increased contractility	Increased sympathetic stimulation
Increased venous return	Sympathetic-mediated venoconstriction
	Pumping action of skeletal muscles
	Decreased intrathoracic pressure with deep inspirations
	Arteriolar vasodilation in exercising muscle
Decreased afterload	Arteriolar vasodilation in exercising muscle (mediated chiefly by local metabolites)
Increased blood pressure	Increased cardiac output
	Vasoconstriction (sympathetic stimulation) on nonexercising vascular beds
Increased O_2 extraction	Shift in oxyhemoglobin dissociation curve as a result of local acidosis

in HR and contractility (thus an increase in CO) before exercise ever starts. With exercise, sympathetic venoconstriction, augmented pumping action of skeletal muscles, and increased respiratory movements of the chest wall result in an increase in venous return to the heart. Through the Frank-Starling relationship, this increase in venous return results in an increase in contractility, thus augmenting CO. Sympathetic activation may also increase contractility; however, most of the increase in CO during exercise (up to 4 to 6 times the normal rate) is a consequence of an increase in HR. The peak HR that can be achieved is dependent on age and can be estimated by the following formula: maximal HR = $(220 - \text{age}) \pm 15$ beats/minute.

Local factors in exercising muscle cause arteriolar dilation, resulting in increased flow to the capillary beds. This vasodilation results in decreased resistance to flow, and

therefore the SVR decreases with exercise. Despite this change in resistance, the systolic BP rises, owing to the augmented CO and to sympathetic vasoconstriction, which leads to the preferential shunting of blood away from non-exercising vascular beds. The diastolic BP, by contrast, generally remains constant during exercise. The pulmonary system is able to tolerate the increased flow with only small increases in pulmonary pressure. The increases in HR and contractility result in a significant increase in MvO_2 (up to 300%), and coronary blood flow subsequently increases.

Various types of exercises have different effects on the circulatory system. The response described in this text occurs with isotonic exercises, such as running or biking. With isometric exercises, such as weight lifting, the predominant response is an increase in BP, owing to an increase in peripheral vasoconstriction.

Prospectus for the Future

Recent years have witnessed an explosion in the growth of basic knowledge governing normal heart development and function of the circulatory system. New insights about the molecular switches and factors that promote the formation of heart chambers and blood vessels are unraveling the genetic basis for unusual causes of congenital heart disease. Similarly, the recent discovery of specific growth factors and

signaling pathways that guide vascular trajectory and ensure vascular stability offer new opportunities to rethink future strategies for promoting cardiac and vascular regeneration and repair. With increasing refinement in this basic knowledge, future milestones appear on the horizon for diagnosis, early treatment, and even prevention of cardiovascular diseases.

Evaluation of the Patient with Cardiovascular Disease

Sheldon E. Litwin and Ivor J. Benjamin

History

As with diseases of most organ systems, the ability of the physician to diagnose diseases of the cardiovascular system is in large part dependent on eliciting and interpreting the patient's clinical history. A thorough history can enable the physician to identify a patient's symptoms as characteristic of a specific cardiovascular disorder or to suggest that symptoms are unlikely to be caused by cardiovascular disease. In addition, a complete history will reveal the presence of other systemic diseases that may have cardiovascular manifestations, identify existing risk factors that may be modified to prevent the future development of cardiovascular disease (see Chapter 9), enable the selection of appropriate further diagnostic testing (see Chapter 5), and allow the assessment of functional capacity and extent of cardiovascular disability. The patient should be asked about prior medical conditions, including childhood illnesses (e.g., rheumatic fever), as well as intravenous drug use, which may lead to the development of valvular heart disease. Several cardiovascular disorders are inherited (e.g., hypertrophic cardiomyopathy, Marfan syndrome, long QT syndrome), and a thorough family history may bring this potential to the examiner's attention.

The classic symptoms of cardiac disease include precordial discomfort or pain, dyspnea, palpitations, syncope or presyncope, and edema. Although characteristic of heart disease, these symptoms are nonspecific and may also occur as a result of diseases of other organ systems (e.g., musculoskeletal, pulmonary, renal, gastrointestinal). Furthermore, some patients with established cardiovascular disease may be asymptomatic or have atypical symptoms.

Chest pain is a frequent symptom and may be a manifestation of cardiovascular or noncardiovascular disease (Tables 4-1 and 4-2). Full characterization of the pain with regard

to quality, quantity, frequency, location, duration, radiation, aggravating or alleviating factors, and associated symptoms may help distinguish among various causes. Reversible myocardial ischemia caused by obstructive coronary artery disease commonly results in episodic chest pain or discomfort during exertion or stress (angina pectoris). Patients frequently deny having pain and, instead, describe a discomfort in their chest. Sometimes they will refer to the discomfort as a *squeezing, tightening, pressing, or burning* sensation or as a *heavy weight* on their chest, and they will sometimes clench their fist over their chest while describing the discomfort (Levine sign). Anginal discomfort is classically located substernally or over the left chest. It frequently radiates to the epigastrium, neck, jaw, or back and down the ulnar aspect of the left arm. Radiation to the right chest or arm is less common, whereas radiation above the jaw or below the epigastrium is not typical of cardiac disease. Angina is usually brought on by either physical or emotional stress, is mild to moderate in intensity, lasts 2 to 10 minutes, and resolves with rest or sublingual administration of nitroglycerin. It may occur more frequently in the morning, in cold weather, after a large meal, or after exposure to environmental factors, including cigarette smoke, and is frequently accompanied by other symptoms, such as dyspnea, diaphoresis, nausea, palpitations, or lightheadedness. Patients frequently report a stable pattern of angina that is predictably reproducible with a given amount of exertion. Unstable angina occurs when a patient reports a significant increase in the frequency or severity of angina or when angina occurs with progressively decreasing exertion or at rest. When anginal-type pain occurs mainly at rest, it may be of a noncardiac origin, or it may reflect true cardiac ischemia resulting from coronary spasm (Prinzmetal or variant angina). The pain of an acute myocardial infarction may be similar

Table 4-1 Cardiovascular Causes of Chest Pain

Condition	Location	Quality	Duration	Aggravating or Alleviating Factors	Associated Symptoms or Signs
Angina	Retrosternal region; radiates to or occasionally isolated to neck, jaw, shoulders, arms (usually left), or epigastrium	Pressure, squeezing, tightness, heaviness, burning, indigestion	<2-10 min	Precipitated by exertion, cold weather, or emotional stress; relieved by rest or nitroglycerin; variant (Prinzmetal) angina may be unrelated to exertion, often early in the morning	Dyspnea; S ₃ , S ₄ , or murmur of papillary dysfunction during pain
Myocardial infarction	Same as angina	Same as angina, although more severe	Variable; usually longer than 30 min	Unrelieved by rest or nitroglycerin	Dyspnea, nausea, vomiting, weakness, diaphoresis
Pericarditis	Left of the sternum; may radiate to neck or left shoulder, often more localized than pain of myocardial ischemia	Sharp, stabbing, knifelike	Lasts many hours to days; may wax and wane	Aggravated by deep breathing, rotating chest, or supine position; relieved by sitting up and leaning forward	Pericardial friction rub
Aortic dissection	Anterior chest; may radiate to back, interscapular region	Excruciating, tearing, knifelike	Sudden onset, unremitting	Usually occurs in setting of hypertension or predisposition, such as Marfan syndrome	Murmur of aortic insufficiency; pulse or blood pressure asymmetry; neurologic deficit

to angina, although the former is usually more severe and prolonged (>30 minutes).

The pain of acute pericarditis is usually sharper than anginal pain, is located to the left of the sternum, and may radiate to the neck or left shoulder. In contrast to angina, the pain may last hours, typically worsens with inspiration, and improves when the patient sits up and leans forward; it may be associated with a pericardial friction rub. Acute aortic dissection produces severe, sharp, *tearing* pain that radiates to the back and may be associated with asymmetrical pulses and a murmur of aortic insufficiency. Pulmonary emboli may produce the sudden onset of sharp chest pain that is worse on inspiration, is associated with shortness of breath, and may have an associated pleural friction rub, especially if a pulmonary infarction is present. A multitude of noncardiac conditions may also produce chest pain (see Table 4-2). The clinical history and physical examination findings will often help distinguish these causes from ischemic chest pain.

Dyspnea, an uncomfortable, heightened awareness of breathing, is commonly a symptom of cardiac disease. Patients with decreased left ventricular function may exhibit significant abnormalities of the aortic or mitral valves or decreased myocardial compliance (i.e., left ventricular hypertrophy, acute ischemia), left ventricular diastolic, or left atrial pressure increases transmitted through the pulmonary veins to the pulmonary capillary system, producing vascular congestion. This congestion results in exudation of fluid into the alveolar space and impairs gas exchange across the alveolar-capillary membrane, producing the subjective

sensation of dyspnea. Dyspnea frequently occurs on exertion; however, in patients with severe cardiac disease, it may be present at rest. Patients with heart failure commonly sleep on two or more pillows because the augmented venous return that occurs on assuming the recumbent position produces an increase in dyspnea (orthopnea). In addition, these patients report awakening 2 to 4 hours after the onset of sleep with dyspnea (paroxysmal nocturnal dyspnea), which is likely caused by the central redistribution of peripheral edema in the supine position.

Dyspnea may be associated with diseases of the lungs or chest wall and is also seen in anemia, obesity, deconditioning, and anxiety disorders. In addition, the sudden onset of dyspnea, with or without chest pain, may be present with pulmonary emboli. It is frequently difficult to distinguish cardiac from pulmonary causes of dyspnea by history alone because both may produce resting or exertional dyspnea, orthopnea, or cough. Wheezing and hemoptysis are classically results of pulmonary disease, although they are also frequently present in the patient with pulmonary edema resulting from left ventricular dysfunction or mitral stenosis. True paroxysmal nocturnal dyspnea is, however, more specific for cardiac disease. In patients with coronary artery disease, dyspnea may be an *anginal equivalent*; that is, the dyspnea is the result of ischemia and occurs in a pattern consistent with angina but in the absence of chest discomfort.

Palpitation refers to the subjective sensation of the heart beating. Patients may describe a *fluttering* or *pounding* in the chest or a feeling that their heart *races* or *skips a beat*. Some

Table 4-2 Noncardiac Causes of Chest Pain

Condition	Location	Quality	Duration	Aggravating or Alleviating Factors	Associated Symptoms or Signs
Pulmonary embolism (chest pain often not present)	Substernal or over region of pulmonary infarction	Pleuritic (with pulmonary infarction) or angina-like	Sudden onset (minutes to hours)	Aggravated by deep breathing	Dyspnea, tachypnea, tachycardia; hypotension, signs of acute right ventricular heart failure, and pulmonary hypertension with large emboli; pleural rub; hemoptysis with pulmonary infarction
Pulmonary hypertension	Substernal	Pressure; oppressive	—	Aggravated by effort	Pain usually associated with dyspnea; signs of pulmonary hypertension
Pneumonia with pleurisy	Located over involved area	Pleuritic	—	Aggravated by breathing	Dyspnea, cough, fever, bronchial breath sounds, rhonchi, egophony, dullness to percussion, occasional pleural rub
Spontaneous pneumothorax	Unilateral	Sharp, well localized	Sudden onset; lasts many hours	Aggravated by breathing	Dyspnea; hyperresonance and decreased breath and voice sounds over involved lung
Musculoskeletal disorders	Variable	Aching, well localized	Variable	Aggravated by movement; history of exertion or injury	Tender to palpation or with light pressure
Herpes zoster	Dermatomal distribution	Sharp, burning	Prolonged	None	Vesicular rash appears in area of discomfort
Esophageal reflux	Substernal or epigastric; may radiate to neck	Burning, visceral discomfort	10-60 min	Aggravated by large meal, postprandial recumbency; relief with antacid	Water brash
Peptic ulcer	Epigastric, substernal	Visceral burning, aching	Prolonged	Relief with food, antacid	—
Gallbladder disease	Right upper quadrant; epigastric	Visceral	Prolonged	Spontaneous or following meals	Right upper quadrant tenderness may be present
Anxiety states	Often localized over precordium	Variable; location often moves from place to place	Varies; often fleeting	Situational	Sighing respirations; often chest wall tenderness

people feel post-extrasystolic beats as a painful or uncomfortable sensation. Common arrhythmic causes of palpitations include premature atrial or ventricular contractions, supraventricular tachycardia, ventricular tachycardia, and sinus tachycardia. Occasionally, patients report palpitations even when no rhythm disturbance is noted during monitoring, as occurs commonly in patients with anxiety disorders. The pattern of palpitations, especially when correlated to the pulse, may help narrow the differential diagnosis: rapid, regular palpitations are noted with supraventricular tachycardia or ventricular tachycardia; rapid, irregular palpita-

tions are noted with atrial fibrillation; and *skipped beats* are noted with premature atrial or ventricular contractions.

Syncope is the transient loss of consciousness resulting from inadequate cerebral blood flow and may be the result of a variety of cardiovascular diseases (see Chapter 10). True syncope must be distinguished from primary neurologic causes of loss of consciousness (i.e., seizures) and metabolic causes of loss of consciousness (e.g., hypoglycemia, hyperventilation). Cardiac syncope occurs after an abrupt decrease in cardiac output, as may occur with acute myocardial ischemia, valvular heart disease (aortic or mitral stenosis),

hypertrophic obstructive cardiomyopathy, left atrial tumors, tachyarrhythmias (ventricular, or less commonly supraventricular, tachycardias), or bradyarrhythmias (e.g., sinus arrest, atrioventricular block, Stokes-Adams attacks). Reflex vasodilation or bradycardia may also result in syncope (vasovagal syncope, carotid sinus syncope, micturition syncope, cough syncope, or neurocardiogenic syncope), as may acute pulmonary embolism and hypovolemia. Because global, or at the very least bilateral, cortical ischemia is required to produce syncope, it rarely occurs as a result of unilateral carotid artery disease. However, syncope is occasionally the result of bilateral carotid artery disease and can also occur when disease of the vertebrobasilar system results in brainstem ischemia. In up to 50% of patients, the cause of a syncopal episode cannot be determined; however, in the cases in which a cause is determined, the most important factor in establishing the diagnosis is obtaining an accurate history of the event.

Edema is a nonspecific symptom that commonly accompanies cardiac disease as well as renal disease (e.g., nephrotic syndrome), hepatic disease (e.g., cirrhosis), and local venous abnormalities (e.g., thrombophlebitis, chronic venous stasis). When edema occurs as a result of cardiac disease, it reflects an increase in venous pressure. This increased pressure alters the balance between the venous hydrostatic and oncotic forces, resulting in extravasation of fluid into the extravascular space. When this process occurs as a result of elevated left-sided heart pressure, pulmonary edema results, whereas elevated right-sided heart pressure results in peripheral edema. Characteristically, the peripheral edema of heart failure is *pitting*; that is, an indentation is left in the skin after pressure is applied to the edematous region. The edema is exacerbated by long periods of standing, is worse in the evening, improves after lying down, and may first be noted when a patient has difficulty in fitting into his or her shoes. The edema may shift to the sacral region after a patient lies down for several hours. When visible edema is noted, it is usually preceded by a moderate weight gain (i.e., 5 to 10 lb), indicative of volume retention. As heart failure progresses, the edema may extend to the thighs and involve the genitalia and abdominal wall, and fluid may collect in the abdominal (ascites) or thoracic (pleural effusion) cavities. Anasarca with ascites should raise suspicion for constrictive pericarditis because this disease may progress very slowly and insidiously.

Cyanosis is an abnormal bluish discoloration of the skin resulting from an increase in the level of reduced hemoglobin in the blood and, in general, reflects an arterial oxygen saturation of 85% or less (normal arterial oxygen saturation, $\geq 95\%$). Central cyanosis exhibits as cyanosis of the lips or trunk and often reflects right-to-left shunting of blood caused by structural cardiac abnormalities (e.g., atrial or ventricular septal defects) or pulmonary parenchymal or vascular disease (e.g., chronic obstructive pulmonary disease, pulmonary embolism, pulmonary arteriovenous fistula). Peripheral cyanosis may occur because of systemic vasoconstriction in the setting of poor cardiac output or may be a localized phenomenon resulting from venous or arterial occlusive or vasospastic disease (e.g., venous or arterial thrombosis, arterial embolic disease, Raynaud disease). When cyanosis occurs in childhood, it usually reflects congenital heart disease with right-to-left shunting of blood.

Myriad *other symptoms*, many of them nonspecific, may occur with cardiac disease. Fatigue frequently occurs in the setting of poor cardiac output or may occur secondary to the medical therapy of cardiac disease from overdiuresis, aggressive blood pressure lowering, or use of β -blocking agents. Nausea and vomiting frequently occur during an acute myocardial infarction and may also reflect intestinal edema in the setting of right ventricular heart failure. Anorexia and cachexia may occur in severe heart failure. Positional fluid shifts may result in polyuria and nocturia in patients with edema. In addition, epistaxis, hoarseness, hiccups, fever, and chills may reflect underlying cardiovascular disease.

Many patients with significant cardiac disease are asymptomatic. Patients with coronary artery disease frequently have periods of asymptomatic ischemia that can be documented with ambulatory electrocardiographic monitoring. Furthermore, nearly one third of patients who suffer an acute myocardial infarction are unaware of the event. This silent ischemia appears to be more common in older adults and in patients with diabetes. Patients may also be asymptomatic despite having severely depressed ventricular function; this usually bespeaks a chronic, slowly progressive process. Reduced exercise capacity may only be seen during provocative testing. Similarly, recent findings show that a high percentage of episodes of atrial fibrillation are unrecognized by patients.

Assessment of Functional Capacity

In patients with cardiac disorders, the ability or inability to perform various activities (functional status) plays an important role in determining their extent of disability, deciding when to institute various therapies or interventions, and assessing their response to therapy as well as determining their overall prognosis. The New York Heart Association Functional Classification is a standardized method for the assessment of functional status (Table 4-3) and relates functional capacity to the presence or absence of cardiac symptoms during the performance of *usual activities*. The

Table 4-3 Classification of Functional Status

Class	Functional Status	Symptoms
Class I	Uncompromised	Ordinary activity does not cause symptoms.* Symptoms only occur with strenuous or prolonged activity.
Class II	Slightly compromised	Ordinary physical activity results in symptoms; no symptoms at rest.
Class III	Moderately compromised	Less than ordinary activity results in symptoms; no symptoms at rest.
Class IV	Severely compromised	Any activity results in symptoms; symptoms may be present at rest.

*Symptoms refer to undue fatigue, dyspnea, palpitations, or angina in the New York Heart Association classification and refer specifically to angina in the Canadian Cardiovascular Society classification.

Canadian Cardiovascular Society has provided a similar classification of functional status specifically in patients with angina pectoris. These tools are useful in that they allow a patient's symptoms to be classified and then compared with their symptoms at a different point in time.

Physical Examination

EXAMINATION OF THE JUGULAR VENOUS PULSATIIONS

The examination of the neck veins allows for estimation of the right atrial pressure and for identification of the venous waveforms. The right internal jugular vein is used for this examination because it more accurately reflects right atrial pressure than the external jugular or left jugular vein. With the patient lying at a 45-degree angle (higher in patients with elevated venous pressure, lower in patients with low venous pressure) with the head turned to the left, the vertical distance from the sternal angle (angle of Louis) to the top of the venous pulsation can be determined. Because the right atrium lies about 5 cm vertically below the sternal angle, distention of the internal jugular vein 4 cm above the sternal angle reflects a right atrial pressure of 9 cm H₂O. The right atrial pressure is normally 5 to 9 cm H₂O and is increased with congestive heart failure, tricuspid insufficiency or stenosis, and restrictive or constrictive heart disease. With inspiration, negative intrathoracic pressure develops, venous blood drains into the thorax, and the normal venous pressure falls; the opposite is true with expiration. This pattern is reversed (Kussmaul sign) in the setting of right ventricular heart failure, constrictive pericarditis, or restrictive myocardial disease. With right ventricular heart failure, the elevated venous pressure results in passive congestion of the liver. Pressure applied over the liver for 1 to 3 minutes in this setting results in an increase in the jugular venous pressure (hepatojugular reflux).

The normal waveforms of the venous pulsation consist of the a, c, and v waves and the x and y descents; these waveforms are shown in Figure 4-1A and reflect events in the right side of the heart. The a wave results from atrial contraction. Subsequent atrial relaxation results in a decrease in the right atrial pressure, which is seen as the x descent. This descent is interrupted by the c wave, generated by the bulging of the tricuspid valve cusps into the right atrium during ventricular systole. As the atrial pressure increases owing to venous return, the v wave is generated. This wave is normally smaller than the a wave and is followed by the y descent as the tricuspid valve opens and blood flows from the right atrium to the right ventricle during diastole.

Abnormalities of the venous waveforms reflect underlying structural, functional, or electrical abnormalities of the heart (see Fig. 4-1B through G). The a wave increases in any condition in which greater resistance to right atrial emptying occurs (e.g., tricuspid stenosis, right ventricular hypertrophy or failure, pulmonary hypertension). *Cannon a waves* are seen when the atrium contracts against a closed tricuspid valve, as occurs with complete heart block, with junctional or ventricular rhythms, and occasionally with ventricular pacemakers. The a wave is absent in atrial fibrillation. In tricuspid regurgitation, the v wave is prominent and may

merge with the c wave (c-v wave), thus diminishing or eliminating the x descent altogether. The y descent is attenuated in tricuspid stenosis, owing to the impaired atrial emptying. In pericardial constriction and restrictive cardiomyopathy, as well as in right ventricular infarction, the y descent becomes rapid and deep, and the x descent may also become prominent (w waveform). In pericardial tamponade, the x descent is prominent, but the y descent is diminished or absent.

EXAMINATION OF THE ARTERIAL PULSE

The arterial blood pressure can be measured with the use of a sphygmomanometer. The cuff is applied to the upper arm, rapidly inflated to 30 mm Hg above the anticipated systolic pressure, and then slowly deflated (= 3 mm Hg/sec) while listening for the sounds produced by blood entering the previously occluded brachial artery (Korotkoff sounds). The pressure at which the first sound is heard (usually a clear, tapping sound) represents the systolic pressure. Diastolic pressure occurs at the point at which the Korotkoff sounds disappear. Normally, the pressure in both arms is the same (about 120/70 mm Hg), and the systolic pressure in the legs is 10 to 20 mm Hg higher. Asymmetrical arm pressures can result from atherosclerotic disease of the aorta, aortic dissection, and stenosis of the innominate or subclavian arteries. Coarctation of the aorta and severe atherosclerotic disease of the aorta or the femoral or iliac arteries can result in a lower blood pressure in the legs than in the arms. Aortic insufficiency is frequently associated with a leg pressure more than 20 mm Hg higher than the arm pressure (Hill sign). Use of a cuff that is too small for a patient's arm will result in erroneously high pressure measurements. Similarly, a cuff that is too large results in erroneously low measurements.

The arterial examination should include assessments of the carotid, radial, brachial, femoral, popliteal, posterior tibial, and dorsalis pedis pulses, although the carotid artery pulse most accurately reflects the central aortic pulse. The rhythm, strength, contour, and symmetry of the pulses should be noted. The normal arterial pulse (Fig. 4-2A) rises rapidly to a peak in early systole, plateaus, and then falls. The descending pressure wave is interrupted by the dicrotic notch, related to aortic valve closure. This normal pattern is altered in a variety of cardiovascular disease states (see Fig. 4-2B through F). The amplitude of the pulse increases in aortic insufficiency, anemia, pregnancy, and thyrotoxicosis and decreases in conditions such as hypovolemia, tachycardia, left ventricular failure, and severe mitral stenosis. Aortic insufficiency results in a *bounding* pulse (Corrigan pulse or water-hammer pulse), owing to an increased pulse pressure (the difference between systolic and diastolic pressure), and is accompanied by a multitude of abnormalities in the peripheral pulses that reflect this increased pulse pressure. Aortic stenosis characteristically results in an attenuated carotid pulse with a delayed upstroke (pulsus parvus et tardus) and may be associated with a palpable thrill over the aortic area (the carotid shudder). A bisferious pulse is commonly felt in the presence of pure aortic regurgitation and is characterized by two systolic peaks. The first peak is the percussion wave, resulting from the rapid ejection of a large volume of blood early in systole; the second peak is the tidal

Figure 4-1 Normal and abnormal jugular venous pulse tracings. **A**, Normal jugular pulse tracing with simultaneous electrocardiogram (ECG) and phonocardiogram. **B**, Loss of the a wave in atrial fibrillation. **C**, Large a wave in tricuspid stenosis. **D**, Large c-v wave in tricuspid regurgitation. **E**, Prominent x and y descents in constrictive pericarditis. **F**, Prominent x descent and diminutive y descent in pericardial tamponade. **G**, Jugular venous pulse (JVP) tracing and simultaneous ECG during complete heart block demonstrating cannon a waves occurring when the atrium contracts against a closed tricuspid valve during ventricular systole.

wave, a reflected wave from the periphery. This bifid pulse may also be noted in hypertrophic cardiomyopathy in which the initial rapid upstroke of the pulse is cut short by the development of a left ventricular outflow tract obstruction, resulting in a fall in the pulse. The reflected wave again produces the second impulse. In severe left ventricular dysfunc-

tion, the intensity of the pulse may alternate from beat to beat (*pulsus alternans*), and in atrial fibrillation, the pulse intensity is variable. With inspiration, negative intrathoracic pressure is transmitted to the aorta, and the systolic pressure normally decreases by up to 10 mm Hg. Pulsus paradoxus is an exaggeration of this normal inspiratory fall in systolic

Figure 4-2 Normal and abnormal carotid arterial pulse contours. **A**, Normal arterial pulse with simultaneous electrocardiogram (ECG). The dirotic wave (D) occurs just after aortic valve closure. **B**, Wide pulse pressure in aortic insufficiency. **C**, Pulsus parvus et tardus (small amplitude with a slow upstroke) associated with aortic stenosis. **D**, Bisferious pulse with two systolic peaks, typical of hypertrophic obstructive cardiomyopathy or aortic insufficiency, especially if concomitant aortic stenosis is present. **E**, Pulsus alternans, characteristic of severe left ventricular failure. **F**, Paradoxical pulse (systolic pressure decrease of >10 mm Hg with inspiration), most characteristic of cardiac tamponade.

pressure and is characteristically seen with pericardial tamponade, although it may also occur as a result of severe obstructive lung disease, constrictive pericarditis, hypovolemic shock, and pregnancy.

Atherosclerotic disease of the peripheral vascular system frequently accompanies coronary atherosclerosis; therefore, the presence of peripheral vascular disease warrants a search for symptoms or signs of coronary artery disease and vice versa. When atherosclerosis occurs in a peripheral artery to the lower extremity and impairs blood flow distally, the patient may complain of intermittent cramping in the buttocks, thigh, calf, or foot (claudication). Severe peripheral vascular disease may result in digital ischemia or necrosis, without or with associated erectile dysfunction (Leriche syndrome). The peripheral pulses should be palpated and the abdominal aorta assessed for enlargement in all cardiac patients; a pulsatile, expansile, periumbilical mass suggests the presence of an abdominal aortic aneurysm. With significant stenosis of the peripheral vasculature, the distal

pulses may be diminished or absent, and the blood flow through the stenotic artery may be audible (a *bruit*). With normal aging, the elastic arteries lose their compliance, and this change in physical property may obscure abnormal findings.

EXAMINATION OF THE PRECORDIUM

Inspection and palpation of the precordium may yield valuable clues as to the existence of cardiac disease. Chest wall abnormalities should be noted, such as pectus excavatum, which may be associated with Marfan syndrome or mitral valve prolapse; pectus carinatum, which may be associated with Marfan syndrome; and kyphoscoliosis, which is occasionally a cause of secondary pulmonary hypertension and right ventricular heart failure. The presence of visible pulsations in the aortic (second right intercostal space and suprasternal notch), pulmonic (third left intercostal space), right ventricular (left parasternal region), and left ventricu-

lar (fourth to fifth intercostal space and left mid-clavicular line) regions should be noted and will help direct the palpation of the heart. Retraction of the left parasternal area may be seen with severe left ventricular hypertrophy, and systolic retraction of the chest wall at the cardiac apex or left axilla (Broadbent sign) is characteristic of constrictive pericarditis.

Precordial palpation is best performed with the patient supine or in the left lateral position, with the examiner standing to the patient's right side. In this position, firm placement of the examiner's right hand over the patient's lower left chest wall places the fingertips over the region of the cardiac apex and the palm over the region of the right ventricle. The normal cardiac apical impulse is a brief, discrete impulse (about 1 cm) located in the fourth to fifth intercostal space in the left mid-clavicular line generated as the left ventricle strikes the chest wall during early systole. In a patient with a structurally normal heart, the apex is the point of maximal impulse (PMI) of the heart against the chest wall. Enlargement of the left ventricle results in lateral displacement of the apical impulse, whereas chronic obstructive pulmonary disease may result in inferior displacement of the PMI. Volume overload states, such as aortic insufficiency and mitral regurgitation, produce ventricular enlargement primarily from dilation and result in a hyperdynamic apical impulse; that is, the impulse is brisk and increased in amplitude. Pressure overload states, such as aortic stenosis and long-standing hypertension, produce ventricular enlargement primarily from hypertrophy. In this setting, the apical impulse is sustained, and atrial contraction is frequently detected (a palpable S_4). Hypertrophic cardiomyopathy characteristically produces a double or triple apical impulse. Left ventricular aneurysms produce an apical impulse that is larger than normal and dyskinetic.

The right ventricular impulse is not normally palpable. When an impulse is felt over the left parasternal region, it usually reflects right ventricular hypertrophy or dilation. Aortic aneurysms may be palpable (or visible) in the suprasternal notch or the second right intercostal space. Pulmonary hypertension may produce a palpable systolic impulse in the left third intercostal space and may also be associated with a palpable pulmonic component of the second heart sound (P_2). Harsh murmurs originating from valvular or congenital heart disease may be associated with palpable vibratory sensations (thrills), as can occur with aortic stenosis, hypertrophic cardiomyopathy, and ventricular septal defects.

Auscultation

TECHNIQUE

Auscultation of the heart should ideally be performed in a quiet room with the patient in a comfortable position and the chest fully exposed. Certain heart sounds are better heard with either the bell or diaphragm of the stethoscope. Low-frequency sounds are best heard with the bell applied to the chest wall with just enough pressure to form a seal. As more pressure is applied to the bell, low-frequency sounds are filtered out. High-frequency sounds are best heard with the diaphragm firmly applied to the chest wall. In a patient

with a normally situated heart, four major zones of cardiac auscultation are assessed. Aortic valvular events are best heard in the second right intercostal space. Pulmonary valvular events are best heard in the second left interspace. The fourth left interspace is ideal for auscultating tricuspid valvular events, and mitral valvular events are best heard at the cardiac apex or PMI. Because anatomic abnormalities, both congenital and acquired, can alter the location of the heart in the chest, the auscultatory areas may vary among patients. For instance, in patients with emphysema, the heart is shifted downward, and heart sounds may be best heard in the epigastrium. In dextrocardia, the heart lies in the right hemithorax, and the auscultatory regions are reversed. Additionally, auscultation in the axilla or supraclavicular areas or over the thoracic spine may be helpful in some settings, and having the patient lean forward, exhale, or perform various maneuvers may help accentuate particular heart sounds (Table 4-4).

NORMAL HEART SOUNDS

The two major heart sounds heard during auscultation are termed S_1 and S_2 . These heart sounds are high-pitched sounds originating from valve closure (**Web Sounds, normal**). S_1 occurs at the onset of ventricular systole and corresponds to closure of the atrioventricular valves. It is usually perceived as a single sound, although occasionally its two components, M_1 and T_1 , corresponding to closure of the mitral and tricuspid valves, respectively, can be heard. M_1 occurs earlier, is the louder of the two components, and is best heard at the cardiac apex. T_1 is somewhat softer and heard at the left lower sternal border. The second heart sound results from closure of the semilunar valves. The two components, A_2 and P_2 , originating from aortic and pulmonary valve closure, respectively, can be easily distinguished. A_2 is usually louder than P_2 and is best heard at the right upper sternal border. P_2 is loudest over the second left intercostal space. During expiration, the normal S_2 is perceived as a single event. However, during inspiration, the augmented venous return to the right side of the heart and the increased capacitance of the pulmonary vascular bed result in a delay in pulmonic valve closure. In addition, the slightly decreased venous return to the left ventricle results in slightly earlier aortic valve closure. Thus, *physiologic splitting* of the second heart sound, with A_2 preceding P_2 during inspiration, is a normal respiratory event.

Occasionally, additional heart sounds may be heard in normal individuals. A third heart sound (see later discussion) can be heard in normal children and young adults, in whom it is referred to as a *physiologic S_3* ; it is rarely heard after the age of 40 years in healthy individuals (**Web Sounds, S_3**).

A fourth heart sound (S_4) is generated by forceful atrial contraction and is rarely audible in normal young individuals but is fairly common in older individuals (**Web Sounds, S_4**).

A murmur is an auditory vibration usually generated either by abnormally increased flow across a normal valve or by normal flow across an abnormal valve or structure. *Innocent* murmurs are always systolic murmurs, are usually soft and brief, and are by definition not associated with abnormalities of the cardiovascular system. They arise from

Table 4-4 Effects of Physiologic Maneuvers on Auscultatory Events

Maneuver	Major Physiologic Effects	Useful Auscultatory Changes
Respiration	↑ Venous return with inspiration	↑ Right heart murmurs and gallops with inspiration; splitting of S ₂ (see Fig. 4-3)
Valsalva (initial ↑ BP, phase I; followed by ↓ BP, phase II)	↓ BP, ↓ venous return, ↓ LV size (phase II)	↑ HCM ↓ AS, MR MVP click earlier in systole; murmur prolongs
Standing	↑ Venous return ↑ LV size	↑ HCM ↓ AS, MR MVP click earlier in systole; murmur prolongs
Squatting	↑ Venous return ↑ Systemic vascular resistance ↑ LV size	↑ AS, MR, AI ↓ HCM MVP click delayed; murmur shortens
Isometric exercise (e.g., handgrip)	↑ Arterial pressure ↑ Cardiac output	↑ Gallops ↑ MR, AI, MS ↓ AS, HCM
Post PVC or prolonged R-R interval	↑ Ventricular filling ↑ Contractility	↑ AS Little change in MR
Amyl nitrate	↓ Arterial pressure ↑ Cardiac output ↓ LV size	↑ HCM, AS, MS ↓ AI, MR, Austin Flint murmur MVP click earlier in systole; murmur prolongs
Phenylephrine	↑ Arterial pressure ↑ Cardiac output ↓ LV size	↑ MR, AI ↓ AS, HCM MVP click delayed; murmur shortens

↑, Increased intensity; ↓, decreased intensity; AI, aortic insufficiency; AS, aortic stenosis; BP, blood pressure; HCM, hypertrophic cardiomyopathy; LV, left ventricle; MR, mitral regurgitation; MS, mitral stenosis; MVP, mitral valve prolapse; PVC, premature ventricular contraction; R-R, interval between the R waves on an electrocardiogram.

flow across the normal aortic or pulmonic outflow tracts and are present in a large proportion of children and young adults. Murmurs associated with high-flow states (e.g., pregnancy, anemia, fever, thyrotoxicosis, exercise) are not considered innocent, although they are not usually associated with structural heart disease. These are termed *physiologic murmurs*, owing to their association with altered physiologic states. Diastolic murmurs are never *innocent* or *physiologic*.

ABNORMAL HEART SOUNDS

Abnormalities of S₁ and S₂ relate to abnormalities in their intensity (Table 4-5) or abnormalities in their respiratory splitting (Table 4-6). As noted, splitting of the S₁ is normal but not frequently noted. This splitting becomes more apparent with right bundle branch block or with Ebstein anomaly of the tricuspid valve, owing to delay in closure of the tricuspid valve in these conditions (**Web Sounds, Ebstein**). The intensity of S₁ is determined in part by the opening state of the atrioventricular valves at the onset of ventricular systole. If the valves are still widely open, as may occur with tachycardia or a short P-R interval, S₁ will be accentuated. Conversely, in the presence of a long P-R interval, the mitral valve drifts toward a closed position before the onset of ventricular systole, and the subsequent S₁ is soft. The intensity of S₁ may vary in the presence of Mobitz type I heart block, atrioventricular dissociation, and atrial fibrillation when the relationship between atrial and ventricular systole varies. In mitral

stenosis with a pliable valve, the persistent pressure gradient at the end of diastole keeps the mitral valve leaflets relatively open and results in a loud S₁ at the onset of systole. In severe mitral stenosis, when the mitral valve is heavily calcified and has decreased leaflet excursion, S₁ becomes faint or absent (Figs. 4-3 and 4-4).

S₂ may be loud in systemic hypertension, owing to accentuated aortic valve closure (loud A₂), or in pulmonary hypertension, owing to accentuated pulmonic valve closure (loud P₂). When the aortic or pulmonary valves are stenotic, the force of valve closure is decreased, thus A₁ and P₂ become soft or inaudible. In this setting, S₂ may appear to be single; in the setting of aortic stenosis, prolonged left ventricular ejection narrows the normal splitting of S₂; and with severe aortic stenosis, S₂ may become absent altogether as prolonged ejection and its accompanying murmur obscure P₂. Wide splitting of the S₂ with normal respiratory variation occurs when either pulmonic valve closure is delayed (e.g., right bundle branch block, pulmonic stenosis) or aortic valve closure occurs earlier owing to more rapid ejection of left ventricular volume (e.g., mitral regurgitation, ventricular septal defect). Fixed splitting of S₂ without respiratory variation is characteristic of atrial septal defects and also occurs with right ventricular failure (**Web Sounds, ASD**). Paradoxical splitting of S₂ is a reversal of the usual closure sequence of the aortic and pulmonic valves (i.e., P₂ precedes A₂). In this setting, a single S₂ with inspiration and splitting of S₂ with expiration can be heard. This circumstance occurs most commonly when delay occurs in closure of the aortic valve resulting from either delay in electrical conduction to

Table 4-5 Abnormal Intensity of Heart Sounds

	S ₁	A ₂	P ₂
Loud	Short PR interval Mitral stenosis with pliable valve	Systemic hypertension Aortic dilation Coarctation of the aorta	Pulmonary hypertension Thin chest wall
Soft	Long PR interval Mitral regurgitation Poor left ventricular function Mitral stenosis with rigid valve Thick chest wall	Calcific aortic stenosis Aortic regurgitation	Valvular or subvalvular pulmonic stenosis
Varying	Atrial fibrillation Heart block	—	—

Table 4-6 Abnormal Splitting of S₂

Single S ₂	Widely Split S ₂ with Normal Respiratory Variation	Fixed Split S ₂	Paradoxically Split S ₂
—	Right bundle branch block	Atrial septal defect	Left bundle branch block
Pulmonic stenosis	Left ventricular pacing	Severe right ventricular dysfunction	Right ventricular pacing
Systemic hypertension	Pulmonic stenosis	—	Angina, myocardial infarction
Coronary artery disease	Pulmonary embolism	—	Aortic stenosis
Any condition that can lead to paradoxical splitting of S ₂	Idiopathic dilation of the pulmonary artery Mitral regurgitation Ventricular septal defect	—	Hypertrophic cardiomyopathy Aortic regurgitation

the left ventricle (e.g., left bundle branch block) or prolonged mechanical contraction of the left ventricle (e.g., aortic stenosis, hypertrophic cardiomyopathy).

The third heart sound, S₃ (also called the *ventricular diastolic gallop*), is a low-pitched sound occurring shortly after A₂ in mid-diastole and heard best at the cardiac apex with the patient in the left lateral position. A pathologic S₃ is distinguished from a physiologic S₃ by age or the presence of underlying cardiac disease. It is frequently heard with ventricular systolic dysfunction from any cause and likely results either from blood entering the ventricle during the rapid filling phase of diastole or from the impact of the ventricle against the chest wall. Maneuvers that increase venous return accentuate S₃, and maneuvers that decrease venous return make the S₃ softer. An S₃ can also be heard in hyperdynamic states, where it likely results from rapid early diastolic filling. The left ventricular S₃ is best noticed at the cardiac apex, whereas the right ventricular S₃ is heard best at the left lower sternal border and increases in intensity with inspiration. The timing of the S₃ is similar to the sound generated by atrial tumors (*tumor plop*) and constrictive pericarditis (*pericardial knock*) and can also be confused with the *opening snap* of a stenotic mitral valve.

The fourth heart sound, S₄ (also called the *atrial diastolic gallop*), is best heard at the cardiac apex with the bell of the stethoscope. It is a low-pitched sound originating from the active ejection of blood from the atrium into a non-compliant ventricle and is therefore not present in the setting of atrial fibrillation. S₄ is commonly heard in patients

with left ventricular hypertrophy from any cause (e.g., hypertension, aortic stenosis, hypertrophic cardiomyopathy) or acute myocardial ischemia and in hyperkinetic states. Frequently, the S₄ is also palpable at the cardiac apex. S₃ and S₄ are occasionally present in the same patient. In the presence of tachycardia or a prolonged PR interval, the S₃ and S₄ may merge to produce a summation gallop.

The opening of normal cardiac valves is not audible. However, abnormal valves may produce opening sounds. In the presence of a bicuspid aortic valve or in aortic stenosis with pliable valve leaflets, an *ejection sound* is audible as the leaflets open to their maximal extent. A similar ejection sound may originate from a stenotic pulmonic valve, and in this case, the ejection sound decreases in intensity with inspiration. These ejection sounds are high pitched, occur early in systole, and are frequently followed by the typical ejection murmur of aortic or pulmonic stenosis. Ejection sounds are also heard with systemic or pulmonary hypertension, the exact mechanism of which is not clear.

Ejection sounds heard in mid to late systole are referred to as systolic *clicks* and are most commonly associated with mitral valve prolapse. As the redundant mitral valve prolapses and reaches its maximal superior displacement, it produces a high-pitched click. Several clicks may be heard as various parts of the redundant valve prolapse (**Web Sounds, MVP**). Frequently, the click is followed by a mitral regurgitant murmur. Maneuvers that decrease venous return cause the clicks to occur earlier in systole and the murmur to become longer (see Table 4-4).

Figure 4-3 Abnormal heart sounds can be related to abnormal intensity, abnormal presence of a gallop rhythm, or abnormal splitting of S_2 with respiration. ECG, electrocardiogram.

The opening of abnormal mitral or tricuspid valves can also be heard in the presence of rheumatic valvular stenosis, when the sound is referred to as an *opening snap* (**Web Sounds, MS**). The *snap* is heard only if the valve leaflets are pliable and is generated as the leaflets abruptly dome during early diastole. The interval between S_2 and the opening snap is of diagnostic importance; as the stenosis worsens and the atrial pressure increases, the mitral valve

Figure 4-4 The relationship of extra heart sounds to the normal first (S_1) and second (S_2) heart sounds. S_1 is composed of the mitral (M_1) and tricuspid (T_1) closing sounds, although it is frequently perceived as a single sound. S_2 is composed of the aortic (A_2) and pulmonic (P_2) closing sounds, which are usually easily distinguished. A fourth heart sound (S_4) is soft and low pitched and precedes S_1 . A pulmonic or aortic ejection sound (ES) occurs shortly after S_1 . The systolic click (C) of mitral valve prolapse may be heard in mid or late systole. The opening snap (OS) of mitral stenosis is high pitched and occurs shortly after S_2 . A tumor plop or pericardial knock occurs at the same time and can be confused with an OS or an S_3 , which is lower in pitch and occurs slightly later.

Table 4-7 Grading System for Intensity of Murmurs

Grade 1	Barely audible murmur
Grade 2	Murmur of medium intensity
Grade 3	Loud murmur, no thrill
Grade 4	Loud murmur with thrill
Grade 5	Very loud murmur; stethoscope must be on the chest to hear it; may be heard posteriorly
Grade 6	Murmur audible with stethoscope off the chest

opens earlier in diastole, and the interval between the S_2 and the opening snap shortens.

MURMURS

As stated previously, murmurs are a series of auditory vibrations generated when either abnormal blood flow across a normal cardiac structure or normal flow across an abnormal cardiac structure results in turbulent flow. These sounds are longer than the individual heart sounds and can be described by their location, intensity, frequency (pitch), quality, duration, and timing in relation to systole or diastole. The intensity of a murmur is graded on a scale of 1 to 6 (Table 4-7). In general, murmurs of grade 4 or greater are associated with a palpable thrill. The loudness of a murmur does not necessarily correlate with the severity of the underlying abnormality. For instance, flow across a large atrial septal defect is essentially silent, whereas flow across a small ventricular

Figure 4-5 Abnormal sounds and murmurs associated with valvular dysfunction displayed simultaneously with left atrial (LA), left ventricular (LV), and aortic pressure tracings. AVO, aortic valve opening; E, ejection click of the aortic valve; MVO, mitral valve opening; OS, opening snap of the mitral valve. The shaded areas represent pressure gradients across the aortic valve during systole or mitral valve during diastole, characteristic of aortic stenosis and mitral stenosis, respectively.

septal defect is frequently associated with a loud murmur (**Web Sounds, VSD**). Higher-frequency murmurs correlate with a higher velocity of flow at the site of turbulence. Important to note are the pattern or configuration of the murmur (e.g., crescendo, crescendo-decrescendo, decrescendo, plateau) (Fig. 4-5) and the quality of the murmur (e.g., harsh, blowing, rumbling) as well as the location of maximal intensity and the pattern of radiation of the murmur. Various physical maneuvers may help clarify the nature of a particular murmur (see Table 4-4).

Murmurs can be divided into three categories—(1) systolic, (2) diastolic, and (3) continuous (Table 4-8)—and can result from abnormalities on the right or left side of the heart as well as the great vessels. Right-sided murmurs may become significantly louder after inspiration, owing to the resulting augmentation of venous return, whereas left-sided murmurs are relatively unaffected by respiration. Systolic murmurs can be further divided into ejection-type murmurs and regurgitant murmurs. Ejection murmurs reflect turbulent flow across the aortic or pulmonic valve (**Web Sounds, AS and PS**). They begin shortly after S_1 , increase in intensity as the velocity of flow increases, and subsequently decrease in intensity as the velocity falls (crescendo-decrescendo). Examples of ejection-type murmurs include innocent murmurs and the murmurs of aortic sclerosis, aortic stenosis, pulmonic stenosis, and hypertrophic cardiomyopathy. Innocent murmurs and aortic sclerotic murmurs are short in duration and do not radiate (**Web Sounds, benign murmur**). The duration of aortic or pulmonic stenotic murmurs varies depending on the severity of the stenosis (compare **Web Sounds, AS—early** and **AS—late**). With

more severe stenosis, the murmur becomes longer, and the time to peak intensity of the murmur lengthens (i.e., early-, mid-, and late-peaking murmurs). The murmur of aortic stenosis is usually harsh, radiates to the carotid arteries, and at times may radiate to the cardiac apex (Gallavardin phenomenon). The murmur of hypertrophic cardiomyopathy may be confused with aortic stenosis, but it does not radiate to the carotids, and it is the only ejection murmur that becomes louder with decreased venous return. Mitral regurgitation associated with mitral valve prolapse may also show this response, but it is not a typical ejection murmur.

The classic regurgitant systolic murmurs of mitral (MR) and tricuspid regurgitation (TR) last throughout all of systole (holosystolic), are plateau in pattern, and terminate at S_2 (**Web Sounds, MR**). With acute MR, the murmur may be limited to early systole and may be somewhat decrescendo in pattern. When MR is secondary to mitral valve prolapse, it starts in mid to late systole and is preceded by a mitral valve click. Ventricular septal defects may also result in holosystolic murmurs, although a small muscular ventricular septal defect may have a murmur limited to early systole.

Early-diastolic murmurs result from aortic or pulmonic insufficiency and are decrescendo in pattern. The duration of the murmur reflects chronicity: a short murmur is heard in acute aortic insufficiency or mild insufficiency, whereas chronic aortic insufficiency may produce a murmur throughout diastole. A Graham Steell murmur denotes a pulmonic insufficiency murmur in the setting of pulmonary hypertension. Mid-diastolic murmurs classically result from mitral or tricuspid stenosis, are low pitched, and are referred to as

Table 4-8 Classification of Heart Murmurs

Timing	Class	Description	Characteristic Lesions
Systolic	Ejection	Begins in early systole; may extend to mid or late systole Crescendo-decrescendo pattern Often harsh in quality Begins after S ₁ and ends before S ₂	Valvular, supra- and subvalvular aortic stenoses Hypertrophic cardiomyopathy Pulmonic stenosis Aortic or pulmonary artery dilation Malformed but nonobstructive aortic valve ↑ Transvalvular flow (e.g., aortic regurgitation, hyperkinetic states, atrial septal defect, physiologic flow murmur)
	Holosystolic	Extends throughout systole* Relatively uniform in intensity	Mitral regurgitation Tricuspid regurgitation Ventricular septal defect Mitral valve prolapse
	Late	Variable onset and duration, often preceded by a nonejection click	Mitral valve prolapse
Diastolic	Early	Begins with A ₂ or P ₂ Decrescendo pattern with variable duration Often high pitched, blowing	Aortic regurgitation Pulmonic regurgitation
	Mid	Begins after S ₂ , often after an opening snap Low-pitched <i>rumble</i> heard best with bell of stethoscope Louder with exercise and left lateral position Loudest in early diastole	Mitral stenosis Tricuspid stenosis ↑ Flow across atrioventricular valves (e.g., mitral regurgitation, tricuspid regurgitation, atrial septal defect)
	Late	Presystolic accentuation of mid-diastolic murmur	Mitral stenosis Tricuspid stenosis
Continuous	—	Systolic and diastolic components “machinery murmurs”	Patent ductus arteriosus Coronary atrioventricular fistula Ruptured sinus of Valsalva aneurysm into right atrium or ventricle Mammary souffle Venous hum

*Encompasses both the first and second heart sounds.

diastolic rumbles. Similar murmurs may be heard with obstructing atrial myxomas or in the presence of augmented diastolic flow across an unobstructed mitral or tricuspid valve, as occurs with an atrial or ventricular septal defect or with significant MR or TR. Severe, chronic aortic insufficiency may also produce a diastolic rumble, owing to premature closure of the mitral valve (Austin Flint murmur). Late-diastolic murmurs reflect presystolic accentuation of the mid-diastolic murmurs, owing to augmented mitral or tricuspid flow after atrial contraction.

Continuous murmurs are murmurs that last throughout all of systole and continue into at least early diastole. These murmurs are referred to as *machinery murmurs* and are generated by continuous flow from a vessel or chamber with high pressure into a vessel or chamber with low pressure. A patent ductus arteriosus produces the classic continuous murmur (Web Sounds, PDA).

OTHER CARDIAC SOUNDS

Pericardial rubs occur in the setting of pericarditis. These rubs produce coarse, scratching sounds heard best at the left

sternal border with the patient leaning forward and holding his or her breath at end expiration. The classic rub has three components corresponding to atrial systole, ventricular systole, and ventricular diastole, although frequently only one or two of the components are audible (Web Sounds, **pericardial rubs**). Localized irritation of the surrounding pleura may result in an associated pleural friction rub (pleuropericardial rub), which varies with respiration.

Continuous venous murmurs, or venous *hums*, are almost universally present in children. They are also frequent in adults, especially during pregnancy or in the setting of thyrotoxicosis or anemia. These murmurs are best heard at the base of the neck with the patient's head turned to the opposite direction and can be eliminated by gentle pressure over the vein.

PROSTHETIC HEART SOUNDS

Prosthetic valves produce characteristic auscultatory findings. Porcine or bovine bioprosthetic valves produce heart sounds that are similar to native valve sounds; however, because these valves are smaller than the native valves that

they replace, they almost always have an associated murmur (systolic ejection murmur when placed in the aortic position and diastolic rumble when placed in the mitral position). Mechanical valves result in crisp, high-pitched sounds related to valvular opening and closure. With ball-in-cage valves (e.g., Starr-Edwards valves, the opening sound is louder than the closure sound. With all other mechanical

valves (e.g., Björk-Shiley valves, St. Jude valves), the closure sound is louder. These valves also produce an ejection-type murmur. Listening for all of the expected prosthetic sounds in patients with prosthetic valves is important because dysfunction of these valves may first be suggested by a change in the intensity or quality of the heart sounds or the development of a new or changing murmur.

Prospectus for the Future

Thanks to advances in chip technology, the essential art of cardiac auscultation is making a resurgence with the use of the computerized heart sound phonocardiography or acoustic cardiography. Students and experienced practitioners alike will be able to use an algorithm for predicting left ventricular dysfunction based on the characteristics of the S_3 and S_4 heart sounds

and biomarkers of disease compensation and progression. Personal digital assistants, smartphones, and other technologies will make inroads for more accurate diagnosis during initial screening evaluation and bedside management of patients with cardiovascular disease.

Diagnostic Tests and Procedures in the Patient with Cardiovascular Disease

Sheldon E. Litwin

Chest Radiography

The chest radiograph is an integral part of the cardiac evaluation and gives valuable information regarding structure and function of the heart, lungs, and great vessels. A routine examination includes posteroanterior and lateral projections (Fig. 5-1).

In the posteroanterior view, cardiac enlargement may be present when the transverse diameter of the cardiac silhouette is greater than one half the transverse diameter of the thorax. The heart may appear falsely enlarged when it is displaced horizontally, such as with poor inflation of the lungs, and if the film is an anteroposterior projection, which magnifies the heart shadow. Left atrial enlargement is suggested when the left-sided heart border is straightened or bulges toward the left. In addition, the main bronchi may be widely splayed, and a circular opacity or *double density* within the cardiac silhouette may be seen. Right atrial enlargement may be present when the right-sided heart border bulges toward the right. Left ventricular enlargement results in downward and lateral displacement of the apex. A rounding of the displaced apex suggests ventricular hypertrophy. Right ventricular enlargement is best assessed in the lateral view and may be present when the right ventricular border occupies more than one third of the retrosternal space between the diaphragm and thoracic apex.

The aortic arch and thoracic aorta may become dilated and tortuous in patients with severe atherosclerosis, long-standing hypertension, and aortic dissection. Dilation of the proximal pulmonary arteries may occur when pulmonary pressures are elevated and pulmonary vascular resistance is increased. Disease states associated with increased pulmonary artery flow and normal vascular resistance, such as

atrial or ventricular septal defects, may result in dilation of the proximal and distal pulmonary arteries.

Pulmonary venous congestion secondary to elevated left ventricular heart pressures results in redistribution of blood flow in the lungs and prominence of the apical vessels. Transudation of fluid into the interstitial space may result in fluid in the fissures and along the horizontal periphery of the lower lung fields (Kerley B lines). As venous pressures further increase, fluid collects within the alveolar space, which early on collects preferentially in the inner two thirds of the lung fields, resulting in a characteristic *butterfly* appearance.

Fluoroscopy or plain films may identify abnormal calcification involving the pericardium, coronary arteries, aorta, and valves. In addition, fluoroscopy can be instrumental in evaluating the function of mechanical prosthetic valves.

Specific radiographic signs of congenital and valvular diseases are discussed in their respective sections.

Electrocardiography

The electrocardiogram (ECG) represents the electrical activity of the heart recorded by skin electrodes. This wave of electrical activity is represented as a sequence of deflections on the ECG (Fig. 5-2). The horizontal scale represents time such that, at a standard paper speed of 25 mm/second, each small box (1 mm) represents 0.04 second, and each large box (5 mm) represents 0.20 second. The vertical scale represents amplitude (10 mm = 1 mV). The heart rate can be estimated by dividing the number of large boxes between complexes (R-R interval) into 300.

In the normal heart, the electrical impulse originates in the sinoatrial (SA) node and is conducted through the atria.

Figure 5-1 Schematic illustration of the parts of the heart, whose outlines can be identified on a routine chest radiograph. **A**, Posteroanterior chest radiograph. **B**, Lateral chest radiograph. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Figure 5-2 Normal electrocardiographic complex with labeling of waves and intervals.

Given that depolarization of the SA node is too weak to be detected on the surface ECG, the first, low-amplitude deflection on the surface ECG reflects atrial activation and is termed the *P wave*. The interval between the onset of the P wave and the next rapid deflection (QRS complex) is known as the PR interval and primarily represents the time taken for the impulse to travel through the atrioventricular (AV) node. The normal PR segment ranges from 0.12 to 0.20 second. A PR interval greater than 0.20 second defines AV nodal block.

After the wave of depolarization has moved through the AV node, the ventricular myocardium is depolarized in a sequence of four phases. First, the interventricular septum depolarizes from left to right. This phase is followed by

depolarization of the right ventricle and inferior wall of the left ventricle, then the apex and central portions of the left ventricle, and, finally, the base and the posterior wall of the left ventricle. Ventricular depolarization results in a high-amplitude complex on the surface ECG known as the *QRS complex*. The first downward deflection of this complex is the Q wave, the first upward deflection is the R wave, and the subsequent downward deflection is the S wave. In some individuals, a second upward deflection may be present after the S wave and is termed *R prime* (*R'*). Normal duration of the QRS complex is less than 0.10 second. Complexes greater than 0.12 second are usually secondary to some form of interventricular conduction delay.

The isoelectric segment after the QRS complex is the ST segment and represents a brief period during which relatively little electrical activity occurs in the heart. The junction between the end of the QRS complex and the beginning of the ST segment is the J point. The upward deflection after the ST segment is the T wave and represents ventricular repolarization. The QT interval, which reflects the duration and transmural gradient of ventricular depolarization and repolarization, is measured from the onset of the QRS complex to the end of the T wave. The QT interval varies with heart rate, but for rates between 60 and 100 beats/minute, the normal QT interval ranges from 0.35 to 0.44 second. For heart rates outside this range, the QT interval can be corrected by the following formula:

$$QT_c = QT \text{ (sec)} / R\text{-R interval}^{1/2} \text{ (sec)}$$

In some individuals, a U wave (of varying amplitude) may be noted after the T wave, the cause of which is unknown.

The standard ECG consists of 12 leads: six limb leads (I, II, III, aVR, aVL, and aVF) and six chest or precordial leads (V_1 to V_6) (Fig. 5-3). The electrical activity recorded in each

Figure 5-3 Normal 12-lead electrocardiogram.

lead represents the direction and magnitude (vector) of the electrical force as seen from that particular lead position. Electrical activity directed toward a particular lead is represented as an upward deflection, and an electrical impulse directed away from a particular lead is represented as a downward deflection. Although the overall direction of electrical activity can be determined for any of the waveforms previously described, the mean QRS axis is the most clinically useful and is determined by examining the six limb leads. Figure 5-4 illustrates Einthoven triangle and the polarity of each of the six limb leads of the standard ECG. Skin electrodes are attached to both arms and legs, with the right leg serving as the ground. Leads I, II, and III are bipolar leads and represent electrical activity between two leads: lead I represents electrical activity between the right and left arms (left arm positive), lead II between the right arm and left leg (left leg positive), and lead III between the left arm and left leg (left leg positive). Leads aVR, aVL, and aVF are designated the *augmented leads*. With these leads, the QRS will be positive or have a predominant upward deflection when the electrical forces are directed toward the right arm for aVR, left arm for aVL, and left leg for aVF. These six leads form a hexaxial frontal plane of 30-degree arc intervals. The normal QRS axis ranges from -30 to $+90$ degrees. An axis more negative than -30 defines left axis deviation, and an axis greater than $+90$ defines right axis deviation. In general, a positive QRS complex in leads I and aVF suggests a normal QRS axis between 0 and 90 degrees.

Figure 5-4 Hexaxial reference figure for frontal plane axis determination, indicating values for abnormal left and right QRS axis deviations.

Figure 5-5 **A**, Left ventricular hypertrophy as seen on an electrocardiographic recording. Characteristic findings include increased QRS voltage in precordial leads (deep S in lead V₂ and tall R in lead V₅) and downsloping ST depression and T-wave inversion in lateral precordial leads (*strain pattern*) and leftward axis. **B**, Right ventricular hypertrophy with tall R wave in right precordial leads, downsloping ST depression in precordial leads (RV strain), right axis deviation, and evidence of right atrial enlargement.

The six standard precordial leads (V₁ to V₆) are attached to the anterior chest wall (Fig. 5-5). Lead placement should be as follows: V₁—fourth intercostal space, right sternal border; V₂—fourth intercostal space, left sternal border; V₃—midway between V₂ and V₄; V₄—fifth intercostal space, left mid-clavicular line; V₅—level with V₄, left anterior axillary line; V₆—level with V₄, left mid-axillary line. The chest leads should be placed under the breast. Electrical activity directed toward these leads results in a positive deflection on the ECG tracing. Leads V₁ and V₂ are closest to the right ventricle and interventricular septum, and leads V₅ and V₆ are closest to the anterior and anterolateral walls of the left ventricle. Normally, a small R wave occurs in lead V₁ reflecting septal depolarization and a deep S wave reflecting predominantly left ventricular activation. From V₁ to V₆, the R wave becomes larger (and the S

wave smaller) because the predominant forces directed at these leads originate from the left ventricle. The transition from a predominant S wave to a predominant R wave usually occurs between leads V₃ and V₄. Right-sided chest leads are used to look for evidence of right ventricular infarction. ST-segment elevation in V_{4R} has the best sensitivity and specificity for making this diagnosis. For right-sided leads, standard V₁ and V₂ are switched, and V_{3R} to V_{6R} are placed mirror image to the standard left-sided chest leads. Some groups have advocated the use of posterior leads to increase the sensitivity for diagnosing lateral and posterior wall infarction or ischemia (areas that are often deemed to be *electrically silent* on traditional 12-lead ECGs). To do this, six additional leads are placed in the fifth intercostal space continuing posteriorly from the position of V₆.

Abnormal Electrocardiographic Patterns

CHAMBER ABNORMALITIES AND VENTRICULAR HYPERTROPHY

The P wave is normally upright in leads I, II, and F; inverted in aVR; and biphasic in V₁. Left atrial abnormality (defined as enlargement, hypertrophy, or increased wall stress) is characterized by a wide P wave in lead II (0.12 second) and a deeply inverted terminal component in lead V₁ (1 mm). Right atrial abnormality is present when the P waves in the limb leads are peaked and 2.5 mm or more in height.

Left ventricular hypertrophy may result in increased QRS voltage, slight widening of the QRS complex, late intrinsicoid deflection, left axis deviation, and abnormalities of the ST-T segments (see Fig. 5-5A). Multiple criteria with variable sensitivity and specificity for detecting left ventricular hypertrophy are available. The most frequently used criteria are given in Table 5-1.

Right ventricular hypertrophy is characterized by tall R waves in leads V₁ through V₃; deep S waves in leads I, aVL, V₅, and V₆; and right axis deviation (see Fig. 5-5B). In patients with chronically elevated pulmonary pressures, such as with chronic lung disease, a combination of ECG abnormalities reflecting a right-sided pathologic condition may be present and include right atrial abnormality, right ventricular hypertrophy, and right axis deviation. In patients with acute pulmonary embolus, ECG changes may suggest right

ventricular strain and include right axis deviation; incomplete or complete right bundle branch block; S waves in leads I, II, and III; and T-wave inversions in leads V₁ through V₃.

INTERVENTRICULAR CONDUCTION DELAYS

The ventricular conduction system consists of two main branches, the right and left bundles. The left bundle further divides into the anterior and posterior fascicles. Conduction block can occur in either of the major branches or in the fascicles (Table 5-2).

Fascicular block results in a change in the sequence of ventricular activation but does not prolong overall conduction time (QRS duration remains < 0.10 second). Left anterior fascicular block is a relatively common ECG abnormality and is sometimes associated with right bundle branch block. This conduction abnormality is present when extreme left axis deviation occurs (more negative than -45 degrees); when the R wave is greater than the Q wave in leads I and aVL; and when the S wave is greater than the R wave in leads II, III, and aVF. Left posterior fascicular block is uncommon but is associated with right axis deviation (>90 degrees); small Q waves in leads II, III, and aVF; and small R waves in leads I and aVL. The ECG findings associated with fascicular blocks can be confused with myocardial infarction (MI). For example, with left anterior fascicular block, the prominent QS deflection in leads V₁ and V₂ can mimic an anteroseptal MI, and the rS deflection in leads II, III, and aVF can be confused with an inferior MI. Similarly, the rS deflection in leads I and aVL in left posterior fascicular block may be confused with a high lateral infarct. The presence of abnormal ST- and T-wave segments and pathologic Q waves (see

Table 5-1 Electrocardiographic Manifestations of Atrial Abnormalities and Ventricular Hypertrophy

Left Atrial Abnormality

P-wave duration ≥ 0.12 second
Notched, slurred P wave in leads I and II
Biphasic P wave in lead V₁ with a wide, deep, negative terminal component

Right Atrial Abnormality

P-wave duration ≤ 0.11 second
Tall, peaked P waves of ≥ 2.5 mm in leads II, III, and aVF

Left Ventricular Hypertrophy

Voltage criteria
R wave in lead aVL ≥ 12 mm
R wave in lead I ≥ 15 mm
S wave in lead V₁ or V₂ + R wave in lead V₅ or V₆ ≥ 35 mm
Depressed ST segments with inverted T waves in the lateral leads
Left axis deviation
QRS duration ≥ 0.09 second
Left atrial enlargement

Right Ventricular Hypertrophy

Tall R waves over right precordium (R:S ratio in lead V₁ > 1.0)
Right axis deviation
Depressed ST segments with inverted T waves in leads V₁ to V₃
Normal QRS duration (if no right bundle branch block)
Right atrial enlargement

Table 5-2 Electrocardiographic Manifestations of Fascicular and Bundle Branch Blocks

Left Anterior Fascicular Block

QRS duration ≤ 0.1 second
Left axis deviation (more negative than -45 degrees)
rS pattern in leads II, III, and aVF
qR pattern in leads I and aVL

Right Posterior Fascicular Block

QRS duration ≤ 0.1 second
Right axis deviation (+90 degrees or greater)
qR pattern in leads II, III, and aVF
rS pattern in leads I and aVL
Exclusion of other causes of right axis deviation (chronic obstructive pulmonary disease, right ventricular hypertrophy)

Left Bundle Branch Block

QRS duration ≥ 0.12 second
Broad, slurred, or notched R waves in lateral leads (I, aVL, V₅, and V₆)
QS or rS pattern in anterior precordium leads (V₁ and V₂)
ST-T-wave vectors opposite to terminal QRS vectors

Right Bundle Branch Block

QRS duration ≥ 0.12 second
Large R' wave in lead V₁ (rsR')
Deep terminal S wave in lead V₆
Normal septal Q waves
Inverted T waves in leads V₁ and V₂

“Myocardial Ischemia and Infarction” later) are helpful findings to differentiate MI from a fascicular block.

Bundle branch blocks are associated with QRS duration longer than 120 milliseconds. In left bundle branch block, depolarization proceeds down the right bundle, across the interventricular septum from right to left, and then to the left ventricle. Characteristic ECG findings include a wide QRS complex; a broad R wave in leads I, aVL, V₅, and V₆; a deep QS wave in leads V₁ and V₂; and ST depression and T-wave inversion opposite the QRS deflection (Fig. 5-6A). Given the abnormal sequence of ventricular activation with left bundle branch block, many ECG abnormalities, such as Q-wave MI and left ventricular hypertrophy, are difficult to evaluate. In some cases, acute MI is still apparent even with LBBB. Left bundle branch block almost always indicates the presence of underlying myocardial disease (most commonly fibrosis due to ischemic injury or hypertrophy). With right bundle branch block, the interventricular septum depolarizes normally from left to right, and therefore the initial QRS deflection remains unchanged. As a result, ECG abnormalities such as Q-wave MI can still be interpreted. After septal activation, the left ventricle depolarizes,

followed by the right ventricle. The ECG is characterized by a wide QRS complex; a large R' wave in lead V₁ (R-S-R'); and deep S waves in leads I, aVL, and V₆, representing delayed right ventricular activation (see Fig. 5-6B). Although right bundle branch block may be associated with underlying cardiac disease, it may also appear as a normal variant or be seen intermittently when heart rate is elevated. In the latter case, it is often referred to as *rate-related bundle branch block*.

MYOCARDIAL ISCHEMIA AND INFARCTION

Myocardial ischemia and MI may be associated with abnormalities of the ST segment, T-wave, and QRS complex. Myocardial ischemia primarily affects repolarization of the myocardium and is often associated with horizontal or down-sloping ST-segment depression and T-wave inversion. These changes may be transient, such as during an anginal episode or an exercise stress test, or may be long-lasting in the setting of unstable angina or MI. T-wave inversion without ST-segment depression is a nonspecific finding and must be correlated with the clinical setting.

Figure 5-6 A, Left bundle branch block (LBBB). B, Right bundle branch block (RBBB). Criteria for bundle branch block are summarized in Table 5-2.

A

B

Figure 5-7 A, Evolutionary changes in a posteroinferior myocardial infarction. Control tracing is normal. The tracing recorded 2 hours after onset of chest pain demonstrated development of early Q waves, marked ST-segment elevation, and hyperacute T waves in leads II, III, and aVF. In addition, a larger R wave, ST-segment depression, and negative T waves have developed in leads V₁ and V₂. These are early changes indicating acute posteroinferior myocardial infarction. The 24-hour tracing demonstrates evolutionary changes. In leads II, III, and aVF, the Q wave is larger, the ST segments have almost returned to baseline, and the T wave has begun to invert. In leads V₁ to V₂, the duration of the R wave now exceeds 0.04 seconds, the ST segment is depressed, and the T wave is upright. (In this example, ECG changes of true posterior involvement extend past lead V₂; ordinarily, only leads V₁ and V₂ may be involved.) Only minor further changes occur through the 8-day tracing. Finally, 6 months later, the ECG illustrates large Q waves, isoelectric ST segments, and inverted T waves in leads II, III, and aVF and large R waves, isoelectric ST segment, and upright T waves in leads V₁ and V₂, indicative of an *old* posteroinferior myocardial infarction. **B**, Example of an ECG from a patient with an underlying LBBB who experienced an acute anterior myocardial infarction. Characteristic ST segment elevation and hyperacute T-waves are seen in leads V1-V6 and leads I and AVL despite the presence of the LBBB. Note that this is not always the case, as a patient with typical symptoms and a LBBB as well as no definite ischemic ST segment elevations should still be treated as if the individual is having an MI or acute coronary syndrome.

Localized ST-segment elevation suggests more extensive myocardial injury and is often associated with acute MI (see Fig. 5-7). Vasospastic or Prinzmetal angina may be associated with reversible ST-segment elevation without MI. ST-segment elevation may occur in other settings not related to acute ischemia or infarction. Persistent, localized ST-segment elevation in the same leads as pathologic Q waves is consistent with a ventricular aneurysm. Acute pericarditis is associated with diffuse ST-segment elevation and PR depression. Diffuse J-point elevation in association with upward-coving ST segments is a normal variant common among young men and is often referred to as *early repolarization*.

The presence of a Q wave is one of the diagnostic criteria used to verify MI. Infarcted myocardium is unable to conduct electrical activity, and therefore electrical forces will be directed away from the surface electrode overlying the infarcted region, resulting in a Q wave on the surface ECG. Knowing which region of the myocardium each lead represents enables the examiner to localize the area of infarction (Table 5-3). A pathologic Q wave has a duration of greater than or equal to 0.04 second or a depth one fourth or more the height of the corresponding R wave.

Not all MIs result in the formation of Q waves. In addition, small R waves can return many weeks to months after an MI.

Abnormal Q waves, or *pseudoinfarction*, may also be associated with nonischemic cardiac disease, such as ventricular pre-excitation, cardiac amyloidosis, sarcoidosis, idiopathic or hypertrophic cardiomyopathy, myocarditis, and chronic lung disease.

ABNORMALITIES OF THE ST SEGMENT AND T WAVE

A number of drugs and metabolic abnormalities may affect the ST segment and T wave (Fig. 5-8). Hypokalemia may result in prominent U waves in the precordial leads and prolongation of the QT interval. Hyperkalemia may result in tall, peaked T waves. Hypocalcemia typically lengthens the QT interval, whereas hypercalcemia shortens it. A commonly used cardiac medication, digoxin, often results in diffuse, scooped ST-segment depression. Minor or *non-specific* ST-segment and T-wave abnormalities may be present in many patients and have no definable cause. In these instances, the physician must determine the significance of the abnormalities based on the clinical setting.

Several excellent websites containing examples of normal and abnormal ECGs are available.

Long-Term Ambulatory Electrocardiographic Recording

Ambulatory ECG (Holter monitoring) is a widely used, noninvasive method to evaluate cardiac arrhythmias and conduction disturbances over an extended period and to detect electrical abnormalities that may be brief or transient. With this approach, ECG data from two to three surface leads are stored on a tape recorder that the patient wears for a minimum of 24 to 48 hours. The recorders have both patient-activated event markers and time markers so that any abnormalities can be correlated with the patient's symptoms or time of day. These data can then be printed in a standard, real-time ECG format for review.

For patients with intermittent or rare symptoms, an event recorder, which can be worn for several weeks, may be helpful in identifying the arrhythmia. The simplest device is a small, hand-held monitor that is applied to the chest wall when symptoms occur. The ECG data are recorded and can be transmitted later by telephone to a monitoring center for analysis. A more sophisticated system uses a wrist recorder that allows continuous-loop storage of 4 to 5 minutes of ECG data from one lead. When the patient activates the system, ECG data preceding the event and for 1 to 2 minutes after the event are recorded and stored for further analysis. With both of these devices, the patient must be physically able to activate the recorder during the episode to store the ECG data. Implantable recording devices (subcutaneous) are sometimes used to diagnose infrequent events.

STRESS TESTING

Stress testing is an important noninvasive tool for evaluating patients with known or suggested coronary artery disease (CAD). During exercise, the increased demand for oxygen by the working skeletal muscles is met by increases in heart rate and cardiac output. In patients with significant CAD, the increase in myocardial oxygen demand cannot be met by an increase in coronary blood flow. As a result, myocardial ischemia may occur, resulting in chest pain and characteristic ECG abnormalities. These changes, combined with the hemodynamic response to exercise, can give useful diagnostic and prognostic information in the patient with cardiac abnormalities. The most frequent indications for stress testing include establishing a diagnosis of CAD in patients

Table 5-3 Electrocardiographic Localization of Myocardial Infarction

Infarct Location	Leads Depicting Primary Electrocardiographic Changes	Likely Vessel* Involved
Inferior	II, III, aVF	RCA
Septal	V ₁ , V ₂	LAD
Anterior	V ₃ , V ₄	LAD
Anteroseptal	V ₁ to V ₄	LAD
Extensive anterior	I, aVL, V ₁ to V ₆	LAD
Lateral	I, aVL, V ₅ to V ₆	CIRC
High lateral	I, aVL	CIRC
Posterior [†]	Prominent R in V ₁	RCA or CIRC
Right ventricular [‡]	ST elevation in V ₁ and, more specifically, V ₄ R in setting of inferior infarction	RCA

*This is a generalization; variations occur.

[†]Usually in association with inferior or lateral infarction.

[‡]Usually in association with inferior infarction.

CIRC, circumflex artery; LAD, left anterior descending coronary artery; RCA, right coronary artery.

Figure 5-8 Metabolic and drug influences on the electrocardiographic recording.

with chest pain, assessing prognosis and functional capacity in patients with chronic stable angina or after an MI, evaluating exercise-induced arrhythmias, and assessing for ischemia after a revascularization procedure.

The most common form of stress testing uses continuous ECG monitoring while the patient walks on a treadmill.

With each advancing stage, the speed and incline of the belt increases, thus increasing the amount of work the patient performs. The commonly used Bruce protocol employs 3 minutes of exercise at each stage. The modified Bruce protocol incorporates two beginning stages with slower speeds and lesser inclines than are used in the standard Bruce pro-

tol. The modified Bruce or similar protocols are generally used for older, markedly overweight, and unstable or more debilitated patients. Exercise testing may also be performed using a bicycle or arm ergometer. The stress test is generally deemed adequate if the patient achieves 90% of his or her predicted maximal heart rate, which is equal to 220 minus the patient's age. Indications for stopping the test include fatigue, severe hypertension (>220 mm Hg systolic), worsening angina during exercise, developing marked or widespread ischemic ECG changes, significant arrhythmias, or hypotension. The diagnostic accuracy of stress testing is improved with adjunctive echocardiography or radionuclide imaging. Contraindications to stress testing include unstable angina, acute MI, poorly controlled hypertension (blood pressure >220/110 mm Hg), severe aortic stenosis (valve area < 1.0 cm²), and decompensated congestive heart failure. In the era of reperfusion therapy (thrombolytic and percutaneous interventions), for acute coronary syndromes or acute MI, little role exists for the pre-discharge submaximal stress test that was commonly used in the past.

The diagnostic accuracy of the exercise test is dependent on the pre-test likelihood of CAD in a given patient, the sensitivity and specificity of the test results in that patient population, and the ECG criteria used to define a positive test. Clinical features that are most useful at predicting important angiographic coronary disease before exercise testing include advanced age, male sex, and the presence of typical (vs. atypical) anginal chest pain. The diagnostic accuracy and cost-effectiveness of exercise testing is best in patients with an intermediate risk for CAD (30% to 70%) and when ischemic ECG changes are accompanied by chest pain during exercise. Exercise testing is less cost-effective in diagnosing CAD in a patient with classic symptoms of angina because a positive test will not significantly increase the post-test probability of CAD, and a negative test would likely represent a false-negative result. Nonetheless, prognostic information and objective information about the efficacy of pharmacologic therapy may still be obtained. Similarly, exercise testing in young patients with atypical chest pain may not be diagnostically useful, given that an abnormal test result will likely represent a false-positive test and will not significantly increase the post-test probability of CAD.

The normal physiologic response to exercise is an increase in heart rate and systolic and diastolic blood pressures. The ECG will maintain normal T-wave polarity, and the ST segment will remain unchanged or, if depressed, will have a rapid upstroke back to baseline. An ischemic ECG response to exercise is defined as (1) 1.5 mm of up-sloping ST-segment depression measured 0.08 second past the J point, (2) at least 1 mm of horizontal ST depression, or (3) 1 mm of down-sloping ST-segment depression measured at the J point. Given the large amount of artifact on the ECG that may occur with exercise, these changes must be present in at least three consecutive depolarizations. Other findings suggestive of more extensive CAD include early onset of ST depression (6 minutes); marked, down-sloping ST depression (>2 mm), especially if present in more than five leads; ST changes persisting into recovery for more than 5 minutes; and failure to increase systolic blood pressure to 120 mm Hg or more or a sustained decrease of 10 mm Hg or more below baseline.

The ECG is not diagnostically useful in the presence of left ventricular hypertrophy, left bundle branch block, Wolff-Parkinson-White syndrome, or chronic digoxin therapy. In these instances, nuclear or echocardiographic imaging is needed to diagnose ischemia. In patients who are unable to exercise, pharmacologic stress testing with myocardial imaging has been shown to have sensitivity and specificity for detecting CAD equal to those of exercise stress imaging. Intravenous dipyridamole and adenosine and newer selective adenosine A2A receptor agonists are coronary vasodilators that result in increased blood flow in normal arteries without significantly changing flow in diseased vessels. The resulting heterogeneity in blood flow can be detected by nuclear imaging techniques and the regions of myocardium supplied by diseased vessels identified. Another commonly used technique to evaluate for ischemia is dobutamine-stress echocardiography. Dobutamine is an inotropic agent that increases myocardial oxygen demand by increasing heart rate and contractility. The echocardiogram is used to monitor for ischemia, which is defined as new or worsening wall motion abnormalities during the infusion. Demonstrating improvement in wall thickening with low-dose dobutamine suggests that there is myocardial viability of abnormal segments (i.e., segments that are hypokinetic or akinetic at baseline).

ECHOCARDIOGRAPHY

Echocardiography is a widely used, noninvasive technique in which sound waves are used to image cardiac structures and evaluate blood flow. A piezoelectric crystal housed in a transducer placed on the patient's chest wall produces ultrasound waves. As the sound waves encounter structures with different acoustic properties, some of the ultrasound waves are reflected back to the transducer and recorded. Ultrasound waves emitted from a single, stationary crystal produce an image of a thin slice of the heart (M mode), which can then be followed through time. Steering the ultrasound beam across a 90-degree arc multiple times per second creates two-dimensional imaging (Fig. 5-9). Transthoracic echocardiography is safe, simple, fast, and relatively inexpensive. Hence it is the most commonly used test to assess cardiac size, structure, and function. The development of three-dimensional echocardiographic imaging techniques offers great promise for more accurate measurements of chamber volumes and mass as well as the assessment of geometrically complex anatomy and valvular lesions (**Web Fig. 5-1** shows a three-dimensional image).

Doppler echocardiography allows assessment of both direction and velocity of blood flow within the heart and great vessels. When ultrasound waves encounter moving red blood cells, the energy reflected back to the transducer is altered. The magnitude of this change (Doppler shift) is represented as velocity on the echocardiographic display and can be used to determine whether the blood flow is normal or abnormal (Fig. 5-10). In addition, the velocity of a particular jet of blood can be converted to pressure using the modified Bernoulli equation ($\Delta P \cong 4v^2$). This process allows for the assessment of pressure gradients across valves or between chambers. Color Doppler imaging allows visualization of blood flow through the heart by assigning a color to the red blood cells based on their velocity and direction

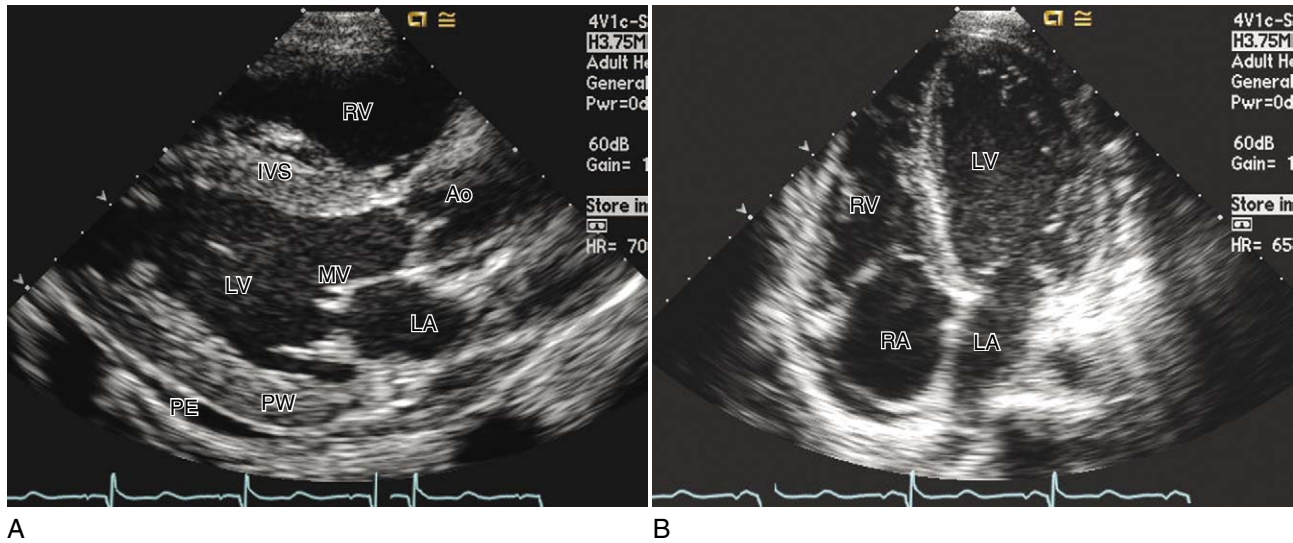

Figure 5-9 Portions of standard two-dimensional echocardiograms (A, parasternal long-axis view; B, apical four-chamber view) showing the major cardiac structures. Ao, aorta; IVS, interventricular septum; LA, left atrium; LV, left ventricle; MV, mitral valve; PE, pericardial effusion; PW, posterior LV wall; RV, right ventricle. See **Web Figure 5-3** for a moving image of a two-dimensional echocardiogram. (Image courtesy of Sheldon E. Litwin, MD, Division of Cardiology, University of Utah.)

Figure 5-10 Doppler tracing in a patient with aortic stenosis and regurgitation. The velocity of systolic flow is related to the severity of obstruction.

(Fig. 5-11; **Web Fig. 5-2**). By convention, blood moving away from the transducer is represented in shades of blue, and blood moving toward the transducer is represented in red. Color Doppler imaging is particularly useful in identifying valvular insufficiency and abnormal shunt flow between chambers. Recently, the use of Doppler techniques to record myocardial velocities or strain rates has provided new insight into myocardial function and hemodynamics.

Two-dimensional echocardiography and Doppler echocardiography are often used in conjunction with exercise or pharmacologic stress testing. Although variability occurs among studies, the sensitivity of stress echocardiography is apparently slightly lower, but the specificity is slightly

higher, compared with myocardial perfusion imaging with nuclear tracers. The overall cost-effectiveness of stress echocardiography is estimated to be significantly better than nuclear perfusion imaging because of the lower cost.

The development of ultrasound contrast agents composed of microbubbles that are small enough to transit through the pulmonary circulation has greatly improved the ability to use ultrasound to image obese patients, patients with lung disease, and those with otherwise difficult acoustic windows (Fig. 5-12; **Web Fig. 5-3** shows a dynamic contrast echocardiographic image). These agents are also being developed as molecular imaging agents by complexing the bubbles to

compounds that can selectively bind to the target site of interest (i.e., clots, neovessels).

Transesophageal echocardiography (TEE) allows two-dimensional and Doppler imaging of the heart through the esophagus by having the patient swallow a gastroscope mounted with an ultrasound crystal within its tip. Given

the close proximity of the esophagus to the heart, high-resolution images can be obtained, especially of the left atrium, mitral valve apparatus, and aorta. TEE is particularly useful in diagnosing aortic dissection, endocarditis, prosthetic valve dysfunction, and left atrial masses (Fig. 5-13; Web Fig. 5-4).

Figure 5-11 Color Doppler recording demonstrating severe mitral regurgitation. The regurgitant jet seen in the left atrium (LA) is represented in blue because blood flow is directed away from the transducer. The yellow components are the mosaic pattern traditionally assigned to turbulent or high-velocity flow. The arrow points to the hemisphere of blood accelerating proximal to the regurgitant orifice (proximal isovelocity surface area [PISA]). The size of the PISA can be used to help grade the severity of regurgitation. LA, left atrium; LV, left ventricle. See Web Figure 5-2 for a dynamic echocardiographic image in a patient with mitral regurgitation. (Image courtesy of Sheldon E. Litwin, MD, Division of Cardiology, University of Utah.)

NUCLEAR CARDIOLOGY

Radionuclide imaging of the heart allows quantification of left ventricular size and systolic function as well as myocardial perfusion. With radionuclide ventriculography, the patient's red blood cells are labeled with a small amount of a radioactive tracer (usually technetium-99m). Left ventricular function can then be assessed by one of two methods. With the first-pass technique, radiation emitted by the tagged red blood cells as they initially flow through the heart is detected by a gamma camera positioned over the patient's chest. With the gated equilibrium method, or multigated acquisition (MUGA) method, the tracer is allowed to achieve an equilibrium distribution throughout the blood pool before count acquisition begins. This second method improves the resolution of the ventriculogram. For both techniques, the gamma camera can be gated to the ECG, allowing for determination of the total emitted end-diastole counts (EDC) and end-systole counts (ESC). Left ventricular ejection fraction (LVEF) can then be calculated as follows:

$$LVEF = (EDC - ESC) / EDC$$

If scintigraphic information is collected throughout the cardiac cycle, a computer-generated image of the heart can be displayed in a cinematic fashion, allowing for the assessment of wall motion.

Myocardial perfusion imaging is usually performed in conjunction with exercise or pharmacologic (vasodilator) stress testing. Persantine, or more commonly adenosine, is

Figure 5-12 Echocardiogram enhanced with intravenous ultrasound contrast agent (A, apical four-chamber view; B, apical long-axis view). Highly echo-reflectant microbubbles make the left ventricular cavity appear white, whereas the myocardium appears dark. See Web Figure 5-3 for a dynamic image of echocardiographic contrast. (Image courtesy of Sheldon E. Litwin, MD, Division of Cardiology, University of Utah.)

Figure 5-13 Transesophageal echocardiogram demonstrating the presence of a vegetation adherent to the ring of a bi-leaflet tilting-disk mitral valve prostheses (**A**, systole, leaflets closed with vegetation seen in left atrium; **B**, diastole, leaflets open, vegetation prolapsing into left ventricle). Transesophageal echocardiography is the diagnostic test of choice for assessing prosthetic mitral valves because the esophageal window allows unimpeded views of the atrial surface of the valve. LA, left atrium; LV, left ventricle; MV, prosthetic mitral valve disks; V, vegetation. See **Web Figure 5-4** for a dynamic transesophageal echocardiographic image. (Image courtesy of Sheldon E. Litwin, MD, Division of Cardiology, University of Utah.)

used as the coronary vasodilator. Each agent can increase myocardial blood flow by fourfold to fivefold. Adenosine is more expensive, but has the advantage over Persantine of a very short half-life. Newer adenosine-like agents with reduced side-effect profiles are starting to be used clinically. Technetium-99m sestamibi is the most frequently used radionuclide and is usually injected just before completion of the stress test. Tomographic (single-photon emission computed tomography [SPECT]) images of the heart are obtained for qualitative and quantitative analyses at rest and after stress. In the normal heart, radioisotope is relatively equally distributed throughout the myocardium. In patients with ischemia, a localized area of decreased uptake will occur after exercise but partially or completely fill in at rest (redistribution). A persistent defect at peak exercise and rest (fixed defect) is consistent with MI or scarring. However, in some patients with apparently fixed defects, repeat rest imaging at 24 hours or after reinjection of a smaller quantity of isotope will demonstrate improved uptake, indicating the presence of viable, but severely ischemic, myocardium. The use of new approaches such as combined low-level exercise and vasodilators, prone imaging, attenuation correction, and computerized data analysis has improved the quality and reproducibility of the data from these studies.

Myocardial perfusion imaging may also be combined with ECG-gated image acquisition to allow for simultaneous assessment of ventricular function and perfusion. Not only can LVEF be quantitated with this technique, but also regional wall motion can be assessed to help rule out artifactual perfusion defects (**Web Fig. 5-5**).

Positron-emission tomography (PET) is a noninvasive method of detecting myocardial viability by the use of both perfusion and metabolic tracers. In patients with left ventricular dysfunction, the presence of metabolic activity in a region of myocardium supplied by a severely stenotic coronary artery suggests viable tissue that may regain more

normal function after revascularization (**Fig. 5-14**). PET is less widely available than conventional SPECT imaging; however, PET offers improved spatial resolution because of the higher energy of the isotopes used for this type of imaging.

CARDIAC CATHETERIZATION

Cardiac catheterization is an invasive technique in which fluid-filled catheters are introduced percutaneously into the arterial and venous circulation. This method allows for the direct measurement of intracardiac pressures and oxygen saturation and, with the injection of a contrast agent, visualization of the coronary arteries, cardiac chambers, and great vessels. Cardiac catheterization is generally indicated when a clinically suggested cardiac abnormality requires confirmation and its anatomic and physiologic importance needs to be quantified. In the current era, coronary angiography for the diagnosis of CAD is the most common indication for this test. Noninvasive testing, compared with catheterization, is safer, cheaper, and equally effective in the evaluation of most valvular and hemodynamic questions. Most often, catheterization will precede some type of beneficial intervention, such as coronary artery angioplasty, coronary bypass surgery, or valvular surgery. Although cardiac catheterization is generally safe (0.1% to 0.2% overall mortality rate), procedure-related complications such as vascular injury, renal failure, stroke, and MI can occur.

An important objective during the cardiac catheterization is to document the filling pressures within the heart and great vessels. This task is accomplished through use of fluid-filled catheters that transmit intracardiac pressures to a transducer that displays the pressure waveform on an oscilloscope. During a right ventricular heart catheterization, pressures within the right atrium, right ventricle, and pulmonary artery are routinely measured in this manner. The

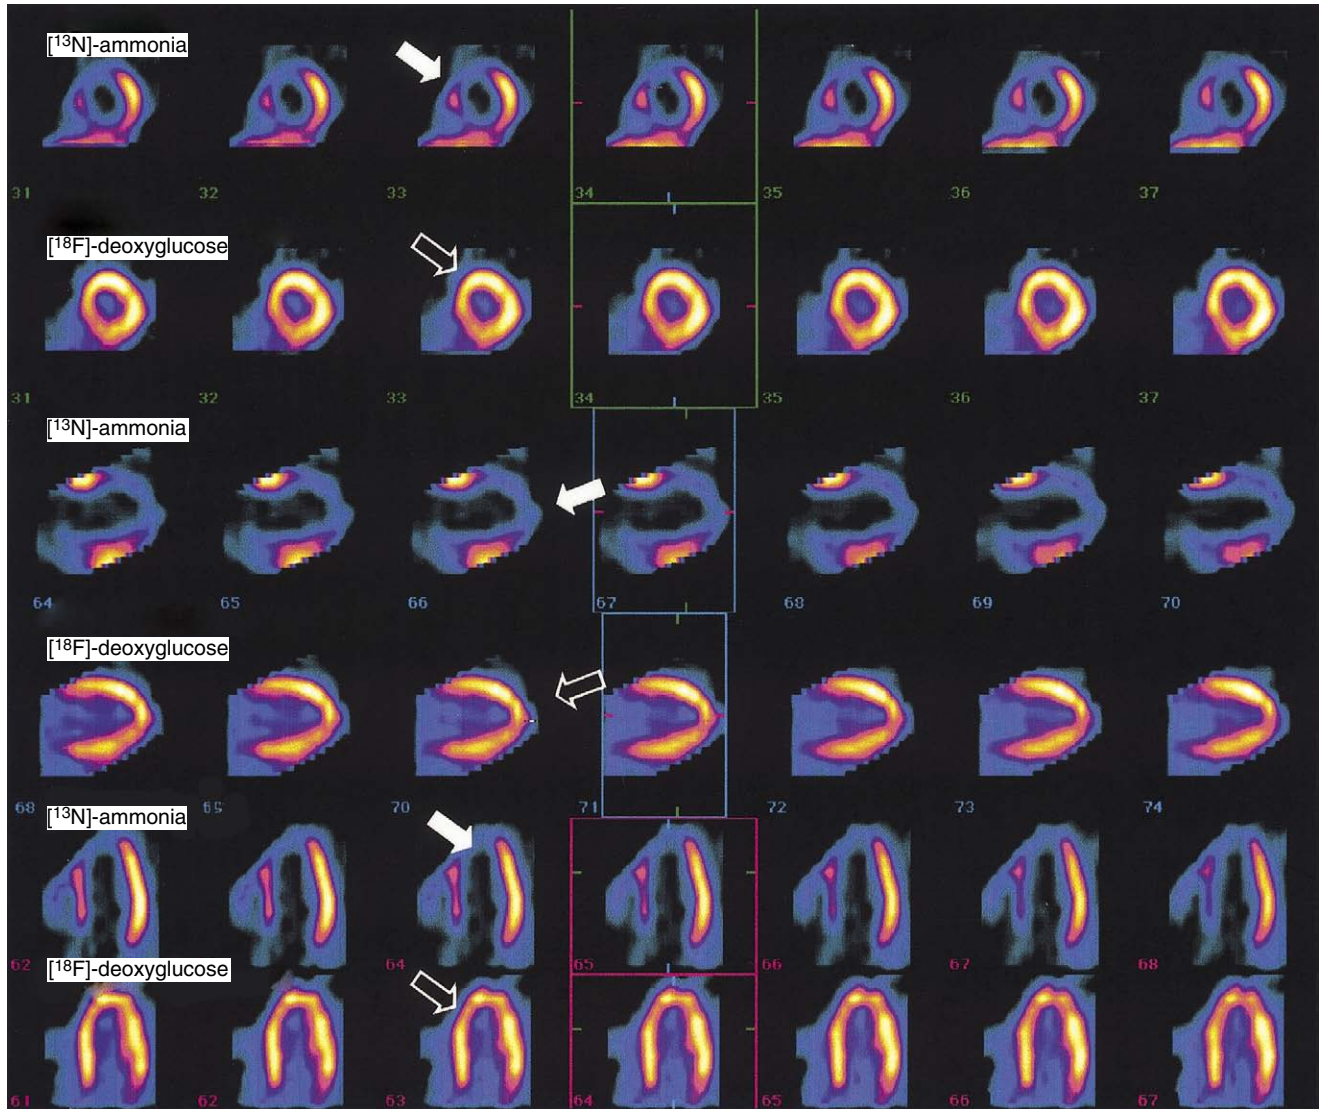

Figure 5-14 Resting myocardial perfusion (obtained with [¹³N]-ammonia) and metabolism (obtained with [¹⁸F]-deoxyglucose) positron-emission tomography images of a patient with ischemic cardiomyopathy. The study demonstrates a perfusion-metabolic mismatch (reflecting hibernating myocardium) in which large areas of hypoperfused (*solid arrows*) but metabolically viable (*open arrows*) myocardium are involving the anterior, septal, and inferior walls and the left ventricular apex. See **Web Figure 5-5** for a dynamic image obtained with cardiac single-photon emission computed tomography imaging. (Courtesy of Marcelo F. Di Carli, MD, Brigham and Women’s Hospital, Boston.)

catheter can then be advanced further until it *wedges* in the distal pulmonary artery. The transmitted pressure measured in this location originates from the pulmonary venous system and is known as the *pulmonary capillary wedge pressure*. In the absence of pulmonary venous disease, the pulmonary capillary wedge pressure reflects left atrial pressure and, similarly, if no significant mitral valve pathologic condition exists, reflects left ventricular diastolic pressure. A more direct method of obtaining left ventricular filling pressures is to advance an arterial catheter into the left ventricular cavity. With these two methods of obtaining intracardiac pressures, each chamber of the heart can be assessed and the gradients across any of the valves determined (Fig. 5-15).

Cardiac output can be determined by one of two widely accepted methods: the Fick oxygen method and the indicator dilution technique. The basis of the Fick method

is that total uptake or release of a substance by an organ is equal to the product of blood flow to that organ and the concentration difference of that substance between the arterial and venous circulation of that organ. If this method is applied to the lungs, the substance released into the blood is oxygen; if no intrapulmonary shunts exist, pulmonary blood flow is equal to systemic blood flow or cardiac output. Thus the cardiac output can be determined by the following equation:

$$\text{Cardiac output} = \frac{\text{oxygen consumption}}{(\text{arterial oxygen content} - \text{venous oxygen content})}$$

Oxygen consumption is measured in milliliters per minute by collecting the patient’s expired air over a known period while simultaneously measuring oxygen saturation in a

Figure 5-15 Electrocardiographic and left ventricular (LV) and aortic (AO) pressure curves in a patient with aortic stenosis. A pressure gradient occurs across the aortic valve during systole.

sample of arterial and mixed venous blood (arterial and venous oxygen content, respectively, measured in milliliters per liter). The cardiac output is expressed in liters per minute and then corrected for body surface area (cardiac index). The normal range of cardiac index is 2.6 to 4.2 L/min/m². Cardiac output can also be determined by the indicator dilution technique, which most commonly uses cold saline as the indicator. With this method, cold saline is injected into the blood, and the resulting temperature change *downstream* is monitored. This action generates a curve in which temperature change is plotted over time, and the area under the curve represents cardiac output.

Detection and localization of intracardiac shunts can be performed by sequential measurement of oxygen saturation in the venous system, right side of the heart, and two main pulmonary arteries. In patients with left-to-right shunt flow, an increase in the oxygen saturation, or *step-up*, will occur as one sample from the chamber where arterial blood is mixing with venous blood. By using the Fick method for calculating blood flow in the pulmonary and systemic systems, the shunt ratio can be calculated. Noninvasive approaches have largely supplanted catheterization laboratory assessment of shunts.

Left ventricular size, wall motion, and ejection fraction can be accurately assessed by injecting contrast into the left ventricle (left ventriculography). Aortic and mitral valve insufficiency can be qualitatively assessed during angiography by observing the reflux of contrast medium into the left ventricle and left atrium, respectively. The degree of valvular stenosis can be determined by measuring pressure gradients across the valve and determining cardiac output (Gorlin formula).

The coronary anatomy can be defined by injecting contrast medium into the coronary tree. Atherosclerotic lesions appear as narrowing of the internal diameter (lumen) of the vessel. A hemodynamically important stenosis is defined as 70% or more narrowing of the luminal diameter. However, the hemodynamic significance of a lesion can be underesti-

mated by coronary angiography, particularly in settings in which the atherosclerotic plaque is eccentric or elongated. Use of intravascular ultrasound, Doppler flow wires, or miniaturized pressure sensors can be used during invasive procedures to help evaluate the severity or estimate the physiologic significance of intermediate lesions.

Biopsy of the ventricular endomyocardium can be performed during cardiac catheterization. With this technique, a biptome is introduced into the venous system through the right internal jugular vein and guided into the right ventricle by fluoroscopy. Small samples of the endocardium are then taken for histologic evaluation. The primary indication for endomyocardial biopsy is the diagnosis of rejection after cardiac transplantation and documentation of cardiac amyloidosis; however, endomyocardial biopsy may have some use in diagnosing specific etiologic agents responsible for myocarditis.

RIGHT VENTRICULAR HEART CATHETERIZATION

A right ventricular heart catheterization can be performed at the bedside with a balloon-tipped pulmonary artery (Swan-Ganz) catheter. This technique allows for serial measurements of right atrial, pulmonary artery, and pulmonary capillary wedge pressures as well as cardiac output by thermodilution (Fig. 5-16). Such measurements may be useful in monitoring the response to various treatments, such as diuretic therapy, inotropic agents, and vasopressors (Table 5-4). The pulmonary artery catheter is most useful in the critically ill patient for assessing volume status and differentiating cardiogenic from noncardiogenic pulmonary edema. Notably, however, several papers have suggested no improvements in outcomes of critically ill patients in whom pulmonary artery catheterization was performed. Improvements in noninvasive imaging techniques have made the pulmonary artery catheter much less important in diagnosing cardiac conditions, such as pericardial tamponade, constrictive pericarditis, right ventricular infarction, and ventricular septal defect.

MAGNETIC RESONANCE IMAGING

Magnetic resonance angiography or imaging (MRI) is an increasingly used noninvasive method for studying the heart and vasculature, especially in patients who have contraindications to standard contrast angiography. MRI offers high-resolution dynamic and static images of the heart that can be obtained in any plane. Good-quality images can be obtained in a higher number of subjects than is typically possible with echocardiography. Obesity, claustrophobia, inability to perform multiple breath-holds of 10 to 20 seconds, and arrhythmias are all causes of reduced image quality. Currently, the presence of cardiac pacemakers or implantable defibrillators is considered a contraindication for MRI. Magnetic resonance angiography is useful in the evaluation of cerebral, renovascular, and lower extremity arterial disease. MRI offers significant advantages over other imaging techniques for the characterization of different tissues (e.g., muscle, fat, scar). MRI is useful in the evaluation of ischemic heart disease because stress-rest myocardial perfusion (Fig. 5-17A) and areas of prior infarction

Figure 5-16 Electrocardiographic (ECG) and Swan-Ganz flotation catheter recordings are shown in tracings A and C, respectively. The left portion of tracing C was obtained with the balloon inflated, yielding the pulmonary arterial wedge pressure. The right portion of tracing C was recorded with the balloon deflated, depicting the pulmonary arterial pressure. In this patient, the pulmonary arterial wedge pressure (left ventricular filling pressure) is normal, and the pulmonary artery pressure is elevated because of lung disease.

(see Fig. 5-17B to D) can be visualized with excellent special resolution. The presence of delayed gadolinium contrast enhancement within the myocardium is characteristic of scar or permanently damaged tissue (**Web Fig. 5-6**). The greater the transmural extent of delayed enhancement in a given segment, the lower is the likelihood of improved function in that segment after revascularization. Because of the better spatial resolution, delayed enhancement imaging can depict localized or subendocardial scars that are not detectable with nuclear imaging techniques. The combined use of stress-rest perfusion and delayed enhancement imaging

has performance characteristics for diagnosing CAD that are at least as good as, and probably superior to, those of conventional stress tests using nuclear scintigraphy or echocardiography. MRI is excellent for evaluating a variety of cardiomyopathies (Fig. 5-18). In addition to morphology and function, characteristic patterns of delayed enhancement have been reported in myocarditis, hypertrophic cardiomyopathy, and cardiac amyloidosis. MRI has also been used to help assess right ventricular morphology and function in patients with suspected arrhythmogenic right ventricular cardiomyopathy.

Table 5-4 Differential Diagnosis Using a Bedside Balloon Flow-Directed (Swan-Ganz) Catheter

Disease State	Thermodilution Cardiac Output	PCW Pressure	RA Pressure	Comments
Cardiogenic shock	↓	↑	nl or ↓	↑ Systemic vascular resistance
Septic shock (early)	↑	↓	↓	↑ Systemic vascular resistance; myocardial dysfunction can occur late
Volume overload	nl or ↑	↑	↑	—
Volume depletion	↓	↓	↓	—
Noncardiac pulmonary edema	nl	nl	nl	—
Pulmonary heart disease	nl or ↑	nl	↑	↑ PA pressure
RV infarction	↓	↓ or nl	↑	—
Pericardial tamponade	↓	nl or ↑	↑	Equalization of diastolic RA, RV, PA, and PCW pressure
Papillary muscle rupture	↓	↑	nl or ↑	Large v waves in PCW tracing
Ventricular septal rupture	↑	↑	nl or ↑	Artifact caused by RA → PA sampling higher in PA than RA; may have large v waves in PCW tracing

↑, Increased; ↓, decreased; nl, normal; PA, pulmonary artery; PCW, pulmonary capillary wedge; RA, right atrium; RV, right ventricle.

COMPUTED TOMOGRAPHY OF THE HEART

New applications of computed tomography (CT) have greatly advanced our ability to diagnose cardiovascular disease noninvasively. The development of fast gantry rotation speeds and the addition of multiple rows of detectors

(multidetector CT) has allowed unprecedented visualization of the great vessels, heart, and coronary arteries with images acquired during a single breath-hold (10 to 15 seconds). Until recently, CT has been used most frequently to diagnose aortic aneurysm and acute aortic dissection and pulmonary embolism. CT is also useful for defining con-

Figure 5-18 Use of cardiac magnetic resonance imaging in the evaluation of chest pain or ischemic heart disease. **A**, First-pass perfusion study during vasodilator stress showing large septal perfusion defect. The hypoperfused area appears dark compared with the myocardium with normal perfusion. **B**, Example of delayed enhancement imaging with nearly transmural infarction of the mid-inferolateral wall, including the posterior papillary muscle. Infarcted myocardium appears white, whereas normal myocardium is black. **C**, Nontransmural (subendocardial) infarction of the septum and apex. **D**, Patient with acute myocarditis mimicking an acute coronary syndrome. Mid-myocardial, rather than subendocardial, delayed enhancement is characteristic of myocarditis.

genital abnormalities and detecting pericardial thickening or calcification associated with constrictive pericarditis. More recently, ECG-gated dynamic CT images have been used to quantify ventricular size, function, and regional wall motion (**Web Fig. 5-7**), and in contrast to echocardiography, CT is not limited by the presence of lung disease or chest wall deformity. However, obesity and the presence of prosthetic materials (i.e., mechanical valves or pacing wires) may affect image quality.

The greatest excitement and controversy over cardiac CT relates to the evaluation of coronary atherosclerosis. Electron-beam and multidetector CT scans can be used to quickly and reliably visualize and quantitate the extent of coronary artery calcification (Fig. 5-19). The presence of coronary calcium is pathognomonic of atherosclerosis, and the extent of coronary calcium (usually reported as an Agatston score) is a powerful marker of future cardiac events. The coronary calcium score adds substantial, independent

improvement in risk prediction to the commonly employed clinical risk scores (e.g., the Framingham risk score). Although the extent of coronary artery calcification does not reliably predict the severity of stenoses, the calcium score is a good marker of the overall atherosclerotic burden. Contrast-enhanced coronary computed tomographic angiography (CTA) has improved dramatically in recent years. Coronary CTA has been reported to have a sensitivity of more than 95% in diagnosing significant coronary artery obstruction. This is superior to the sensitivity of stress echo or nuclear myocardial perfusion scanning. Given the speed and accuracy of this test, it is likely to assume a major role in the evaluation of patients with acute chest pain syndromes. Some advocates of cardiac CT have proposed the use of this test for the *triple rule-out* in patients with acute chest pain—namely, the ability to diagnose pulmonary embolism, aortic dissection, and coronary artery disease with one imaging study. Formal evaluation of this hypoth-

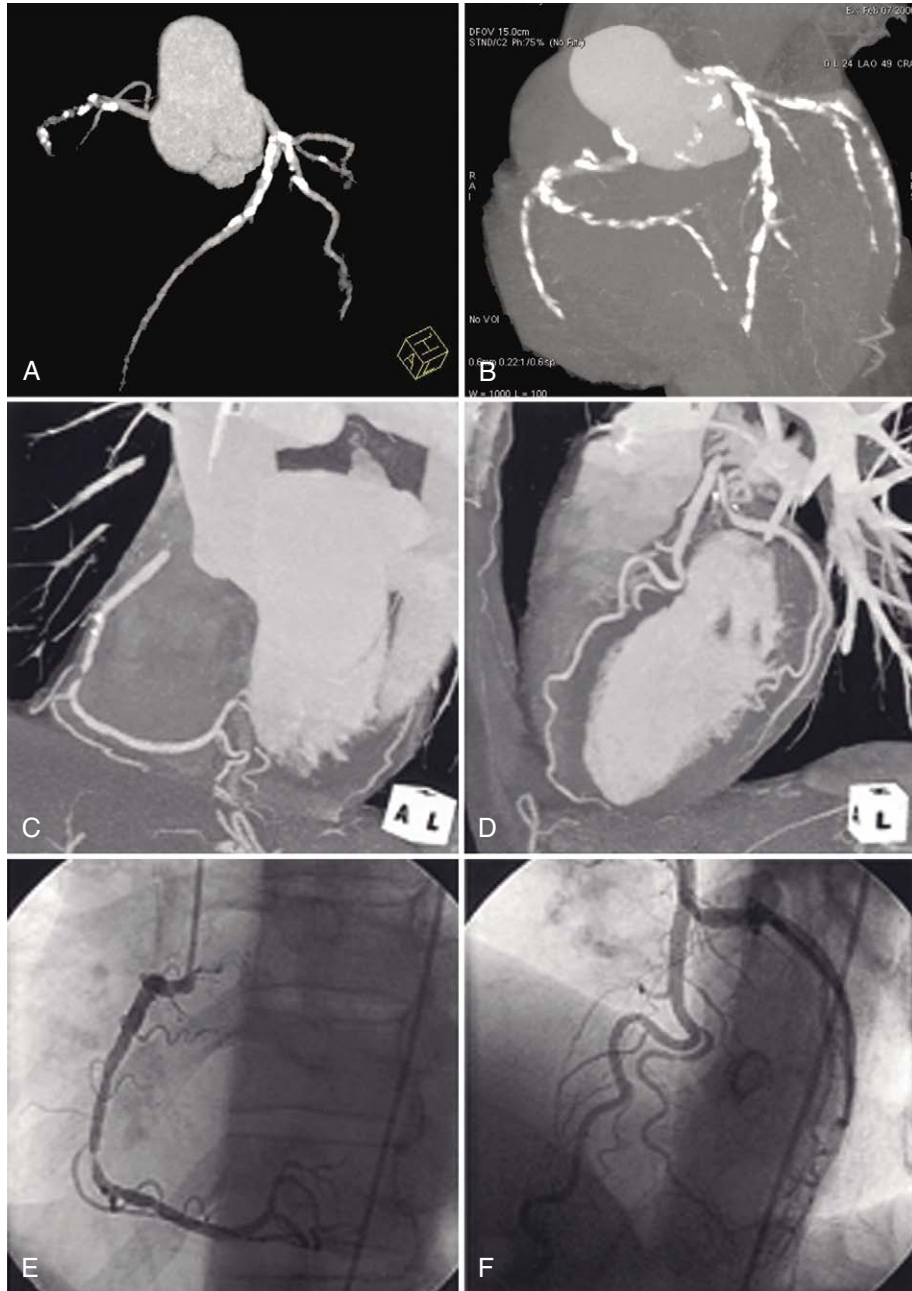

Figure 5-19 Computed tomographic coronary angiography compared with conventional radiographic contrast angiography. **A** and **B**, Volume-rendering technique demonstrating stenosis of the right coronary artery and normal left coronary artery. **C** and **D**, Maximal intensity projection of the same arteries demonstrating severe noncalcified plaque in the right coronary artery with superficial calcified plaque. **E** and **F**, Invasive angiography of the same arteries. esis still needs to be undertaken. Detractors of cardiac CT most frequently cite the risks of radiation and contrast exposure as well as a lack of prospective studies showing improvement in outcome with this testing modality. Of note, the calculated radiation exposure of a cardiac CTA is about double that of a diagnostic invasive coronary angiogram, but is similar to that of a typical nuclear myocardial perfusion scan. As of this writing, the future role of cardiac CTA in routine clinical practice remains uncertain.

NONINVASIVE VASCULAR TESTING

Assessment for the presence and severity of peripheral vascular disease is an important component of the cardiovascular evaluation. Comparison of the systolic blood pressure in the upper and lower extremities is one of the simplest tests to detect the presence of hemodynamically important arterial disease. Normally, the systolic pressure in the thigh is similar to that in the brachial artery. An ankle-to-brachial

pressure ratio (ankle-brachial index) of less than or equal to 0.9 is abnormal. Patients with claudication usually have an index ranging from 0.5 to 0.8, and patients with rest pain have an index less than 0.5. In some patients, measuring the ankle-brachial index after treadmill exercise may be helpful in identifying the importance of borderline lesions. During normal exercise, blood flow increases to the upper and lower extremities and decreases in peripheral vascular resistance, whereas the ankle-brachial index remains unchanged. In the presence of a hemodynamically significant lesion, the increase in systolic blood pressure in the arm is not matched by an increase in blood pressure in the leg. As a result, the ankle-brachial index will decrease, the magnitude of which is proportional to the severity of the stenosis.

After significant vascular disease in the extremities has been identified, plethysmography can be used to determine the location and severity of the disease. With this method, a pneumatic cuff is positioned on the leg or thigh and, when inflated, temporarily obstructs venous return. Volume

changes in the limb segment below the cuff are converted to a pressure waveform, which can then be analyzed. The degree of amplitude reduction in the pressure waveform corresponds to the severity of arterial disease at that level.

Doppler ultrasound uses reflected sound waves to identify and localize stenotic lesions in the peripheral arteries. This test is particularly useful in patients with severely calcified arteries, in whom pneumatic compression is not possible and ankle-brachial indices are inaccurate. In combination with real-time imaging (duplex imaging), this technique is useful in assessing specific arterial segments and bypass grafts for stenotic or occlusive lesions.

Both magnetic resonance angiography and CTA allow high-quality and comprehensive imaging of the entire peripheral arterial circulation in a single study. The three-dimensional nature of these studies and their ability to perform extensive postprocessing views (including cross-sectional views) of any vessel, even those that are very tortuous, are attractive features of these modalities.

Prospectus for the Future

Multidisciplinary teams consisting of cardiologists, cardiac surgeons, vascular surgeons, and radiologists will replace existing and traditional approaches for the evaluation and management of patients with cardiac disease. Such collaboration will foster efficiency and rapid advances for improvements in patient care, education, and research within a seamless, integrated environment. Career opportunities within organiza-

tions with the supporting infrastructure for cardiac imaging will likely realize the promise for patient-oriented, team-based cardiovascular medicine. Tissue enhancement using MRI of either the atria or ventricles will assist practitioners with classification and forecasting of outcomes after interventions such as ablation for atrial fibrillation.

Heart Failure and Cardiomyopathy

Sheldon E. Litwin and Ivor J. Benjamin

The syndrome of heart failure occurs when an abnormality of cardiac function results in failure to provide adequate blood flow to meet the metabolic needs of the body's tissues and organs or in an excessive rise in cardiac filling pressures. In most cases, myocardial dysfunction causes impaired ventricular filling, as well as emptying. Heart failure can result from a large number of heterogeneous disorders (Table 6-1). Idiopathic cardiomyopathy is defined as a primary abnormality of myocardial tissue in the absence of coronary occlusive, valvular, or systemic disease. However, in the clinical setting, the term *cardiomyopathy* is often used to refer to myocardial dysfunction that is the result of a known genetic, cardiac, or systemic disease. These *secondary* cardiomyopathies may be related to a significant number of disorders, but in the United States, they are most often the result of ischemic heart disease. Ventricular dysfunction can also result from excessive pressure overload, such as with long-standing hypertension or aortic stenosis, or volume overload, such as aortic insufficiency or mitral regurgitation. Diseases that result in infiltration and replacement of normal myocardial tissue, such as amyloidosis, are rare causes of heart failure. Hemochromatosis can cause a dilated cardiomyopathy that is believed to result from iron-mediated mitochondrial damage. Diseases of the pericardium, such as chronic pericarditis or pericardial tamponade, can impair cardiac function without directly affecting the myocardial tissue. Long-standing tachyarrhythmias have been associated with myocardial dysfunction that is often reversible. In addition, an individual with underlying myocardial or valvular disease may develop heart failure with the acute onset of an arrhythmia. Finally, multiple metabolic abnormalities (e.g., thiamine deficiency, thyrotoxicosis), drugs (e.g., alcohol, doxorubicin), and toxic chemicals (e.g., lead, cobalt) can damage the myocardium.

Forms of Heart Failure

Heart failure can be classified as predominantly left or right sided, high output or low output, and acute or chronic. High-output failure is an uncommon disorder that can occur with severe anemia, vascular shunting, or thyrotoxicosis. This failure results when the heart is unable to meet the abnormally elevated metabolic demands of the peripheral tissues even though cardiac output is elevated. Fluid retention is a common component of this syndrome. Low-output failure is much more common than high-output failure and is characterized by insufficient forward output, particularly during times of increased metabolic demand. Cardiac dysfunction may predominantly affect the left ventricle, as with a large myocardial infarction, or the right ventricle, as with an acute pulmonary embolus; however, in many disease states, both ventricles will be impaired (biventricular heart failure). *Acute heart failure* usually refers to the situation in which an individual who was previously asymptomatic develops heart failure signs or symptoms following an acute injury to the heart, such as myocardial infarction, myocarditis, or rupture of a heart valve. *Chronic heart failure* refers to the situation in which an individual whose symptoms have developed over a long period, most often when preexisting cardiac disease is present. However, a patient with myocardial dysfunction from any cause may be well compensated for long periods and then develop acute heart failure symptoms in the setting of arrhythmia, anemia, hypertension, ischemia or infection.

The severity of heart failure symptoms does not correlate closely with the usual clinical measures of cardiac function (i.e., left ventricular ejection fraction [LVEF]), although the LVEF is a good prognostic marker. This situation likely reflects the fact that ventricular filling pressures are a more important determinant of symptoms than myocardial

function per se. Heart failure may occur in the setting of a reduced or preserved ejection fraction (EF). Recent data suggest that when sensitive methods for assessing myocardial function (i.e., tissue velocity or strain rate imaging) are used, changes are usually detected in both systolic and diastolic function in patients with heart failure (even when the EF is normal or near normal). Importantly, the predisposing conditions for heart failure (e.g., hypertension, advanced age, coronary artery disease, renal dysfunction) are similar, the prognosis is similar irrespective of whether the LVEF is preserved or reduced. Despite many similarities, medical treatments that have been proved beneficial in heart failure with reduced EF have not shown similar efficacy in heart failure with preserved ejection fraction.

ACUTE PULMONARY EDEMA

In patients with the acute onset of pulmonary edema, initial management should be directed at improving oxygenation

and providing hemodynamic stability. These patients commonly have marked elevation of blood pressure, cardiac ischemia, and worsening mitral regurgitation as contributing factors to the pulmonary edema. Standard therapy includes supplemental oxygen and an intravenous loop diuretic. Sublingual or intravenous nitroglycerin helps reduce preload through venodilation and may provide symptomatic relief in patients with ischemic and nonischemic ventricular dysfunction. Intravenous morphine acts in a similar manner but must be used with caution, given its depressive effects on respiratory drive. In patients with hypertensive urgency, severe hypertension, or congestive heart failure related to aortic or mitral regurgitation, an arterial vasodilator, such as nitroprusside, may be helpful in reducing afterload.

Evaluation of the patient's response to treatment requires frequent assessments of blood pressure, heart rate, end-organ perfusion, and oxygen saturation. In patients with persistent hypoxia or respiratory acidosis, mechanical ventilation or external ventilatory support may be necessary. Pulmonary artery catheterization may be helpful in documenting filling pressures, cardiac output, and peripheral vascular resistance and in monitoring the response to therapy, although invasive monitoring has not been associated with improved patient outcomes. In patients with refractory pulmonary edema or systemic hypotension, an inotropic agent, an intra-aortic balloon pump, or a ventricular assist device may be necessary.

HEART FAILURE WITH PRESERVED EJECTION FRACTION

Slowed relaxation of the left ventricle and increased chamber stiffness impair ventricular filling and may contribute to elevated left ventricular, left atrial, and pulmonary venous pressures. Diastolic filling abnormalities contribute to heart failure symptoms in most patients with reduced left ventricular function. However, some patients with a diagnosis of heart failure have normal or *nearly normal* EF. These patients have been commonly labeled as having *diastolic heart failure*. As described earlier in this chapter, newer imaging techniques have revealed that most of these patients also have a component of systolic dysfunction as well. Thus, the term *heart failure with preserved EF* is now the preferred terminology to describe this condition.

Relaxation abnormalities are present in most people older than 65 years and are almost universal after age 75 years; however, most of these individuals do not have heart failure. Thus, isolated abnormalities of left ventricular relaxation are apparently not sufficient to directly cause heart failure in the absence of other predisposing conditions.

In patients with a variety of cardiovascular diseases, relaxation abnormalities appear at earlier ages than would otherwise be expected. As of this writing, no therapeutic agents that specifically target impaired relaxation have been developed. β -Receptor agonists (dobutamine) and phosphodiesterase inhibitors (milrinone) have potent lusitropic effects (improve relaxation); however, they also directly increase contractility and enhance myocyte calcium cycling. Chronic β -blocker therapy is associated with parallel improvements in systolic and diastolic function, even though both of these may actually deteriorate during the early phases of treatment. Although calcium channel blockers have been

proposed as therapy for diastolic abnormalities, little evidence supports their use for this purpose. Moreover, calcium entry into cardiac myocytes through L-type calcium channels occurs almost exclusively during systole; thus, the theoretical basis for their use is also not firm. In general, all therapies that result in improved systolic function also tend to improve diastolic function, or at least diastolic filling pressures. The use of diuretics to control volume overload and the vigorous treatment of hypertension are the mainstay of therapy for this condition.

RESYNCHRONIZATION THERAPY

Interventricular conduction delays, demonstrated as a prolonged QRS duration, are a common complication in patients with heart failure and have been associated with reduced exercise capacity and a poor long-term prognosis. Biventricular pacing or resynchronization therapy results in more normal ventricular contraction and has been associated with an improvement in cardiac output and LVEF. Biventricular pacing may have a beneficial effect on left ventricular remodeling by reducing left ventricular volume, left ventricular mass, and severity of mitral regurgitation. Clinically, these hemodynamic and structural changes have translated into an improvement in exercise duration, functional capacity, and quality of life. Biventricular pacing has also been shown to reduce mortality. Unfortunately, up to 30% of patients undergoing biventricular pacemaker placements do not respond favorably to the treatment. At present, this therapy is generally reserved for patients with severe heart failure and a widened QRS complex who remain symptomatic despite optimal pharmacologic therapy. Intense research efforts are underway to identify with increased accuracy the patients who are likely to derive the greatest benefit. Efforts are currently focused on the quantification of mechanical asynchrony using newer imaging techniques including tissue Doppler imaging and strain imaging (echocardiography or magnetic resonance imaging), wall thickening analysis by computed tomography, and phase imaging with nuclear scintigraphy. Resynchronization therapy is indicated for ambulatory patients with sinus rhythm and class III or IV symptoms. This therapy has not been well studied in patients with atrial fibrillation. Because of the significant expense of this treatment, it is not currently recommended for patients with short life expectancy, including those with refractory, decompensated heart failure.

Adaptive Mechanisms in Heart Failure

A large number of compensatory changes occur in the cardiovascular and renal systems to maintain adequate blood flow to the vital organs of the body in the setting of myocardial dysfunction. These changes include increases in left ventricular volume and pressure through the Frank-Starling mechanism, ventricular remodeling, and neurohormonal activation.

In the normal heart, increasing the stroke volume or heart rate can augment cardiac output. Stroke volume is dependent on the contractile state of the myocardium, left

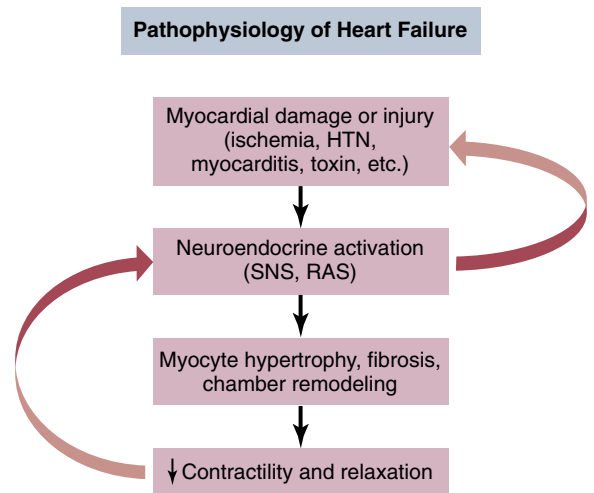

Figure 6-1 Schematic diagram illustrating the progressive nature of left ventricular dysfunction that can follow an initial cardiac insult. Attenuation of the neurohumoral activation (or blockade of the downstream effects) may interrupt the positive feedback and slow or reverse the progression of heart failure. HTN, hypertension; RAS, renin-angiotensin system; SNS, sympathetic nervous system.

ventricular filling (preload), and resistance to left ventricular emptying (afterload). According to the Frank-Starling law (Fig. 6-1), stroke volume can be increased with minimal elevation in left ventricular pressure as long as contractility is normal and outflow is not impeded. In the failing heart with depressed intrinsic contractility (Fig. 6-2, curve A), larger increases in filling pressures are required to produce similar increases in stroke volume. When left ventricular diastolic pressure approaches 20 to 25 mm Hg, the hydrostatic pressure in the pulmonary capillaries exceeds the oncotic pressure, and pulmonary edema may ensue. Both depressed myocardial contractility and increased chamber stiffness can lead to pulmonary congestion through similar mechanisms.

The failing heart may also undergo changes in left ventricular size, shape, and mass to maintain adequate forward flow. This process is known as *remodeling* and occurs in response to myocyte loss, such as after a myocardial infarction, or to hemodynamic overload, such as aortic or mitral valve insufficiency. The initial response to increased cardiac stress or load is usually hypertrophy of the viable myocytes. If the increase occurs mainly in cell length, then ventricular dilation is the predominant form of remodeling (usually seen in volume overload or myocardial infarction). The eccentric pattern of remodeling helps maintain cardiac output but occurs at the expense of increased ventricular wall stress. If the myocytes predominantly increase in width (as in the setting of pressure overload), the heart will tend to thicken with maintenance of cavity volume. This form of remodeling, usually referred to as *concentric hypertrophy*, will tend to reduce wall stress but may do so at the expense of increased filling pressures. If the extent of hypertrophy is inadequate to normalize wall stress, a vicious cycle is established. Overstretching of the myocytes can lead to an increase in myocyte death, ventricular dilation, development of a spherical left ventricular cavity, and further elevation in wall stress.

Figure 6-2 Normal and abnormal ventricular function curves. When the left ventricular end-diastolic pressure acutely rises above 20 mm Hg (A), pulmonary edema often occurs. The effect of diuresis or venodilation is to move leftward along the same curve, with a resultant improvement in pulmonary congestion and with minimal decrease in cardiac output. The stroke volume is poor at any point along this depressed contractility curve; thus, therapeutic maneuvers that would raise it more toward the normal curve would be necessary to improve cardiac output significantly. Unlike the effect of diuretics, the effect of digitalis or arterial vasodilator therapy in a patient with heart failure is to move the patient into another ventricular function curve intermediately between the normal and depressed curves. When the patient's ventricular function moves from A to B by the administration of one of these agents, the left ventricular end-diastolic pressure may also decrease because of improved cardiac function; further administration of diuretics or venodilators may shift the patient further to the left along the same curve from B to C and eliminate the risk for pulmonary edema. A vasodilating agent that has both arteriolar and venous dilating properties (e.g., nitroprusside) would shift this patient directly from A to C. If this agent shifts the patient from A to D because of excessive venodilation or administration of diuretics, then the cardiac output may fall too low, even though the left ventricular end-diastolic pressure would be normal (10 mm Hg) for a normal heart. Thus, left ventricular end-diastolic pressures between 15 and 18 mm Hg are usually optimal in the failing heart to maximize cardiac output but avoid pulmonary edema.

The mechanical changes are triggered, in part, by activation of several neurohormonal systems. The renin-angiotensin-aldosterone system helps maintain cardiac output through expansion of intravascular volume by promoting retention of sodium and water. Stimulating arterial vasoconstriction through the actions of angiotensin II enhances tissue perfusion. In addition, release of vasopressin will promote free water absorption by the kidney. The sympathetic nervous system helps maintain tissue perfusion by increasing arterial tone as well as increasing heart rate and ventricular contractility.

Although adaptive in the short term, activation of these systems is associated with several deleterious effects, including elevation in ventricular filling pressures, depression of stroke volume secondary to an increase in peripheral vascular resistance, and stimulation of myocardial hypertrophy and left ventricular remodeling. These maladaptive changes are ultimately responsible for many of the signs and symptoms associated with congestive heart failure and provide the rationale for treatment.

Table 6-2 New York Heart Association Functional Classification for Heart Failure

Class	Patient Symptoms
I (Mild)	No limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, or dyspnea (shortness of breath).
II (Mild)	Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in fatigue, palpitation, or dyspnea.
III (Moderate)	Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes fatigue, palpitation, or dyspnea.
IV (Severe)	Unable to carry out any physical activity without discomfort. Symptoms of cardiac insufficiency at rest. If any physical activity is undertaken, discomfort is increased.

From the Heart Failure Society of America © 2002 HFSA, Inc. Available at: http://www.abouthf.org/questions_stages.htm.

Countering these effects, and in response to the increase in ventricular filling pressures, the myocardial cells secrete atrial natriuretic peptide and brain natriuretic peptide (BNP). The plasma concentration of both of these hormones has been shown to increase in patients with heart failure. The measurement of serum BNP or its precursors has proved to be clinically useful in the diagnosis of heart failure. Although endogenous natriuretic peptides promote salt and water excretion by the kidneys and result in arterial vasodilation, they are relatively ineffective at reversing the maladaptive changes associated with the powerful renin-angiotensin and sympathetic nervous systems.

Evaluation of Patients with Heart Failure

The history and physical examination are integral parts of the diagnosis of heart failure and the determination of its underlying or precipitating cause. One of the cardinal manifestations of left ventricular heart failure is dyspnea, which is related to elevation in pulmonary venous pressure. In patients with chronic heart failure, shortness of breath initially occurs only with exertion but may progress to occur at rest. Cardiac dyspnea is often worsened by the recumbent position (orthopnea) when increased venous return further elevates pulmonary venous pressure. Paroxysmal nocturnal dyspnea occurs after several hours of sleep and is probably caused by central redistribution of edema. If cardiac output is low but left ventricular filling pressures are normal, the patient may complain primarily of fatigue resulting from diminished blood flow to the exercising muscles. In some instances, heart failure is slow to progress, and the patient may unknowingly restrict his or her activities. Thus, the history should include an assessment not only of the patient's symptoms but also of his or her level of activity (functional capacity; Table 6-2). Many patients complain of peripheral

edema, usually involving the lower extremities. The edema commonly worsens during the day and decreases overnight with elevation of the legs. In patients with severe, long-standing heart failure, the edema can involve the thighs and abdomen, and ascites may develop. Importantly, peripheral edema often does not have a cardiac cause.

Many of the physical findings of heart failure are related to the neurohormonal changes that help compensate for the reduced cardiac output. An increased heart rate may be present as a result of increased sympathetic tone. The pulse pressure may be narrowed secondary to peripheral vasoconstriction and low stroke volume. If left ventricular filling pressures are elevated, then crackles may be heard on auscultation of the lung fields. Elevation in right-sided filling pressures will result in distended neck veins. If the liver is also congested, firm pressure applied to the right upper quadrant will cause the jugular veins to become further engorged (hepatojugular reflux). Palpation of the precordium may reveal left ventricular enlargement. An early-diastolic third heart sound (S_3) or gallop suggests elevated atrial pressure and increased ventricular chamber stiffness. The sound results from rapid deceleration of the passive component of blood flow from the atrium into the noncompliant ventricle. An S_3 can be generated from the left or right ventricle. A fourth heart sound (S_4) suggests an increased atrial contribution to left ventricular filling but is not specific for heart failure. The murmurs of both mitral and tricuspid regurgitation are common in patients with congestive heart failure and may become accentuated during an acute decompensation. As stated earlier, peripheral edema is a common finding on physical examination and may be related to elevation in venous pressure or increased sodium and water retention. In bedridden patients, the edema may predominantly be in the presacral region.

The electrocardiogram in patients with congestive heart failure is not specific, but it may provide insight into the

cause of the cardiac dysfunction, such as prior myocardial infarction, left ventricular hypertrophy, or significant arrhythmias. The chest radiograph may show chamber enlargement and signs of pulmonary congestion (Fig. 6-3). Treatment of heart failure will result in improvement of the vascular congestion on the chest radiograph, but these changes may lag 24 to 48 hours behind clinical improvement. Certain blood chemistries may be altered in the patient with heart failure. The serum sodium concentration may be low, owing to increased water retention with activation of the renin-angiotensin system. The use of potent diuretics is almost always partially responsible for the hyponatremia. Renal function may be impaired secondary to intrinsic kidney disease or reduced perfusion secondary to renal artery vasoconstriction and low cardiac output. Hepatic congestion is common with right ventricular heart failure and may result in elevated liver enzyme levels.

Because many of the signs and symptoms of heart failure may also occur with pulmonary disease, differentiating between these two disease processes may be difficult. Initial therapy will often be directed at both potential pulmonary and cardiac causes until further testing can be performed. Echocardiography is arguably the central means for diagnostic testing in patients with suspected heart failure. This test is fast, safe, and portable and allows for noninvasive assessments of chamber sizes, systolic function, valvular function, both right and left ventricular filling pressures, and quantification of stroke volume or cardiac output. Documentation of heart size, wall thickness, and ventricular function will have important therapeutic implications in most patients (Fig. 6-4). Rapid measurement of the plasma concentration of BNP provides objective and complementary data to aid in the diagnosis of heart failure in the patient with dyspnea. Clinical studies have shown that plasma levels of BNP are elevated in patients with symptomatic left or right ventricular dysfunction but are usually normal in patients with

Figure 6-3 A, Posteroanterior chest radiograph showing cardiomegaly. B, Lateral chest radiograph showing pulmonary vascular congestion typical of pulmonary edema.

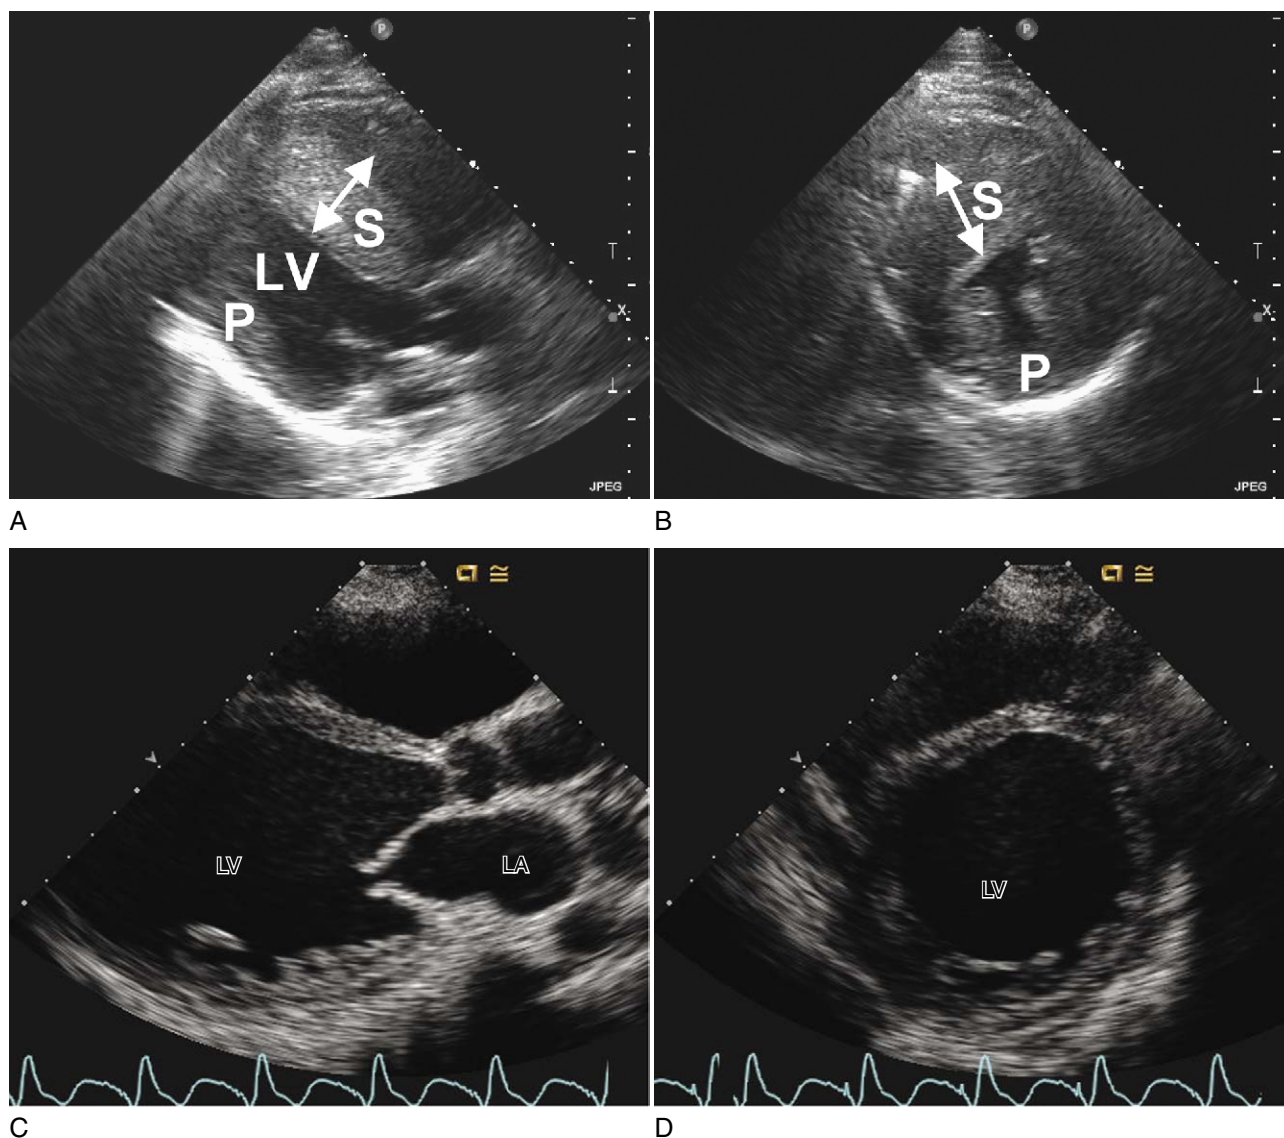

Figure 6-4 Echocardiographic examples of hypertrophic cardiomyopathy seen in long axis (A) and short axis (B) views. Note normal size of left ventricular (LV) cavity and marked thickening of interventricular septum (S) compared with posterior wall (P). In contrast, similar views in a patient with dilated cardiomyopathy (C and D) reveal a markedly enlarged left ventricular cavity with diffuse wall thinning.

dyspnea secondary to noncardiac causes. Unfortunately, a relatively large indeterminate range exists in which the test is not helpful. Advanced age and renal dysfunction also reduce the utility of the test, particularly if the BNP concentration is mildly elevated.

An important point to note is that pulmonary edema may also be secondary to noncardiac causes, such as sepsis, certain pulmonary infections, drug toxicity, or neurologic injury. This syndrome, termed *adult respiratory distress syndrome*, can be differentiated from cardiogenic pulmonary edema by the presence of a low or normal pulmonary capillary wedge pressure. The wedge pressure can be estimated noninvasively using left ventricular filling velocities and mitral annular velocities assessed by conventional and tissue Doppler techniques. Peripheral edema may also occur in disease states other than congestive heart failure. Renal

disease, especially nephrotic syndrome, cirrhosis, and severe venous stasis disease, may be associated with peripheral edema.

Treatment

Treatment of congestive heart failure should be directed not only at relieving the patient's symptoms but also at treating the underlying or precipitating causes (Table 6-3) and preventing progression. Patients should be educated about the importance of compliance with medical therapy as well as dietary salt and fluid restriction. Rhythm disturbances, such as atrial fibrillation, may precipitate congestive heart failure and may require specific therapy. Treatment of active coronary artery disease, hypertension, or valvular disease may

Table 6-3 Precipitants of Heart Failure

Dietary (sodium and fluid) indiscretion
Noncompliance with medications
Development of cardiac arrhythmia
Anemia
Uncontrolled hypertension
Superimposed medical illness (pneumonia, renal dysfunction)
New cardiac abnormality (acute ischemia, acute valvular insufficiency)

relieve heart failure symptoms. In addition, correction of concomitant medical problems may help stabilize heart function.

NONPHARMACOLOGIC TREATMENT

All patients with heart failure should be instructed to restrict sodium intake to about 2 g/day. Fluid intake should also be limited to avoid hyponatremia. Weight reduction in the obese patient helps reduce the workload of the failing heart. Although a growing body of data suggests that a higher body mass index may paradoxically have protective effects in patients with heart failure, each condition is an independent risk factor for increased morbidity and mortality of cardiac disease. A supervised exercise cardiac rehabilitation program can help reduce heart failure symptoms and improve functional capacity in select patients. Although briefly popular, external enhanced counterpulsation (EECP) has fallen out of favor.

PHARMACOLOGIC TREATMENT

Diuretics

Salt and water retention is common in congestive heart failure secondary to activation of the renin-angiotensin-aldosterone system. Diuretics help promote renal excretion of sodium and water and provide rapid relief of pulmonary congestion and peripheral edema. Loop diuretics, such as furosemide, are the preferred agents in the treatment of symptomatic heart failure. In patients who are refractory to high doses of these agents, diuretics that block sodium absorption at different sites within the nephron may be beneficial (i.e., thiazide-type diuretics). Diuretic therapy is currently considered a mainstay in the treatment of patients with heart failure and preserved EF who have elevated left ventricular filling pressures or peripheral edema. Spironolactone is an aldosterone antagonist with weak diuretic effects that has been shown to reduce hospitalizations for heart failure and cardiac mortality in patients with reduced LVEF and New York Heart Association class III or IV symptoms of heart failure.

Notably, diuretic therapy will lower intracardiac filling pressures and thus cardiac output through the Frank-Starling mechanism. In most patients, this change is well tolerated. However, in some patients, the reduced cardiac output will result in decreased renal perfusion and a rise in the blood urea nitrogen and creatinine levels.

Vasodilators

A large number of vasodilators have been shown to reverse the peripheral vasoconstriction that occurs in congestive heart failure. The most important group of vasodilator agents is the angiotensin-converting enzyme (ACE) inhibitors. These agents help relieve heart failure symptoms, in part, by blocking production of angiotensin II and reducing afterload. In addition, ACE inhibitors have been shown to reduce mortality in patients with both symptomatic and asymptomatic left ventricular dysfunction. The major side effects of ACE inhibitors include hypotension, hyperkalemia, and azotemia. Cough may occur in about 10% of patients and is related to increased bradykinin levels associated with ACE inhibitor use.

Hydralazine in combination with oral nitrates has also been shown to reduce mortality in patients with symptomatic congestive heart failure, although not to the degree of ACE inhibitors. This combination provides an alternative to the patient who is ACE inhibitor intolerant or may require additional therapy for blood pressure control. In addition, recent prospective studies reveal that the combination of hydralazine and nitrates was more beneficial than ACE inhibitors in the African American population.

A newer class of agents, the angiotensin II receptor antagonists, prevents the binding of angiotensin II to its receptor. This action has the theoretical advantage of blocking the effects of angiotensin II produced in the bloodstream as well as at the tissue level. In addition, the angiotensin II receptor blockers do not interfere with bradykinin metabolism and therefore are not associated with cough. Several studies comparing ACE inhibitors to angiotensin II blockers suggest that these two classes of agents are equally effective in reducing morbidity and mortality in patients with heart failure. The current guidelines for the management of chronic heart failure, however, recommend that angiotensin II receptor blockers be reserved for patients who are intolerant of ACE inhibitors. ACE inhibitors and angiotensin II receptor blocking agents have both been studied in large randomized trials of patients with heart failure and preserved EF, and they have been found to be ineffective in this large patient group.

The negative inotropic effects of the calcium channel blockers and their activation of the sympathetic nervous system make these agents less attractive in the treatment of patients with congestive heart failure. In particular, several studies have shown worsening of heart failure symptoms in patients treated with nifedipine. Other calcium channel blockers, such as diltiazem, have been shown to relieve symptoms and increase functional capacity without a deleterious effect on survival in patients with idiopathic dilated cardiomyopathy. Amlodipine has been studied in patients with both ischemic and nonischemic cardiomyopathy and also has not been associated with an increased cardiac morbidity and mortality. In addition, patients with nonischemic cardiomyopathy treated with amlodipine may have a modest survival benefit. Further studies with these agents are necessary before general recommendations regarding their use in patients with heart failure can be made.

Inotropic Agents

Inotropic agents help relieve heart failure symptoms by increasing ventricular contractility. The oldest and most commonly used agent in this class is digoxin, which has been

associated with symptomatic improvement in heart failure in patients with systolic dysfunction. However, a recent trial found no significant improvement in survival among patients randomized to digoxin compared with patients treated with placebo. A small reduction in hospitalizations and in death secondary to heart failure was observed, but this was counterbalanced by a slight increase in death secondary to arrhythmias. In general, digoxin therapy should be considered in the patient with left ventricular systolic dysfunction who remains symptomatic after treatment with an ACE inhibitor and a diuretic. No evidence has been found that digoxin should be administered to the patient with asymptomatic left ventricular dysfunction. In addition, digoxin may be harmful in patients with infiltrative cardiomyopathies, such as amyloidosis. Digoxin toxicity results in gastrointestinal, neurologic, and generalized systemic side effects as well as causing a number of tachyarrhythmias and bradyarrhythmias.

Several other classes of oral inotropic agents have been evaluated for treatment of congestive heart failure, such as flosequinan, milrinone, vesnarinone, and xamoterol. All these agents have been associated with increased mortality with long-term use. More recently, promising data have emerged involving the calcium-sensitizing agent levosimendan. This class of agents has the theoretical advantage of not increasing calcium fluxes into the myocyte; therefore, these agents should be less arrhythmogenic and have a more favorable energetic effect.

β Blockers

As previously discussed, many of the symptoms associated with heart failure are related to activation of several neurohormonal systems, including the sympathetic nervous system. Release of catecholamines may initially help maintain blood pressure and cardiac output but, in the long term, may induce further myocardial injury. To date, long-term use of three different β blockers—metoprolol, bisoprolol, and carvedilol—has been shown in clinical trials to improve LVEF and survival in patients with symptomatic left ventricular dysfunction. Of these agents, carvedilol is unique in that it is also an antioxidant and an α blocker, additional properties that may be beneficial in patients with heart failure. Data from clinical trials comparing the efficacy of metoprolol to carvedilol in patients with heart failure have recently been reported. These data suggest superior effects of carvedilol; however, controversy about the experimental design has limited widespread adoption of a single agent. Therapy with one of the aforementioned β blockers should be strongly considered in all patients who have been stabilized on an ACE inhibitor, digoxin, and a diuretic but remain symptomatic (New York Heart Association classes II to IV). β blockers also appear to be effective in patients who are not taking ACE inhibitors. β -blocker therapy is generally withheld from patients with acutely decompensated heart failure or significant volume overload. Gradual up-titration of the dose improves the ability to tolerate these drugs, which are intrinsically negatively inotropic.

Anticoagulation

Thrombosis and thromboemboli occur in patients with left ventricular remodeling and congestive heart failure secondary to stasis of blood, intracardiac thrombi, and atrial

arrhythmias. Although long-term warfarin therapy remains controversial, certain patients may benefit from its use, including patients with chronic atrial fibrillation or flutter, patients with definite mural thrombi noted by echocardiography or ventriculography, and patients in sinus rhythm with LVEF less than 20%. In the general heart failure population, prevention of thromboembolism is roughly balanced by increased bleeding risks. Thus, the routine use of anticoagulation is only recommended in heart failure patients with atrial fibrillation, prior arterial embolic events, or mechanical heart valves and in patients who have had an anterior myocardial infarction in the past 3 months.

Refractory Heart Failure

Despite adequate medical therapy, many patients with congestive heart failure fail to have significant reduction in their symptoms. In these instances, therapy with intravenous inotropic agents for 24 to 96 hours, sometimes with hemodynamic monitoring (Swan-Ganz catheter), may be necessary to stabilize the patient. One commonly used agent is dobutamine, which enhances contractility of the heart and reduces peripheral vasoconstriction through stimulation of β_2 receptors. Milrinone is an intravenous phosphodiesterase inhibitor that has similar effects on contractility and afterload. Administration of these agents often promotes diuresis, especially when given concomitantly with intravenous loop diuretics. In patients with markedly elevated systemic vascular resistance, the use of intravenous vasodilators, such as sodium nitroprusside, can significantly reduce afterload and improve cardiac output. A newly available agent, nesiritide, is a recombinant form of human BNP that has been shown to reduce systemic and pulmonary vascular resistance, increase cardiac output, and promote diuresis comparable to standard inotropic agents and vasodilators. Although nesiritide is less likely to provoke serious dysrhythmias compared with dobutamine, recent data have questioned the safety profile and efficacy of nesiritide. Until further studies document safety, nesiritide is not a first-line agent.

If the previously mentioned measures fail to produce a satisfactory diuretic response, dopamine given in doses ranging from 2 to 5 mcg/kg per minute may facilitate sodium and water excretion by stimulating renal dopaminergic receptors. If heart failure is accompanied by hypotension, higher doses of dopamine may be necessary. With doses higher than 5 mcg/kg per minute, dopamine can increase heart rate and peripheral vascular resistance through stimulation of β_1 and α receptors. Although this dose range of dopamine may help stabilize blood pressure, the increase in afterload may have further deleterious effects on the failing heart. In addition, dopamine may provoke arrhythmias that may lead to further hemodynamic instability. If hypotension persists despite dopamine doses greater than 15 mcg/kg per minute, mechanical assist devices, such as the intra-aortic balloon pump, should be considered as a means to stabilize the patient.

In patients who cannot be weaned from pharmacologic or mechanical support and in ambulatory patients with severe functional impairment refractory to medical therapy, cardiac transplantation should be considered a means to improve

symptoms and prolong survival (see Chapter 12). Currently, the use of cardiac resynchronization therapy is not a routine consideration in this group of patients who have markedly reduced long-term survival.

Cardiovascular Assist Devices

The most commonly used mechanical support device is the intra-aortic balloon pump. This device can be inserted percutaneously through the femoral artery and advanced into the descending thoracic aorta. Inflation of the balloon occurs during diastole such that perfusion pressure in the proximal aorta and coronary arteries is enhanced. Deflation, which occurs just before the onset of systole, greatly reduces aortic impedance and thus significantly reduces afterload. This device is particularly useful in stabilizing patients with severe coronary disease before percutaneous or after surgical revascularization. In addition, this device may provide hemodynamic support in patients with severe mitral regurgitation

or acquired ventricular septal defect before surgical repair. In patients with refractory congestive heart failure, the intra-aortic balloon pump may serve as a temporizing measure until cardiac transplantation can be performed.

In addition to the intra-aortic balloon pump, several ventricular assist devices are available that provide hemodynamic support. These devices can be placed percutaneously but most commonly are implanted through a sternotomy incision. They can be used to support either ventricle. Blood is collected from the right atrium, left atrium, or the left ventricular apex into an extracorporeal reservoir and then actively pumped back into the pulmonary or systemic circulation by the assist device. These units were initially intended to provide hemodynamic support for several days to weeks (most often a *bridge* to transplantation in the patient who is critically ill). Because of the success with these devices and the limited availability of donor hearts, assist devices are now being implanted as *destination* therapy. The pump is placed within the peritoneum, and portable battery packs allow the patient to ambulate. Newer left ventricular assist devices, as well as total artificial hearts, are undergoing clinical investigation as permanent cardiac replacement therapy.

Prospectus for the Future

External Containment Devices

In patients with left ventricular dysfunction, cardiac remodeling characterized by progressive ventricular chamber dilation and wall thinning can lead to elevation in wall stress and activation of neurohormonal mechanisms that further impair myocardial function. Experimental devices that passively contain the heart have been shown, in animal models, to reduce ventricular cavity size and improve myocardial responsiveness to β -adrenergic stimulation without impairing left ventricular filling or interfering with coronary blood flow. Randomized trials evaluating the efficacy of these devices in patients with end-stage cardiomyopathy are underway.

Mitral Valve Repair

Mitral regurgitation contributes to the progression of heart failure in a large number of patients. However, most patients

with severe heart failure are deemed poor surgical candidates. Several new and exciting percutaneous approaches to mitral and aortic valve repair are being explored as ways to treat some of these patients.

Cell-Based Therapies

Permanent loss of myocytes is the final common pathway in most forms of heart failure. Presently, some experimental data support the notion that implantation of cells into the failing heart might effectively regenerate new cardiac muscle. Skeletal myoblasts, bone marrow-derived progenitor cells, and embryonic stem cells are all undergoing testing in both animals and humans. Although many types of transplanted cells are able to contract, ineffective formation of gap junctions and hence ineffective electrical continuity between the transplanted cells and the existing myocardial syncytium continue to be obstacles.

Congenital Heart Disease

Kevin J. Whitehead

About 0.8% of all live births are complicated by congenital cardiac abnormalities, not including infants with bicuspid aortic valve and mitral valve prolapse (see Chapter 8), which are more prevalent (2% and 2.4%, respectively). Congenital heart disease is a major cause of infant morbidity and mortality. As a result of advances in pediatric cardiology and cardiothoracic surgery, about 85% of infants born with congenital heart disease can be expected to survive into adulthood. In turn, adults with congenital heart disease represent a large and growing population that is encountered more frequently in clinical practice. An equal number of adults and children live with congenital heart disease, with an estimated 800,000 adult patients in the United States alone.

Most cases of congenital heart disease occur sporadically, without a known specific cause. Genetic abnormalities are responsible for a proportion of cases and may contribute to cases occurring sporadically as well. Environmental factors are also known to cause congenital heart disease. An increased incidence is found in children of patients with congenital heart disease, with a higher risk in mothers than in fathers. In most cases, the nature of the parent's defect does not predict the lesion in affected offspring.

The size and nature of the congenital defect often determine the onset of symptoms. Normal physiologic changes in cardiovascular hemodynamics at birth can prompt presentation. Symptoms can develop shortly after birth when transition from fetal to adult circulation represents a new dependence on biventricular circulation with a pulmonary circuit. The isolated pulmonary and systemic circulations of D-transposition of the great arteries become apparent on closure of the last fetal connections between circuits, the ductus arteriosus and the foramen ovale. In other conditions, the primary lesion results in changes that delay presentation until such compensatory mechanisms fail. Hypertrophy of the morphologic right ventricle in L-transposition of the great arteries is sufficient to compensate for systemic vascular resistance and maintain normal perfusion for years, with symptoms often developing when the systemic ventricle fails. Still other lesions may develop in adulthood when degenerative changes, such as stenosis

of a previously well-functioning bicuspid aortic valve, are superimposed on an initial lesion. Some congenital defects may go undetected throughout life (e.g., small atrial septal defects [ASDs]), whereas some may resolve spontaneously (small muscular ventricular septal defects [VSDs]). Many adult patients with congenital heart disease will have already undergone palliative or reparative surgical procedures and will have subsequent care directed at residual defects and sequelae of such procedures. This chapter focuses on the most common congenital abnormalities observed in adults, including those that develop in adulthood and those for which surgical correction during infancy and childhood permits survival into adulthood.

Septal Defects

ATRIAL SEPTAL DEFECTS

ASDs are some of the most common congenital defects, representing 10% to 17% of cases, with a higher prevalence in women (60%). Defects are classified according to their location in the interatrial septum. The most common ASD (60%), the ostium secundum defect, involves the fossa ovalis. Ostium primum defects (20%) involve the atrioventricular junction and are at one end of the spectrum of atrioventricular septal defects (or endocardial cushion defects). Primum ASDs are usually associated with a cleft mitral valve and mitral regurgitation. In rare cases, primum ASD can be associated with a large VSD and a single atrioventricular (AV) valve, forming an AV septal defect. Sinus venosus defects are located in the superior septum and may be associated with partially anomalous pulmonary venous drainage into the superior vena cava or right atrium.

In patients with uncomplicated ASDs (e.g., with normal pulmonary vascular resistance), oxygenated blood shunts from the left to the right atrium. The magnitude of the shunting is determined by the size of the defect and the compliance of the left and right ventricles. Small ASDs accommodate the increased blood flow in the right atrium without sequelae and no significant hemodynamic compro-

mise of the right heart. If the defect is large, the right atrium and right ventricle dilate to accommodate the increased volume of shunted blood (Fig. 7-1). Pressure in the pulmonary artery increases secondary to the increased volume of blood; however, with the exception of extremely large, long-standing defects, pulmonary vascular resistance usually remains normal.

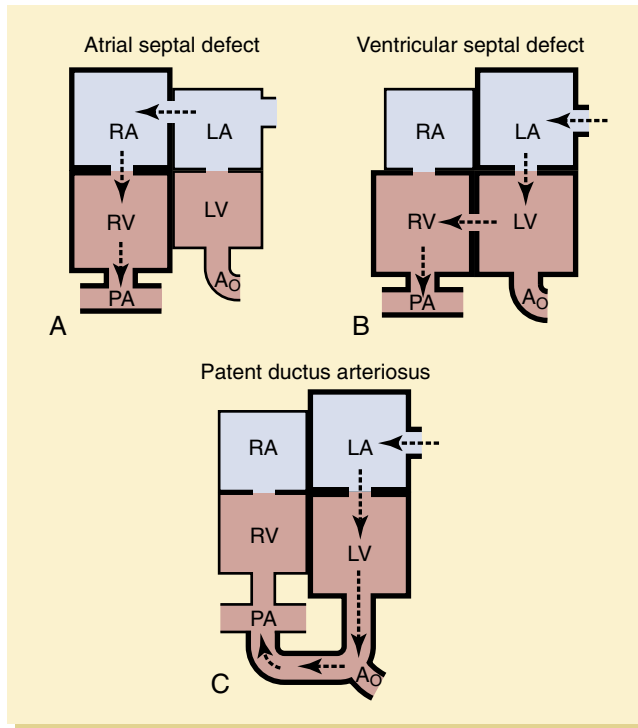

Figure 7-1 Diagram illustrates the three types of shunt lesions that commonly survive until adulthood and their effects on chamber size. **A**, Uncomplicated atrial septal defect demonstrating left-to-right shunt flow across the interatrial septum and resulting in dilation of the right atrium (RA), right ventricle (RV), and pulmonary artery (PA). **B**, Uncomplicated ventricular septal defect, resulting in dilation of the RV, left atrium (LA), and left ventricle (LV). **C**, Uncomplicated patent ductus arteriosus, resulting in dilation of the LA, LV, and PA. Ao, aorta. (From Liberthson RR, Waldman H: Congenital heart disease in the adult. In Kloner RA [ed]: *The Guide to Cardiology*, 3rd ed. Greenwich, Conn, Le Jacq Communications, 1991, pp 24-47. Copyright ©1991 by Le Jacq Communications, Inc.)

Most patients with ASD are asymptomatic until adulthood, when symptoms such as fatigue, dyspnea, and poor exercise tolerance develop, secondary to right ventricular dysfunction. Older patients may decompensate when acquired heart disease leads to a rise in left ventricular filling pressures and more blood is shunted from the left atrium to the already volume-overloaded right heart. Patients with ASD are prone to atrial fibrillation, especially after 50 years of age. Irreversible pulmonary vascular obstruction resulting in right-to-left shunting and cyanosis (Eisenmenger syndrome) is uncommon and occurs infrequently (<5% of patients with ASDs). The presence of an ASD may be heralded by a paradoxical embolus traversing the defect, resulting in stroke or transient ischemic attack.

A prominent right ventricular pulsation may be observed on physical examination, along the left sternal border secondary to a dilated, hyperdynamic right ventricle (Table 7-1). The S_2 sound is widely split and fixed. Wide splitting occurs because right ventricular volume overload results in a prolonged ejection period and delayed closure of the pulmonic valve. Fixed splitting results from a lack of respiratory variation in right ventricular filling with variation in the left-to-right shunt, compensating for varying venous return. An ejection-quality murmur that increases with inspiration is commonly heard at the left sternal border and is secondary to increased blood flow across the pulmonic valve. If severe pulmonary vascular obstruction develops, the P_2 sound becomes loud, the splitting of S_2 narrows, and a right ventricular gallop may be heard.

The diagnosis of ASD is usually made with two-dimensional and color Doppler echocardiography. In particular, transesophageal imaging allows for excellent visualization of the interatrial septum as well as associated congenital defects such as anomalous pulmonary veins, VSDs, and abnormalities of the mitral leaflets. This technique provides additional information pertaining to right ventricular size and function and the degree of shunt flow. Cardiac magnetic resonance imaging (MRI) is another noninvasive imaging modality that provides excellent visualization of the interatrial septum and pulmonary veins and can provide diagnostic information in cases of uncertainty after echo imaging. MRI is particularly well suited for analysis of right ventricular size and function. Cardiac catheterization is useful to assess and define the shunt fraction (Q_p/Q_s ratio) to measure pulmonary arterial pressures and to estimate pulmonary vascular

Table 7-1 Findings in Uncomplicated Shunt Lesions

Type	Physical Findings	Electrocardiogram	Chest Radiograph

LA, left atrium; LV, left ventricle; RV, right ventricle.

resistance, but is rarely necessary after noninvasive imaging. The most common indication for catheterization is now the identification of concomitant coronary artery disease in adults older than 40 years who are contemplating surgical repair.

Once diagnosed, ASDs should be closed without delay. The presence of right ventricular enlargement should prompt referral for closure, even in the absence of symptoms. Paradoxical embolism, elevation of pulmonary artery pressure, or a net left-to-right shunt should also prompt consideration of closure. Defects less than 8 mm in diameter are rarely significant. Significant pulmonary hypertension is a contraindication to ASD closure. When pulmonary arterial pressures exceed two thirds of systemic pressure, evidence of ongoing significant left-to-right shunt must also be present, or the reversibility of pulmonary hypertension with the administration of vasodilators or oxygen must be administered to justify the increased risk for closure.

Percutaneous device closure of a secundum ASD is an acceptable alternative to surgical closure and is becoming the preferred intervention for this condition. A sufficient rim of tissue is required for successful device deployment. Short- and intermediate-term results with the Amplatzer closure device have been excellent. The long-term results remain unknown, and patients who have received such devices should continue to receive close follow-up care. Primum and sinus venosus defects should be surgically closed.

Closure of a hemodynamically significant ASD before the age of 25 years is expected to convey a mortality benefit. Closure before the age of 40 years of age is expected to decrease the long-term risk for atrial arrhythmias. After the fourth decade, symptoms are usually significantly improved after surgical repair; however, some degree of right ventricular dysfunction may persist. Antibiotic prophylaxis for infective endocarditis is not required for small ASDs or patent foramen ovale or after ASD closure.

VENTRICULAR SEPTAL DEFECT

VSD is a common congenital abnormality in newborns and is present in about 1 in 500 normal births. Because nearly 50% of VSDs close spontaneously during childhood and most large defects are surgically corrected at an early age, this defect is rarely encountered in adults. VSDs are classified according to their location within the interventricular septum. Type I VSDs (also known as supracristal VSD) are located beneath the aortic annulus and often lead to aortic valvular incompetence. Type II VSDs (or perimembranous VSD) are the most common (about 80%) and are located in the membranous portion of the septum between the left ventricular outflow tract and the right ventricle near the septal leaflet of the tricuspid valve. Type III defects involve the atrioventricular canal, which is often associated with ostium primum ASDs, along with mitral and tricuspid leaflet abnormalities. Such congenital defects are common in patients with Down syndrome. Type IV defects (or muscular VSDs) make up 5% to 20% of VSDs and involve the muscular portion of the interventricular septum and often close spontaneously during childhood if small.

In patients with uncomplicated VSDs, oxygenated blood from the left ventricle is shunted across the defect into the

right ventricle. If the defect is small, then right ventricular size and function are normal, and pulmonary vascular resistance does not increase. If the defect is large, however, the right ventricle dilates to accommodate the increased volume, and pulmonary blood flow increases (see Fig. 7-1). If the condition is uncorrected, pulmonary vascular obstruction may develop and may lead to pulmonary artery hypertension, reversal of the interventricular shunt, and systemic desaturation and cyanosis (Eisenmenger syndrome).

The clinical course of a patient with VSD depends on the size of the defect. Most small defects spontaneously close, or if still present in adulthood, they are usually not associated with any significant hemodynamic complications. Large defects are usually detected and repaired during infancy. Affected individuals with uncorrected defects who survive to adulthood may have signs and symptoms of right-sided ventricular heart failure. If pulmonary vascular obstruction with reversed central shunt (so-called Eisenmenger physiology) develops, cyanosis and clubbing of the fingers may be present. All patients with VSD (or repaired VSD with residual shunt flow) are at risk for bacterial endocarditis that usually involves the right ventricular outflow tract.

On physical examination, the patient with an uncomplicated VSD has a hyperdynamic precordium and a palpable thrill along the left sternal border (see Table 7-1). The murmur is usually holosystolic and is best heard at the left sternal border. In general, small defects are associated with loud murmurs because of the significant pressure gradient between the left and the right ventricles. As pulmonary hypertension develops and left-to-right shunt flow decreases, the murmur may soften, and a loud P₂ sound may be present.

Two-dimensional and Doppler echocardiography are useful in diagnosing VSDs as well as in assessing right ventricular size and function and associated cardiac abnormalities. The evaluation of VSD can be complemented by cardiac MRI or computed tomography (CT) studies in cases of uncertainty with echo imaging. Cardiac catheterization may be necessary before surgical repair to document the severity of shunt flow and to determine pulmonary artery pressure and pulmonary vascular resistance, especially in cases with suspected pulmonary arterial hypertension. Documentation involves identifying a rise in oxygen content in blood that is sampled from the right ventricle and pulmonary artery compared with blood from the right atrium. Patients with Eisenmenger syndrome and net right-to-left shunt flow are not surgical candidates. Surgical closure of the VSD with sutures or a prosthetic patch is recommended for patients with left-to-right shunt flow greater than 1.5:1 without evidence of irreversible pulmonary hypertension. Percutaneous device closure is an attractive option for muscular VSDs.

Valvular Defects

CONGENITAL AORTIC STENOSIS AND BICUSPID AORTIC VALVE

Congenital left ventricular outflow obstruction may occur at the valvular, subvalvular, or supra-ventricular level. Valvular stenosis is most often secondary to a bicuspid aortic valve,

which is present in about 2% of the population and occurs more frequently in men than in women. Associated cardiovascular abnormalities can occur in less than or equal to 20% of affected persons and include coarctation of the aorta and patent ductus arteriosus (PDA). Bicuspid aortic valves rarely cause significant obstruction during infancy and early childhood. However, their abnormal structure results in turbulent flow that leads to leaflet injury and thickening, calcification, and, ultimately, narrowing of the orifice.

Although a few patients with bicuspid aortic stenosis remain asymptomatic throughout life, most affected individuals develop symptoms during the fifth and sixth decades of life. As with acquired aortic stenosis, chest pain, syncope, and congestive heart failure are the most frequent symptoms. Bicuspid aortic valves may be complicated by aneurismal enlargement of the thoracic aorta and aortic dissection. Other complications include sudden death, particularly in the setting of significant outflow obstruction, and infective endocarditis, which can lead to significant aortic regurgitation. Less commonly, aortic regurgitation is the predominant abnormality associated with a bicuspid aortic valve.

The physical examination of a patient with a stenotic bicuspid aortic valve is similar to that of the patient with acquired aortic stenosis and is usually characterized by an ejection-quality murmur at the left sternal border (Table 7-2). If the leaflets are still pliable, an early systolic ejection click may be appreciated as the leaflets open. The decrescendo diastolic murmur of aortic insufficiency may

also be present, as may typical signs of significant aortic regurgitation.

The diagnosis of bicuspid aortic valve and the determination of degree of stenosis and regurgitation are usually made by two-dimensional and Doppler echocardiography. (Treatment of patients with significant obstruction or insufficiency is outlined in Chapter 8.) Children and young adults with significant stenosis may have improvement with percutaneous valvuloplasty, especially when calcification of the valve cusps is minimal. In older adults or those patients with significant leaflet calcification, aortic valve replacement remains the treatment of choice. Although aortic root enlargement may be identified by echocardiography, cardiac MRI and CT provide more accurate measurements for serial follow-up and should be performed if enlargement is suspected. Although endocarditis is always a concern with bicuspid aortic valves, antibiotic prophylaxis is unlikely to prevent most cases, and the risks are now thought to outweigh the benefits. Meticulous oral hygiene is the recommended practice to prevent endocarditis in these patients.

Other causes of congenital left ventricular outflow tract obstruction are much less common. *Subaortic stenosis* is often first diagnosed in adulthood and is characterized by the presence of a discrete, fibrous diaphragm that encircles the left ventricular outflow tract between the mitral annulus and the basal interventricular septum. Patients with this defect have a characteristic outflow murmur but not the systolic ejection click appreciated in patients with bicuspid

Table 7-2 Findings in Select Uncomplicated, Unrepaired Cardiac Defects

Type	Physical Findings	Electrocardiogram	Chest Radiogram
Congenital aortic stenosis	Decreased carotid upstroke	LV hypertrophy	Post-stenotic aortic dilation
	Sustained apical impulse		Prominent LV
	Single S ₂ , S ₄ Systolic ejection murmur		
Coarctation of aorta	Delayed femoral pulses	LV hypertrophy	Post-stenotic aortic dilation
	Reduced blood pressure in lower extremities		Prominent ascending aorta
	Findings associated with bicuspid aortic valve		LV enlargement
Pulmonic valve stenosis	RV lift	RV hypertrophy RA abnormality	Post-stenotic dilation of the main or left pulmonary artery
	Pulmonic ejection sound		RA and RV enlargement
	Systolic ejection murmur at left sternal border		
	RV S ₄ , widely split S ₂ , soft P ₂		
Tetralogy of Fallot	Usually cyanotic	RV hypertrophy RA abnormality	Boot-shaped heart
	Possible clubbing		Small pulmonary artery
	Prominent ejection murmur at left sternal border		Normal pulmonary vasculature
	Soft or absent P ₂		
Ebstein anomaly	Acyanotic or cyanotic	RA abnormality Right bundle branch block PR prolongation Ventricular pre-excitation	Enlarged RA
	Increased jugular venous pressure		Normal pulmonary vasculature
	Prominent v wave		
	Systolic murmur at sternal border, increases with inspiration		

LV, left ventricle; PR, pulse rate; RA, right atrium; RV, right ventricle.

aortic valves. *Supravalvar aortic stenosis* (SVAS) is a rare form of outflow obstruction characterized by varying degrees of ascending aortic root stricture. Loss-of-function mutations in the extracellular matrix protein, elastin, are responsible for smooth muscle hypertrophy in SVAS, which is a generalized arteriopathy most commonly affecting the sinotubular junction of the ascending aorta but also affecting the pulmonary and other systemic arteries. This abnormality is usually diagnosed in childhood and is often part of a syndrome with hypercalcemia and multiple skeletal, vascular, and developmental abnormalities. Nonsyndromic cases also occur in both sporadic and familial forms.

PULMONIC VALVE STENOSIS

Pulmonic valve stenosis is the most common cause of obstruction to right ventricular outflow and usually occurs as an isolated congenital lesion. Fusion of the pulmonary leaflets creates the pressure-overloaded state and results in right ventricular hypertrophy. Some patients develop discrete hypertrophy of the infundibulum beneath the pulmonic valve, further contributing to outflow obstruction.

Unless the valve is severely stenotic at birth, most affected persons live a normal life until adolescence or young adulthood. The development of symptoms depends on the severity of the stenosis and right ventricular function. Patients with mild-to-moderate stenosis are usually asymptomatic and rarely have complications associated with the defect. Patients with moderate-to-severe obstruction often exhibit progressive fatigue and dyspnea. If right ventricular dysfunction occurs, symptoms and signs of right-sided ventricular heart failure may be present.

On physical examination, the patient with severe stenosis has a right ventricular lift on palpation of the precordium (see Table 7-2). The S_1 sound is usually normal and is followed by an opening click that becomes louder with expiration. The P_2 sound becomes softer and is delayed as the severity of the stenosis increases. The characteristic murmur of pulmonic stenosis is a systolic ejection murmur heard best at the left upper sternal border, which increases with inspiration. As with aortic stenosis, a late-peaking murmur indicates more severe stenosis. A prominent jugular venous wave and right-sided S_3 sound may also be present in patients with severe obstruction to right ventricular outflow.

For asymptomatic patients with mild pulmonic stenosis (<30 mm Hg peak gradient), symptoms are unlikely, and obstruction is unlikely to progress. Patients with moderate stenosis (peak gradient > 50 mm Hg) are likely to develop symptoms and require closer observation. In children and adults with isolated pulmonic stenosis, percutaneous balloon valvuloplasty is a suitable therapeutic option that offers results comparable with those achieved with surgery. Valvuloplasty should be offered to symptomatic patients (who will often have peak gradients higher than 50 mm Hg). Asymptomatic patients with peak gradients higher than 60 mm Hg should also be treated. Balloon valvuloplasty is unlikely to relieve obstruction from significant infundibular stenosis or in cases with moderate or worse pulmonary regurgitation, in which case surgical repair is preferred. Repair of the valve involves separation of the fused commissures and resection of the infundibulum if significant hypertrophy is present. Valve replacement is rarely necessary.

OTHER VALVULAR DEFECTS

Ebstein anomaly is a rare condition (0.5% of patients with congenital heart disease) characterized by apical displacement of the tricuspid valve into the right ventricle. As a result, the basal portion of the right ventricle forms part of the right atrium and leaves a small functional right ventricle. The tricuspid leaflets are often dysplastic and may partially adhere to the interventricular septum or right ventricular free wall, often with significant tricuspid regurgitation. The degree of right ventricular dysfunction depends on the size of the *functioning* right ventricle and the severity of the tricuspid regurgitation. Ebstein anomaly frequently presents in adulthood. A patent foramen ovale or ostium secundum ASD is present in more than 50% of patients and may result in right-to-left shunt flow as right atrial pressure increases. Supraventricular arrhythmias are common in those with Ebstein anomaly, as is ventricular pre-excitation associated with Wolff-Parkinson-White syndrome.

Diseases of the Aorta

COARCTATION OF THE AORTA

Coarctation of the aorta is a fibrotic narrowing of the aortic lumen usually located distal to the left subclavian artery in the region of the ligamentum (ductus) arteriosus. The defect is more common in men than in women (2:1) and represents 5% to 8% of all congenital heart defects. About 25% to 50% of patients have an associated bicuspid aortic valve. The most common extracardiac abnormality is an aneurysm of the circle of Willis (present in 3% to 5% of patients).

Coarctation produces obstruction to left ventricular outflow and results in a rise in blood pressure in the proximal aorta and great vessels relative to the distal aorta and lower extremities. The development of left ventricular hypertrophy helps maintain normal stroke volume in the presence of increased afterload. Most cases of coarctation are diagnosed in infancy or childhood, during which a high mortality rate is observed for severe coarctation that has not been repaired. Occasional cases of mild coarctation will remain undiagnosed until adulthood, when a work-up for secondary causes of hypertension may reveal the abnormality. A coarctation should be excluded in all young patients with hypertension. If the condition is left untreated, more than two thirds of patients will develop left ventricular dysfunction and congestive heart failure by the fourth decade of life. Other complications include aortic dissection or rupture, stroke secondary to chronic hypertension, or spontaneous rupture of cerebral aneurysms. As such, patients with coarctation can be considered to have a generalized arteriopathy. Endocarditis involving the coarctation or the associated bicuspid aortic valve is a dangerous complication.

Clinically, most patients with coarctation have upper extremity hypertension with forceful carotid and upper extremity pulses (Fig. 7-2; see also Table 7-2). The pulses in the lower extremities are typically weak and delayed relative to the carotid upstroke. An ejection-quality murmur may be

Figure 7-2 Three-dimensional reconstruction of cardiac magnetic resonance image from a patient with uncorrected coarctation of the aorta. The coarctation (*arrow*) of the descending thoracic aorta (Ao) occurs in close proximity to the pulmonary artery (PA) in the expected location of the ligamentum arteriosus. Prominent intercostal arterial collaterals are observed.

heard if a bicuspid aortic valve is present. A systolic murmur originating from the coarctation is typically heard over the left upper back. Older adults may have findings of heart failure.

The diagnosis of coarctation may be made by two-dimensional and Doppler echocardiography. Echocardiography may be the only study required for diagnosis in infants and children. However, in adults, MRI and cardiac catheterization are the preferred methods for defining the location of the coarctation and the anatomy of the arch vessels. Repair in adults is recommended at the time of diagnosis, although only about 50% of patients become normotensive after the procedure. Surgical repair is standard in many centers, although primary percutaneous treatment with balloon angioplasty and stenting of discrete coarctation is preferred in others. Restenosis of the aorta may occur postoperatively, although in many instances, this recurrent stenosis may be dilated using percutaneous techniques. A new or unusual headache in a patient with coarctation should prompt an evaluation for intracranial aneurysms. Progressive enlargement of the thoracic aorta with dissection is a concern in patients with coarctation. Hypertension is common after repair of coarctation and may be manifest primarily with exercise.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus functionally closes several hours after birth and anatomically closes within 4 to 8 weeks thereafter. PDA is more common in infants who are premature or who

are born at a high altitude. PDA is also more common in women than in men, and it may be associated with other cardiac abnormalities such as coarctation and VSD.

A persistent communication between the aorta and pulmonary artery is the result of the failure of the ductus arteriosus to close. The hemodynamic consequences of this communication depend on the size of the ductus. If the defect is small, pulmonary artery resistance remains normal, and blood flows from left to right from the aorta to the pulmonary circulation. Most patients with small PDAs are asymptomatic and survive into adulthood without developing significant hemodynamic complications. When the ductus is large, blood flow through the pulmonary circulation and returning to the left side of the heart is significantly increased, resulting in left ventricular volume overload and pulmonary congestion (see Fig. 7-1). Persistence of a large PDA may result in elevated pulmonary vascular resistance with Eisenmenger physiology. When pulmonary vascular resistance exceeds systemic vascular resistance, shunt flow reverses and passes from right to left. Such patients have cyanosis of the lower extremities with clubbing of the toes, whereas the upper extremities are usually normal in color without evidence of clubbing of the fingers. This differential cyanosis is secondary to shunting of poorly oxygenated blood from the pulmonary artery to the aorta distal to the left subclavian artery, whereas well-oxygenated blood from the left ventricle is supplied to the head and upper limbs. The increased volume and pressure load on the right ventricle can precipitate right-sided ventricular failure.

The characteristic physical examination finding of uncomplicated PDA is a loud, continuous, machinery-like murmur best heard in the left infraclavicular region (see Table 7-2). If the PDA is small, the peripheral pulses remain normal. A hemodynamically significant PDA also has a continuous murmur, but it is typically associated with bounding pulses and a wide pulse pressure. The left ventricle may be enlarged, and signs of pulmonary congestion may be present. An Eisenmenger PDA is characterized by the loss of the continuous murmur, signs of pulmonary hypertension, and differential cyanosis and clubbing.

The diagnosis of PDA is usually confirmed with two-dimensional and Doppler echocardiography, at which time the size of the shunt and the pulmonary pressures can be estimated. Oximetry should be performed on both fingers and toes. Cardiac catheterization is usually performed at the same time as percutaneous closure for further confirmation. Evidence for reversibility of pulmonary hypertension at cardiac catheterization is reassuring. Closure of the PDA is indicated in all cases except in those patients with silent PDAs, found only by a screening examination and without audible murmur, and in those with large PDAs associated with severe, irreversible pulmonary vascular disease.

Percutaneous device closure is the preferred intervention in most centers, particularly if calcification of the duct is present. Surgery is reserved for the PDA that is too large for percutaneous closure or with distorted anatomy such as a ductal aneurysm or after endarteritis. Surgical complications include recurrent laryngeal or phrenic nerve injury and thoracic duct damage. As with most congenital heart lesions, infective endocarditis is a concern and should be managed primarily by optimal oral hygiene. Antibiotic prophylaxis is reserved for patients with previous endocarditis.

Cyanotic and Other Complex Conditions

TETRALOGY OF FALLOT

Tetralogy of Fallot is the most common cyanotic congenital heart lesion in adults and represents 10% of all congenital heart defects. It may be exhibited to the physician before or, more commonly, after corrective or palliative surgery (see Table 7-2). Tetralogy is the result of a malalignment of the aorticopulmonary septum that divides the truncus arteriosus into the aorta and pulmonary artery during development, resulting in deviation of the aorta anteriorly toward the pulmonary artery. The four components of tetralogy are the following: (1) overriding of the aorta in relation to the ventricular septum; (2) right ventricular outflow obstruction, which may be valvular, subvalvular, supra-valvular, or a combination of all three; (3) membranous VSD; and (4) right ventricular hypertrophy. The VSD is usually large and allows free communication between the right and left ventricles. The presence of right ventricular outflow obstruction is protective, preventing volume and pressure overload of the pulmonary circulation, which would result in fixed pulmonary hypertension. The degree of right-to-left shunt flow depends on the degree of right ventricular outflow obstruction. If pulmonic stenosis is mild, right-to-left shunt flow is minimal, and the patient remains acyanotic (pink tetralogy). More commonly, the pulmonic stenosis is severe, and a large volume of poorly oxygenated blood is shunted into the systemic circulation with resulting cyanosis. The degree of cyanosis is worsened with exercise, when the fall in systemic vascular resistance increases the degree of right-to-left shunt flow. Tetralogy may also be associated with ASD, muscular VSD, right aortic arch, and other coronary anomalies. A chromosomal deletion (22q11) is found in 15% of cases, particularly in those with associated anomalies. Such a deletion implies a higher risk for transmission of congenital heart disease to offspring.

Surgical correction of tetralogy is usually performed during infancy or childhood and involves relief of right ventricular obstruction and patch closure of the VSD. After reparative surgery, patients are at risk for residual pulmonary stenosis or regurgitation, which may lead to right ventricular enlargement and dysfunction and tricuspid regurgitation. Aortic insufficiency is common after repair and may become clinically significant. Residual VSDs, aneurysms of the right ventricular outflow tract, and sustained arrhythmias are also recognized complications. Arrhythmias may be supraventricular or ventricular, may signify hemodynamic impairment, and may contribute to an increased risk for sudden death. Prolongation of the QRS duration (to >180 milliseconds) on the surface electrocardiographic study is a marker for increased risk for ventricular tachycardia and sudden death.

Palliative surgery may have been performed in childhood to improve pulmonary blood flow. Occasionally, patients may elect not to undergo complete repair. Such palliation involves the creation of a shunt between the systemic and pulmonary circulation (e.g., subclavian artery to ipsilateral pulmonary artery [Blalock-Taussig shunt]), which results in increased pulmonary blood flow and improved oxygenation of the systemic blood. A variety of palliative shunts have

been used for this purpose. Although such procedures often result in long-term palliation of hypoxia, several complications can occur. Patients may outgrow their shunts, or the shunts may spontaneously close and may lead to progressive cyanosis. If the shunt is too large, the increased volume of blood into the pulmonary circulation and left heart may result in pulmonary congestion and progress to irreversible pulmonary vascular obstruction. In patients surviving to adulthood, corrective surgery should still be undertaken, but the operative risk is higher secondary to the presence of right ventricular dysfunction.

COMPLETE TRANSPOSITION OF THE GREAT ARTERIES

Complete transposition (also known as D-transposition) represents 5% to 7% of congenital heart disease and is the most common cyanotic congenital heart disease in the newborn. It is characterized by abnormal ventriculoarterial connections with the aorta arising from the right ventricle and the pulmonary artery arising from the left. The circulation is thus two circuits in parallel. This anatomy can support fetal development, but serious consequences result on closure of the foramen ovale and ductus arteriosus shortly after birth, at which point the systemic and pulmonary circuits are separated and oxygenated blood no longer mixes with the systemic circulation. Uncorrected D-transposition has a 90% mortality rate in the first year of life. Associated defects include VSD, left ventricular outflow tract (subpulmonic) stenosis, and coarctation of the aorta.

The first successful palliative procedure for D-transposition was the atrial switch procedure (e.g., Mustard or Senning procedures) in which the venous return is baffled to the contralateral ventricle to achieve two circuits in series. These procedures result in excellent short- and mid-term outcomes. Complications include failure of the systemic right ventricle, tricuspid regurgitation, sinus node dysfunction, tachyarrhythmias, and baffle leaks or obstruction. Progressive ventricular failure should prompt consideration of heart transplantation.

In the 1980s, the arterial switch procedure supplanted the Mustard and Senning procedures. This technically challenging procedure restores normal anatomy by attaching the aorta to the left ventricle and the pulmonary artery to the right ventricle with reimplantation of the coronary arteries into the new aorta. Less long-term follow-up data are available for patients following arterial switch, but similar favorable mid-term outcomes have been noted, relative to the Mustard and Senning procedures. Late complications include obstruction of the reimplanted coronary arteries with associated myocardial ischemia, and progressive enlargement of the new aortic root with associated valvular regurgitation. It is recommended that all adults be evaluated at least once for coronary artery patency following arterial switch.

CORRECTED TRANSPOSITION OF THE GREAT ARTERIES

Inversion of the ventricles and abnormal positioning of the great arteries characterize congenital-corrected transposition of the great arteries (L-transposition). In this anomaly, the anatomic right ventricle lies on the left and receives oxygenated blood from the left atrium. Blood is ejected into

an anteriorly displaced aorta. The anatomic left ventricle lies on the right and receives venous blood from the right atrium and ejects it into the posteriorly displaced pulmonary artery. This condition is not generally cyanotic and is uncommon, representing 0.5% of cases in patients with congenital heart disease.

The clinical course of patients with corrected transposition depends on the severity of other intracardiac anomalies. When the abnormality is an isolated lesion, many individuals survive into adulthood without symptoms. In some patients, the systemic ventricle (anatomic right ventricle) may fail, and pulmonary congestion may result. Associated anomalies include atrioventricular nodal block, VSD, and Ebstein anomaly.

SINGLE VENTRICLE AND FONTAN OPERATION

A variety of anatomic defects can functionally result in a single ventricle supporting both the pulmonary and systemic circulation. As such, tricuspid atresia, double-inlet left ventricle with VSD, and large atrioventricular septal defect (among others) may all have similar consequences for the patient. The cardiac output is directed in common to both the aorta and the pulmonary artery, with the balance between the two circulatory beds determined by the degree of outflow tract obstruction. If outflow obstruction is equal, the lower pulmonary vascular resistance will tend to favor pulmonary flow; thus, the ideal single ventricle will have some degree of pulmonary outflow obstruction to prevent the development of fixed pulmonary hypertension. Patients with univentricular hearts who are not repaired have a poor prognosis, with a median survival of 14 years of age. Most patients have cyanosis and functional limitations and would benefit from palliative surgery.

The goal with palliation is to optimize pulmonary blood flow without volume loading the ventricle. In suitable patients, the Fontan procedure can offer improved functional status and relieve cyanosis. The Fontan procedure and its modifications connect all systemic venous return to the pulmonary artery without an intervening ventricular pump. This can be accomplished by anastomosis of the right atrium to the pulmonary arteries, separate connections between the superior vena cava and the adjacent right pulmonary artery, and the inferior vena cava through a graft to the left pulmonary artery or a tunnel connecting the vena cava and anastomosed to the pulmonary artery. The Fontan procedure separates the two circulations and provides relief of cyanosis without providing a volume load on the left ventricle or a pressure load on the pulmonary arteries. Complications include thrombosis, obstruction, or leaks in the Fontan circuit, ventricular dysfunction, arrhythmias, hepatic dysfunction, and protein-losing enteropathy. Patients with poor ventricular function or intractable protein-losing enteropathy after the Fontan procedure should be considered for transplantation.

EISENMENGER SYNDROME

In 1897, Victor Eisenmenger first described the clinical and pathologic features of a patient with fixed pulmonary hypertension resulting from a large VSD. In 1958, Paul Wood used

the term *Eisenmenger complex* to describe the combination of a large VSD with systemic pulmonary pressures and a reversed or bidirectional shunt. The same pulmonary pathologic changes can result from a large shunt at any level, and the term *Eisenmenger syndrome* was suggested to describe pulmonary hypertension with reversed or bidirectional shunting at any level. Thus a VSD, a PDA, or an ASD could all result in Eisenmenger physiologic characteristics. The defect size generally exceeds 1.5 cm in diameter for VSD, with about half that diameter for PDA and twice that diameter for ASD. Large surgical shunts can also lead to Eisenmenger syndrome.

Most patients with Eisenmenger syndrome survive to adulthood, with complications generally occurring from the third decade onward. The prognosis is better than that for patients with other causes of pulmonary hypertension such as primary pulmonary hypertension.

Complications include hyperviscosity syndrome, hemorrhage or thrombosis, arrhythmias and sudden death, endocarditis and cerebral abscess, ventricular dysfunction, hyperuricemia and gout, and renal impairment, among others. Hyperviscosity syndrome results from excessive erythrocytosis driven by increased erythropoietin in response to chronic hypoxia. Symptoms include headache, myalgias, and altered mentation. Many patients can tolerate a high hematocrit level with mild or no symptoms, and phlebotomy should not be undertaken simply in response to the hematocrit level. Excessive phlebotomy can lead to iron deficiency. Iron-deficient erythrocytes are less distensible and result in higher blood viscosity for any given hematocrit level, with microcytosis being the strongest independent predictor for cerebrovascular events.

Patients with Eisenmenger syndrome have achieved a delicate balance, and management of such patients should respect that balance. Prevention of complications is the preferred strategy. Influenza inoculations, endocarditis prophylaxis, and an avoidance of inappropriate phlebotomy are the mainstays of management. Extreme caution should be exercised with noncardiac surgery to avoid precipitous changes in vascular resistance that may lead to cardiovascular collapse. Pregnancy is strongly discouraged, considering the high risk to both the mother and the fetus. Sterilization is preferred because oral contraceptives can aggravate the risk for thrombosis. Pulmonary vasodilator therapy may improve quality of life, but carries recognized risks and should be supervised by expert care.

Other Conditions

Congenital anomalies of the coronary arteries are not uncommon and may be asymptomatic or associated with myocardial ischemia. The left circumflex or left anterior descending artery may arise from the right sinus of Valsalva and is usually not associated with abnormalities of myocardial perfusion. Either coronary artery may arise from the right sinus and may pass between the pulmonary trunk and aorta. This abnormality may result in myocardial ischemia, infarction, or sudden death in young adults, especially during exertion. Coronary artery fistulas with drainage into the right ventricle, vena cava, or pulmonary vein may be associated with myocardial ischemia if a significant amount of coronary blood flow is shunted into the venous system. Diagnosis of these abnormalities is made by coronary angiography.

Prospectus for the Future

The growing population of patients with successful outcomes after intervention for congenital heart disease is posing new challenges during adulthood. The increasing prevalence of genetic studies must be linked to genetic counseling. Early prenatal diagnoses that are linked to specific molecular defects

will engender therapeutic strategies in utero. Genetic epidemiologic studies will provide important insights about the influences of the in utero environment on the subsequent susceptibility and risk factors for heart disease during adulthood.

Acquired Valvular Heart Disease

Sheldon E. Litwin

Aortic Stenosis

Aortic stenosis can be congenital or acquired in origin (Table 8-1). The most common congenital cardiac abnormality affects the bicuspid aortic valve. Significant narrowing of the orifice usually occurs during middle age after years of turbulent flow through the valve results in leaflet injury, thickening, and calcification. Rheumatic aortic stenosis results from fusion of the leaflet commissures and is usually associated with mitral valve disease. The most common cause of aortic stenosis in adults is degenerative or senile aortic stenosis, which usually occurs in patients older than 65 years. Aortic stenosis is more common in men than it is in women.

In patients with aortic stenosis, the outflow obstruction gradually increases over many years, resulting in left ventricular hypertrophy. This response allows the left ventricle to generate and maintain a large pressure gradient across the valve without a reduction in stroke volume. However, left ventricular hypertrophy often results in increased diastolic chamber stiffness because greater intracavitary pressure is required to maintain left ventricular filling. Systolic dysfunction may also occur as a result of changes in expression of myocyte contractile and calcium-cycling proteins.

Patients with severe aortic stenosis may be asymptomatic for many years despite the presence of severe obstruction. The cardinal symptoms associated with aortic stenosis are angina, syncope, and congestive heart failure. Angina can occur in the absence of epicardial coronary artery disease because of the increased oxygen demand of the hypertrophied ventricle and decreased coronary blood flow secondary to elevated left ventricular diastolic pressure. Syncope may result from transient arrhythmias but more commonly occurs with exertion when cardiac output is insufficient to maintain arterial pressure in the presence of exercise-induced peripheral vasodilation. Dyspnea may result from increased filling pressures associated with the noncompliant, hypertrophied left ventricle or may signal the onset of systolic

dysfunction. Once patients with severe aortic stenosis develop symptoms, the prognosis is poor unless surgical correction is undertaken. Previous studies have shown that the mean survival rate after the onset of symptoms is about 2 years in patients with heart failure, 3 years in patients with syncope, and 5 years in patients with angina (Fig. 8-1).

On physical examination, the patient with aortic stenosis may have a laterally displaced, sustained apical impulse secondary to left ventricular hypertrophy (Table 8-2). An audible or palpable S_4 may also be present if the patient is in sinus rhythm. Decreased mobility of the aortic cusps may cause the A_2 component of S_2 to be soft or absent. The murmur of aortic stenosis is a harsh, crescendo-decrescendo murmur that is best heard over the right upper sternal border and often radiates to the neck. As the obstruction increases, the *peak* of the murmur occurs later in systole. If left ventricular dysfunction develops, the murmur may decrease in intensity secondary to a reduction in stroke volume. The carotid impulse is often diminished in intensity and delayed (i.e., *pulsus parvus et tardus*) (see Chapter 4), although in older adults, these changes may be present secondary to intrinsic vascular disease in the absence of significant aortic stenosis.

The principal electrocardiographic finding in aortic stenosis is left ventricular hypertrophy. Heart block may develop as a result of calcification from the aortic valve extending into the conducting system. Echocardiography is the most important diagnostic test and is useful to determine the cause of the aortic stenosis and to quantitate the degree of obstruction. The mean transvalvular gradient and valve area can be measured and calculated using Doppler techniques. Patients with severe stenosis will often undergo cardiac catheterization both to confirm the presence of severe aortic stenosis and to determine whether concomitant coronary artery disease is present. A valve area less than or equal to 0.7 cm^2 defines critical aortic stenosis (normal valve area is 3 cm^2) and is usually associated with a mean transvalvular gradient of more than 50 mm Hg when normal left

ventricular function is present. It should be noted that in patients with reduced systolic function, the mean gradient might be low despite the presence of severe aortic stenosis. Moreover, symptoms are often present with valve areas of 0.7 to 1 cm².

Treatment in most adults with symptomatic aortic stenosis is surgical replacement of the valve. The operative risk and prognosis are best in patients with preserved left ventricular systolic function. However, surgery should still be considered in patients with left ventricular dysfunction because relief of the obstruction can result in significant clinical and hemodynamic improvement. A more nuanced approach is required for patients with asymptomatic aortic stenosis in whom a recommendation for surgical intervention might be based on the functional assessment by exercise stress testing. Advanced age is associated with higher operative morbidity but is not a contraindication to surgical therapy. Balloon aortic valvuloplasty is a percutaneous technique in which a balloon catheter is positioned across the aortic valve. Inflation results in fracture or separation of the fused and calcified cusps. This procedure is most effective in young patients with noncalcified congenital aortic stenosis and is rarely used in adult patients with calcific aortic stenosis because of significant complications and a high restenosis rate (about 30% at 6 months). Medical interventions with cholesterol-lowering therapies to slow the progression of mild to moderate aortic stenosis are still under clinical inves-

Figure 8-1 A, Natural history of aortic stenosis without surgical therapy. **B**, Natural history of mitral and aortic valve disease in an era when surgical therapy was not widely available. Survival rates in 42 patients with aortic stenosis (AS, orange circles with dotted line), 35 patients with aortic insufficiency (AI, orange circles with solid line), and 133 patients with mitral insufficiency (MI, yellow circles with solid line). Clinical course in AI, MS (red circles with dotted line), and MI is similar with a 5-year survival rate of about 80% and a 10-year survival rate of about 60%. Patients with AS have a worse prognosis, with 5- and 10-year survival rates of about 40% and 20%, respectively. (A from Ross J Jr, Braunwald E: Aortic stenosis. *Circulation* 38[Suppl V]:61, 1968. tigation. Routine antibiotic prophylaxis is no longer recommended unless there is prior history of endocarditis.

Aortic Regurgitation

Aortic regurgitation (AR) may be secondary to primary disease of the aortic leaflets, aortic root, or both (see Table 8-1). Abnormalities of the aortic leaflets may be secondary

to rheumatic disease, congenital abnormalities, endocarditis, or use of certain anorexigenic drugs. In addition, AR is commonly a consequence of degenerative and bicuspid aortic stenosis. An aortic root pathologic condition associated with annular and root dilation may result in separation or prolapse of the leaflets.

With chronic AR, the left ventricle must accommodate the normal inflow from the left atrium in addition to the aortic regurgitant volume. As a result, the left ventricle dilates and hypertrophies to maintain normal effective forward flow and to minimize wall stress. As the AR progresses, these changes in left ventricular size and wall thickness may be insufficient to maintain normal left ventricular filling pressures, and irreversible myocyte damage may occur. As a result, the left ventricle will dilate further, and systolic function and effective stroke volume will decrease.

Clinically, patients with chronic, severe AR may be asymptomatic for long periods secondary to the compensatory changes in the left ventricle. When symptoms do develop, they are primarily related to an elevation in left ventricular filling pressures and include dyspnea on exertion, orthopnea, and paroxysmal nocturnal dyspnea. Many patients will describe chest or head pounding secondary to the hyperdynamic circulation. If effective cardiac output is reduced, the patient may complain primarily of fatigue and weakness. As with aortic stenosis, angina may occur in patients with AR even in the absence of epicardial coronary artery disease secondary to elevated left ventricular filling pressures and reduced coronary perfusion pressure.

On physical examination, patients with severe AR have a widened pulse pressure (difference between the systolic and diastolic pressures) as a result of the runoff of blood back into the left ventricle (see Table 8-2). The arterial pulse is usually bounding, with a rapid upstroke and quick collapse (Corrigan disease or water-hammer pulse) (see Chapter 4). The cardiac impulse is hyperdynamic and is displaced laterally and inferiorly. The murmur of AR is a high-pitched, decrescendo diastolic murmur best heard at the lower left sternal border with the patient sitting up and leaning forward. Asking the patient to hold his or her breath at end expiration while the hands are held behind the head may also improve the ability to auscultate the murmur of AR. A systolic ejection murmur is often heard secondary to increased forward flow across the aortic valve. An S_3 gallop may be present, especially if the patient has developed symptoms of heart failure. A low-pitched, diastolic murmur (Austin Flint murmur) may be heard at the apex and confused with the murmur of mitral stenosis (MS). This sound is thought to be secondary to the incomplete opening of the mitral leaflets (functional MS) secondary to elevated left ventricular filling pressures or impingement of the AR jet on the anterior mitral leaflet.

The natural history of chronic AR is varied. Many patients with moderate to severe AR will remain asymptomatic for many years and generally have a favorable prognosis. Other patients may have progression of AR severity and develop left ventricular dysfunction and symptoms of congestive heart failure. Echocardiography is the primary tool to monitor the progression of disease and optimize the timing of surgery. Prior studies have shown that patients at high risk are those with left ventricular end-systolic

diameters greater than 50 mm or an ejection fraction of less than 50%. Surgery is usually recommended before developing this degree of left ventricular enlargement or dysfunction. Therefore patients with known moderate to severe AR should be monitored regularly with noninvasive testing to detect early signs of cardiac (i.e., left ventricular) decompensation.

Treatment of patients with moderate to severe AR theoretically should include vasodilator therapy, such as nifedipine or angiotensin-converting enzyme (ACE) inhibitors, because these agents unload the left ventricle. Although some published data suggest that these agents may slow the progression of myocardial dysfunction and delay the need for surgery, more recent data do not support that contention.

Valve replacement surgery should be considered in symptomatic patients and those with evidence of significant left ventricular enlargement or left ventricular systolic dysfunction. In patients with reduced left ventricular ejection fraction of short duration (14 months), valve replacement usually results in significant improvement in ventricular function. If left ventricular dysfunction has been present for a prolonged period, then permanent myocardial damage may occur. Although such patients should not be excluded from surgery, their long-term prognosis remains poor.

As compared with chronic AR, acute AR is a medical emergency that often requires immediate surgical intervention. The causes of acute AR include infective endocarditis, traumatic rupture of the aortic leaflets, aortic root dissection, and acute dysfunction of a prosthetic valve. Acute AR is the result of hemodynamic instability because the left ventricle is unable to dilate to accommodate the increased diastolic volume, resulting in decreased effective forward flow. Left ventricular and left atrial pressures rise quickly, leading to pulmonary congestion.

Patients with acute AR often exhibit symptoms and signs of cardiogenic shock. The patient is usually pale with cool extremities as a result of peripheral vasoconstriction. The pulse is weak and rapid, and the pulse pressure is normal or decreased. The murmur of acute AR is low pitched and short because of rapid equilibration of aortic and left ventricular pressures during diastole. An S_3 gallop is often present. Echocardiography is useful to assess AR severity and to determine its cause and can be quickly performed at the bedside in the patient who is acutely ill.

The medical treatment of acute AR includes vasodilator therapy and diuretics if the blood pressure is stable. In patients who are hemodynamically compromised, inotropic support and vasopressors may be necessary. For most patients with acute AR, urgent valve replacement remains the treatment of choice. Intra-aortic balloon counterpulsation is relatively contraindicated because it may worsen AR severity.

Mitral Stenosis

MS occurs when thickening and immobility of the mitral leaflets impede flow from the left atrium to the left ventricle. Rheumatic fever is by far the most common cause of MS. Rarely, congenital abnormalities, connective tissue disorders, left atrial tumors, and overly aggressive surgical repair

Figure 8-2 Graphic illustration of the relationship between the diastolic gradient across the mitral valve and the flow through the mitral valve. As the mitral valve becomes more stenotic, the pressure gradient across the mitral valve must increase to maintain flow into the left ventricle. When the mitral valve area is 1 cm² or less, the flow rate into the left ventricle cannot be significantly increased, despite a significantly elevated pressure gradient across the mitral valve. (Adapted from Wallace AG: Pathophysiology of cardiovascular disease. In Smith LH Jr, Thier SO [eds]: The International Textbook of Medicine, vol 1. Philadelphia, WB Saunders, 1981, p 1192.)

of a regurgitant valve may lead to obstruction of the mitral valve. Two thirds of patients with MS are women. The pathologic changes that occur with rheumatic MS include fusion of the leaflet commissures and thickening, fibrosis, and calcification of the mitral leaflets and chordae. These changes occur over many years before dysfunction becomes hemodynamically important.

The initial hemodynamic change that occurs with MS is an elevated left atrial pressure created by obstruction to left ventricular inflow (Fig. 8-2). This pressure change is transmitted back to the pulmonary venous system and may result in pulmonary congestion. Initially, this change may only occur at more rapid heart rates, such as with exercise or atrial arrhythmias, when higher left atrial pressures develop during the shortened diastolic period. As the MS becomes more severe, left atrial pressure remains elevated even at normal heart rates, and symptoms related to elevated pulmonary venous pressures may be present at rest. Chronic elevations in pulmonary venous pressures may lead to an increase in pulmonary vascular resistance and pulmonary arterial pressures. If the MS is not corrected, irreversible changes in the pulmonary vasculature may occur, and signs and symptoms of right ventricular heart failure may develop. In contrast, left ventricular filling pressures are usually normal or low with mild to moderate MS. As the stenosis becomes severe, filling of the left ventricle is impaired, and stroke volume and cardiac output are reduced.

Patients with MS of rheumatic origins usually develop symptoms during the third or fourth decade of life. Dyspnea, orthopnea, and atrial fibrillation are the most common symptoms. Some patients may have sudden hemoptysis secondary to rupture of the dilated bronchial veins (pulmonary apoplexy) or blood-tinged sputum associated with pulmonary edema. Peripheral embolism from left atrial thrombus

may also occur, even in the absence of atrial fibrillation. In long-standing, severe MS, patients may develop peripheral edema secondary to elevated right ventricular pressures and right ventricular dysfunction. Compression of the left recurrent laryngeal nerve from a severely dilated left atrium may result in hoarseness (Ortner syndrome).

On physical examination, S₁ is loud early in the course of MS because the leaflets remain fully open throughout diastole and then quickly close (see Table 8-2). As the leaflets become more calcified and immobile, S₁ will become softer or completely absent. The opening snap is a high-pitched sound after the S₂ and reflects the abrupt mitral valve opening. As the MS becomes more severe, the interval between the S₂ and opening snap becomes shorter because left atrial pressure exceeds left ventricular pressure earlier in diastole. The characteristic low-pitched rumbling murmur of MS is best heard at the left ventricular apex with the patient in the left lateral decubitus position. The murmur is loudest in early diastole when rapid ventricular filling occurs. If sinus rhythm is present, the murmur may increase in intensity after atrial contraction (presystolic accentuation). In some patients, the murmur may only be heard at times of increased blood flow through the mitral valve, such as after exercise. If pulmonary artery pressures are elevated, a palpable P₂ may be detected at the upper left sternal border. On auscultation, the pulmonic component of S₂ is prominent and a right ventricular gallop may be present.

Echocardiography is the most useful tool for pathologic assessment of the mitral apparatus as well as the severity of the stenosis. The characteristic rheumatic deformity observed with two-dimensional imaging is doming (i.e., hockey stick deformity) of the anterior mitral valve leaflet, which is secondary to fusion of the commissures and tethering of the leaflet tips (Fig. 8-3). In addition, the mobility of the leaflets

Figure 8-3 Example of hockey stick deformity of mitral valve in chronic rheumatic heart disease as visualized by echocardiography. Tips of anterior mitral valve leaflet (AMVL) are tethered, thus restricting opening of the valve. Posterior mitral valve leaflet (PMVL) is thickened and has reduced mobility. Left atrium (LA) is characteristically enlarged.

and the extent of valvular calcification can be assessed and used to determine treatment options. Doppler techniques allow calculation of the mitral valve area and the transvalvular gradient. Transesophageal echocardiography is a useful tool for studying the mitral apparatus and examining the left atrium for thrombus before percutaneous valvuloplasty.

The severity of MS and associated hemodynamic changes can also be evaluated with cardiac catheterization. Measurements of the cardiac output and transvalvular gradient can be used to calculate the valve area by means of the Gorlin formula. A normal mitral valve area is 4 to 6 cm², and critical MS is defined as a valve area less than 1 cm².

Patients with mild to moderate MS can usually be managed medically. Heart rate control is imperative in these patients because more rapid rates reduce the length of the diastolic filling period. This is especially true in patients with atrial fibrillation, in whom loss of atrial contraction may further reduce left ventricular filling. Anticoagulant therapy is indicated for patients with atrial fibrillation and for those with sinus rhythm who have had prior embolic events or who have moderate to severe MS. Diuretics are useful in relieving pulmonary congestion and signs of right ventricular heart failure. All patients should be instructed on the importance of endocarditis prophylaxis. Prophylaxis against recurrent bouts of rheumatic fever may be used in patients younger than 30 years.

Patients with severe symptoms (New York Heart Association classes III through IV) and moderate to severe MS should be considered for a percutaneous or surgical intervention. Percutaneous balloon valvuloplasty is a new technique in which a balloon catheter positioned across the

mitral valve is quickly inflated, resulting in separation of the fused cusps. Optimal short- and long-term results are obtained in patients with pliable, noncalcified leaflets and chords, minimal mitral regurgitation (MR), and no evidence of left atrial thrombus. A surgical option in this same group of patients is open mitral valve commissurotomy. With direct visualization of the mitral valve, the surgeon is able to debride the valve, separate the fused cusps, and remove left atrial thrombi. Although the valve remains abnormal, this procedure is associated with a low operative mortality and a good hemodynamic result and may spare the patient from a valve replacement for many years. If mitral commissurotomy is not an option, valve replacement with a bioprosthetic or mechanical prosthesis can be performed.

Mitral Regurgitation

MR can result from abnormalities of the mitral leaflets, annulus, chordae, or papillary muscles (see Table 8-1). The most common leaflet abnormality resulting in chronic MR is myxomatous degeneration of the mitral valves. This condition results in mitral valve prolapse (MVP), which progresses as the chordae become elongated or rupture (Fig. 8-4). Both acute and chronic rheumatic fever may also cause MR.

With chronic MR, the left ventricle dilates to compensate for the increased regurgitant volume. However, in contrast to aortic insufficiency, the increased volume is ejected into the low-pressure left atrium. Thus, left ventricular wall stress and pressure remain normal for a significant period. If the left atrium dilates sufficiently to accommodate the increased

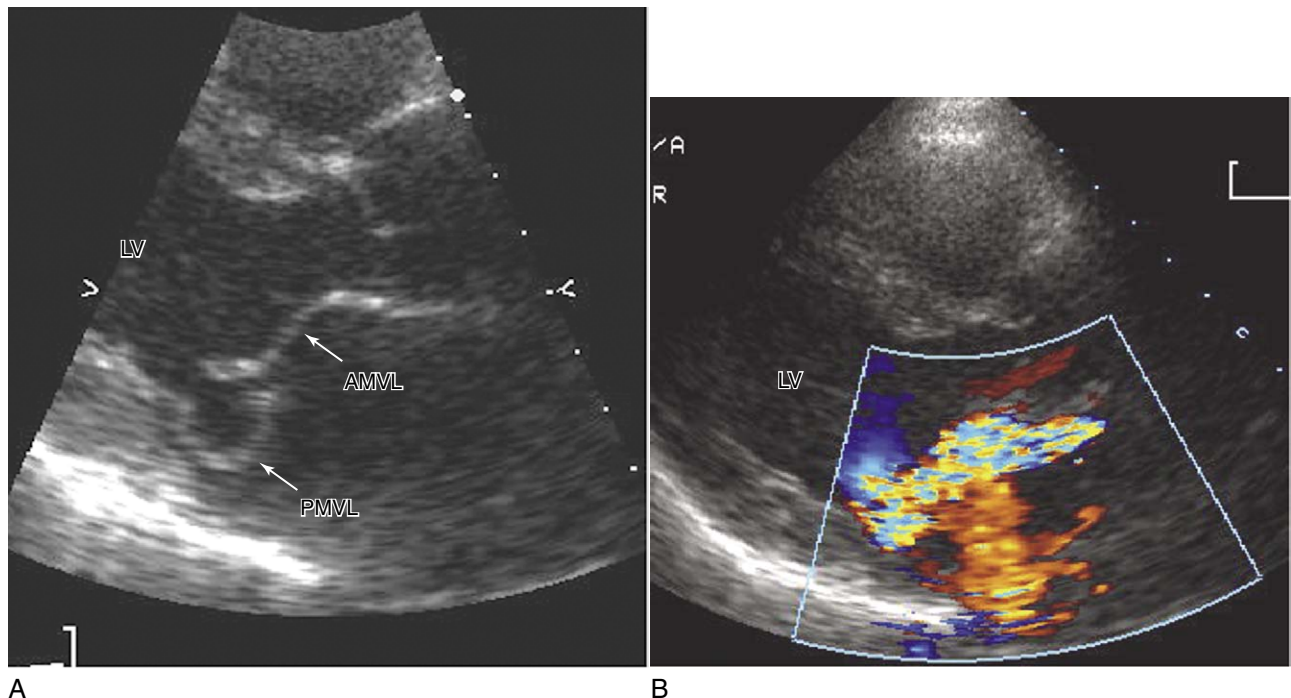

Figure 8-4 Typical example of mitral valve prolapse is visualized with transthoracic echocardiography. **A**, Prolapse of the posterior mitral valve leaflet (PMVL) behind the mitral valve annular plane results from lengthening and rupture of chordae tendineae. In this patient, a highly eccentric (blue) jet of moderate-to-severe mitral regurgitation is observed (**B**). AMVL, anterior mitral valve leaflet; LV, left ventricle.

volume, left atrial and pulmonary venous pressures will remain normal. As the MR progresses, myocyte damage may occur, resulting in further left ventricular dilation, an elevation in diastolic filling pressures, and a reduction in left ventricular systolic function. As left atrial and pulmonary venous pressures increase, pulmonary congestion may occur.

Patients with chronic compensated MR are usually asymptomatic and have normal functional capacity. When symptoms do occur, left ventricular systolic function is sometimes depressed. Patients may initially complain of fatigue and dyspnea with exertion secondary to reduced cardiac output and elevation in pulmonary venous pressures. If the MR remains untreated, pulmonary hypertension and right ventricular heart failure may occur.

MR characteristically produces a holosystolic murmur best heard at the apex and radiating to the axilla and back (see Table 8-2). If an eccentric, anteriorly directed jet of MR is present, an ejection-quality murmur may be present and confused with an aortic outflow murmur. If the MR is secondary to MVP, a mid-systolic click may be present, followed by a late systolic murmur. MR associated with rheumatic mitral disease may be accompanied by heart sounds typical of MS.

Echocardiography is the primary noninvasive method for defining mitral valve pathologic evaluation and assessing left ventricular size and function. Doppler techniques are useful in grading the severity of MR. Quantitative echocardiographic measures of MR severity are predictive of long-term survival, even in patients who are asymptomatic. Mitral valve repair appears to normalize the survival curves in this group of patients. MR can also be assessed during cardiac catheterization by estimating the amount of contrast medium that is ejected into the left atrium during left ventriculography. In addition, left ventricular size and systolic function can be quantitated, filling pressures can be measured, and the coronary anatomy can be defined.

The medical treatment of patients with compensated chronic MR is afterload reduction with vasodilator therapy, such as ACE inhibitors or hydralazine. The timing of surgery is difficult because the development of symptoms often indicates the presence of left ventricular dysfunction and irreversible myocardial damage. In addition, mitral valve replacement with disruption of the chordal apparatus often results in further left ventricular dilation and decline in systolic function.

Echocardiographic parameters that identify patients at risk for a poor response to mitral valve replacement are a left ventricular end-diastolic diameter greater than 70 mm, an end-systolic diameter greater than 45 mm, and a low-normal or reduced left ventricular ejection fraction. Patients with known MR should be followed with yearly studies to monitor left ventricular function and size so that surgery can be performed *before* irreversible myocyte damage and left ventricular remodeling occur. The development of either atrial fibrillation or pulmonary hypertension may be an indication for earlier surgical intervention, even if left ventricle size and function are still normal.

In many patients, the mitral valve may be repaired, thus avoiding many of the potential complications associated with valve replacement. With this surgery, sections of redundant leaflet can be excised, leaflets débrided, and chordae

shortened. A prosthetic ring (annuloplasty) can be sewn into the mitral annulus to reduce the size of the orifice and increase the degree of leaflet coaptation. The advantage of this procedure is that preservation of the mitral apparatus helps maintain normal left ventricular geometry and function. In addition, long-term anticoagulation is not necessary in most patients in sinus rhythm. Valve repair is generally not indicated if the mitral valve is heavily calcified or disrupted secondary to papillary muscle disease or endocarditis. In these instances, valve replacement is the procedure of choice.

Based on excellent surgical outcomes and long-term durability, mitral valve repair is the procedure of choice in all patients in whom it is technically feasible. Severe MR, even in the absence of symptoms or left ventricular dysfunction, may be an appropriate reason for surgical intervention. A variety of percutaneous mitral valve repair techniques are in development.

Acute severe MR is often a life-threatening condition that can result from a variety of papillary muscle, chordal, and leaflet abnormalities (see Table 8-1). Patients with acute MR usually become severely ill because the left atrium does not dilate to accommodate the regurgitant volume. As a result, left atrial and pulmonary venous pressures abruptly increase, resulting in pulmonary congestion. In addition, the decreases in stroke volume and cardiac output result in an increase in systemic vascular resistance and, as a consequence, an increase in the severity of MR. Patients usually exhibit pulmonary edema and signs of cardiogenic shock. On auscultation, the MR murmur is often a soft, low-pitched sound in early systole, resulting from rapid equilibration of left ventricular and left atrial pressures. Afterload reduction with either an intravenous vasodilator, such as nitroprusside, or an intra-aortic balloon pump may help stabilize the patient before urgent valve replacement surgery. Ischemia of the posterior wall or papillary muscles may cause acute but transient MR.

Mitral Valve Prolapse

MVP is reported to be present in about 1% to 3% of the population. Although MVP can be observed in all ages and in both sexes, epidemiologic studies suggest that the prevalence is greater in women than it is in men. In some patients, MVP is inherited as an autosomal dominant trait with variable penetrance.

MVP is present when superior displacement in ventricular systole of one or both mitral valve leaflets exists across the plane of the mitral annulus toward the left atrium (see Fig. 8-4). Primary or classic MVP occurs when myxomatous degeneration of the mitral valve occurs without evidence of systemic disease. Secondary MVP is also characterized by myxomatous degeneration of the mitral apparatus but in the presence of a recognizable systemic or connective tissue disease, such as Marfan syndrome or systemic lupus erythematosus. Functional MVP results from structural abnormalities of the mitral annulus or papillary muscles or reduced left ventricular volume, but the mitral leaflets are anatomically normal.

Most patients with MVP are asymptomatic. Although a variety of nonspecific symptoms have been associated with

MVP (e.g., chest pain, palpitations, dizziness, anxiety [MVP syndrome]), the frequency of these symptoms is no different from that in the general population. MVP may be associated with varying degrees of MR. MR severity is probably the main determinant of long-term complications. The characteristic physical examination finding in MVP is the mid-systolic click, followed by a late systolic murmur (see Table 8-2). The auscultatory findings of MVP are subtle and are greatly affected by changes in left ventricular volume. Maneuvers that reduce left ventricular volume will result in prolapse of the redundant leaflets early in systole; as a result, the click will occur early in systole, and the MR murmur will sound more holosystolic. If left ventricular volume is increased, the click will be heard late in systole, followed by a short systolic murmur. The diagnosis of MVP is usually confirmed by echocardiography, which allows examination of the mitral apparatus and determination of the MR severity.

Most patients with mild prolapse and insignificant MR are asymptomatic and require no specific intervention. Endocarditis prophylaxis is generally recommended only if mild or greater MR exists. However, in some individuals, the MR may progress to such a degree that serial examinations and echocardiograms are necessary to monitor MR severity and left ventricular function. Middle-aged and older men and patients with asymmetrical prolapse are at highest risk for developing complications from MVP, such as severe MR and endocarditis. MR that acutely worsens may be related to rupture of the chordae tendineae. Sudden death in the absence of hemodynamically significant MR is rare.

Patients with MVP and evidence of structural leaflet abnormalities or significant MR should receive endocarditis prophylaxis. Symptomatic arrhythmias should be treated as discussed in Chapter 10. For patients with severe MR, mitral valve repair or replacement may be indicated as discussed earlier (see “Mitral Regurgitation”).

Tricuspid Stenosis

Tricuspid stenosis is most often rheumatic in origin and is usually associated with mitral or aortic disease. Other rare causes include carcinoid syndrome, congenital valve abnormalities, and leaflet tumors or vegetations.

Similar to MS, tricuspid stenosis is more common in women than it is in men and tends to be a slowly progressive disease. Patients generally exhibit symptoms and signs of right ventricular heart failure, such as fatigue, abdominal bloating, and peripheral edema. On physical examination, a prominent jugular venous wave may be present if the patient is in sinus rhythm and may be confused with an arterial pulsation. In addition, a palpable presystolic pulsation coinciding with atrial contraction may be felt on palpation of the liver. On auscultation, the findings of tricuspid stenosis may not be detected secondary to the presence of mitral and aortic valve disease. However, an opening snap may be audible at the left sternal border, followed by a soft, high-pitched diastolic murmur. In contrast to MS, the murmur of tricuspid stenosis is shorter in duration and accentuated with inspiration.

Tricuspid stenosis can be diagnosed by echocardiography or right ventricular catheterization. Because the right heart

is a low-pressure system, the mean gradient across the tricuspid valve may be quite small (5 mm Hg) yet still clinically important.

Tricuspid Regurgitation

Tricuspid regurgitation (TR) is most often secondary to dilation of the right ventricle and tricuspid annulus that may occur with right ventricular heart failure of any cause. Other causes include endocarditis, carcinoid syndrome, congenital abnormalities, and chest wall trauma.

In the absence of pulmonary hypertension, TR is usually well tolerated. However, if right ventricular dysfunction is present, patients usually have symptoms of right ventricular heart failure. On physical examination, the jugular veins are distended, and a prominent v wave is usually present. Hepatic congestion is common and often associated with a palpable systolic pulsation. The murmur of TR is high pitched and pansystolic and is best heard along the sternal border. Maneuvers that increase venous return, such as inspiration or leg raising, accentuate the murmur and are helpful in differentiating TR from MR or aortic outflow tract murmurs. If the TR is acute, the murmur is usually soft and present only during early systole.

TR related to pulmonary hypertension and right ventricular dysfunction will usually significantly improve with treatment of the underlying cause. Repair of the tricuspid annulus (annuloplasty) may restore tricuspid valve competence in patients with persistent symptoms despite treatment. In individuals with a primary leaflet pathologic condition, tricuspid valve replacement may be necessary.

Pulmonic Stenosis and Regurgitation

Pulmonic stenosis is most often congenital in origin and is discussed further in Chapter 7. Rheumatic deformity of the pulmonic valve is rare and not usually associated with hemodynamically important obstruction.

Pulmonic regurgitation is most often the result of dilation of the annulus secondary to pulmonary hypertension of any cause. Symptoms are usually related to the primary disease and in most cases are secondary to right ventricular heart failure. In this setting, the murmur of pulmonic regurgitation is a high-pitched, blowing murmur best heard at the second left intercostal space (Graham Steell murmur). In the absence of pulmonary hypertension, the murmur is usually low pitched and occurs late in diastole. Treatment is usually directed at the underlying cause of the pulmonary hypertension. Rarely and usually in the setting of congenital or previously repaired pulmonic valve disease, the valve will need to be replaced because of intractable right ventricular heart failure.

Multivalvular Disease

Multivalvular disease is common, especially in patients with rheumatic heart disease and in the older adult population.

Often, regurgitant lesions, such as TR and pulmonic regurgitation, are the result of another valve lesion, such as MS in association with pulmonary hypertension. In general, symptoms are most often related to the most proximal valve lesion. However, the severity of each individual lesion may be difficult to assess clinically, and, therefore, careful evaluation with echocardiography and right and left ventricular heart catheterization is necessary to assess valve function before any planned surgery. Failure to correct all significant valvular lesions may result in a poor clinical outcome. Double valve replacement is associated with a higher operative and long-term mortality than single valve replacement.

Rheumatic Heart Disease

Acute rheumatic fever (ARF) is the sequelae of group A β -hemolytic streptococcal infection. The disease is thought to be secondary to an abnormal immunologic response to the streptococcal infection. ARF usually occurs in children 4 to 9 years of age, with boys and girls being equally affected. Although the prevalence of this disease has significantly decreased in the United States over the past several decades, it still poses a major health care problem in many developing nations, and endemic outbreaks have been identified even in the United States.

ARF is characterized by a diffuse inflammation of the heart (pancarditis). An exudative pericarditis is common and often results in fibrosis and obliteration of the pericardial sac. Constrictive pericarditis is rare. The myocardium is often infiltrated with lymphocytes, and areas of necrosis may occur. The characteristic histologic finding in the myocardium is the Aschoff body, which is a confluence of monocytes and macrophages surrounded by fibrous tissue. Valvulitis is characterized by verrucous lesions on the leaflet edge, which are composed of cellular infiltrates and fibrin. The mitral valve is most frequently involved, followed by the aortic valve. Involvement of the tricuspid or pulmonic valve is rare. Valvulitis can be recognized by the presence of a new insufficiency murmur. Aortic stenosis and MS do not occur for many years, when progression of the fibrosis results in restricted leaflet mobility.

The presentation of ARF is usually an acute, febrile illness 2 to 4 weeks after a streptococcal pharyngitis infection. Because the diagnosis of ARF cannot be made by laboratory tests alone, guidelines based on the symptoms and a physical examination have been established (modified Jones criteria) (Table 8-3). A diagnosis of ARF can be made

Table 8-3 Revised Jones Criteria

Major Criteria

Carditis (pleuritic chest pain, friction rub, heart failure)
Polyarthritis
Chorea
Erythema marginatum
Subcutaneous nodules

Minor Criteria

Fever
Arthralgia
Previous rheumatic fever or known rheumatic heart disease

if two major, or one major and two minor, criteria are present after a recent, documented streptococcal pharyngitis infection. Major criteria include evidence of carditis (e.g., pleuritic chest pain, friction rub, heart failure, MR), polyarthritis, chorea, erythema marginatum, and subcutaneous nodules. Minor criteria include fever, arthralgia, and a history of rheumatic fever or known rheumatic heart disease.

Once the diagnosis is established, a course of therapy with penicillin is indicated to eradicate the streptococcal infection. Salicylates are effective for the treatment of fever and arthritis. Corticosteroids and immunosuppressive therapy have not been proved beneficial in the management of the carditis. Heart failure should be treated with standard therapy.

Recurrent attacks of rheumatic fever are common, especially during the first 5 to 10 years after the primary illness. Rheumatic fever prophylaxis should be continued during this period, and for 10 years in patients with a high exposure rate to streptococcal infection (e.g., health care professionals, child care workers, military recruits). Patients with significant rheumatic heart disease should receive prophylaxis indefinitely, considering the high rate of recurrence in these individuals. The recommended therapy for prophylaxis is an intramuscular injection of 1.2 million units of benzathine penicillin monthly. Alternatively, oral penicillin or erythromycin may be used. Noncompliance with these agents reduces the effectiveness of this mode of therapy.

Prosthetic Heart Valves

Two types of artificial heart valves are available: mechanical valves (tilting disk and bi-leaflet) and tissue valves (bioprostheses) (Fig. 8-5). The mechanical valves have a favorable

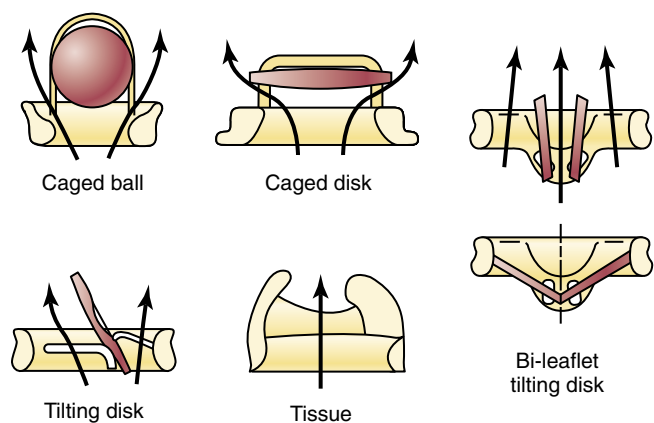

Figure 8-5 Designs and flow patterns of major categories of prosthetic heart valves: caged ball, caged disk, tilting disk, bi-leaflet tilting disk, and bioprosthetic (tissue) valves. Whereas flow in mechanical valves must course along both sides of the occluder, bioprostheses have a central flow pattern. (From Schoen FJ, Titus JL, Lawrie GM: Bioengineering aspects of heart valve replacement. *Ann Biomed Eng* 10:97-128, 1982; Schoen FJ: Pathology of cardiac valve replacement. In Morse D, Steiner RM, Fernandez J [eds]: *Guide to Prosthetic Cardiac Valves*. New York, Springer-Verlag, 1985, p 208. Copyright © 1985 Springer-Verlag.)

hemodynamic profile and are extremely durable. However, mechanical valves carry a high thromboembolic risk and require long-term anticoagulation. Bioprosthetic use is less likely to be complicated by thromboembolic disease, but the durability of the valve is significantly less than with mechanical valves, especially in young patients. The type of prosthesis used in a particular patient is dependent on multiple factors, including the patient's age, suitability for long-term anticoagulation, and valve position. The American College of Cardiology/American Heart Association guidelines are available for anticoagulation therapy in patients with prosthetic heart valves. All patients with mechanical valves require warfarin therapy. Aspirin (75 to 100 mg/day) is recommended as sole long-term therapy in patients with biologic prosthetic valves and in combination with warfarin in patients with mechanical valves. Warfarin is recommended during the first 3 months after surgery in patients receiving biologic prostheses. The INR should be maintained at 2.3 to 3 in low-risk patients with mechanical aortic valves. High-risk features (e.g., atrial fibrillation, left ventricular dysfunction, previous thromboembolism, and hypercoagulable state) should lead to an INR goal of 2.5 to 3.5 in patients with mechanical AVR. The INR should be maintained at 2.5 to 3.5 in all patients with mechanical mitral valves.

Replacement of a diseased valve with an artificial valve results in a new set of potential risks and complications with the prosthesis. All valve prostheses result in some degree of stenosis because the effective valve orifice is smaller than that of the native valve. Thrombosis or calcification of the prosthetic valve can result in prosthetic dysfunction and hemodynamically important stenosis. Prosthetic valve insufficiency can result from perivalvular leaks in the area of the sewing ring. With bioprosthetic valves, deterioration of the prosthetic valve leaflets can lead to valve insufficiency and stenosis. Hemolysis is a frequent complication of the older mechanical valves (e.g., ball cage, disk cage) and can occur with present-day prostheses if turbulent flow associated with prosthetic valve dysfunction exists, especially regurgitation. Endocarditis remains a potential complication in all patients with prosthetic valves. The guidelines for endocarditis prophylaxis are provided later (see “Endocarditis Prophylaxis”).

Evaluation of prosthetic valve function is best performed with two-dimensional and Doppler echocardiographic techniques. Transesophageal echocardiography is particularly useful in studying prosthetic valves when thrombosis or endocarditis is suggested. Mechanical valves can be assessed with fluoroscopy to determine whether leaflet excursion is normal. Gated cardiac computed tomography may also be helpful (Fig 8-6; Web Fig 8-1).

Endocarditis Prophylaxis

Patients with valvular heart disease and prosthetic heart valves are at increased risk for developing endocarditis (Table 8-4) (see Chapter 100). In the past, endocarditis prophylaxis was widely recommended for abnormal valves. However, recently updated guidelines reflect the fact that only an extremely small number of cases of infective endocarditis may be prevented by antibiotic prophylaxis, even if it were 100% effective. Infective endocarditis is more likely

Figure 8-6 Images of mechanical heart valves obtained with gated cardiac CT. Maximum intensity projection of bileaflet tilting disk mechanical aortic prosthesis in closed (A) and open (B) positions. Dynamic images of this valve can be seen on Web Figure 8-1. (C) Volume-rendered image showing closed, single-leaflet aortic valve and open bi-leaflet tilting disk mitral valve in diastole. Both valves were clearly seen to open and close normally on the dynamic line images. This patient had suspected prosthetic valve dysfunction that was incompletely evaluated by both fluoroscopy and transesophageal echocardiography.

Table 8-4 Cardiac Conditions in which Antibiotic Prophylaxis Is Recommended

Prosthetic heart valves
 Previous bacterial endocarditis
 Congenital cardiac malformations (class IIa)
 Unrepaired cyanotic
 Repaired with residual shunt
 First 6 months after repair with prosthetic material
 Cardiac transplant recipients with valve regurgitation due to structurally abnormal valve

Table 8-5 Dental and Surgical Procedures in which Endocarditis Prophylaxis Is Recommended

For patients with the underlying cardiac conditions shown in Table 8-4, prophylaxis is reasonable for all dental procedures that involve manipulation of either gingival tissue or the periapical region of teeth or perforation of oral mucosa.
 Prophylaxis is not recommended solely on the basis of an increased lifetime risk for acquisition of infective endocarditis.
 Administration of antibiotics solely to prevent endocarditis is not recommended for patients who undergo a genitourinary or gastrointestinal tract procedure.

to result from frequent exposure to random bacteremia associated with daily activities than from bacteremia caused by a dental, gastrointestinal tract, or genitourinary procedure. Lastly, the risk for antibiotic-associated adverse events exceeds the benefit (if any) of prophylactic therapy. The role of antibiotic prophylaxis is to prevent infection of the abnormal valve during procedures that are associated with transient bacteremia (Table 8-5). The flora commonly found in the part of the body being instrumented determines the choice of antibiotics. All patients with known valve disease or prosthetic heart valves should carry a card indicating the nature of their valve lesion and the type of endocarditis prophylaxis recommended.

The Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the American Heart Association does not recommend routine antibiotic prophylaxis in patients with valvular heart disease undergoing uncomplicated vaginal delivery or caesarean section unless infection is suspected. Antibiotics are optional for high-risk patients with prosthetic heart valves, a previous history of endocarditis, complex congenital heart disease, or a surgically constructed systemic-pulmonary conduit.

Prospectus for the Future

Infectious disease such as ARF as the principal cause of acquired valvular heart disease will continue to decline worldwide. For isolated mitral valvular stenosis, for example, percutaneous approaches by a skilled operator will become the standard and the preferred treatment modality over a surgical procedure. Aortic and mitral regurgitation caused by degenerative and

other acquired diseases will create the major morbidity and mortality rates with advancing age. In the next decade, rapid advances in percutaneous approaches to address mitral regurgitation and aortic stenosis may radically change our practice and strategies for treating these conditions.

Coronary Heart Disease

Andrew D. Michaels

Epidemiology

Coronary heart disease (CHD) is the leading cause of death in the industrialized world. Apart from its influence on mortality, it causes substantial morbidity, disability, and loss of productivity. With improvements in diagnosis, prevention, and treatment, the mortality rate from CHD has declined gradually over the past several decades. Nonetheless, 1.2 million people have a myocardial infarction (MI) or fatal cardiac event each year in the United States alone. Nearly half of all deaths in industrialized nations and 25% of those in developing countries are due to CHD. By the year 2020, CHD is predicted to surpass infectious disease as the world's leading cause of death and disability.

Pathophysiology of Atherosclerosis

In the industrialized world, atherosclerosis often begins in the early decades of life. One in six American teenagers dying accidentally has pathologic evidence of coronary atherosclerosis. Several processes contribute to the initiation and progression of atherosclerosis, including accumulation of lipoproteins, endothelial injury, and inflammation.

In the early phase of atherosclerosis, small lipoprotein particles penetrate the vascular endothelium, where they are oxidized and coalesce into aggregates in the intimal layer. This process is accelerated at sites of endothelial injury, which may be caused or accelerated by systemic hypertension, hypercholesterolemia, cigarette smoking, or excessive shear forces. The accumulation of intimal lipid aggregates stimulates the expression of adhesion molecules (e.g., intracellular adhesion molecule-1, vascular cell adhesion molecule-1, selectins) on the luminal surface of the endothelial cells, thereby enabling them to bind circulating monocytes (e.g., macrophages). The adherent monocytes intercalate between the endothelial cells into the intimal layer in response to chemokines and cytokines produced by endothelial and medial smooth muscle cells. The intimal monocytes

ingest the lipoprotein aggregates to become lipid-filled monocytes, or *foam cells*. Aggregates of these foam cells make up the earliest visible evidence of atherosclerosis, or the *fatty streak*.

Foam cells replicate and release proinflammatory mediators, thereby perpetuating the local inflammatory process with resultant lesion progression. In addition, they release enzymes that cause endothelial denudation. Because the endothelium is involved in the control of vascular tone through its production of vasodilating substances such as prostacyclin and nitric oxide (e.g., endothelium-derived relaxing factor) and thrombosis, injury to these cells impairs vasodilation and creates a local prothrombotic state. Circulating platelets adhere to sites of endothelial injury and release growth factors, which stimulate the migration and proliferation of smooth muscle cells and fibroblasts from the media. This leads to formation of a fibrous cap over the lipid-rich core (**Web video 1—Coronary Atherosclerosis**, <http://www.heartsite.com/html/cad.html>). 

As lipids continue to accumulate in the foam cells, they undergo necrosis and leave a remnant lipid pool in the core of the plaque. Metalloproteinase enzymes (e.g., collagenase, gelatinase) released by macrophages and mast cells in the plaque degrade collagen and extracellular matrix proteins adjacent to the lipid pool, whereas cytokines (e.g., interferon- α) released by T lymphocytes inhibit the formation of collagen by vascular smooth muscle cells. This combination of increased collagen degradation and decreased collagen production creates a vulnerable plaque, which is predisposed to fissure or rupture. Such vulnerable plaques have a lipid-laden core and a thin, weakened fibrous cap. When the thin fibrous cap fissures or ruptures, highly thrombogenic collagen and lipid are exposed to circulating blood with resultant adhesion of platelets and formation of an intraluminal thrombus. Activated platelets release substances (e.g., thromboxane, serotonin) that promote vasoconstriction and thrombus propagation. When the extent of platelet aggregation and thrombosis is sufficient to impair blood flow (partially or completely), an acute coronary event (unstable angina, non-ST-segment elevation myocardial infarction [NSTEMI] or ST-segment elevation myocardial infarction [STEMI]) occurs.

Figure 9-1 Angiograms of the right coronary artery. **A**, Discrete stenosis is observed in the middle segment of the artery (arrow). **B**, Same artery is shown after successful balloon angioplasty of the stenosis and placement of an intracoronary stent.

When the atherosclerotic plaque is covered with a thick fibrous cap, rupture is less likely, but the plaque may gradually increase in size. As plaque volume increases, the coronary arterial lumen is compromised, and blood flow is impaired (Fig. 9-1). The hemodynamic significance of plaque is determined by the length and severity of the luminal narrowing; in general, a 70% decrease in the luminal diameter of a coronary artery limits blood flow in the presence of increased myocardial oxygen demands (e.g., exercise, emotional excitement), leading to the clinical condition of exertional angina. A 90% decrease in luminal diameter is sufficient to limit flow even when myocardial oxygen demands are normal. For intermediate-severity lesions with a diameter stenosis between 40% and 70%, assessing the hemodynamic significance of the stenosis with either fractional flow reserve (FFR; ratio of the mean coronary pressure distal to the stenosis [acquired by a micromanometer pressure transducer on a coronary angioplasty guidewire] divided by the mean arterial pressure proximal to the stenosis) or stress testing may help determine the requirement for coronary revascularization.

Risk Factors

Several risk factors for the development of atherosclerosis have been identified (Table 9-1). Nonmodifiable risk factors include (1) advanced age, (2) male sex, and (3) family history of premature atherosclerosis. The prevalence of coronary artery disease (CAD) increases with age. At any given age, the prevalence is higher in men than in women. On average, the clinical manifestations of CAD become evident about 10 years later in women than in men. A family history of premature atherosclerosis (occurring in men before age 55 years and in women before age 65 years) increases the risk for atherosclerosis in an individual, likely as a result of environ-

Table 9-1 Risk Factors and Markers for Coronary Artery Disease

Nonmodifiable Risk Factors

Age
Male sex
Family history of premature coronary artery disease

Modifiable Independent Risk Factors

Hyperlipidemia
Hypertension
Diabetes mellitus
Metabolic syndrome
Cigarette smoking
Obesity
Sedentary lifestyle
Heavy alcohol intake

Markers

Elevated lipoprotein(a)
Hyperhomocysteinemia
Elevated high-sensitivity C-reactive protein (hsCRP)
Coronary arterial calcification detected by electron-beam computed tomography (EBCT) or multidetector computed tomography (MDCT)

mental factors (e.g., dietary habits, cigarette smoking) and a genetic predisposition to the disease.

Other risk factors are modifiable, and their treatment may decrease the risk for atherosclerosis. These modifiable risk factors include hyperlipidemia, hypertension, diabetes mellitus, metabolic syndrome, cigarette smoking, obesity, sedentary lifestyle, and excessive alcohol intake. Although several definitions of the metabolic syndrome have been endorsed, the definition adopted by the National Cholesterol Education Program Adult Treatment Panel requires at least three of the following five criteria: waist circumference

more than 102 cm in men and more than 88 cm in women; triglyceride level 150 mg/dL or higher; high-density lipoprotein (HDL) cholesterol level lower than 40 mg/dL in men and lower than 50 mg/dL in women; blood pressure 130/85 mm Hg or higher; and serum glucose 110 mg/dL or higher. Using these criteria, nearly 25% of the U.S. population has metabolic syndrome. Finally, markers associated with an increased incidence of CAD include lipoprotein(a), hyperhomocysteinemia, high-sensitivity C-reactive protein (hsCRP), and coronary arterial calcification.

Lipids play a central role in the atherosclerotic process, and elevated levels of cholesterol, primarily low-density lipoprotein (LDL) cholesterol, are associated with accelerated atherosclerosis (**Web video 1—Coronary Atherosclerosis**, <http://www.heartsite.com/html/cad.html>). HDL cholesterol, by contrast, functions as a protective agent, and its serum level is inversely related to the risk of CAD. Elevated triglycerides are often associated with reduced levels of HDL cholesterol and are an independent risk factor for CAD. Large trials of lipid-lowering therapy have demonstrated the effectiveness of cholesterol reduction in the primary and secondary prevention of CAD.

Systemic hypertension, defined as a systolic arterial pressure greater than 140 mm Hg or a diastolic pressure greater than 90 mm Hg, increases the risk for CAD. The risk increases proportionally with the extent of blood pressure elevation, and proper treatment of hypertension reduces the risk.

Diabetes mellitus increases both the risk for developing CAD and the mortality associated with it. Although CAD is the leading cause of death in adult patients with diabetes, tight glycemic control has not been shown to reduce the risk. Diabetes mellitus often co-exists with other risk factors, including dyslipidemia (elevated triglyceride level, low HDL level), hypertension, and obesity. This grouping of risk factors has been termed the *metabolic syndrome*, and its presence identifies a person at increased risk for having or developing atherosclerotic disease.

Cigarette smoking has adverse effects on the lipid profile, clotting factors, and platelet function and is associated with a twofold to threefold increase in the risk for CAD. Cessation of smoking reduces the excess risk for a coronary event by 50% within the first 1 to 2 years of quitting.

Obesity, defined as a body mass index greater than 30 kg/m², is often associated with other risk factors (e.g., hypertension, dyslipidemia, glucose intolerance); in addition, obesity appears to be an independent risk factor for CAD. The distribution of body fat is important, with abdominal adiposity posing a substantially greater risk for CAD in both men and women.

Multiple observational studies have demonstrated an inverse relationship between the amount of physical activity and the risk for CAD. Although the ideal duration, frequency, and intensity of such physical activity have not been determined, numerous studies have shown that exercise is beneficial in healthy patients and those with or at risk for CAD.

Moderate alcohol intake (1 to 2 drinks daily) is associated with a reduction in the risk for cardiovascular events; in contrast, heavy alcohol intake increases cardiovascular mortality.

Lipoprotein(a) consists of LDL cholesterol linked to an apo(a) molecule. It has a homologous structure with plas-

minogen and interferes with the generation of plasmin, thereby creating a predisposition to thrombosis.

Elevated levels of homocysteine are associated with an increased risk for coronary, cerebral, and peripheral vascular disease. Hyperhomocysteinemia can be treated effectively with dietary folate supplementation. However, such treatments have not been shown to reduce the incidence of stroke or cardiovascular events in patients with elevated serum homocysteine levels.

CRP, a marker of inflammation, may indicate or contribute to an increased propensity for plaque rupture and thrombosis. Elevated serum CRP levels—when measured with the new high-sensitivity assays (i.e., hsCRP)—strongly correlate with the risks for MI, stroke, peripheral arterial disease, and sudden cardiac death. Levels of hsCRP lower than 1 mg/L are associated with a low risk for vascular events; levels of 1 to 3 mg/L pose an intermediate risk; levels greater than 3 mg/L create a high risk. In healthy patients without hyperlipidemia but with an hsCRP greater than 2 mg/L, statin therapy has been shown to reduce the risk for myocardial infarction, stroke, revascularization for unstable angina, and death from cardiovascular causes.

Coronary arterial calcification is a prominent feature of coronary atherosclerosis, and it correlates with the presence and severity of CAD. Electron-beam computed tomography (EBCT) or multidetector computed tomography (MDCT) can accurately quantify coronary calcification, thereby serving as screening tests for CAD in asymptomatic patients. Currently, the usefulness of EBCT or MDCT and hsCRP in the clinical setting is poorly defined. However, the finding of coronary calcification in patients without known CAD or risk factors for CAD may identify those who warrant aggressive risk factor modification.

Nonatherosclerotic Causes of Cardiac Ischemia

Although atherosclerosis is the most common disease affecting the coronary arteries, several nonatherosclerotic processes may produce myocardial ischemia or MI. Embolization from infective endocarditis, mural thrombi in the left atrium or ventricle, prosthetic valves, intracardiac tumors, or paradoxical emboli from the venous system across an atrial or a ventricular septal defect or pulmonary arteriovenous malformation may compromise coronary blood flow, leading to myocardial ischemia or MI. Chest wall trauma may result in coronary arterial dissection or thrombosis. Aortic dissection can propagate to the aortic root and occlude a coronary artery at its origin. Coronary arterial dissection may occur spontaneously during pregnancy or with connective tissue disorders such as Marfan syndrome or Ehlers-Danlos syndrome.

Several forms of arteritis may involve the coronary arteries, including syphilis, Takayasu arteritis, polyarteritis nodosa, systemic lupus erythematosus, and giant cell arteritis. These syndromes may result in obstruction, occlusion, or thrombosis of the coronary arteries. Kawasaki disease, a

mucocutaneous lymph node syndrome, is a systemic disease of children that causes coronary vasculitis with resultant coronary aneurysms. Spontaneous in situ coronary thrombosis may occur in the setting of hematologic disorders (e.g., polycythemia vera, essential thrombocytosis, disseminated intravascular coagulation, sickle cell anemia, paroxysmal nocturnal hemoglobinuria). Congenital coronary anomalies may cause myocardial ischemia. Spontaneous coronary spasm (e.g., Prinzmetal vasospastic angina) with or without underlying CAD may cause myocardial ischemia or, rarely, MI. Cocaine use may result in myocardial ischemia or MI through several mechanisms, including coronary vasospasm, thrombosis, and accelerated atherosclerosis. An occasional patient treated with sumatriptan for migraine headaches or paclitaxel for cancer may experience MI in the absence of CAD.

In 10% to 20% of patients with suggested angina, coronary angiography reveals normal epicardial coronary arteries. In some of these individuals, microvascular or small vessel disease, the *syndrome X*, has been implicated. Studies have suggested that women have a higher prevalence of syndrome X compared with men presenting with possible acute coronary syndrome. The small resistance vessels in these patients, which are not visualized angiographically, have reduced vasodilatory capability. This dysfunction may lead to myocardial ischemia, as evidenced by exercise-related abnormalities on echocardiographic or nuclear scintigraphic studies. Some patients respond to treatment with common anti-anginal medications; although, in general, these drugs are less effective in patients with syndrome X than in those with atherosclerotic CAD.

Finally, myocardial ischemia may result when significant increases in the demand for myocardial oxygen exceed oxygen supply. Such an oxygen supply-demand imbalance may occur in individuals with thyrotoxicosis, aortic stenosis, aortic insufficiency, tachyarrhythmia, or sepsis. Diminished oxygen supply may occur as a result of acute blood loss, hypotension, severe anemia, or carbon monoxide poisoning.

Pathophysiology and Consequences of Myocardial Ischemia

In the normal myocardium, a balance between myocardial oxygen supply and demand is present at rest and during physical exertion or emotional excitement. In response to an increase in oxygen demand, an appropriate increase in oxygen supply maintains adequate tissue oxygenation. When oxygen demand increases in the setting of limited oxygen supply, myocardial ischemia results. At rest, the myocardium extracts most of the oxygen that is delivered to it through the coronary arteries. As a result, any increase in myocardial oxygen demand, as a result of an increase in heart rate, wall stress, or contractility, must be accompanied by a concomitant proportional increase in myocardial blood flow. Regulation of coronary blood flow occurs at the level of the arterioles and is dependent on autonomic tone and an intact, functioning endothelium.

Endothelial dysfunction secondary to atherosclerosis impairs the ability of the coronary arterioles to dilate when oxygen demands increase. In addition, when a flow-limiting stenosis is present in an epicardial coronary artery, the arterioles distal to the stenosis may already be maximally or nearly maximally dilated in the resting state. The inability of the arterioles to dilate and increase coronary arterial flow during periods of increased demand (e.g., decreased coronary vasodilator reserve) results in a supply-demand mismatch, with resultant ischemia and the clinical pattern of stable angina.

When myocardial oxygen supply cannot meet oxygen demand, myocardial ischemia occurs. This ischemia, in turn, initiates a series of pathophysiologic events. Regional myocardial hypoxia causes anaerobic glycolysis, lactate production, intracellular acidosis, and disordered calcium homeostasis. These intracellular changes induce abnormalities in myocardial relaxation, leading to reduced compliance and contraction, which cause regional wall motion abnormalities. Finally, electrocardiographic (ECG) evidence of ischemia (i.e., ST-segment depression or elevation) occurs, and angina pectoris ensues.

If myocardial ischemia is transient, the duration of the resultant mechanical dysfunction may be short. In contrast, more prolonged ischemia may produce myocardial stunning, hibernation, or even an MI. *Myocardial stunning* refers to a prolonged period (e.g., hours, days) of reversible myocardial dysfunction after an ischemic event. Hibernation occurs in the setting of chronic ischemia when oxygen delivery is adequate to maintain myocardial viability but inadequate to maintain normal function. The clinical importance of the hibernating state is that restoration of blood flow to the involved myocardium results in improved mechanical function.

Because of limited energy expenditure, conduction tissue is more resistant to ischemia than contractile tissue. Nevertheless, ischemia may result in altered ionic transport, altered autonomic tone, and injury to the conduction system, resulting in a variety of ischemia-induced arrhythmias and conduction abnormalities.

Angina Pectoris

For many years, patients with chronic, stable angina pectoris were believed to develop myocardial ischemia because of a transient increase in myocardial oxygen demand as a result of physical exertion or emotional excitement in the setting of limited oxygen supply caused by fixed atherosclerotic CAD. Effort-induced angina was thought to be a problem of excessive oxygen demand with limited oxygen supply. However, some patients with chronic, stable angina may develop myocardial ischemia because of dynamic coronary vasoconstriction in the setting of fixed atherosclerotic CAD. Such *inappropriate coronary vasoconstriction* has been shown to occur during exposure to cold, while under mental stress, and during isometric or isotonic exercise as well as during exposure to cigarette smoking. In short, chronic, stable angina is a syndrome of both increased myocardial oxygen demands in the setting of limited supply and dynamic reductions in myocardial oxygen supply, most of which are induced by common, everyday events.

Table 9-2 Angina Pectoris

Type	Pattern	ECG	Abnormality	Medical Therapy
Stable	Stable pattern, induced by physical exertion, exposure to cold, eating, emotional stress	Baseline often normal or nonspecific ST-T changes	≥70% Luminal narrowing of one or more coronary arteries from atherosclerosis	Aspirin Sublingual nitroglycerin
	Lasts 5-10 min Relieved by rest or nitroglycerin	Signs of previous MI ST-segment depression during angina		Anti-ischemic medications Statin
Unstable	Increase in anginal frequency, severity, or duration	Same as stable angina, although changes during discomfort may be more pronounced	Plaque rupture with platelet and fibrin thrombus, causing worsening coronary obstruction	Aspirin and clopidogrel Anti-ischemic medications
	Angina of new onset or now occurring at low level of activity or at rest	Occasional ST-segment elevation during discomfort		Heparin or LMWH Glycoprotein IIb/IIIa inhibitors
	May be less responsive to sublingual nitroglycerin			Statin
Prinzmetal or variant angina	Angina without provocation, typically occurring at rest	Transient ST-segment elevation during pain Often with associated AV block or ventricular arrhythmias	Coronary artery spasm	Calcium channel blockers Nitrates

AV, atrioventricular; ECG, electrocardiography; LMWH, low-molecular-weight heparin; MI, myocardial infarction.

The patient with exertional angina pectoris (Table 9-2) usually complains of a retrosternal pressure or dull ache during physical exertion, while eating, during exposure to cold, or with emotional excitement. Other adjectives that the patient may use to describe the chest discomfort include “viselike,” “constricting,” “crushing,” “heavy,” and “squeezing.” In many patients, the retrosternal pain radiates to the jaw, neck, and left shoulder and arm. Dyspnea often accompanies exertional angina pectoris and may be associated with diaphoresis and nausea. Although its duration varies considerably from one patient to another, the episode usually lasts 3 to 10 minutes. On occasion, however, it may linger for as long as 20 to 30 minutes. It is typically relieved by sublingual nitroglycerin within 1 to 3 minutes.

At a time when the patient is not experiencing angina, the physical examination is usually normal. During an episode of chest discomfort, the patient may become somewhat pale and diaphoretic, and the respiratory rate and effort may increase. The heart rate and systemic arterial pressure are usually greater than at rest. Pulmonary congestion (e.g., rales at both bases posteriorly) may be evident. On auscultation of the heart, an S_4 is usually audible as a result of decreased left ventricular compliance, and a transient S_3 may be present if left ventricular systolic dysfunction occurs. In an occasional patient, ischemia-induced papillary muscle dysfunction will cause a murmur of mitral regurgitation to be audible at the cardiac apex. As the episode of angina resolves, the pulmonary rales, diastolic heart sounds, and systolic murmur may quickly disappear.

Three noninvasive techniques have been used to demonstrate transient episodes of myocardial ischemia in the patient with exertional angina pectoris: (1) During exercise-induced or spontaneous chest pain, the ECG usually shows ST-segment depression that is reflective of subendocardial

ischemia, which resolves within minutes of the pain's disappearance (Fig. 9-2). (2) During episodes of angina, global left ventricular systolic function may decline, and segmental wall motion abnormalities may develop. These abnormalities can be observed with two-dimensional echocardiography, magnetic resonance imaging, or gated blood pool scintigraphy. The assessment of regional abnormalities and systolic function using two-dimensional echocardiography performed during exercise or intravenous dobutamine infusion is a particularly useful technique for detecting myocardial ischemia. As with the ECG alterations, these segmental wall motion abnormalities may resolve within minutes after relief of pain, or they may linger for hours. (3) Myocardial perfusion may be assessed during exercise-induced angina by the intravenous injection of a radioactive tracer, such as thallium-201 or technetium sestamibi, followed by imaging with the appropriate equipment.

EVALUATION OF THE PATIENT WITH ANGINA

For the patient in whom the cause of chest pain is unclear, stress testing may help clarify the diagnosis by reproducing the patient's symptoms and demonstrating objective evidence of ischemia. Submitting the patient to exercise or pharmacologic stress provides an opportunity to assess the evidence of ischemia through the evaluation of ECG abnormalities (e.g., routine stress testing), perfusion defects (e.g., radionuclide imaging), or segmental wall motion abnormalities (e.g., echocardiography). As with all diagnostic tests, the predictive value of exercise testing is influenced by the pre-test probability that the patient has CAD. For example, in the patient with a high pre-test probability of having CAD, a positive test is highly predictive, whereas a test with

A

B

Figure 9-2 Electrocardiogram obtained during angina (A) and after the administration of sublingual nitroglycerin and subsequent resolution of angina (B). During angina, transient ST-segment depression and T-wave abnormalities are present.

negative results has a high likelihood of being falsely negative. Conversely, in the individual with a low likelihood of having CAD, a negative test is highly predictive, but a positive test result has a high likelihood of being falsely positive.

Stress testing may also be useful in the patient with chronic stable angina for the determination of exercise capacity, documentation of the effectiveness of medications, and risk stratification (i.e., identifying patients at risk for CAD in whom more aggressive therapies may be warranted) (Fig. 9-3). The Clinical Outcomes Utilizing Revascularization and

Aggressive Drug Evaluation (COURAGE) trial has demonstrated that patients with a large degree of ischemic myocardium during stress testing are most likely to benefit with coronary revascularization.

In a patient with a normal resting ECG, routine stress testing with ECG monitoring is usually sufficient. However, in patients with baseline ECG abnormalities (e.g., nonspecific ST-segment abnormalities, left ventricular hypertrophy, left bundle branch block [LBBB], or ventricular pre-excitation) and in patients taking digoxin, the specificity of exercise-induced ST-T-wave changes is diminished. In these

Figure 9-3 Treadmill exercise test demonstrates a markedly ischemic electrocardiogram (ECG) response. The resting ECG is normal. The test was stopped when the patient developed angina at a relatively low workload, accompanied by ST-segment depression in lead II and ST-segment elevation in lead V₂. These changes worsened early in recovery and resolved after administration of sublingual nitroglycerin. Only leads II and V₂ are shown; however, ischemic changes were seen in 10 of the 12 recorded leads. Severe atherosclerotic disease of all three coronary arteries was documented at subsequent cardiac catheterization.

individuals, echocardiographic, nuclear scintigraphic, or magnetic resonance imaging improves both the sensitivity and the specificity of stress testing, albeit at substantially increased cost. Nuclear imaging is preferred over echocardiography in patients with LBBB. Exercise-induced ECG changes in women are less specific than in men; for this reason, many physicians perform exercise testing with imaging in all women. Several prognostic markers associated with a poor clinical outcome have been identified in the patient undergoing routine stress testing; these include (1) ischemic ECG changes (ST-segment depression) that occur early in exercise, in multiple leads, or persist for several minutes after the completion of exercise; (2) an associated decrease (rather than the normal increase) in blood pressure levels; and (3) poor exercise tolerance (e.g., less than 6 minutes exercise duration on the standard Bruce protocol).

In patients whose baseline ECG is sufficiently abnormal to preclude an adequate interpretation during exercise, the standard exercise test may be combined with radionuclide perfusion imaging, ECG assessment of left ventricular global and segmental function, or magnetic resonance imaging of left ventricular function. When stress testing is combined with imaging, the sensitivity for detecting CAD is about 90%, which is greater than that achieved with standard ECG-guided exercise testing. The specificity is about 80%, and the predictive value is about 90%.

When a radionuclide stress perfusion imaging study is performed, a radioactive tracer, such as thallium-201, technetium-99m sestamibi, or technetium-99m tetrofosmin, is immediately administered intravenously before exercise is terminated. Because the radioactive tracer is distributed to the myocardium in proportion to coronary arterial blood flow, segments of myocardium that become ischemic during exercise have decreased uptake of the radioactive tracer relative to normally perfused areas of myocardium. Within 4

hours of the injection of thallium, about 50% is redistributed throughout viable myocardium, which results in a *filling in* of areas that were hypoperfused at peak exercise. Unlike thallium, technetium sestamibi and tetrofosmin do not redistribute to areas that were ischemic. The presence and extent of exercise-induced perfusion abnormalities provide prognostic information. Patients with a normal stress perfusion study—with or without CAD—have an extremely low risk for future cardiac events (<1% per year), whereas those with an abnormal stress perfusion study have an event rate of about 7% annually, the risk in correlation with the magnitude of the perfusion defects.

When exercise induces ischemia, global left ventricular systolic function may decline, and regional wall motion abnormalities may develop. These changes can be observed with two-dimensional echocardiography, magnetic resonance imaging, or gated equilibrium blood pool scintigraphy (e.g., radionuclide ventriculography, multigated acquisition [MUGA] scanning). The extent of wall motion abnormalities correlates with the extent of CAD and the risk for future cardiac events.

For patients who are able to ambulate, exercise stress is preferable to pharmacologic stress because it provides more physiologic information. In patients who are nonambulatory or have limited exercise capacity, pharmacologic stress may provide similar diagnostic information, but it cannot yield information regarding exercise capacity or the hemodynamic response to exercise. A vasodilator (dipyridamole or adenosine) or an intravenous inotropic agent (dobutamine) is typically administered to perform a pharmacologic stress test. With the former, blood flow in unobstructed coronary arteries increases to a greater extent than in obstructed arteries, and this can be detected with perfusion imaging. In contrast, dobutamine infusion increases myocardial contractility—and hence myocardial oxygen demand—and is combined with radionuclide perfusion,

Table 9-3 Indications for Coronary Angiography in Patients with Stable Angina Pectoris

- Unacceptable angina despite medical therapy (for consideration of revascularization)
- Noninvasive testing results with high-risk features
- Angina or risk factors for coronary artery disease in the setting of depressed left ventricular systolic function
- For diagnostic purposes in the individual in whom the results of noninvasive testing are unclear

magnetic resonance imaging, or echocardiographic imaging to assess the presence of perfusion defects or regional wall motion abnormalities.

As previously noted, EBCT has been used for the detection of CAD. The absence of calcification on computed tomography (CT) strongly correlates with the absence of hemodynamically significant coronary atherosclerosis. Moreover, the extent of coronary calcification is predictive of the risk for myocardial infarction. The presence of coronary calcification is diagnostic of coronary atherosclerosis, although the extent of luminal diameter narrowing cannot be predicted by the extent of calcification. With the addition of intravenous contrast administration, MDCT machines may perform a noninvasive CT coronary angiogram (CTA) to visualize coronary arterial stenoses in addition to detecting coronary calcification. Their roles in the detection and management of CAD are evolving.

Invasive cardiac catheterization with coronary angiography allows visual assessment of the extent and severity of CAD. The anatomic information obtained must be interpreted in light of functional information (e.g., stress testing) because the anatomic severity of a given coronary stenosis does not necessarily correlate with its physiologic significance. FFR measurements may be performed in the cardiac catheterization laboratory to demonstrate the functional significance of intermediate-severity coronary stenoses. Coronary angiography is invasive and is associated with a small risk. Nonetheless, the risk-benefit analysis of catheterization favors the procedure in many patients with angina (Table 9-3).

MEDICAL MANAGEMENT OF STABLE ANGINA

The approach to the management of the patient with angina involves (1) risk factor modification and lifestyle changes to slow or to arrest the progression of CAD and thrombosis, (2) pharmacotherapy to prevent or to relieve angina, and (3) revascularization to improve symptoms, prognosis, or both. In addition, concurrent medical conditions (e.g., anemia, congestive heart failure, chronic obstructive pulmonary disease, obstructive sleep apnea, hyperthyroidism) that may precipitate or worsen angina should be corrected, if possible.

Control of hypertension, diabetes mellitus, hyperlipidemia, and smoking cessation are important in controlling the progression of disease in patients with coronary atherosclerosis. Guidelines for aggressive risk factor reduction have

Table 9-4 Goals of Risk Factor Modification

Risk Factor	Goal
Dyslipidemia Elevated LDL cholesterol level Patients with CAD or CAD equivalent*	LDL < 70 mg/dL
Without CAD, at least two risk factors†	LDL < 130 mg/dL (or <100 mg/dL‡)
Without CAD, zero or one risk factor†	LDL < 160 mg/dL
Elevated TG	TG < 200 mg/dL
Reduced HDL cholesterol level	HDL > 40 mg/dL
Hypertension	Systolic blood pressure < 140 mm Hg Diastolic blood pressure < 90 mm Hg
Smoking	Complete cessation
Obesity	<120% of ideal body weight for height
Sedentary lifestyle	30-60 min moderate intensity activity (e.g., walking, jogging, cycling, rowing) 5 times per week

*CAD equivalents include diabetes mellitus, noncoronary atherosclerotic vascular disease, or >20% 10-year risk for a cardiovascular event as predicted by the Framingham risk score.

†Risk factors include cigarette smoking, blood pressure \geq 140/90 mm Hg or on antihypertensive medication, HDL cholesterol level < 40 mg/dL, family history of premature coronary atherosclerosis (e.g., male, \leq 45 years; female, \leq 55 years).

‡Target of 100 mg/dL should be strongly considered for men \geq 60 years of age and individuals with a high burden of subclinical atherosclerosis (>75th percentile of patient's age and sex for coronary calcification), hsCRP > 3 mg/dL, or metabolic syndrome.

CAD, coronary artery disease; CRP, C-reactive protein; HDL, high-density lipoprotein; hsCRP, high-sensitivity C-reactive protein; LDL, low-density lipoprotein; TG, triglycerides.

been established (Table 9-4). Patients should be instructed on dietary changes; an evaluation by a nutritionist may be helpful. Patients with CAD generally should be treated aggressively for hyperlipidemia management. Statin medications are most commonly prescribed for a goal LDL lower than 100 mg/dL. Recent studies suggest that further LDL reductions below 70 mg/dL provide further risk reduction. For those CAD patients with normal cholesterol levels, statin therapy may be helpful in stabilizing atherosclerotic plaque, resulting in a reduced risk for MI and stroke. For those with low HDL, niacin or fibrate agents may be helpful, in addition to aerobic exercise, to achieve a goal HDL of greater than 40 mg/dL.

All patients with known or suggested CAD should be placed on antiplatelet therapy (e.g., aspirin, 75 to 325 mg daily; clopidogrel, 75 mg daily for patients allergic to aspirin) unless a contraindication to antiplatelet therapy is present. These agents decrease the rates of MI and death in patients with angina or previous MI. In addition, they may decrease the risk for MI in individuals without suggested CAD but with multiple risk factors. Angiotensin-converting enzyme (ACE) inhibitors should be prescribed to patients with CAD who have diabetes mellitus or left ventricular systolic dysfunction unless contraindicated. Angiotensin receptor

blockers may be used in patients who develop an ACE inhibitor–induced dry cough. Although exercise is often limited by angina, regular activity at a level that is tolerated should be encouraged. Isometric exercise, such as weight lifting and high-intensity activities, especially in the cold (e.g., skiing, shoveling snow), are not advisable. However, many patients with stable angina may perform vigorous activities, including moderate physical exertion at work. For obese patients and those with a sedentary lifestyle, regular aerobic activity is recommended.

As previously noted, the pathophysiologic characteristics of angina are one of supply-demand mismatch. Therefore, its therapy is directed at correcting the mismatch by decreasing myocardial oxygen demands, augmenting myocardial oxygen supply, or both. Nitrates, β blockers, and calcium channel blockers are among the pharmacologic options most commonly used for the control of symptoms in patients with chronic stable angina (Table 9-5). They appear to be of similar efficacy in controlling anginal symptoms. When a single agent fails to control angina, combination therapy is usually effective. Ranolazine, a selective inhibitor of late sodium influx, is an effective antianginal agent that has no effect on heart rate or systemic blood pressure. Ranolazine may be used as either a first- or second-line agent for patients with angina. Unlike aspirin and lipid-lowering therapy, none of these agents has been convincingly shown to decrease mortality in patients with CAD.

Nitrate preparations have been used in the medical management of exertional angina for many years. The effect of nitrates is mediated through relaxation of vascular smooth muscle. Dilation of arterioles reduces systemic vascular resistance and therefore afterload. Nitrates have a more pronounced effect on the venous system; venodilation results in venous pooling, decreased venous return, and therefore decreased preload. The arteriolar and venodilatory effects substantially reduce myocardial oxygen demands, thereby decreasing angina. In addition, nitrates augment coronary blood flow by dilating epicardial coronary arteries (although this effect is minimal in extensively diseased arteries) and increasing blood flow through collateral vessels. Several formulations are available. Sublingual nitroglycerin tablets or oral spray is effective for the acute treatment of anginal episodes and as prophylactic therapy before an activity that is likely to provoke angina. Topical nitroglycerin ointment and oral preparations are effective for the chronic management of stable angina, whereas intravenous nitroglycerin is appropriate for patients with unstable angina and acute MI. The chronic use of nitrates may result in tolerance, an effect that can be minimized by allowing for a daily nitrate-free period; for example, removing topical nitrate preparations during sleeping hours or prescribing oral nitrates that avoid around-the-clock administration.

β -adrenergic blocking drugs are competitive inhibitors of catecholamine β receptors. They decrease myocardial oxygen

Table 9-5 Medications for Angina Pectoris

Drug Class	Examples	Anti-anginal Effect	Physiologic Side Effects	Comments
Nitroglycerin	Sublingual Topical Intravenous Oral	Decreased preload and afterload Coronary vasodilation Increased collateral blood flow	Headache Flushing Orthostasis	Tolerance develops with continuous use
β -adrenergic blocking agents	Metoprolol Atenolol Propranolol Nadolol	Decreased heart rate Decreased blood pressure Decreased contractility	Bradycardia Hypotension Bronchospasm Depression	May worsen heart failure and AV conduction block; avoid in vasospastic angina
Calcium channel blocking agents	Phenylalkylamine (verapamil) Benzothiazepine (diltiazem)	Decreased heart rate Decreased blood pressure Decreased contractility Coronary vasodilation	Bradycardia Hypotension Constipation with verapamil	May worsen heart failure and AV conduction
Calcium channel blocking agents	Dihydropyridine (nifedipine, amlodipine)	Decreased blood pressure Coronary vasodilation	Hypotension, reflex tachycardia Peripheral edema	Short-acting nifedipine associated with increased risk for cardiovascular events
Late sodium current blocking agents	Ranolazine	Inhibits cardiac late I_{Na} Prevents calcium overload	Dizziness Headache Constipation Nausea	No effects on blood pressure or heart rate Modest QTc prolongation

AV, atrioventricular; I_{Na} , sodium current.

demands by reducing heart rate, blood pressure, and contractility. These agents are effective in controlling anginal symptoms (especially exercise-induced symptoms), and they decrease mortality and reinfarction in survivors of MI. β blockers differ in their lipid solubility, duration of action, and β -receptor selectivity. β_1 receptors predominate in the heart, where they mediate increases in heart rate, contractility, and atrioventricular (AV) conduction. β_2 receptors predominate in the vascular and bronchial smooth muscle. Blockade of β_1 receptors produces several beneficial cardiac effects, whereas β_2 -receptor blockade may induce bronchospasm and peripheral vasoconstriction. Atenolol and metoprolol are β_1 selective at low doses; however, at the moderate to high doses often used in clinical practice, all β blockers lose their selectivity. Because β blockers may worsen underlying conduction system abnormalities, they should be used with caution in patients with conduction system dysfunction. In addition, these agents may result in a mild increase in the triglyceride level and a mild decrease in the HDL cholesterol level.

Calcium ions play a critical role in myocardial and vascular smooth muscle contraction and in the genesis of the cardiac action potential (see Chapter 10). Blocking these effects with a calcium antagonist results in a decrease in heart rate, myocardial contractility, and peripheral arterial vasodilation, all of which decrease myocardial oxygen demand. In addition, coronary vasodilation occurs, resulting in augmented oxygen supply. Three major classes of calcium antagonists are available, and the specific agent of choice should be individualized for the particular patient. The dihydropyridine medications (e.g., nifedipine, amlodipine) predominantly cause vasodilation with little or no effect on heart rate, contractility, or AV conduction. In fact, the vasodilation may lead to a reflex tachycardia. The phenylalkylamine medications (e.g., verapamil) reduce heart rate, slow AV conduction, depress contractility, and have less of an effect on peripheral vascular tone than the dihydropyridine medications. They may not be tolerated in patients with depressed ventricular systolic function or underlying conduction system disease. The benzothiazepine medications (e.g., diltiazem) have less vasodilatory action than the dihydropyridine medications and less myocardial suppressant action than the phenylalkylamine medications.

REVASCULARIZATION IN PATIENTS WITH ANGINA

In patients for whom medical therapy does not effectively control anginal symptoms and in patients considered to be at increased risk clinically (e.g., unstable angina, angina associated with heart failure, angina associated with arrhythmia, poor exercise capacity) or by noninvasive testing (e.g., large amount of ischemic myocardium, depressed left ventricular systolic function), coronary revascularization plays an important therapeutic role. Several modalities for coronary revascularization exist, including surgical revascularization (e.g., coronary artery bypass grafting [CABG]) and catheter-based percutaneous techniques (e.g., percutaneous coronary intervention [PCI]).

With advances in equipment, adjunctive pharmacologic agents, and increasing operator experience, PCI can now be achieved with high success rates and at relatively low risk.

More than 1 million PCI procedures are performed each year in the United States alone. (**Web video 9-1—Angioplasty**, <http://www.heartsite.com/html/ptca.html>). With percutaneous transluminal coronary angioplasty (PTCA), a high-pressure inflation of a distensible balloon is performed at the site of coronary arterial narrowing with resultant enlargement of the lumen. Balloon inflation causes denudation of the endothelial surface, fracture of the atherosclerotic plaque, and disruption of the vessel intima. The vessel lumen can be successfully dilated in greater than 90% of cases. In 2% to 5% of patients undergoing PTCA, the coronary arterial injury is severe, and, as a result, the artery occludes abruptly. Such patients are usually treated with intracoronary stenting or rarely urgent CABG to prevent acute MI. In patients in whom PTCA is initially successful, up to 50% develop restenosis at the site of balloon dilation within 1 to 6 months of the angioplasty. Of the patients who develop restenosis, about 50% experience recurrent angina. Restenosis is a complex process involving elastic recoil of the artery, vascular remodeling, and hyperplasia of the vascular intima. It is not prevented by the administration of antiplatelet, anticoagulant, anti-anginal, or hypolipidemic medications.

During the past decade, intracoronary stenting now has become the technique of choice for PCI (**Web video 9-2—Intracoronary Stenting**, <http://www.heartsite.com/html/stent.html>). The coronary stent—a cylindrical, expandable metal structure available in varying diameters and lengths—is premounted on an angioplasty balloon. When the balloon is positioned at the site of the stenosis and inflated to expand the stent, the stent becomes permanently embedded in the arterial wall. Subsequently, the balloon is deflated and removed, but the stent maintains its expanded cylindrical configuration, thereby acting as a scaffold to maintain vessel patency. In this way, stenting results in a greater increase in luminal size than can be achieved with balloon angioplasty alone (see Fig. 9-1B). Stents can be used to treat PTCA-related coronary arterial dissections, thereby avoiding the need for urgent CABG. In comparison with balloon angioplasty, stenting is associated with a reduced incidence of abrupt closure (about 1% to 2%) and restenosis (about 20% to 25%), thereby explaining why it is the procedure of choice in more than 90% of PCIs. At the same time, stenting may not be the procedure of choice in small coronary arteries (luminal diameter < 2.0 mm) because these vessels are too small for the smallest available stents. The person in whom intracoronary bare metal stenting (BMS) has been performed should receive aspirin indefinitely and clopidogrel for 2 to 4 weeks to prevent thrombosis. During the weeks after stent deployment, the stent becomes endothelialized, at which time it is no longer thrombogenic or subject to abrupt closure. Studies have demonstrated that a 1-year course of clopidogrel is superior compared with a 4-week course after bare metal stenting, with a reduction in adverse ischemic events.

Beginning in 2003, drug-eluting stents (DES) have been coated with antiproliferative drugs (e.g., sirolimus [Rapamycin], paclitaxel [Taxol]), which are extremely effective in preventing restenosis. There are five FDA-approved DES in the United States, listed in order of their approval with the year of approval: Cordis Cypher (sirolimus; 2003), Boston Scientific Taxus (paclitaxel; 2004), Medtronic Endeavor (zotarolimus; 2007), Abbott Xience V (everolimus;

2008), and Boston Scientific Promus (everolimus; 2008). The incidence of restenosis with DES is 5% to 10%. Randomized trials have demonstrated a roughly 70% reduction in stent restenosis with DES compared with BMS. In stenting procedures in the United States, roughly 65% involve DES, and 35% involve BMS. The person who receives a DES should take aspirin indefinitely and clopidogrel for at least 12 months. The antiproliferative agent that coats the stent delays the process of endothelialization; as a result, these stents are subject to thrombosis and abrupt closure for months after their placement.

Other percutaneous interventional techniques that have a limited role in coronary revascularization include rotational and directional atherectomy; thrombectomy; brachytherapy, which is the application of local radiation therapy to treat restenosis after stenting; and coronary laser therapy. Of these, thrombectomy has the most promising role in PCI procedures for STEMI patients.

Studies performed in the 1970s and 1980s established the effectiveness of CABG for the control of anginal symptoms and, in some patients, offered an improvement in survival when compared with anti-anginal medical therapy. Harvesting a segment of saphenous vein or radial artery and anastomosing it to the ascending aorta (proximally) and the distal portion of the diseased coronary artery (distally) is performed with CABG. The internal mammary artery can be dissected free from the pleural surface and its distal end anastomosed to a diseased coronary artery. These procedures effectively bypass the sites of atherosclerotic narrowing, thereby allowing blood to flow freely to the myocardium perfused by the diseased artery. The left internal mammary artery is most commonly used to bypass the left anterior descending coronary artery, and has 10-year patency rates of roughly 90%. In comparison, the patency rate for saphenous vein grafts is 50% at 10 years. Whenever possible, the mammary artery is used because its long-term patency is superior to that of venous or radial arterial conduits. Experienced surgeons perform CABG with a peri-operative mortality rate of 1% to 2%, a stroke rate of 1% to 2%, and a peri-operative MI rate of 5% to 10%.

CABG improves survival (when compared with medical therapy) in patients with greater than 50% luminal diameter narrowing of the left main coronary artery or narrowing of all three major epicardial coronary arteries in conjunction with mildly or moderately depressed left ventricular systolic function (e.g., ejection fraction, 35% to 50%). In addition, CABG improves long-term survival in patients with a narrowing of two or three epicardial coronary arteries and normal left ventricular systolic performance, provided that the proximal portion of the left anterior descending coronary artery is significantly narrowed.

In the short term (within 1 to 2 years of the procedure), those having PCI are more likely than those undergoing CABG to require anti-anginal medications or a subsequent revascularization procedure largely because of the incidence of symptomatic restenosis after successful percutaneous coronary revascularization. Because of the progressive decline of graft patency between 5 and 10 years postoperatively, the benefits of surgery over percutaneous revascularization are less apparent in the long term. Small, randomized studies comparing the two approaches to revascularization in patients with multivessel CAD and preserved left ven-

tricular systolic function (e.g., ejection fraction > 50%) demonstrate no difference in mortality after 1 to 5 years of follow-up, except in patients with diabetes, who fare better with CABG. Recently, however, larger observational studies showed that CABG is associated with higher long-term survival than stenting in patients with multivessel CAD. A recently completed trial showed no difference between CABG and DES for left main or multivessel CAD in mortality or myocardial infarction. DES did have higher rates of repeat revascularization because of restenosis, but lower rates of stroke. There are ongoing randomized trials in diabetic patients with multivessel CAD randomized to CABG or DES.

Unfortunately, neither percutaneous nor surgical revascularization techniques halt the underlying atherosclerotic process, and new stenoses may develop at previously uninvolved sites in native coronary arteries and in the bypass grafts. Aspirin should be administered immediately after CABG and continued thereafter because it improves graft patency. If a stenosis develops in a bypass graft, percutaneous revascularization is often effective. In addition, repeat CABG is possible, although the surgical risks are higher than with the first procedure.

For patients with severe angina refractory to maximal medical therapy and coronary revascularization, treatment options include external counterpulsation and spinal cord stimulation. External counterpulsation involves inflation of three lower extremity cuffs during diastole and deflation during systole. This treatment is performed in 1-hour sessions for a total of 35 treatments. Roughly 75% of patients report an improvement in angina severity, and the treatment is generally well-tolerated. The likely mechanism of action involves improved endothelial function. Spinal cord stimulation provides analgesia for patients with severe angina by placing a stimulating electrode in the dorsal epidural space at the C7-T1 level. Although preliminary data appear promising, there is a paucity of data on intermediate- or long-term outcomes. Transmyocardial laser revascularization is no longer recommended for refractory angina.

VARIANT ANGINA

In 1959, Prinzmetal and colleagues described a group of patients with *variant* angina. These patients usually experienced chest pain at rest rather than with physical exertion or emotional excitement, and the ECG recorded during chest pain showed ST-segment elevation rather than depression, which resolved as the pain subsided (Fig. 9-4). On occasion, episodes of chest discomfort were accompanied by varying degrees of AV block or ventricular ectopy, but MI was uncommon. Patients with variant angina did not often have the usual risk factors for coronary atherosclerosis, although cigarette smoking was frequent. Subsequent angiographic studies demonstrated that variant angina is the result of epicardial coronary arterial spasm, which may occur either at the site of an atherosclerotic plaque or in the setting of angiographically normal coronary arteries.

During coronary angiography, coronary vasospasm may be provoked by the intracoronary infusion of acetylcholine or ergonovine. In addition, methacholine, a parasympathomimetic agent, has been used to induce coronary arterial spasm, similar to the arterial spasm in response to exposure

Figure 9-4 Continuous electrocardiogram recording in a patient with Prinzmetal (variant) angina. The spontaneous onset of chest discomfort began during the *top strip*, accompanied by transient ST-segment elevation. By the *bottom strip*, several minutes later, both discomfort and ST-segment elevation had resolved.

to cold (e.g., cold pressor test), the production of a significant alkalosis (e.g., vigorous hyperventilation during the intravenous infusion of an alkalotic buffer solution), and histamine administration.

Calcium channel blockers, alone or in combination with long-acting nitrate preparations, are highly effective in patients with coronary arterial spasm. They are the treatment of choice for patients with variant angina. β blockers are contraindicated in patients with vasospastic angina because blockade of the vasodilatory effects of β_2 -receptor stimulation may result in unopposed α -adrenergic vasoconstriction. For the rare patient who has continued episodes of coronary arterial spasm despite maximal medical therapy, intracoronary stenting may be performed.

Acute Coronary Syndromes

The term *acute coronary syndrome* encompasses the clinical syndromes of unstable angina, NSTEMI, and STEMI. Patients with unstable angina or NSTEMI are usually indistinguishable by history, physical examination, and ECG findings. The distinction between these two groups is made only after the results of the serum cardiac enzyme analyses are available.

The patient with unstable angina or NSTEMI may develop myocardial ischemia or MI through several mechanisms. Most commonly, these individuals have subendocardial ischemia or necrosis as a result of decreased coronary blood flow, which is due to platelet aggregation or a partially occlusive intracoronary thrombus at the site of an ulcerated atherosclerotic plaque. In addition, concomitant platelet-mediated coronary arterial vasoconstriction at the site of plaque ulceration may occur. Alternatively, the patient may develop myocardial ischemia or MI because of an increase in myocardial oxygen demand that cannot be met by an appropriate increase in coronary blood flow. In some indi-

viduals, the coronary blood flow cannot appropriately increase because of severe CAD. In those without CAD, subendocardial ischemia or infarction may occur solely as a result of significantly augmented myocardial oxygen demands in the setting of a normal supply (e.g., uncontrolled hypertension, thyrotoxicosis) or a decrease in myocardial oxygen delivery (e.g., profound anemia, hypoxemia). Patients with left ventricular hypertrophy (due to hypertension or aortic stenosis) are at increased risk for subendocardial ischemia.

The patient with unstable angina pectoris usually complains of retrosternal chest pain similar in character and consistency to that of the patient with stable, exertional chest pain. In contrast to the patient whose angina is stable, however, these individuals usually report that their anginal frequency, severity, or duration has worsened, and they may report pain at rest. Furthermore, the patient may note that nitroglycerin is ineffective or less effective in relieving the chest pain.

On physical examination, the patient may exhibit no visible or audible abnormalities at a time when he or she is pain free. During an episode of chest pain, however, the patient may become anxious, diaphoretic, and dyspneic. The heart rate often increases, although bradycardia may occur secondary to enhanced vagal tone or transient AV block and most commonly with inferior wall ischemia or infarction. On cardiac auscultation, an S_4 may be audible as a result of decreased left ventricular compliance. An S_3 may be present if left ventricular systolic dysfunction occurs, and a systolic murmur of mitral valve papillary muscle dysfunction may be appreciated. Evidence of pulmonary congestion is often present and may reflect an elevated left ventricular filling pressure as a result of decreased left ventricular compliance or systolic dysfunction. If a large area of myocardium is involved and left ventricular systolic dysfunction ensues, then frank pulmonary edema may occur.

For the patient who is experiencing chest pain, a 12-lead ECG should be immediately obtained because it is frequently diagnostic of myocardial ischemia or MI and is important

Figure 9-5 Acute anterolateral myocardial infarction. Leads I, aVL, and V_2 to V_6 demonstrate ST-segment elevation. Reciprocal ST-segment depression is seen in leads II, III, and aVF. Deep Q waves have developed in leads V_2 and V_3 .

in determining the appropriate treatment plan. STEMI, previously referred to by the pathologically inaccurate term, *transmural infarction* or *Q-wave myocardial infarction*, refers to an acute coronary syndrome in which ST-segment elevation (e.g., ST-segment elevation at the J point in two contiguous leads at least 0.2 mV in men or at least 0.15 mV in women in leads V_2 to V_3 or at least 0.1 mV in other leads) is present on the surface ECG. These infarctions typically are the result of complete thrombotic occlusion of a coronary artery and may first be exhibited on the ECG by symmetrically peaked or hyperacute T waves. These peaked T waves resolve after several minutes as the characteristic ST-segment elevation develops (Fig. 9-5). The distribution of leads with ST-segment elevation can identify the myocardial location and the culprit coronary artery: anterior MI, V_2 to V_5 , left anterior descending coronary artery; inferior MI, II, III, aVF, right coronary artery; lateral MI, I, aVL, V_6 , left circumflex or diagonal; posterior, V_7 to V_9 , left circumflex coronary artery; right ventricular RV_4 , right coronary artery.

NSTEMI, previously termed *subendocardial infarction* or *non-Q-wave myocardial infarction*, and unstable angina occur as a result of a subtotally occlusive thrombus or a thrombus that was initially totally occlusive but not sustained, enabling partial or complete lysis to occur within minutes to hours of its formation. They are associated with ST-segment depression and T-wave inversions on the surface ECG (Fig. 9-6).

In one fourth to one half of patients with acute MI, the first ECG does not demonstrate typical ST-segment changes. In this situation, serial ECGs should be obtained to increase the diagnostic yield. If a patient has ongoing chest pain without ST-segment changes, posterior lead ECG recording of leads V_7 to V_9 should be performed. A posterior lead ECG is used to assess for posterior wall injury, usually the result of left circumflex coronary artery occlusion, which is not readily apparent on a standard 12-lead ECG. If acute MI is

suggestive but the initial ECG does not confirm the diagnosis, demonstration of new regional wall motion abnormalities with echocardiography may be helpful in confirming the diagnosis.

Myocardial necrosis results in the release of certain intracellular enzymes into the blood. Their appearance in the blood allows the identification of myocardial necrosis, and their quantitation over a number of hours allows for the estimate of its amount. Because 20% of patients with acute MI have atypical or no symptoms (i.e., *silent* MI) and the initial ECG is nondiagnostic in up to 50% of patients, serologic identification of myocyte necrosis has become an important diagnostic tool. Several serum markers have been identified (Fig. 9-7).

Creatine kinase (CK) and its myocardial-specific isoenzyme, creatine kinase muscle band (CK-MB) are detectable in the blood within 3 to 6 hours of the onset of MI. They reach their peak concentration at 24 hours and return to normal within 48 hours. Although CK-MB is relatively specific for cardiac injury, it may be elevated in subjects with extensive skeletal muscle injury or disease, chronic renal disease, or hypothyroidism.

Troponins I and T are regulatory proteins involved in the interaction of cardiac actin and myosin. Because they are not present to any extent in other organs and are not detectable in blood under normal circumstances, an increase in their serum concentration is more specific and sensitive for myocyte necrosis than an increase in the concentration of other enzymes. After cardiac injury, the serum troponin concentration begins to rise within 4 to 6 hours and remains elevated for 7 to 10 days. False-positive elevations of troponin T, but not troponin I, have been observed in patients with renal failure. The presence of heterophilic antibodies or fibrin may interfere with the assay for troponin I and give false-positive results. The former is found in 3% of the general population and a high percentage of patients with autoimmune disease; the latter may be found in blood that

Boston University Hospital

Figure 9-6 Marked ST-segment depression in a patient with prolonged chest pain is the result of an acute non-ST-segment elevation myocardial infarction (NSTEMI). Between 1 and 3 mm of ST-segment depression is seen in leads I, aVL, and V₄ to V₆. The patient is known to have had a previous inferior myocardial infarction.

Figure 9-7 Typical time course for the detection of enzymes released after myocardial infarction. AST, serum aspartate aminotransferase; CPK, creatine kinase; cTnI, cardiac troponin I; cTnT, cardiac troponin T; LDH, lactate dehydrogenase.

has been heparinized. Because serum troponin concentration is an extremely sensitive measure of myocardial necrosis, such elevations are sometimes observed in patients with myocardial necrosis as a result of increased myocardial oxygen demand (i.e., subjects with a significantly elevated

heart rate or blood pressure, pulmonary embolism, hypoxemia) or reduced supply (i.e., hypotension) in the absence of epicardial CAD.

TREATMENT OF UNSTABLE ANGINA AND NON-ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION

Unstable angina and NSTEMI may be clinically indistinguishable with ECG studies. They are differentiated only by the presence of serologic evidence of myocardial necrosis. Accordingly, the initial treatment of these patients is similar and includes (1) hospital admission with serial assessment of ECGs and sequential measurements of cardiac enzymes; (2) aggressive anti-anginal, antiplatelet, and antithrombotic therapy; and (3) identification of the patient at increased risk for recurrent ischemia, MI, or death who may benefit from revascularization. With optimal medical therapy, the 1-year mortality rate of patients with unstable angina or NSTEMI is 3% to 5% (Fig. 9-8).

Rest for 24 to 48 hours with continuous ECG monitoring, analgesics, and supplemental oxygen therapy are frequently prescribed. Sublingual nitroglycerin should be given initially, followed by oral or topical nitroglycerin. Intravenous nitroglycerin should be administered if recurrent chest pain occurs. In the absence of a contraindication, β blockers should be promptly instituted because they decrease heart rate and blood pressure levels and left ventricular contractility, thereby reducing myocardial oxygen demand. The calcium antagonists, verapamil and diltiazem, may be useful for the patient who fails to respond to nitrates and β blockers as well as for the patient with a contraindication to β blockers. However, calcium antagonists should not be used in the patient with known depressed left ventricular systolic function or with evidence of pulmonary vascular congestion on

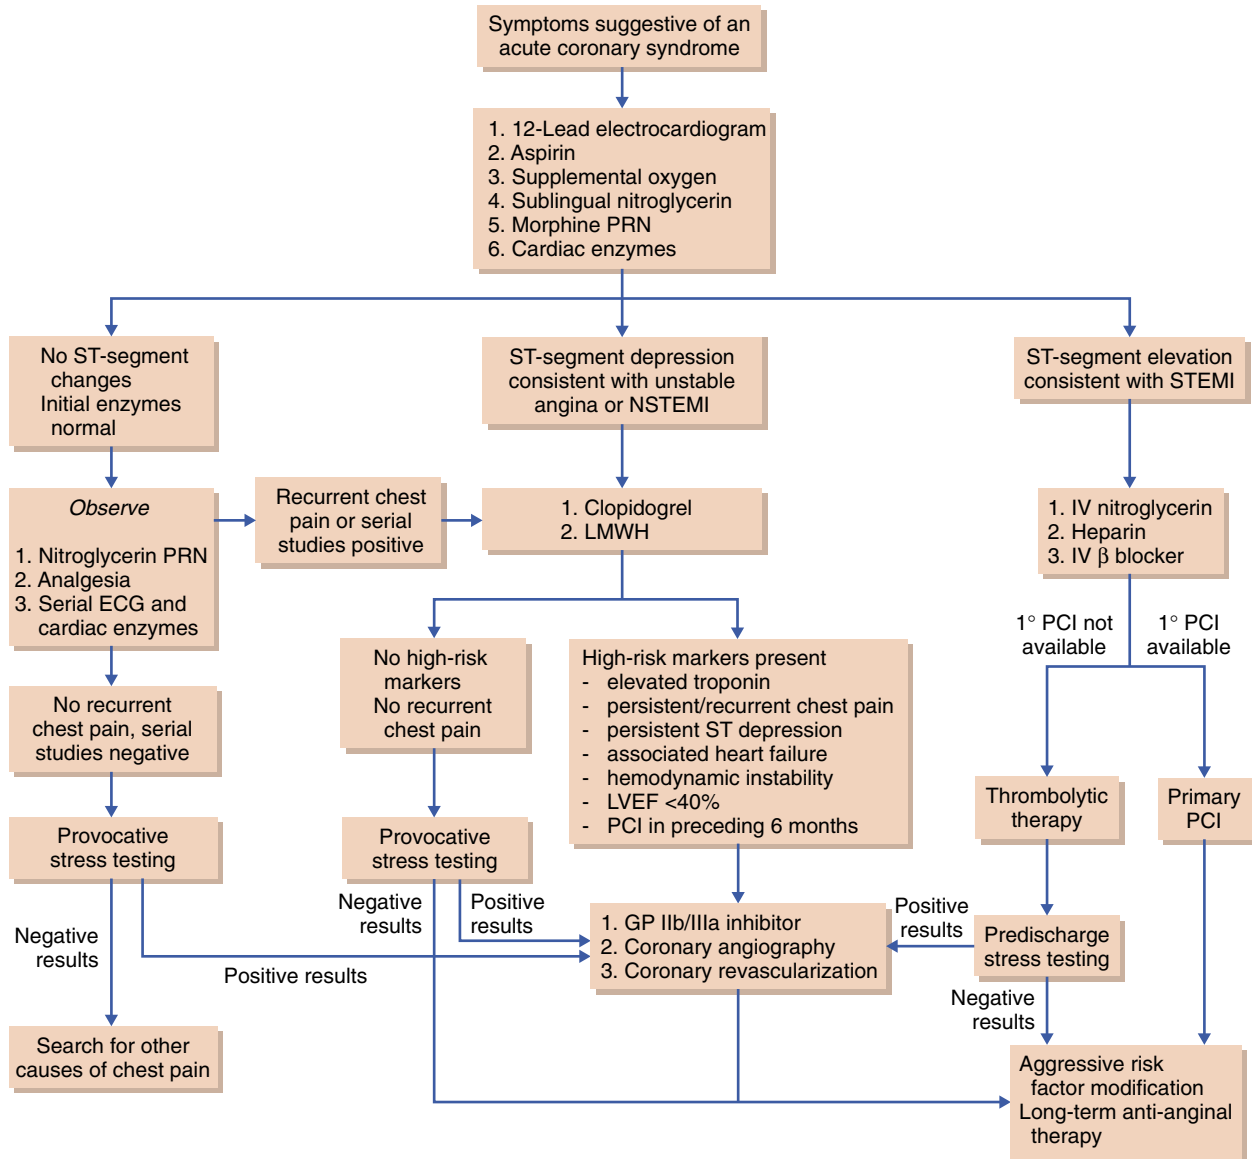

Figure 9-8 Treatment algorithm for patients with symptoms suggestive of an acute coronary syndrome. ECG, electrocardiogram; LMWH, low-molecular-weight heparin; NSTEMI, non-ST-segment elevation myocardial infarction; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction.

physical examination or chest radiograph. Because dihydropyridine calcium antagonists (e.g., nifedipine, amlodipine) may cause a reflex tachycardia with a resultant worsening of angina, they should be avoided unless they can be used in combination with a β blocker.

As noted, enhanced platelet aggregation and partial coronary arterial occlusion by platelet-rich thrombus play important pathophysiologic roles in most patients with unstable angina or NSTEMI. Aspirin has been shown to decrease mortality and rates of recurrent MI in these patients. Accordingly, the patient without a contraindication should receive oral aspirin, an initial 325-mg dose followed by 75 to 325 mg daily. The addition of oral clopidogrel or an intravenous glycoprotein IIb/IIIa inhibitor (e.g., tirofiban, eptifibatid) provides more effective platelet inhibition, thereby reducing the risk for recurrent ischemia or infarction. If

clopidogrel is administered, it is continued for 9 to 12 months. If a glycoprotein IIb/IIIa inhibitor is used, it is infused for 48 to 96 hours. Glycoprotein IIb/IIIa inhibitors are typically used in patients who have high-risk features predictive of a subsequent cardiac event, such as ST-segment depressions, T-wave inversions, or positive biomarkers, or those in whom percutaneous revascularization is planned.

Heparin, unfractionated or low-molecular-weight, is given concomitantly with antiplatelet therapy. If unfractionated heparin is used, it is usually infused for 48 hours. Enoxaparin, a low-molecular-weight heparin, may be used instead of unfractionated heparin. It is administered subcutaneously twice daily and continued until hospital discharge. Unlike unfractionated heparin, it does not require monitoring of its anticoagulant effects by serially measuring the activated partial thromboplastin time. In patients considered at

Table 9-6 Selection Criteria for Thrombolytic Therapy in Acute Myocardial Infarction

- Chest pain consistent with acute myocardial infarction
- Electrocardiographic changes:
 - ST-segment elevation at the J point in two or more contiguous leads with ≥ 0.2 mV in men or ≥ 0.15 mV in women in leads V_2 - V_3 and/or ≥ 0.1 mV in other leads
 - New or presumed new left bundle branch block
 - ST-segment depression with prominent R wave in leads V_2 and V_3 if believed to represent posterior infarction
- Time from onset of symptoms: <12 hr
- Age:
 - <75 years: definite benefit
 - ≥ 75 years: benefit less clear

risk for a subsequent cardiac event, low-molecular-weight heparin is superior to unfractionated heparin in preventing recurrent ischemia. Thrombolytic therapy or abciximab have not been shown to be beneficial for the treatment of individuals with unstable angina or NSTEMI. In these patients, in fact, it may be detrimental (Table 9-6).

For the patient with unstable angina or NSTEMI who promptly and completely responds to medical therapy, subsequent evaluation should be aimed at determining the patient's risk for a subsequent cardiac event. The patient deemed to be at low risk might undergo exercise or pharmacologic stress testing. The patient considered to be at high risk for subsequent events should receive maximal antiplatelet therapy with aspirin and a glycoprotein IIb/IIIa inhibitor, low-molecular-weight heparin, and coronary angiography within 4 to 48 hours, followed by revascularization with PCI or CABG, if indicated. Patients most likely to benefit from this early invasive approach are those with elevated serum cardiac enzyme values and those with three or more at-risk variables, including the following: (1) age 65 years or older, (2) at least three risk factors for atherosclerosis, (3) a previously documented coronary arterial stenosis of 50% or greater, (4) ECG ST-segment deviation at the time of hospital arrival, (5) at least two anginal episodes in the 24 hours before hospitalization, or (6) use of aspirin during the 7 days before hospitalization. This risk stratification system is termed the *TIMI risk score*.

Urgent coronary angiography should be performed in the patient with continued or recurrent chest pain despite optimal medical therapy or hypotension or severe heart failure during medical therapy. (**Web video 9-3, Cardiac Cath**, http://www.heartsite.com/html/cardiac_cath.html). Coronary angiography should be considered for the patient with an acute coronary syndrome and any of the following risk factors: (1) previous PCI or CABG, (2) congestive heart failure or depressed left ventricular systolic function, (3) life-threatening ventricular arrhythmias, (4) recurrent low-threshold ischemia, or (5) exercise or pharmacologic stress testing that indicates a high likelihood of severe CAD. Based on coronary anatomy, the experience of the medical personnel, the presence of co-existing medical conditions, and the preferences of the patient, a recommendation for percutaneous or surgical revascularization can be made.

TREATMENT OF ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION

Numerous studies have shown that coronary thrombosis is the cause of most STEMIs. Postmortem studies have demonstrated that 85% to 95% of patients dying of STEMI have a fresh thrombotic occlusion of a large epicardial coronary artery, and angiographic studies performed within several hours of the onset of STEMI have shown a similar incidence of total occlusion. After as little as 15 minutes of coronary occlusion, irreversible cellular injury and necrosis ensue. The subsequent extent of myocardial injury is determined by the duration of coronary occlusion, the presence or absence of collateral vessels, and the amount of myocardium perfused by the infarct-related artery. Prompt restoration of antegrade flow in the infarct-related artery minimizes the extent of myocardial necrosis. In arteries with gradually developing stenoses, sufficient collateral vessels may develop to prevent irreversible myocardial injury even with complete arterial occlusion. In contrast, if acute plaque rupture and thrombotic occlusion occur at the site of a previously non-obstructive stenosis, collateral circulation does not have sufficient time to develop, and extensive infarction ensues. With infarction of 20% to 25% of the left ventricle, congestive heart failure usually ensues. With infarction of 40% or more of the left ventricle, cardiogenic shock usually develops (Fig. 9-9). Cardiogenic shock is defined as inadequate tissue perfusion due to cardiac dysfunction and is discussed in the upcoming section (see "Post-Myocardial Infarction Complications").

In the patient with suggested acute MI, a 12-lead ECG should be performed within 5 minutes of the patient's arrival, and serum cardiac enzyme levels should be assessed. If ST-segment elevation in contiguous ECG leads or LBBB is present, subsequent care should be focused on sedation and pain relief, prompt restoration of antegrade flow in the occluded infarct-related coronary artery, management of ventricular dysfunction or arrhythmias, and prevention or treatment of immediate and late complications.

A large-bore intravenous line should be introduced for the administration of fluids and medications, and supplemental oxygen should be initiated. Intravenous morphine sulfate should be used to relieve chest pain and to decrease sympathetic stimulation. However, it should be given cautiously because it may cause hypotension, respiratory depression, or bradycardia. The usual dose is 2 to 5 mg every 5 to 10 minutes until chest pain is relieved; systemic arterial pressure should be monitored carefully during its administration. The patient should be kept on bed rest for the first 24 hours of hospitalization. Intravenous nitroglycerin should be administered to patients with continued chest pain, congestive heart failure, or systemic arterial hypertension. The nitroglycerin infusion should be initiated at 5 to 10 mcg/minute and gradually increased up to 200 mcg/minute until a 10% reduction in systolic arterial pressure in normotensive patients or a 25% to 30% reduction in systolic arterial pressure in hypertensive patients is realized. Morphine and nitroglycerin should be avoided in the patient suggested as having right ventricular infarction because a medication-induced reduction in preload may cause profound systemic arterial hypotension. The patient with acute MI should receive oral or rectal aspirin, 325 mg immediately and then

Figure 9-9 Right coronary artery angiogram in a patient with acute inferior myocardial infarction. The *left panel* demonstrates total occlusion of the right coronary artery. The *right panel* depicts restoration of flow 90 minutes after the intravenous administration of tissue-type plasminogen activator.

daily (75 to 325 mg) thereafter, because of its effectiveness in reducing mortality. In addition to aspirin, clopidogrel should be initiated with a 300- to 600-mg oral loading dose followed by a 75 mg daily maintenance dose. In patients older than 75 years treated with thrombolytics, there is a higher risk for bleeding complications with the addition of clopidogrel.

Restoration of antegrade flow in the occluded infarct-related artery within 12 hours of pain onset reduces morbidity and mortality. This reduction can be accomplished mechanically with a primary PCI or with a pharmacologic intervention using a thrombolytic agent. Randomized trials have established the superiority of PCI over thrombolytics in patients who can receive PCI expeditiously, generally within 90 minutes of presentation to medical attention. Thrombolytic therapy should be reserved for patients in whom PCI cannot be completed within 2 hours of medical attention. A delay in immediate reperfusion therapy increases the extent of myocardial damage and mortality.

An intravenous β blocker may be administered cautiously for those without a contraindication (i.e., heart rate < 60 beats/minute, systolic arterial pressure < 100 mm Hg, any congestive heart failure or peripheral hypoperfusion, first-degree AV block with a PR interval > 0.24 second, second- or third-degree AV block, severe obstructive lung disease, asthma). In the STEMI patient treated with intravenous β blocker, the beneficial effects of a reduction in arrhythmia, recurrent ischemia, and reinfarction are offset by an increased risk for cardiogenic shock. Therefore, intravenous β blockade is contraindicated in STEMI patients with any signs of heart failure or evidence of a low cardiac output state. Intravenous β blockade is reserved for hypertensive patients without any evidence of ventricular dysfunction, risk factors for cardiogenic shock, or contraindications to therapy. The β blocker most often used in this setting is metoprolol. Metoprolol is administered as three 5-mg boluses at 2- to 5-minute intervals to achieve a resting heart rate less than 70 beats/minute. Oral β blockade, initiated within 1 day and continued indefinitely, reduces the risk for nonfatal reinfarction and cardiovascular mortality by 20% to 25% when compared with placebo. The specific oral β blockers shown to exert this beneficial effect are propranolol, timolol, metoprolol, and atenolol. Although the mechanisms by which β

blockers exert their beneficial effect are not completely understood, they appear to have an anti-arrhythmic and anti-ischemic influence. For the patient in whom β blockers are contraindicated, verapamil may decrease the incidence of reinfarction and mortality; however, verapamil should be avoided in patients with ventricular systolic dysfunction, clinical heart failure, or any evidence of a low cardiac output state. The other calcium antagonists are not beneficial, and the dihydropyridine agents actually increase mortality.

In the patient with congestive heart failure or depressed left ventricular systolic function (ejection fraction < 0.40%) without systemic arterial hypotension, the administration of an oral ACE inhibitor improves outcome. Randomized, placebo-controlled trials have demonstrated that ACE inhibitor therapy with captopril, enalapril, ramipril,trandolapril, or zofenopril begun 24 hours to 16 days after MI limits left ventricular dilation, improves left ventricular ejection fraction, reduces the incidence of reinfarction and heart failure, and improves short- and long-term survival. In two large trials, the administration of ACE inhibitors within 1 day of hospitalization reduced short-term mortality. The recommended initial regimens include captopril (initial dose, 6.25 mg, increased every 6 to 8 hours to a maximum of 50 mg 3 times daily as long as the systolic arterial pressure is > 90 to 100 mm Hg); enalapril (initial dose, 2.5 mg/day, gradually increased to 20 mg twice daily), or lisinopril (initial dose, 2.5 mg/daily, increased to a maximum of 40 mg/day). ACE inhibitors should not be administered to patients with systemic arterial hypotension (systolic pressure < 90 to 100 mm Hg), an allergy to ACE inhibitors, hyperkalemia, a history of bilateral renal arterial stenosis, previous worsening of renal failure with ACE inhibitors, or pregnancy. Intravenous ACE inhibitors are not recommended for acute STEMI management because of the risk for hypotension.

During the hours after the initiation of the therapies previously described, the patient should be closely observed for the development of early complications related to the MI. Systemic arterial hypotension during the early hours of infarction may be due to intravascular volume depletion, right ventricular infarction, severe left ventricular systolic dysfunction, medications (most notably morphine or nitroglycerin), bradycardia, or tachyarrhythmia. Less commonly, a mechanical complication (e.g., left ventricular free-wall

rupture, ventricular septal defect, papillary muscle rupture with resultant mitral regurgitation) can occur within hours of the onset of MI.

Immediate Reperfusion Therapy

In patients with STEMI, early restoration of blood flow to the jeopardized myocardium can limit necrosis, improve left ventricular function, and reduce mortality. This can be mechanically accomplished with primary PCI or pharmacologically with a thrombolytic agent. If a cardiac catheterization facility is accessible and experienced physicians and personnel can quickly perform primary PCI (i.e., within 90 minutes of the patient's first contact with medical personnel), it is the preferred method of restoring antegrade flow in most patients. On the other hand, if primary PCI is not immediately available or the delay in transporting the patient to a catheterization facility would be inordinately long, thrombolytic therapy should be given. Primary PCI is particularly preferable in patients with a contraindication to thrombolytic therapy, with prior CABG, in cardiogenic shock, or older than 70 years.

Thrombolytic therapy is effective in restoring infarct-related artery patency. In 50% to 60% of patients, normal coronary flow is reestablished within 90 minutes of thrombolytic administration. It should be administered to the STEMI patient who seeks medical attention at a center without catheterization facilities or appropriately experienced personnel as well as to the patient with a condition that would make catheterization inappropriate (i.e., allergy to radiographic contrast material, severe renal insufficiency, severe peripheral vascular disease). In the United States, five thrombolytic agents are currently approved for use in patients with STEMI (Table 9-7): (1) streptokinase, (2) anistreplase (anisoylated plasminogen streptokinase activator complex [APSAC]), (3) alteplase (tissue plasminogen activator [t-PA]), (4) reteplase plasminogen activator (r-PA), and (5) tenecteplase tissue plasminogen activator (TNK-tPA). Currently, r-PA and TNK-tPA are the most commonly used

thrombolytics. Although slight differences in their effectiveness and bleeding complications have been reported, the choice of agent is less important than the timely decision to administer it.

Streptokinase (1.5 million units) is given as a 1-hour infusion. Rarely, the recipient may experience an acute allergic reaction. Although its administration is frequently associated with mild hypotension, the drop in systemic arterial pressure is rarely of sufficient magnitude to warrant interruption of the infusion. Because antibodies to streptokinase develop within days of its administration, it should not be given to patients who have previously received it or who have had a recent streptococcal infection. APSAC is derived from and has the same limitations as streptokinase, but it is significantly more costly. These agents are seldom used in the United States.

t-PA and its derivatives r-PA and TNK-tPA are much more expensive than streptokinase and are associated with a slightly higher rate of intracranial hemorrhage (0.7% versus 0.5%, respectively). However, they are also more *clot specific* in that they do not cause a generalized fibrinolytic state, and they are more effective at lysing older thrombi (e.g., those associated with an MI of >4 hours' duration). t-PA and its derivatives do not elicit an antibody response or hypotension. t-PA is given as an initial bolus or *front loaded*, followed by a 90-minute infusion (15 mg as a bolus, another 50 mg infused over 30 minutes, and the remaining 35 mg infused over the next 60 minutes). r-PA is administered as a double bolus (two 10-unit boluses delivered 30 minutes apart), and TNK-tPA is administered as a single bolus (0.5 mg/kg to a maximum of 50 mg). Although r-PA and TNK-tPA are somewhat more likely than t-PA to restore early patency of the infarct-related artery, the mortality rate with these three agents is similar.

Overall, thrombolytic therapy decreases short-term mortality in subjects with STEMI by about 20%. Angiographic studies comparing thrombolytic regimens demonstrate that restoration of blood flow in the infarct-related artery is faster and more complete with t-PA than with streptokinase, and this translates into a modestly decreased mortality rate with t-PA, especially when it is given in a front-loaded fashion. Specifically, in the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Occluded Coronary Arteries (GUSTO) trial, t-PA was associated with a statistically significant 1% absolute reduction in mortality when compared with streptokinase. Most of this benefit occurred in patients younger than 70 years within 4 hours of the onset of an anterior STEMI. In older patients, in patients more than 4 hours after symptom onset, and in those with an MI in a territory other than the anterior wall, the mortality difference between these two agents was negligible.

The contraindications to thrombolytic therapy are listed in Table 9-8; they identify those with an unacceptably high risk for bleeding complications. The most catastrophic potential complication of thrombolytic therapy is intracranial hemorrhage. This risk is substantially increased in patients with a history of hemorrhagic stroke, uncontrolled hypertension, body weight less than 70 kg, and age more than 65 years.

Aspirin is an obligatory adjunct to thrombolysis; its use is associated with an additive benefit on mortality and a decrease in recurrent ischemic events. Clopidogrel therapy

Table 9-7 Dosing Regimens of Commonly Used Thrombolytic Agents

Thrombolytic Agent	Dosing Regimen
t-PA (alteplase)	15 mg bolus IV, followed by 0.75 mg/kg body weight (not to exceed 50 mg) over 30 min, followed by 0.5 mg/kg (not to exceed 35 mg) over 60 min
r-PA (reteplase)	Two 10U IV boluses, given 30 min apart
TNK-tPA (tenecteplase)	Single bolus IV 0.5 mg/kg (dose rounded to the nearest 5 mg, ranging from 30 to 50 mg)
Streptokinase	1.5 million U IV over 60 min

IV, intravenous; PA, plasminogen activator; r-PA, reteplase plasminogen activator; TNK-tPA, tenecteplase tissue plasminogen activator; U, units.

Table 9-8 Contraindications to Thrombolytic Therapy in Acute Myocardial Infarction**Absolute**

Suspected aortic dissection
 Active bleeding*
 Any prior cerebral hemorrhage
 Intracranial neoplasm
 Cerebral aneurysm or arteriovenous malformation
 Ischemic cerebrovascular accident within 3 months

Relative

Bleeding diathesis, coagulopathy, or anticoagulant use
 Major surgery within 3 weeks
 Puncture of a noncompressible vessel, internal bleeding, or head or major body trauma within previous 2 weeks
 Nonhemorrhagic stroke or gastrointestinal hemorrhage within 6 months
 Proliferative retinopathy
 Active peptic ulcer disease
 History of chronic, severe, poorly controlled hypertension
 Severe uncontrolled hypertension on presentation (systolic blood pressure > 180 mm Hg or diastolic blood pressure > 110 mm Hg)
 Traumatic or prolonged (>10 min) cardiopulmonary resuscitation
 Pregnancy

*Does not include menstrual bleeding.

with a 300-mg load followed by a daily maintenance dose of 75 mg improves mortality compared with placebo in STEMI patients 75 years and older. Intravenous heparin administered for 48 hours is necessary to maintain patency of the infarct-related artery after successful thrombolysis when a t-PA is administered, but not with streptokinase. Low-molecular-weight heparin may be slightly more effective than unfractionated heparin as adjunctive therapy after successful thrombolysis. Its use is associated with a higher rate of vessel patency and a lower rate of reocclusion, leading to fewer episodes of recurrent ischemia and infarction, albeit with a somewhat increased risk for hemorrhagic complications. For patients who do not reperfuse within 90 minutes of receiving thrombolytics (as evidenced by continued chest pain or continued ST-segment elevation), rescue PCI is generally recommended. Even with successful thrombolysis, there is a 30% chance of culprit vessel reocclusion within 3 months. Risk stratification with a submaximal, symptom-limited stress test or coronary angiography is required during the STEMI hospitalization for thrombolized patients.

POST-MYOCARDIAL INFARCTION COMPLICATIONS

The complications of MI may be categorized as electrical or mechanical (Table 9-9).

Arrhythmias and Conduction Abnormalities

Cardiac arrhythmias may occur in patients with acute coronary syndromes. Those that cause symptoms or hemodynamic compromise almost always warrant treatment, whereas those that do not often can be managed expectantly.

Table 9-9 Complications of Acute Myocardial Infarction**Functional**

Left ventricular failure
 Right ventricular failure
 Cardiogenic shock

Mechanical

Free-wall rupture
 Ventricular septal defect
 Papillary muscle rupture with acute mitral regurgitation

Electrical

Bradyarrhythmias (first-, second-, and third-degree atrioventricular blocks)
 Tachyarrhythmias (supraventricular, ventricular)
 Conduction abnormalities (bundle branch and fascicular blocks)

Although most of these arrhythmias are a direct result of the ischemic process, other reversible aggravating factors, such as electrolyte disturbances, hypoxemia, and medication toxicity, must be excluded.

Premature ventricular complexes, ventricular couplets, and nonsustained ventricular tachycardia (VT) occur frequently in the peri-infarction period. Although such ectopy can be effectively suppressed with anti-arrhythmic agents, treatment is not warranted in the absence of symptoms or hemodynamic compromise. The presence of frequent ventricular ectopy does not predict the development of more malignant arrhythmias, and empiric therapy of such ectopy is associated with an increased mortality rate. Accelerated idioventricular rhythm, or *slow VT*, often occurs shortly after successful reperfusion, is self-limited, and does not require treatment.

During the past several decades, mortality in hospitalized patients with acute MI has substantially declined in large part because of the early recognition and treatment of lethal arrhythmias. Because most deaths from acute MI occur as a result of sustained VT or ventricular fibrillation (VF), these rhythm disturbances should be treated with immediate electrical defibrillation, after which administering intravenous anti-arrhythmic medications (e.g., lidocaine, amiodarone) is reasonable for 24 to 48 hours. Sustained but hemodynamically stable VT can be treated initially with anti-arrhythmic agents with electrical cardioversion held in reserve. In the absence of electrolyte abnormalities, polymorphic VT is usually a marker of recurrent or persistent ischemia, and aggressive anti-ischemic treatment is warranted. When sustained VT or VF occurs in the first 48 hours after MI, it does not portend the same poor prognosis as it does when it occurs later.

Transient supraventricular tachyarrhythmias may occur in patients with acute MI, with sinus tachycardia and atrial fibrillation being the most common. The cause of sinus tachycardia (e.g., anxiety, pain, fever, anemia, hypoxemia, hypovolemia, pulmonary vascular congestion, thyrotoxicosis) should be promptly identified and corrected. If atrial fibrillation is accompanied by a rapid ventricular response, with resultant ongoing ischemia or hemodynamic compromise, electrical shock cardioversion should be considered. In the patient with atrial fibrillation and a rapid ventricular

response, intravenous β blockers or amiodarone is usually effective for controlling the ventricular response, provided no contraindications to their use exist. Calcium channel blocking agents are also effective but should be avoided in the patient with heart failure. (These arrhythmias are discussed at length in Chapter 10.)

Bradyarrhythmias may complicate acute MI. The most common bradyarrhythmia is sinus bradycardia, which is observed in 20% to 25% of patients with acute MI and is more common in those with inferior than anterior MI. In patients with inferior MI, sinus bradycardia is often associated with hypotension caused by increased vagal tone as a result of stimulation of vagal afferent fibers in the inferoposterior portion of the left ventricle (Bezold-Jarisch reflex). Unless accompanied by hemodynamic instability, sinus bradycardia should be simply observed. If treatment is necessary, intravenous atropine (0.5 to 2 mg) should be administered, aiming for a heart rate of 60 beats/minute and a resolution of symptoms. Temporary pacing is rarely required.

Ischemia and infarction can result in transient or permanent injury to the conduction system. Varying degrees of AV block may occur in patients with acute MI. Ischemia of the AV node can result in first-degree or Mobitz type I second-degree (Wenckebach phenomenon) AV block. These rhythms are most often associated with inferior MI; they are transient, do not adversely affect survival, and do not require treatment unless the ventricular rate is sufficiently slow to produce syncope, congestive heart failure, or angina. Mobitz type II second-degree AV block is a rare complication of acute MI (1% of cases) and usually results from injury to the His-Purkinje system in the setting of an extensive anterior MI. It often is associated with progression to complete or third-degree AV block and is an indication for temporary transvenous or transcutaneous pacing in anticipation of implantation of a permanent pacemaker. Complete or third-degree AV block may occur with inferior or anterior MI. When it occurs in the setting of an inferior MI, the block is usually at the level of the AV node. It is associated with a stable escape rhythm and tends to be transient, although it may take up to 1 to 2 weeks to resolve. As a result, treatment with only a temporary and not a permanent pacemaker is usually required. In contrast, when complete AV block occurs in the setting of an anterior MI, the His-Purkinje system is usually involved. The block is usually permanent, and a permanent pacemaker should be implanted.

Block in one or more branches of the conduction system may occur with acute MI and is more common with anterior than with inferior infarction. Patients with isolated left anterior or left posterior fascicular block or right bundle branch block (RBBB) do not require specific therapy. Conversely, temporary pacing is suggested in patients with new bifascicular blocks (e.g., LBBB or RBBB with left anterior or left posterior fascicular block) because progression to complete heart block is common. If bifascicular block persists after an MI, a permanent pacemaker should be placed.

Congestive Heart Failure and Cardiogenic Shock

Patients who die of cardiac failure after acute MI have extensive myocardial necrosis with loss of at least 40% of the functioning left ventricular muscle mass, as either a conse-

quence of new infarction or a combination of old and new infarctions.

The patient with an acute MI and no evidence on physical examination or chest radiographic studies of left ventricular failure has an excellent prognosis, with only a 2% to 5% in-hospital mortality rate (Killip class I). The individual with some evidence of pulmonary vascular congestion (e.g., basilar rales, S_3 , radiographic evidence of pulmonary venous congestion) is classified as Killip class II and has a short-term mortality rate of 10% to 15%. In the patient with overt pulmonary edema evidenced on physical examination or chest radiographic studies, mortality rate is 20% to 30% (Killip class III). Finally, the patient with cardiogenic shock is said to be Killip class IV and has a mortality rate of 50% to 60% even with maximal therapy. In these individuals, infarction is associated with systemic arterial hypotension and diminished peripheral perfusion, as manifested by mental confusion, cold and clammy skin, peripheral cyanosis, and oliguria. Hemodynamically, the systemic arterial systolic pressure is less than 90 mm Hg, the cardiac index is less than 1.8 L/m² per minute, the systemic arteriolar resistance is greatly increased (>2000 dynes/cm⁵ per second), and the left ventricular filling pressure is elevated (more than 20 mm Hg) for more than 30 minutes. The reduced systemic arterial pressure further diminishes coronary arterial perfusion pressure, thereby increasing myocardial ischemia. The low cardiac output and systemic arterial pressure induce an intense sympathetic discharge that produces peripheral vasoconstriction, further decreasing tissue perfusion and causing a systemic lactic acidosis, which depresses myocardial function. In response to a reduced cardiac output, the heart rate increases, thereby increasing myocardial oxygen demand. As left ventricular filling pressure rises, subendocardial perfusion is further compromised. In short, the hemodynamic and metabolic consequences of cardiogenic shock cause worsening myocardial ischemic injury, which, in turn, leads to worsening left ventricular dysfunction. A cycle of severe hemodynamic impairment and deteriorating myocardial oxygenation is established.

The therapy of the patient with an acute MI and resultant left ventricular dysfunction depends on the extent of such dysfunction. The normotensive individual with symptoms and signs of Killip class II congestive heart failure (i.e., mild orthopnea, basilar rales, S_3) usually responds to bed rest, salt restriction, a loop diuretic, and low-dose vasodilator therapy with an ACE inhibitor. Additional therapy with digitalis or other inotropic agents is not usually necessary, nor is invasive hemodynamic monitoring. The management of the patient with more severe heart failure (Killip class III or IV) should be based on a careful assessment of hemodynamic variables obtained with a balloon-tipped flotation catheter in the pulmonary artery and an intra-arterial cannula. Adequate oxygenation should be ensured by continuous pulse oximetry with supplemental oxygen or ventilator support as needed. Placement of a urinary catheter enables the urine output to be assessed accurately, and endotracheal intubation and assisted ventilation may reduce the work of breathing and improve tissue oxygenation. Intravenous furosemide should be administered in an attempt to reduce the pulmonary capillary wedge pressure in the range of 18 to 20 mm Hg; this appears to be the optimal preload in the setting of acute MI. In the normotensive individual, vasodilator therapy

with nitroglycerin and oral ACE inhibitors should be instituted to reduce afterload, increase cardiac output, and lower left ventricular filling pressure. The resultant decrease in left ventricular wall stress reduces myocardial oxygen requirements, improves subendocardial perfusion, and helps relieve ischemia. Nitroglycerin should be administered to avoid an excessive reduction in systemic arterial pressure, which may compromise myocardial perfusion, while keeping pulmonary capillary wedge pressure in the range of 18 to 20 mm Hg. The patient with heart failure and hypotension or an inadequate response to diuretics and vasodilators (i.e., cardiac output $< 1.8 \text{ L/m}^2$ per minute pulmonary capillary wedge pressure $> 20 \text{ mm Hg}$) should be treated with intravenous inotropic agents (e.g., dopamine or dobutamine, depending on the systemic arterial pressure). If the patient is only mildly hypotensive, dobutamine is the preferred inotropic agent. Dopamine should be reserved for the patient with more severe hypotension because it may increase pulmonary capillary wedge pressure.

In the patient with severe heart failure or cardiogenic shock, a careful search for a potentially correctable cause should be undertaken. Two-dimensional and color Doppler echocardiography, which can rapidly be performed at the bedside, will allow the clinician to determine whether the shock is due to extensive left ventricular dysfunction or a mechanical problem, such as acute mitral regurgitation, acute ventricular septal defect, extensive right ventricular infarction, or a contained rupture of the left ventricular free wall (see “Mechanical Complications”).

Patients with shock who are examined within the first few hours of the onset of MI should be considered for immediate reperfusion therapy. Thrombolytic agents are less effective in opening the occluded infarct-related artery in the patient with cardiogenic shock, and these agents have not convincingly exerted a beneficial effect in such patients. Conversely, early coronary revascularization within 12 hours of the onset of cardiogenic shock, accomplished percutaneously or surgically, has been shown to improve in-hospital and 1-year survival.

By reducing afterload and increasing myocardial perfusion pressure, intra-aortic balloon counterpulsation may be effective in stabilizing the patient with cardiogenic shock. Although initial hemodynamic improvement in this setting may be dramatic, balloon counterpulsation alone probably does not improve the poor prognosis associated with cardiogenic shock. Rather, counterpulsation should be considered a supportive measure in patients with potentially reversible abnormalities before cardiac catheterization, cardiac surgery, or, in some cases, cardiac transplantation. In patients who remain hemodynamically unstable despite pressors and intra-aortic balloon counterpulsation, percutaneous left ventricular support device implantation should be considered. If these therapies do not improve hemodynamics, a surgical ventricular assist device could be considered.

Right Ventricular Infarction

Right ventricular infarction usually occurs in association with inferior MI because the blood supply to both these areas usually comes from the right coronary artery. The presence of a concomitant right ventricular infarction substantially increases the mortality of an inferior MI. Right ventricular

MI results in the clinical triad of hypotension, clear lungs (i.e., normal pulmonary capillary wedge pressure), and prominent jugular venous distention. In the absence of hemodynamic measurements, right ventricular infarction may be confused with hypovolemia, pulmonary embolism, or cardiac tamponade. In fact, the patient with acute right ventricular failure may have a prominent y descent in the atrial pressure tracing (Fig. 9-10), Kussmaul sign, and pulsus paradoxus, all of which mimic pericardial tamponade. Demonstrating ST-segment elevation in the right precordial leads (e.g., $>0.1 \text{ mV}$ elevation in V_4R) confirms the diagnosis of right ventricular infarction. For this reason, a right-sided precordial ECG should be obtained in all patients with inferior MI. The treatment of hypotension in the patient with right ventricular infarction often requires rapid intravascular volume repletion (with a goal right atrial pressure of 12 to 15 mm Hg) and inotropic agents (e.g., dobutamine). A balloon-tipped flotation catheter in the pulmonary artery and an intra-arterial cannula should be used for hemodynamic monitoring. Diuretic and vasodilator (e.g., nitroglycerin) therapy should be avoided because they may provoke hypotension in this setting. If the patient can be supported during the first few days of hemodynamic instability, considerable improvement in right ventricular function often occurs.

Figure 9-10 Electrocardiographic (ECG), arterial, and Swan-Ganz bedside catheter recordings in a patient with right ventricular infarction. Hypotension is present, and cardiac output, estimated by thermodilution (*not shown*), is reduced. The pulmonary arterial pressures are normal, whereas the right atrial pressure is elevated, and it demonstrates a prominent y descent.

Mechanical Complications

Mechanical complications of acute MI include papillary muscle rupture, ventricular septal defect, and ventricular free-wall rupture. Patients with these complications frequently experience hemodynamic collapse 3 to 5 days after acute MI. These complications are associated with high mortality rates; they account for about 15% of the mortality from acute MI. Successful immediate reperfusion therapy has reduced the appearance of these complications. Patients with late or unsuccessful reperfusion therapy are at higher risk for these mechanical complications.

Papillary muscle rupture results in acute mitral regurgitation. The resultant sudden increase in left atrial volume causes a significantly elevated left atrial pressure, with resultant pulmonary edema. Papillary muscle rupture occurs most commonly with inferior MI because the posteromedial papillary muscle usually has a single source of blood supply from the right coronary artery. Conversely, the anterolateral papillary muscle has a dual blood supply. A loud, apical holosystolic murmur is usually audible, although an occasional patient with severe mitral regurgitation has no audible murmur. The diagnosis may be rapidly confirmed with transthoracic echocardiography or right-heart ventricular catheterization, with the latter demonstrating large v waves in the pulmonary capillary wedge tracing in the absence of an oxygen *step-up* in the right ventricle.

An acute ventricular septal defect may occur after anterior or inferior MI. On physical examination, a harsh holosystolic murmur is audible at the left lower sternal border, which may be difficult to differentiate from acute mitral regurgitation; this murmur is often accompanied by a palpable thrill. The diagnosis can be confirmed by obtaining blood samples from each of the cardiac chambers during right heart ventricular catheterization and by demonstrating a higher oxygen saturation in the samples obtained from the right ventricle or pulmonary artery compared with those obtained from the right atrium (e.g., oxygen *step-up*). Specifically, an increase in oxygen saturation of more than 6% between the right atrium and pulmonary artery strongly suggests the presence of a ventricular septal defect with concomitant left-to-right shunting. Doppler echocardiography also allows visualization of left-to-right shunting of blood through the ventricular septal defect.

Treatment of acute papillary muscle rupture or ventricular septal defect includes inotropic agents, vasodilators, and intra-aortic balloon counterpulsation. These temporizing measures help prepare the patient for urgent cardiac surgery to repair the ventricular septal defect or replace the mitral valve.

Free-wall rupture of the left ventricle almost always results in hemopericardium, cardiac tamponade, and electromechanical dissociation. Survival is uncommon and depends on prompt recognition and emergent surgical repair. In an occasional patient, a pseudoaneurysm or false aneurysm develops when free-wall rupture occurs, so that the rupture is confined by the adherent pericardium, organized thrombus, and hematoma. Because the wall of the pseudoaneurysm contains no myocardium, it may rupture at a later date. The pseudoaneurysm maintains continuity with the left ventricular cavity through a narrow connecting orifice (e.g., neck). In contrast, a true aneurysm represents an area of infarcted myocardium that has become thinned and dilated

through a process of ventricular remodeling. True aneurysms have a wide orifice or neck, their walls always contain some myocardial elements, and they rarely rupture. Pseudoaneurysms should undergo prompt surgical resection because of the risk for rupture. Conversely, a true aneurysm does not require urgent surgical resection. Medical treatment of post-MI aneurysms includes aggressive heart failure management with ACE inhibitors, β blockers, aldosterone inhibitors for those with class III or IV heart failure, and consideration of anticoagulant therapy. Those undergoing subsequent CABG and those with aneurysm-related chest pain may be considered for aneurysmectomy.

SECONDARY PREVENTION OF ACUTE CORONARY SYNDROME

Secondary prevention therapies are a critical component of the management of all patients with acute coronary syndrome. About 70% of coronary heart disease deaths and 50% of MIs occur in patients with a prior history of coronary artery disease. Secondary prevention therapies in patients recovering from acute coronary syndrome represent a major opportunity to reduce cardiovascular morbidity and mortality.

Before hospital discharge, patients should be educated regarding adherence to the recommended lifestyle changes and pharmacologic therapies. Patients and their families should receive discharge instructions about recognizing acute cardiac symptoms and appropriate actions to take in order to ensure early evaluation and treatment should symptoms recur. Family members should be advised about cardiopulmonary resuscitation and automatic external defibrillator (AED) training programs.

Lipid management involves dietary therapy that is low in saturated fat and cholesterol (<7% of total calories as saturated fat and <200 mg/day cholesterol). Consumption of fruits, vegetables, fiber, whole grains, and foods enriched with omega-3 fatty acids are encouraged. Antioxidants are not recommended for the secondary prevention of MI. Statins are recommended for patients following an acute coronary syndrome for a goal LDL of less than 70 mg/dL. Weight reduction is recommended to achieve a desirable body mass index range between 18.5 and 24.9 kg/m². Patients should be advised regarding strategies for weight management and regular aerobic physical activity, usually prescribed initially with cardiac rehabilitation. Patients are encouraged to exercise for at least 30 minutes, preferably daily. Cardiac rehabilitation is recommended for patients with heart failure and after MI or coronary revascularization. Patients with a history of cigarette smoking should be encouraged to stop smoking and avoid secondhand smoke. In addition to smoking cessation counseling, pharmacologic therapy (nicotine replacement, varenicline, bupropion) should be considered. For those with systemic hypertension, a low-sodium diet and antihypertensive medication should be prescribed. Typically, ACE inhibitors and β blockers are recommended. An angiotensin receptor blocker may be used in patients who develop a cough attributed to the ACE inhibitor. For those with systolic dysfunction, diuretics may be prescribed to promote euvoolemia. In addition to ACE inhibitors and β blockers (most commonly carvedilol or metoprolol succinate), aldosterone inhibitors are recommended

for patients with class III or IV heart failure symptoms. Antiplatelet therapy with both aspirin (75 to 162 mg daily indefinitely) and clopidogrel (75 mg daily for 1 year) is recommended. Warfarin may be used for patients with persistent or paroxysmal atrial fibrillation or flutter and those with a left ventricular thrombus. For patients with an indication for anticoagulation who received a stent, aspirin (75 to 162 mg), clopidogrel (75 mg), and warfarin (goal INR 2 to

3) may be given to those younger than 75 years with a low bleeding risk. Diabetic patients should have hypoglycemic therapy for a goal hemoglobin A1c of less than 7%. Hormone replacement therapy with estrogen plus progestin should not be started for postmenopausal women recovering from an acute coronary syndrome. Women already taking hormone therapy at the time of an acute coronary syndrome should not continue hormone therapy.

Prospectus for the Future

- New methods are needed to identify patients at risk for CAD using genomics and proteomics.
- New treatments are required for treating components of ischemic heart disease (e.g., raising HDL level, lowering hsCRP level, targeting antiplatelet therapy) to reduce cardiac events.
- Evaluation is needed to compare the efficacy and safety of drug-eluting stents with CABG for patients needing coronary revascularization.
- Development of regional cardiac centers is necessary to provide reperfusion therapy for patients with acute MI who enter a hospital that does not have a catheterization laboratory.

Cardiac Arrhythmias

Mohamed H. Hamdan

Cardiac Action Potential and Normal Conduction

The electrical activity of a single cardiac cell can be recorded with the aid of a microelectrode and demonstrates that the resting potential of a myocyte is -80 to -90 mV. This resting potential is maintained by the accumulation of potassium inside the cell and the removal of sodium from the cell by the energy-requiring sodium-potassium adenosine triphosphatase (Na^+, K^+ -ATPase). When a cardiac myocyte is depolarized to below threshold level (threshold potential), an action potential is produced by a complex series of ionic shifts (Fig. 10-1A). The action potential can be divided into five phases. Phase 0 is the rapid initial depolarization and is mediated by an increased permeability of the sarcolemma to sodium ions. This phase is followed by phase 1, an early, rapid, repolarization resulting from the movement of potassium out of the cell. The plateau phase (phase 2) of the action potential is mainly determined by the inward movement of calcium ions but also by the movement of sodium, chloride, and potassium ions. Phase 3 constitutes the repolarization phase of the action potential and is the result of the movement of potassium ions out of the cell. Phase 4 of the action potential represents the outward flow of potassium and the inward flow of sodium and results in the gradual depolarization of the cell from resting to threshold potential (see Fig. 10-1B). During the action potential and shortly thereafter, a period occurs during which an adequate depolarizing stimulus fails to elicit an action potential. This period is termed the *absolute refractory period* and is most closely related to the duration of phase 3 of the action potential.

The appearance of the action potential of sinus and atrioventricular (AV) nodal cells is different from that of the typical myocyte. The normal resting potential of these cells is higher (-60 mV), the initial upstroke of depolarization is slower and calcium dependent, and the phase 4 depolariza-

tion is highly pronounced (see Fig. 10-1B). The slope of the phase 4 depolarization determines the rate at which a cell will spontaneously depolarize (automaticity) until it reaches threshold potential, thus generating an action potential that is then propagated to surrounding cells. The sinus node usually has the fastest phase 4 depolarization and thus functions as the normal pacemaker of the heart, producing a rate of contraction (heart rate) of 60 to 100 beats/min. If the sinus node fails, the AV node has the next fastest pacemaker rate (about 50 beats/minute). The ventricular myocytes have slow phase 4 depolarization and produce a heart rate of 30 to 40 beats/minute if higher pacemakers fail. When a lower pacemaker focus appropriately fires in the setting of slowing of the higher focus, the firing is termed an *escape beat* (if single) or an *escape rhythm* (if sustained).

The autonomic nervous system has important effects on the generation and propagation of cardiac impulses. The sinus and AV nodes are the most richly innervated regions of the heart and are most affected by changes in autonomic tone. Sympathetic stimulation, either directly from sympathetic nerve endings in the heart or indirectly by means of circulating catecholamines, increases the heart rate by increasing the rate of phase 4 depolarization and also increases intercellular conduction velocity. Parasympathetic stimulation has the opposite effects. Vagal tone is, in part, controlled by the baroreceptors of the carotid sinus and aortic arch and responds to increases in blood pressure by increasing vagal output, with a resulting decrease in heart rate and AV nodal conduction velocity.

The normal cardiac impulse starts at the sinoatrial node, passes through the atria to the AV node, where it slows, and then continues down the His-Purkinje system to the ventricular myocardium, where the wave of depolarization terminates because no further tissue exists to depolarize. Further conduction occurs only after a new impulse is formed in the sinoatrial node.

Figure 10-1 Genesis of the cardiac action potential. **A**, Ventricular action potential with predominant ionic currents. **B**, Sinus node action potential with predominant ionic currents. See text for details. I_f, Hyperpolarization-activated current.

Cardiac Arrhythmias

Cardiac arrhythmias result from disorders of (1) *impulse formation* and (2) *impulse conduction*. Disorders of impulse formation include enhanced or abnormal automaticity and triggered activity. Disorders of impulse conduction include conduction block with or without re-entry (defined later). One or more of the previously described electrophysiologic (EP) mechanisms can explain most cardiac arrhythmias.

DISORDERS OF IMPULSE FORMATION

Cardiac depolarization is driven by the sinus node (normal pacemaker), which is located in the high right atrium along the crista terminalis. This waveform propagates down the AV node and His-Purkinje system, resulting in synchronized activation of both ventricles. Subsidiary pacemakers with a lower discharge rate are mainly present in the AV junction and the His-Purkinje system. These pacemakers do not reach threshold because of overdrive suppression by the sinus node. However, under certain conditions, such as sinus node slowing or conduction block, these pacemaker sites may become active and discharge at their normal rate.

Enhanced automaticity refers to pacemaker cells discharging at a rate faster than their normal rate. By definition, these cells have intrinsic automaticity (slow response type of action potential; see Fig. 10-1B), but under certain conditions (partial depolarization, decrease in threshold, or increase in the slope of phase 4), the automaticity rate is enhanced. *Abnormal automaticity* refers to spontaneous depolarization resulting in impulse formation in cardiac tissues that lack intrinsic automaticity (fast response type of action potential; see Fig. 10-1A). Under certain conditions, these cells may show spontaneous automaticity, resulting in premature depolarizations, which, if repetitive, can lead to tachycardia. Singular premature atrial or ventricular depolarizations may arise by this mechanism. Some sustained rhythms, including ectopic atrial tachycardia, accelerated junctional or idioventricular rhythms, and some forms of ventricular tachycardia (VT), may also result from increased automaticity. Ischemia, digoxin, methylxanthine toxicity, electrolyte abnormalities, and high catecholamine states are well-known causes of abnormal and enhanced automaticity.

Triggered activity means impulse initiation caused by afterdepolarizations. Afterdepolarizations are oscillations in membrane potentials that occur after the upstroke of the action potential. If the amplitude is large enough to reach threshold, afterdepolarizations can generate a subsequent action potential. By definition, afterdepolarizations must be preceded by at least one action potential, thus the term triggered activity. They do not occur spontaneously but, rather, are triggered by prior activation of the heart. When afterdepolarizations occur during repolarization, they are called *early afterdepolarizations* (EADs). EADs are usually exacerbated by hypokalemia or potassium channel blockade or drugs and may be catecholamine driven or provoked by a critical heart rate. EADs may also occur spontaneously in patients with congenital long QT syndrome (LQTS). When afterdepolarizations occur after full repolarization, they are called *delayed afterdepolarizations* (DADs). DADs are more pronounced at fast heart rates, are facilitated by intracellular calcium overload, and account for the mechanism underlying most digoxin-toxic rhythms. They are usually caused by ischemia, catecholamines, and digitalis.

DISORDERS OF IMPULSE CONDUCTION

Disorders of impulse conduction include conduction block with or without *reentry*. Reentry is the most common mechanism of arrhythmogenesis. During reentry, a depolarization propagates in one direction while blocking in adjacent tissue, returns to depolarize the area not initially excited, and, if successful, will travel around repeating its course. Therefore, three criteria are needed for reentry to be present: (1) two available pathways, (2) unidirectional block in one, and (3) conduction delay in the other with return excitation. Based on these general concepts, three types of reentry have been described: (1) anatomic, (2) functional (leading circle or reentry), and (3) reentry by reflection. Describing these mechanisms in detail is not the purpose of this chapter; however, it should be emphasized that the presence of a discrete anatomic obstacle (such as a scar) is not always needed for reentry, given that conduction delay and block can be caused by many factors, including differences in refractoriness, ischemia, fibrosis, electrolyte abnormalities, and drug

toxicity. An example of reentry in which two distinct pathways are present is provided in Figure 10-2. Pathway A conducts rapidly but has a relatively long refractory period. Pathway B conducts slowly but has a relatively short refractory period. In the usual state (see Fig. 10-2A), an impulse enters the two pathways by means of a proximal common pathway. Conduction occurs rapidly down pathway A and, after reaching the distal common pathway, continues distally and proceeds retrograde up pathway B until it intercepts the slow antegrade impulse traveling down this pathway and is extinguished. The surface electrocardiogram (ECG) may appear normal, without evidence of the dual pathways. If a premature depolarization occurs, it also enters the two pathways through the proximal common pathway. If it occurs early enough, it is unable to conduct down pathway A because of the long refractory period of this path (see Fig. 10-2B). The impulse therefore travels down pathway B, which has the short refractory period, and reaches the distal common pathway, where it continues distally. However, because pathway B conducts relatively slowly, by the time the impulse reaches the distal aspect of pathway A, this path is no longer refractory, and the impulse rapidly conducts in a retrograde direction up pathway A, reenters the loop by means of pathway B, and conducts retrograde up the proximal common pathway. If the reentrant circuit is in the AV node, the resulting surface ECG demonstrates a premature complex, initiating a tachycardia, and retrograde P waves may be seen.

Reentry can occur at any point along the normal conduction system, including the sinoatrial node, the AV node, and atrial or ventricular myocardium. It may occur in a small focus of cardiac tissue such as the AV node (a micro-reentrant circuit) or involve anatomically distinct pathways such as bypass tracts (a macro-reentrant circuit).

As stated previously, cardiac arrhythmias are the result of disorders in impulse formation or impulse conduction, with reentry being the most common underlying mechanism. Clinically, cardiac arrhythmias can be divided into three categories: (1) premature beats, (2) bradyarrhythmias (slow heart rates), and (3) tachyarrhythmias (fast heart rates).

Premature Beats

ATRIAL PREMATURE COMPLEXES

An atrial premature complex (APC) is defined as a premature activation of the atria arising from a site other than the sinus node. APCs appear on the surface ECG as P waves with morphologic characteristics different from those of the sinus P wave occurring before the anticipated sinus beat (Fig. 10-3A). An APC may conduct with a short, normal, or prolonged PR interval, or it may not conduct at all. The PR interval is determined by the site of origin and the degree of prematurity. If conducted, an APC may be associated with either a normal or a wide (aberrant) QRS complex. Distinguishing aberrant APCs from ventricular premature depolarizations may be difficult. The presence of a full compensatory pause (RR interval surrounding the APC = twice the sinus cycle length) suggests lack of sinus node resetting, thus favoring a ventricular rather than an atrial site of origin. Because the right bundle branch has a longer refractory period than the left bundle branch, an early APC is more likely to conduct with right bundle branch block (RBBB) aberrancy. When nonconducted, an APC may produce only as a small deformity on the T wave followed by a pause. The pause is the result of sinus node resetting, which is common with APCs regardless of whether conducted.

Twenty-four-hour Holter studies have shown that APC frequency increases with age. APCs occur in patients with normal hearts but appear to be more frequent in patients with structural heart disease such as chronic renal failure and chronic pulmonary disease. APCs have been shown to increase in the early stages of a myocardial infarction (MI), with a subsequent decrease in frequency after 10 days. This characteristic may be related to atrial ischemia, increased filling pressures, or the increased catecholamine state often seen during MI. APCs also appear to be frequent in the setting of pericarditis.

The most common symptoms include palpitations, or the sensation of skipped beats. Dizziness and heart failure–like

Figure 10-2 Mechanism of reentry.

Reentry requires two distinct pathways with disparate conductive and repolarizing properties. **A**, An impulse enters the two pathways and conducts rapidly down pathway A and slowly down pathway B. When the impulse reaches the distal common pathway, it proceeds distally, as well as traveling retrograde up pathway B, where it is extinguished, owing to collision in this pathway. **B**, A premature depolarization enters the pathways but is blocked in pathway A, owing to the long refractory period of this pathway. The impulse travels down pathway B (slowly conducting and rapidly repolarizing) to the distal common pathway, where it proceeds distally, as well as traveling up pathway A, which by then is fully repolarized and able to conduct in a retrograde fashion, allowing the impulse to reenter the loop and produce the reciprocating rhythm.

Figure 10-3 Premature complexes. **A**, Atrial premature complexes (APCs) with a trigeminal rhythm. An atrial premature beat occurs after every two sinus beats. Note the presence of a P wave (arrows) preceding the QRS complex with a long PR interval caused by decremental conduction in the AV node. The QRS complex is narrow because the origin of the impulse is supraventricular. **B**, Junctional premature complexes (JPCs) (arrows). JPCs often conduct in a retrograde fashion, resulting in a P wave that is buried in the QRS complex. Similar to APCs, the QRS complex is narrow because the origin of the impulse is supraventricular. **C**, Ventricular premature complexes (VPCs). Note the wide QRS morphology and the presence of a retrograde P wave (arrow). PVCs might conduct retrograde, resulting in a P wave that follows the QRS.

symptoms might occur in the setting of atrial bigeminy with nonconducted atrial premature beats. Therapy is aimed at treating the underlying disease and eliminating factors that are known to cause ectopic beats such as alcohol and caffeine intake. In patients with symptoms, β blockers should be the first line of therapy, followed by calcium channel blockers and class IC agents such as flecainide and propafenone. Class III agents such as sotalol and amiodarone should be avoided because of pro-arrhythmia risks.

JUNCTIONAL PREMATURE COMPLEXES

A junctional premature complex (JPC) refers to a premature beat originating from the AV junction area, which includes the AV node, the peri-nodal area, and the His bundle. After impulse formation, propagation occurs both in the antegrade direction down the His bundles and in the retrograde direction up to the atria. The result is nearly simultaneous atrial and ventricular depolarization with a surface P wave buried in the QRS complex (see Fig. 10-3B). At times, retrograde atrial activation precedes ventricular activation, resulting in a PR interval as long as 90 minutes. This action is more common when the impulse originates from a peri-nodal site. When the impulse originates from the His bundle, retrograde atrial activation always follows ventricular depolarization, resulting in a retrograde P wave that follows the QRS complex. On some occasions, the impulse fails to propagate in the antegrade direction, resulting in a retrograde P wave that mimics an APC. When a JPC fails to conduct in the retrograde direction, the result is a QRS complex without a P wave. Finally, the impulse might not conduct in either direction but may affect the conduction of subsequent impulses (concealed JPCs), resulting in AV block. In such

instances, the diagnosis is based on the presence of manifest JPC in a patient with otherwise normal QRS duration and evidence of intermittent AV block. The mechanism of JPC is believed to be abnormal automaticity, although triggered activity may also be a potential mechanism. They can occur in both normal and abnormal hearts. JPCs are more common in the setting of digitalis toxicity, high-catecholamine states, hypokalemia, and MI.

Most patients with JPCs are asymptomatic. When symptoms occur, skipped beats and palpitations are the most common complaints. More severe symptoms such as dizziness, near syncope, and syncope might occur if the patient has AV block caused by concealed JPCs. Management of JPCs should be focused on correcting the underlying problems. In symptomatic patients with no underlying cause, β blockers are often helpful in suppressing JPCs. Classes I and III antiarrhythmic drugs should only be used in patients with symptoms refractory to β -blocker therapy. In patients with AV block secondary to concealed JPCs, therapy should be aimed at suppressing the junctional beats rather than implanting a pacemaker.

VENTRICULAR PREMATURE COMPLEXES

A ventricular premature complex (VPC) refers to a premature depolarization originating from the ventricles. The impulse often does not conduct to the atria and thus does not reset the sinus node. The result is a wide QRS complex with a compensatory pause (see Fig. 10-3C). When retrograde conduction occurs and the sinus node is reset, a non-compensatory pause will be inscribed. A VPC that occurs early and fails to affect both the next ventricular depolarization and sinus node activity is referred to as *interpolated*

VPC. With an interpolated VPC, the RR interval surrounding the VPC is equal to the sinus RR interval. A supraventricular premature beat may conduct with aberrancy, resulting in a wide QRS complex similar to a VPC. Criteria in favor of a ventricular origin include (1) the absence of a preceding P wave, (2) AV dissociation, (3) marked left axis deviation, (4) a QRS interval longer than 160 minutes, (5) certain configurational characteristics such as Rsr' in lead V₁, QS or rS in lead V₆, and concordance (upright or downward QRS in all precordial leads), and finally (6) the presence of a full compensatory pause. VPCs occur in patients with normal and abnormal hearts. The underlying mechanisms include reentry, abnormal automaticity, and triggered activity.

When associated with symptoms, patients with VPCs often complain of *skipped* beats and palpitations. The presence of frequent VPCs such as in a bigeminal rhythm (VPCs alternating with sinus beats) can significantly lower the effective heart rate, resulting in a low cardiac output state. In such instances, symptoms might include dizziness, near syncope, and syncope. In addition to the presence of symptoms, VPCs can have an impact on prognosis and risk for sudden death. Although VPCs have no prognostic significance in patients with a normal heart, their presence in patients with heart disease is often associated with poor outcome. In patients with a history of MI, the presence of VPCs increases mortality. Suppression of VPCs with antiarrhythmic drugs, however, has not been shown to reduce mortality. In the Cardiac Arrhythmia Suppression Trial (CAST), randomization of patients with a history of MI, ventricular arrhythmias, and documented arrhythmia suppression with flecainide or encainide showed increased mortality. The largest trial that assessed the effect of amiodarone on the risk for arrhythmic death among MI survivors with frequent VPCs was the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT). The consensus from this trial was that, unlike other antiarrhythmic drugs, amiodarone was not associated with excess risk for death. At present, the first drug of choice for the treatment of symptomatic VPCs should be a β blocker. If β -blocker therapy fails, amiodarone or catheter ablation should be considered. With catheter ablation, the VPC site of origin is identified, and radiofrequency energy is applied to eliminate the ectopy. Both amiodarone therapy and catheter ablation should only be considered in patients who continue to have symptomatic VPCs despite β -blocker therapy. In the asymptomatic patient, no drug therapy is needed.

Bradyarrhythmias

Bradyarrhythmias are usually the result of either *sinus node dysfunction* or *atrioventricular block*.

SINUS NODE DYSFUNCTION

Sinus node dysfunction may be exhibited as sinus bradycardia, sinus pauses or arrest, or sinoatrial exit block. Patients with sinus node disease may have lightheadedness, dizziness, near syncope, or syncope, or may not have any symptoms at all.

Sinus bradycardia indicates, by definition, a sinus rate less than 60 beats/minute (Fig. 10-4A). The diagnosis of sinus node disease requires that secondary causes be excluded. Increases in vagal tone are frequently seen in young healthy athletes and are a common cause of sinus node slowing. Increased vagal tone also occurs during carotid sinus massage, Valsalva maneuvers, vomiting, increased intracranial pressure, and vasovagal syncope. Other causes of sinus bradycardia include drugs (digitalis, β blockers, calcium channel blockers, and some antiarrhythmic agents such as sotalol and amiodarone), hyperkalemia, hypothyroidism, and hypothermia. Sinus bradycardia also occurs in the setting of many organic heart diseases, including coronary artery disease, cardiomyopathy, and myocarditis.

Sinus pause is the result of transient failure of impulse formation in the sinus node. When this inactivity is prolonged, it is called *sinus arrest*. Both conditions are visualized on the ECG as a flat line with no P waves. Depending on the duration of sinus node inactivity, the pause may be terminated by a junctional or ventricular escape beat. Sinus pause or arrest should be differentiated from (1) nonconducted atrial premature beats and (2) sinoatrial exit block (see later discussion). A nonconducted APC usually shows as a small deformity on the T wave (see Fig. 10-4B). Causes of sinus pauses and sinus arrest are similar to those of sinus bradycardia.

Sinoatrial exit block is the result of abnormal transmission between the sinus node and the atrium. Several types of sinoatrial conduction block exist (see later discussion). Because sinoatrial electrograms are not routinely available, only second-degree sinoatrial block might be diagnosed from the surface ECG. Second-degree (type II) sinoatrial exit block is usually inferred by the presence of a pause equal to a multiple of the basic PP interval (see Fig. 10-4C). In some instances, the Wenckebach phenomenon (second-degree [type I]) is observed, resulting in progressive shortening of the PP interval before seeing the absence of a P wave (see Fig. 10-4D). Patients with sinoatrial exit block often have other arrhythmias, including atrial fibrillation, atrial tachycardia (tachycardia-bradycardia syndrome) (see Fig. 10-4E), sinus bradycardia, and AV block.

ATRIOVENTRICULAR BLOCK

The sinus impulse has to traverse the atrium, the AV node, and the His-Purkinje system before reaching the ventricles. This interval is reflected on the ECG as the PR interval. Conduction delay or block can occur at any level, resulting in various types of AV block. AV block is classified into (1) first-degree AV block, (2) second-degree AV block (types I and II), and (3) third-degree AV block.

First-degree AV block occurs when enough prolongation in AV conduction occurs, resulting in a PR interval longer than 200 minutes (Fig. 10-5A). Despite the prolonged PR interval, each P wave is followed by a QRS interval. In patients with first-degree AV block and a narrow QRS complex, the site of block is usually in the AV node. In the setting of a wide QRS complex, the site of block can be at any level but remains most commonly at the level of the AV node. A PR interval longer than 290 milliseconds is almost always associated with AV nodal disease.

Figure 10-4 Sinus node disturbances. **A**, Sinus bradycardia at a rate of 49 beats/minute in a patient receiving metoprolol. **B**, Nonconducted atrial premature complexes (APCs). Note the small deformity on the T wave (*arrows*) caused by the APCs. The following pause is caused by resetting of the sinus node. **C**, Sinoatrial exit (second-degree type II) block. Note that the pause is equal to a multiple of the basic PP interval (twice). **D**, Sinoatrial exit (Wenckebach) block. Note the progressive shortening of the PP interval before seeing the absence of a P wave. **E**, Sick sinus syndrome. Coarse atrial fibrillation was followed by a prolonged spontaneous period of asystole before restoration of sinus rhythm (tachy-brady syndrome).

Second-degree AV block is associated with intermittent failure of the P wave to be conducted to the ventricles. The ratio of P waves to QRS complexes may vary in the same patient. Two types of second-degree AV block have been classified: *type I*, also called Mobitz type I or Wenckebach phenomenon, and *type II*, or Mobitz type II. *Type I* second-degree AV block is characterized by (1) progressive lengthening of the PR interval until a P wave is blocked, (2) progressive shortening of the RR interval until a P wave is blocked, and (3) the RR interval surrounding the blocked P wave is shorter than two PP intervals (see Fig. 10-5B). In the presence of narrow QRS complex, the site of AV block is in the AV node. In patients with a wide QRS complex, the site of AV block can be infranodal in up to 25% of instances. *Type II* AV block is characterized by intermittent blocked P waves with no change in the PR interval (see Fig. 10-5C). The sinus cycle length is usually constant with the RR interval surrounding the nonconducted P wave equal to twice the sinus cycle length. In the presence of a wide QRS complex, the site of AV block is usually infranodal. In the setting of a narrow QRS complex, the site of block is

usually in the His bundle above the bifurcation but may occasionally be in the AV node. In 2:1 AV block (see Fig. 10-5D), the site of block is unknown. Findings that favor infranodal block include (1) a history of near syncope or syncope, (2) a QRS duration above 120 minutes, (3) the presence of type II second-degree AV block or third-degree AV block during continuous ECG monitoring, (4) improved AV conduction with carotid sinus massage, and (5) worsening AV conduction with atropine and exercise. Identifying the site of block is important in the asymptomatic patient with 2:1 AV block because infranodal block is associated with worse prognosis and mandates the implantation of a pacemaker.

Third-degree AV block or complete AV block is defined by the presence of atrioventricular dissociation *and* an atrial rate that is faster than the ventricular rate. By definition, the sinus P waves are not conducted, and the QRS complexes are from a subsidiary pacemaker, which usually has a slower rate. The RR and PP intervals are usually constant but bear no relation to each other. The PR interval will vary because the P is independent of the QRS (see Fig. 10-5E).

Figure 10-5 Heart block. **A**, First-degree atrioventricular (AV) block; the PR interval is prolonged (>200 minutes). **B**, Second-degree AV block, type 1 (Wenckebach). Progressive PR prolongation preceding a nonconducted P wave (arrows) occurs. **C**, Second-degree AV block, type II. Nonconducted P waves are seen (arrows) in the absence of progressive PR prolongation. **D**, 2:1 AV block in which every other P wave is conducted. **E**, Third-degree (complete) AV block with AV dissociation and a narrow-complex (AV nodal) escape rhythm.

Tachyarrhythmias

Tachyarrhythmias are divided into *supraventricular*, *ventricular*, and *preexcited tachycardias*. During supraventricular tachycardia (SVT), the ventricles are depolarized through the normal His-Purkinje system, with or without aberrancy, resulting in a narrow or wide complex tachycardia. During VT, the impulse originates from the ventricle and depolarizes the ventricles in an asynchronized fashion, resulting in a wide QRS complex. With preexcited tachycardias, some or all ventricular activation is caused by antegrade conduction down an accessory pathway, resulting in a wide complex tachycardia. A summary of the most common tachyarrhythmias follows.

ATRIAL TACHYARRHYTHMIAS

Atrial Tachycardia

Atrial tachycardia results from an ectopic atrial focus discharging at a rate faster than the sinus rate. The rate is usually 100 to 250 beats/minute, and the P-wave morphology is different from the sinus P wave (Fig. 10-6A) unless the tachycardia focus site is close to the sinus node. The PR

interval is usually normal or longer than the PR interval during sinus rhythm. The rhythm is usually regular, although episodes of AV block may result in some irregularities. Most commonly, AV conduction is 1:1; however, variable AV block might be seen. When atrial tachycardia occurs with AV block, digoxin toxicity is suggested. Atrial tachycardias are more likely to occur in patients with concomitant heart disease, including coronary artery disease, valvular disease, cardiomyopathies, cor pulmonale, and congenital heart disease. The mechanism of atrial tachycardia can be automaticity, reentry, or triggered activity. In a young patient, automaticity is the most likely mechanism, and, as the age increases, reentry becomes more common. Triggered activity has been suggested, but its role remains poorly defined. In patients with cardiac surgery resulting in atrial scars, reentry around the existing scar can result in atrial tachycardia, called *incisional tachycardia*. The ECG manifestation of the latter is similar to focal atrial tachycardia, except that the P-wave duration is usually longer. The P-wave morphology and axis are determined by the exit site. Vagal maneuvers usually do not terminate atrial tachycardias but can result in transient AV block, thus unmasking the P waves. When the arrhythmia is not a result of digoxin toxicity, β blockers and calcium channel blockers are the mainstays of therapy, with

Figure 10-6 Atrial tachyarrhythmias. **A**, Atrial tachycardia with 2:1 and variable AV conduction. Note the presence of more P waves (arrows) than QRS complexes. **B**, Multifocal atrial tachycardia demonstrating an irregularly irregular rhythm at a rate of about 110 beats/minute, with at least three different P-wave morphologies (arrows) and without a dominant underlying rhythm. **C**, Atrial flutter. Flutter waves are seen as the discrete undulations of the baseline (sawtooth pattern). The conduction rate is variable. **D**, Atrial fibrillation. The rhythm is irregularly irregular without evidence of organized atrial electrical activity.

class I or class III anti-arrhythmic agents reserved for refractory patients. Catheter ablation can eliminate this arrhythmia in 75% to 90% of patients. When atrial tachycardia is the result of digoxin therapy, withholding the agent should be the first step, followed by the administration of digoxin-specific antibodies if the patient is symptomatic.

Multifocal atrial tachycardia (MAT) is an irregular rhythm defined by the presence of three or more P-wave morphologies and a rate greater than 100 beats/minute (see Fig. 10-6B). It occurs most commonly in patients with underlying lung disease; it is also seen in the setting of an acute MI, hypokalemia, or hypomagnesemia; and it may be a precursor of atrial fibrillation. Aminophylline use may also be a contributing factor. Treatment is directed at the underlying disease. Rate control of this arrhythmia may be difficult, although verapamil is frequently effective.

Atrial Flutter

Atrial flutter (AFL) is a reentrant tachycardia localized to the right atrium with passive activation of the left atrium. The reentrant circuit is limited anteriorly by the tricuspid valve and posteriorly by the cristae terminalis and the eustachian ridge. The direction of impulse propagation around the tricuspid annulus determines the P-wave morphology. If propagation is in the counterclockwise direction, the impulse propagates up the septum and down the lateral wall, resulting in a negative P wave in the inferior leads with a typical

sawtooth pattern (see Fig. 10-6C), called *typical AFL*. If propagation is in the clockwise direction, the P wave is upright in the inferior leads, and the tachycardia is called *atypical AFL*. The atrial rate during AFL is usually about 250 to 350 beats/minute, with an average rate of 300 beats/minute. The ventricular rate depends on the conduction down the AV node. Usually, conduction is 2:1, resulting in a ventricular rate of about 150 beats/minute. In young patients with enhanced AV nodal conduction, the ventricular rate can be as high as the atrial rate, reaching 300 beats/minute. Similarly, in the presence of an accessory pathway, the ventricular rate can be rapid, resulting in hemodynamic compromise and ventricular fibrillation.

AFL may occur in patients with or without structural heart disease and may be precipitated by thyrotoxicosis, pericarditis, and alcohol ingestion. When AFL is associated with hemodynamic compromise or angina, immediate cardioversion should be performed. Relatively low-energy shocks are frequently effective because of the stable nature of the circuit. When the patient is hemodynamically stable, the focus should be on rate control to reduce the risk for tachycardia-induced cardiomyopathy and anticoagulation to reduce the risk for stroke. If patients remain symptomatic despite rate control, rhythm control either pharmacologically or with catheter ablation should be attempted. When class IA anti-arrhythmic agents are used to convert AFL to sinus rhythm, the ventricular rate must first be controlled

with digoxin, β blockers, or calcium channel blockers. Class IA agents may slow the flutter rate and augment AV nodal conduction, resulting in 1:1 conduction with rapid ventricular rates. Radiofrequency catheter ablation of the reentrant flutter circuit is effective, resulting in the restoration of sinus rhythm in 90% to 95% of patients.

Atrial Fibrillation

Atrial fibrillation (AF) is the most common sustained supraventricular tachyarrhythmia. According to *Moe's hypothesis*, AF is maintained by having a critical number of wavelets circulating in the atria. These wavelets may shrink, undergo decremental conduction, collide with another wavelet or a boundary and be mutually annihilated, or encounter functional or anatomic obstacles and create new wavelets by wave breaks, a mechanism referred to as *vortex shedding*. Other mechanisms such as rapidly firing foci leading to *fibrillatory conduction*, and the presence of a *mother rotor* defined as a stable, high-frequency rotating pattern that drives AF, have recently emerged. Technologic advances using optical mapping and frequency analysis have provided evidence for such alternative theories. During AF, multiple reentrant loops continuously circulating in both atria result in ineffective atrial contraction. In addition, the AV node is bombarded at rates greater than 400 beats/minute. Because of the conductive properties, many of the impulses are blocked at the AV node. The resultant ventricular rhythm is irregularly irregular at rates between 120 and 170 beats/minute. At rapid ventricular rates, the rhythm may appear to be regular, although careful measurements will disclose the irregularity. A truly regular ventricular rate in the setting of AF suggests the development of a junctional or ventricular rhythm, both of which may be a reflection of digoxin toxicity. AF may be paroxysmal or chronic and may be the only arrhythmia present or be part of a more generalized rhythm disturbance (sick sinus syndrome). The surface ECG demonstrates an irregular ventricular pattern and the absence of organized atrial activity; that is, no P waves are present (see Fig. 10-6D). Physical examination of a patient in AF reveals variation in the intensity of S_1 , an irregular cardiac rhythm, and absence of waves in the jugular venous pulsations. At the very short RR intervals that occur intermittently during rapid heart rates, the minimal diastolic filling time and subsequent low stroke volume fail to produce a palpable pulse. A discrepancy may therefore exist between the auscultated heart rate and the palpable pulse rate, with the auscultated rate being a more accurate reflection of the true ventricular rate.

A clear association of AF with age exists, and a sharp increase in incidence is noted after the seventh decade of life. AF may occur without any identifiable cardiac abnormality but is common in the setting of underlying cardiac disease, including valvular heart disease (especially rheumatic), heart failure, and ischemic cardiac disease. The most frequent predisposing cardiovascular condition for the development of AF is hypertension. AF may also be precipitated by pericarditis, thyrotoxicosis, pulmonary emboli, pneumonia, and acute alcohol ingestion and occurs postoperatively in about one third of patients who undergo cardiac surgery. AF is frequently asymptomatic or associated with only minor symptoms, such as palpitations. In patients with obstructive coronary artery disease, the rapid heart rate associated with

the onset of AF may precipitate ischemia. In patients with aortic or mitral stenosis and in other patients who are dependent on the atrial contribution to cardiac output (e.g., patients with left ventricular hypertrophy or with a dilated or hypertrophic cardiomyopathy), the loss of effective atrial contraction with the onset of AF may result in significant hemodynamic compromise. In addition, in patients with bypass tracts (see later discussion), AF may result in extremely rapid ventricular rates with subsequent hemodynamic collapse.

The treatment of AF is threefold: (1) prevention of thromboembolic complications, (2) rate control, and (3) restoration and maintenance of sinus rhythm.

Prevention of Thromboembolic Complications

Because of the ineffective mechanical function of the atria during fibrillation, stasis of blood may occur, especially in the atrial appendages, and result in thrombus formation and subsequent thromboembolic events. In the absence of anticoagulation therapy, AF is associated with a 5%- to 6%-per-year risk for embolic stroke. This risk is increased in the setting of rheumatic valvular disease (>10%). Other clinical factors that increase the risk for stroke in patients with AF include prior stroke, diabetes, hypertension, heart failure, left atrial enlargement, and increasing age. No difference in stroke rate occurs between paroxysmal and chronic AF. Restoration of normal sinus rhythm has not been shown to reduce the risk for stroke. In fact, in the Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) trial, a trend toward a higher incidence of stroke in patients randomized to rhythm control was found when compared with rate control, albeit not statistically significant. This trend was most likely caused by the decreased use of warfarin in the rhythm control group. Therefore, any patient with paroxysmal, persistent, or permanent AF who does not have a contraindication to anticoagulation should be treated with warfarin therapy with a target international normalized ratio between 2 and 3.

Rate Control

Rate control in AF is important for several reasons. It has been shown to improve symptoms and quality of life. Symptoms and hemodynamic compromise are increased at faster ventricular rates, and the tachycardic response may induce ischemia in patients with coronary artery disease. In addition, the poorly controlled heart rate may result in the development of progressive ventricular dysfunction. The heart rate can usually be controlled with digoxin, β blockers, or calcium channel blockers. In rare instances, the ventricular rate cannot be controlled by pharmacologic means, and catheter ablation of the AV node and permanent pacemaker implantation are necessary for adequate heart rate control. Occasionally, patients exhibit AF and a relatively slow ventricular rate in the absence of rate-lowering medications. This circumstance usually reflects significant underlying conduction system disease that also often involves the sinus node.

Rhythm Control

Rhythm control has several advantages, including (1) abolition of symptoms, (2) halting atrial enlargement (an independent predictor of stroke), and (3) improvement of left

ventricular function and exercise capacity. The main disadvantage is subjecting patients to a drug therapy or procedure that might be associated with complications. As stated before, rhythm control has not been shown to reduce the risk for stroke or to have an impact on mortality when compared with rate control. Therefore, rhythm control should be attempted in patients who are symptomatic despite rate control and in those who have left ventricular dysfunction. When AF is associated with hemodynamic compromise, electrical cardioversion (with 100 to 360 joules) is the treatment of choice. In hemodynamically stable patients with less than 48 hours of AF, the risk for thromboembolism is low, and pharmacologic or electrical cardioversion can be attempted without the need for 3 weeks of anticoagulation (see later discussion). Patients with more than 48 hours of AF, or in whom the duration of the arrhythmia is unknown, are at increased risk for atrial thrombi and should be treated with anticoagulation for at least 3 weeks before an attempt at cardioversion. An alternative approach is to perform a transesophageal echocardiogram; if atrial thrombi are not present, cardioversion can be safely performed. Anticoagulation should be continued for at least 4 weeks after successful cardioversion because effective atrial contraction may be slow to return. The options for maintaining rhythm control include (1) pharmacologic therapy, (2) catheter ablation, and (3) surgical Maze procedure. The class IA (quinidine, procainamide, and disopyramide), class IC (propafenone and flecainide), and class III (sotalol and amiodarone) agents are effective in restoring sinus rhythm and for long-term maintenance therapy. However, the benefits of such therapy must be weighed against the risks for toxicity with these agents, and the probability of maintaining sinus rhythm must be taken into account. The preferred choice of drug therapy for the maintenance of sinus rhythm in patients with paroxysmal and persistent AF, based on the most recent American College of Cardiology/American Heart Association guidelines, is provided in Figure 10-7. Radiofrequency

ablation of the ostia of the pulmonary veins or electrical isolation of the pulmonary veins from the left atrium is a procedure that should be reserved to symptomatic patients who have failed drug therapy. Ablation therapy frequently abolishes the arrhythmia, improving symptoms and, at times, left ventricular function in patients with baseline congestive heart failure. The surgical maze procedure involves making surgical lesions in the atria that interrupt reentrant circuits and may restore sinus rhythm in more than 90% of patients. This procedure is usually performed in conjunction with mitral valve surgery.

ATRIOVENTRICULAR NODAL (JUNCTIONAL) RHYTHM DISTURBANCES

Atrioventricular Nodal Reentrant Tachycardia

Atrioventricular nodal reentrant tachycardia (AVNRT) is the most common type of paroxysmal SVT and is characterized by the sudden onset and termination of a regular narrow QRS complex tachycardia at rates of 150 to 250 beats/minute (Fig. 10-8A). A wide QRS complex may occur if aberrant conduction occurs in the His-Purkinje system. These rhythms may occur at any age, are somewhat more common in women than men, may occur in the absence of organic heart disease, may be short lived or sustained, and may produce palpitations, chest pain, dyspnea, and presyncope. The substrate for this tachycardia is dual AV node pathways with different effective refractory period (ERP): a fast pathway with a longer ERP and a slow pathway with a shorter ERP. Whether these pathways are exclusively intranodal or not remains controversial, but catheter ablation studies of these pathways have revealed distinct atrial insertion sites, with the fast pathway inserting anteriorly near the His bundle and the slow pathway posteriorly near the coronary sinus ostium.

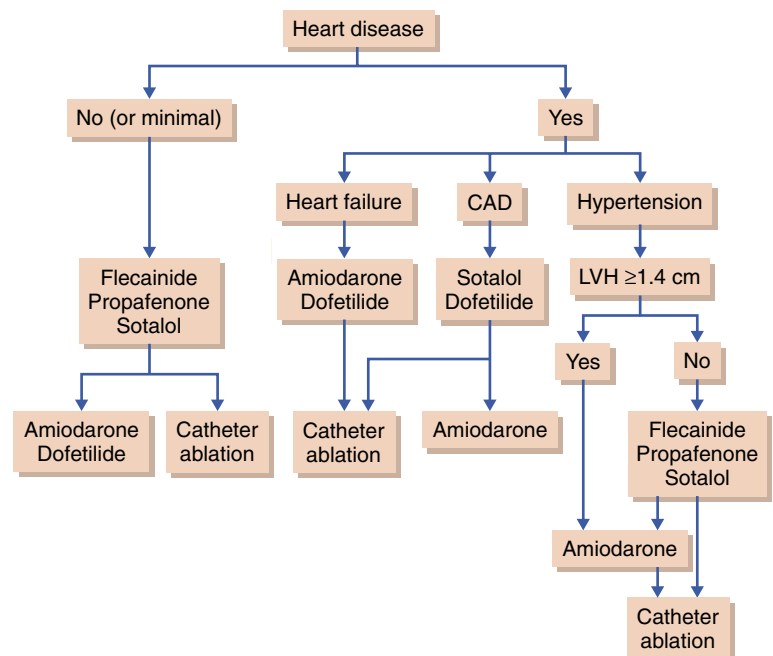

Figure 10-7 Drug therapy to maintain sinus rhythm in patients with recurrent paroxysmal or persistent atrial fibrillation. CAD, coronary artery disease; LVH, left ventricular hypertrophy.

Figure 10-8 Atrioventricular (AV) nodal (junctional) rhythm disturbances. **A**, AV nodal reentrant tachycardia at a rate of 185 beats/minute. The retrograde P waves are hidden in the QRS complexes. **B**, Automatic junctional tachycardia. Note the presence of AV dissociation during tachycardia. The P waves (arrows) are dissociated from the QRS complexes. **C**, Normal sinus rhythm in a patient with Wolff-Parkinson-White (WPW) syndrome. Note the short PR interval (<120 minutes), the *slurring* of the initial portion of the QRS (delta wave), and the wide QRS complex. **D**, Normal sinus rhythm in a patient with Lown-Ganong-Levine pattern. Note the short PR interval without the presence of a delta wave or wide QRS complex. **E**, Orthodromic AV reentrant tachycardia at a rate of 146 beats/minute in a patient with WPW syndrome. The retrograde P waves are clearly seen altering the normal T-wave contour (arrow). **F**, Atrial fibrillation in a patient with WPW syndrome. Note the rapid and irregular ventricular response with widening of the QRS secondary to preexcitation.

At least two types of AVNRT have been identified. In the usual form (typical), the impulse propagates antegrade down the slow pathway and retrograde up the fast pathway. Because retrograde conduction is over the fast pathway, atrial and ventricular depolarizations are almost simultaneous, resulting in a P wave buried in the QRS complex, or appearing at its terminal portion, resulting in pseudo S wave in the inferior leads and a pseudo R' in lead V₁ (see Fig. 10-8A). In the unusual form of AVNRT, antegrade conduction is over the fast pathway, and retrograde conduction is over the slow pathway, resulting in a P wave after the QRS complex with a long RP interval. AVNRT is usually initiated with premature stimuli and terminated by premature beats, vagal maneuvers, adenosine, or other cardiac medications known to cause block in the AV node. Vagal maneuvers (e.g., carotid sinus massage, Valsalva maneuver, coughing) may terminate an episode by causing a transient AV nodal blockade. Adenosine (6 to 12 mg intravenously) terminates

episodes in more than 95% of patients and is the treatment of choice if vagal maneuvers fail. In rare instances, direct current cardioversion is necessary. Intravenous β blockers, digoxin, or calcium channel blockers are also an extremely effective acute therapy, and their oral formulations are effective chronically. Classes IC and III anti-arrhythmic agents are useful in resistant patients. In rare instances, direct current cardioversion is necessary. Radiofrequency catheter ablation of one limb of the reentrant circuit (slow pathway) can cure AVNRT in more than 90% of patients, with a low risk for inducing complete heart block (<2%) that might require the placement of a permanent pacemaker.

Automatic Junctional Tachycardia

Automatic junctional tachycardia (AJT) is characterized as a rapid irregular SVT with episodes of AV dissociation (see Fig. 10-8B). The rate ranges between 110 and 250 beats/minute, and the QRS interval is usually narrow but may be

wide secondary to bundle branch block. AJT was first described in infants and children but has also been reported in adults in which the prognosis is more benign. Abnormal automaticity is believed to be the mechanism responsible for AJT. This tachycardia is usually sensitive to catecholamines but can sometimes be terminated with carotid sinus massage and adenosine. β blockers, calcium channel blockers, and classes IC and III anti-arrhythmic drugs should be the first line of therapy. When drug therapy fails, radiofrequency can result in cure; however, it is associated with a significant risk for AV block (20%), requiring the implantation of a permanent pacemaker. AJT must be differentiated from the more common nonparoxysmal junctional tachycardia. The latter is regular, has a slower rate (70 to 120 beats/minute) and occurs in the setting of digitalis toxicity, inferior MI, metabolic derangements, chronic lung disease, or after cardiac surgery. The mechanism of nonparoxysmal junctional tachycardia is believed to be triggered activity secondary to DADs. Digoxin toxicity must always be excluded as a cause. Specific therapy for nonparoxysmal junctional tachycardia is usually not necessary.

WOLFF-PARKINSON-WHITE SYNDROME AND ATRIOVENTRICULAR RECIPROCATING ARRHYTHMIAS

Normally, the AV node is the only pathway that allows the wave of depolarization to conduct from the atria to the ventricles. However, anomalous bands of tissue (accessory pathways or bypass tracts) may exist and form an additional conduction pathway. The conductive properties of these bypass tracts differ from those of the AV node in that they do not produce the decremental conduction property of normal conduction tissue. In other words, they do not conduct slower at rapid rates. Conduction through the bypass tracts may be unidirectional or bidirectional. These properties provide the substrate for macro-reentrant arrhythmias (see previous discussion) using the bypass tract as one limb of the reentrant circuit and the AV node as the other. Other, less frequent pathways have been reported, such as AV nodal bypass tract, a direct communication between the atria and the His-Purkinje system, nodoven-tricular fibers connecting the AV node to the ventricular myocardium, and fasciculoventricular connections from the His-Purkinje system to the ventricles. Most patients with bypass tracts have otherwise anatomically normal hearts, although the incidence of right-sided accessory pathways is increased in patients with Ebstein anomaly of the tricuspid valve. Similarly, an association with left-sided accessory pathways and mitral valve prolapse and hypertrophic cardiomyopathy has been noted.

Wolff-Parkinson-White Syndrome during Normal Sinus Rhythm

During normal sinus rhythm, when the AV bypass tract conducts in an antegrade fashion, the ventricular muscle will be activated by the atrial impulse sooner than would be expected if the impulse reached the ventricles only by way of the normal AV conduction. This activity is referred to as *preexcitation*. The result is a short PR interval (<120 minutes) and a wide QRS complex with *slurring* of the initial portion

of the QRS, referred to also as a *delta wave*. The QRS is wide because it is a fusion complex created by ventricular activation through two separate pathways, the AV node and the accessory pathway (see Fig. 10-8C). The extent of preexcitation is determined by the conductive properties of the pathway and the AV node in addition to the accessory pathway location. Wolff-Parkinson-White (WPW) syndrome refers to the presence of preexcitation and a history of paroxysmal tachycardia. When preexcitation is present alone without paroxysmal tachycardia, the patient is referred to as having WPW pattern. Occasionally, the accessory pathway conducts only in the retrograde direction, that is, from the ventricle to the atrium without any antegrade conduction and thus ventricular preexcitation. This circumstance is referred to as a *concealed* accessory pathway because its presence is not evident on the surface ECG when the patient is in normal sinus rhythm. As stated before, some accessory pathways connect the atria to the His-Purkinje system. The result is a short PR interval because the atrial impulse will be bypassing the AV node, but a normal QRS complex is seen because the ventricles are activated through the normal His-Purkinje system (see Fig. 10-8D). This circumstance is referred to as *Lown-Ganong-Levine pattern*; when it is associated with a history of tachycardias, it is referred to as the *Lown-Ganong-Levine syndrome*.

Arrhythmias in Patients with Wolff-Parkinson-White Syndrome

The most common arrhythmia in WPW syndrome is *orthodromic* AV reentrant tachycardia (AVRT) in which the AV node is used as the antegrade limb of the circuit and the bypass tract as the retrograde limb. This circumstance results in a narrow-complex QRS tachycardia on the surface ECG (see Fig. 10-8E), unless aberrant conduction is present. A retrograde P wave may be noted, usually with a short RP interval. Less commonly, *antidromic* AVRT may occur that uses the accessory pathway as the antegrade limb and the AV node as the retrograde limb. This circumstance results in complete preexcitation of the ventricles with a wide, bizarre QRS complex on the ECG. Because the AV node is an intrinsic component of both forms of AVRT, transient blockade of the AV node by vagal maneuvers or medications will interrupt the circuit and terminate the tachyarrhythmia. The incidence of *atrial tachyarrhythmias*, such as AF or AFL, is increased in patients with bypass tracts. When these arrhythmias occur, rapid ventricular rates often occur and may precipitate hemodynamic collapse and sudden death (see Fig. 10-8F).

Treatment of Patients with Wolff-Parkinson-White Syndrome

In a patient with a delta wave noted on the ECG but without any symptoms, no specific therapy is required. In patients with frequent episodes of AVRT, *transient* blockade of the AV node by vagal maneuvers or medications will interrupt the circuit and terminate the tachyarrhythmia. Chronic pharmacologic therapy with drugs that prolong the refractory period of the accessory pathway (class IA, IC, or III anti-arrhythmic agents) is effective. Drugs that slow conduction in the AV node (digoxin, β blockers, or calcium channel

blockers) should be avoided in patients with WPW because they may enhance conduction down the accessory pathway and increase the ventricular rate during AF and AFL. Indeed, when atrial tachyarrhythmias occur in patients with WPW, AV nodal-blocking drugs are contraindicated; in this setting, digoxin, β blockers, or calcium channel blockers may result in slowing of conduction through the AV node with resultant preferential excitation of the ventricles through the accessory AV connection. Intravenous procainamide is the drug of choice for acutely controlling the rate of AF or AFL in patients with bypass tracts. Electrical cardioversion should be considered early in these patients. Radiofrequency catheter ablation of the accessory pathway has become the therapy of choice for symptomatic patients and has a success rate in excess of 95%.

VENTRICULAR RHYTHM DISTURBANCES

Ventricular Tachycardia

VT is defined as three or more consecutive ventricular depolarizations occurring at a rate greater than 100 beats/minute. The resulting QRS complexes on the surface ECG are aberrant, as described earlier for VPCs, and may be monomorphic or polymorphic (Fig. 10-9A). Evidence of independent atrial activity may be present (AV dissociation); however, when retrograde conduction to the atria is present, AV dissociation is not seen. Occasionally, a normal sinus depolarization may be conducted to the ventricles before the pathologic ventricular depolarization occurs and results in a normal-appearing QRS complex, called a *capture* beat. If the atrial depolarization reaches the ventricles simultaneously with the spontaneous ventricular depolarization, a *fusion* complex will result. These abnormalities are pathognomonic for VT. VT that lasts for more than 30 seconds or requires termination because of hemodynamic instability is considered *sustained*; VT that lasts less than 30 seconds and is hemodynamically stable is considered *nonsustained*.

VT occurs most frequently in patients with underlying heart disease, including acute ischemia, prior infarction with scar formation, congestive cardiomyopathy, right ventricular dysplasia, and hypertrophic heart disease. The mechanism is usually reentry in the ventricular myocardium, although it may also arise in a diseased portion of the conduction system (e.g., bundle branch reentry). Metabolic abnormalities, such as hyperkalemia and hypoxia, and medications, such as digoxin and antiarrhythmic agents, may also precipitate VT, likely as a result of triggered activity. On the other hand, VT can occur in the absence of structural heart disease. This type of VT accounts for only 6% of all clinical VTs and is called idiopathic VT. Idiopathic VT is best classified according to its site of origin. Right ventricular outflow tract VT (RVOT-VT) is the most common type of idiopathic VT originating from the right ventricular outflow tract with left bundle branch block–inferior axis morphology. The mechanism of this tachycardia is believed to be triggered activity. This tachycardia occurs in otherwise healthy individuals, is very sensitive to catecholamines, and terminates with adenosine, thus the term *adenosine-sensitive VT*. The other type of idiopathic VT originates from the septum near the apex of the left ventricle resulting in RBBB–superior axis morphology. The mechanism of idiopathic left VT has been shown to be reentry with involvement of the distal His-Purkinje system. Idiopathic left VT is known to be verapamil sensitive, thus the term *verapamil-sensitive VT*.

Nonsustained VT requires no treatment unless the patient is symptomatic. In most instances, nonsustained VT is associated with left ventricular dysfunction, which independently, if moderate to severe, is an indication for the implantation of an implantable cardioverter-defibrillator (ICD). When patients are symptomatic, the choice of medical therapy is dictated by the presence or absence of structural heart disease. In patients with normal left ventricular function, β blockers, calcium channel blockers, and class IC and class III agents should be used, in that order. In patients with left ventricular dysfunction, β blockers followed by

Figure 10-9 Ventricular rhythm disturbances. **A**, Monomorphic ventricular tachycardia at a rate of 200 beats/minute. The QRS complex is wide, and P waves are seen to occasionally alter the QRS morphology (arrows), reflecting AV dissociation. **B**, Ventricular fibrillation. An agonal rhythm is initially present (arrows) but deteriorates into ventricular fibrillation. The baseline is irregular without evidence of organized ventricular electrical activity.

amiodarone are usually the drugs of choice. An important point to note is that, although this arrhythmia is often a marker for increased cardiac mortality in some patients with structural or ischemic heart disease, suppression of this arrhythmia with pharmacologic treatment has not been shown to decrease mortality in most settings. Patients with *sustained VT* that is associated with hemodynamic compromise, angina, or heart failure should undergo synchronized cardioversion. When stable, sustained VT should be managed with intravenous drug therapy such as amiodarone or lidocaine. If left ventricular function is normal, procainamide and sotalol may also be used. If drug therapy fails, synchronized cardioversion should be performed. Following the acute treatment, most patients receive an ICD unless a reversible cause has been identified (e.g., ischemia, metabolic abnormalities, drug toxicity). Ventricular tachyarrhythmias that occur in the setting of acute MI respond to treatment of the ischemia and do not necessarily require prolonged anti-arrhythmic therapy. In the rare instances of idiopathic VT, catheter ablation may provide a permanent cure, with a success rate of 90%. Catheter ablation is also used as an adjunctive therapy in patients with ICDs who have recurrent or incessant VT. With improvements in interventional techniques, localization of the abnormal ventricular foci and subsequent radiofrequency ablation may be curative in many forms of VT, including those associated with previous MI.

Ventricular Flutter

Ventricular flutter (VFL) is a form of monomorphic VT occurring at a rate of 280 to 300 beats/minute and is a hemodynamically unstable rhythm. *Ventricular fibrillation* (VF) is a disorganized, chaotic, ventricular rhythm that results in ineffective ventricular contraction, rapid hemodynamic collapse, and death if not immediately terminated (see Fig. 10-9B). VF is recognized on ECG by coarse undulations of the baseline without identifiable QRS complexes, ST segments, or T waves. It may occur in the setting of ischemia, metabolic abnormalities, and drug toxicity, or it may degenerate from VT, either spontaneously or after attempted cardioversion. Treatment with immediate nonsynchronized direct current shock at 360 joules (or equivalent biphasic) is required in all instances. Several shocks may be required for termination of this arrhythmia, and concurrent treatment of precipitating causes is essential. Once the rhythm has been successfully terminated, an intravenous anti-arrhythmic agent such as amiodarone or lidocaine should be started to prevent recurrences. If VF is the result of an acute reversible cause, no chronic therapy is required. However, if VF occurs as a result of fixed underlying cardiac disease, implantation of an ICD is indicated.

Approach to the Patient with Suspected Arrhythmias

HISTORY

Many, if not most, arrhythmias occur intermittently, and patients are often asymptomatic at the time of evaluation. Therefore, with the suggestion of an arrhythmic problem,

the necessity and urgency for further evaluation must frequently be determined by the history alone. Palpitations, syncope, presyncope, dizziness, chest pain, and symptoms of heart failure are the most common complaints of patients with arrhythmic disorders. Palpitations give a sensation of a rapid or irregular heartbeat. Characterizing the pattern (regular or irregular, intermittent or continuous) and rate of palpitations by having patients tap their fingers on a table to the rhythm of the palpitations may help determine their cause. For instance, occasional *skipped beats* are likely the result of premature atrial or ventricular beats, whereas periods of rapid, irregular heartbeats may be reflective of paroxysmal AF. The perception of palpitations does not invariably correlate with arrhythmias; some patients have tachyarrhythmias without palpitations, whereas other patients have palpitations without tachyarrhythmias. Only simultaneously recording the ECG and documenting the symptoms can confirm the correlation between the symptoms and an arrhythmia. Syncope is the sudden, transient loss of consciousness. Obtaining a complete history of the events immediately preceding and after a syncopal episode will suggest the diagnosis in most patients for whom a diagnosis is eventually determined. Chest pain may be a manifestation of palpitations or may represent arrhythmia-induced cardiac ischemia. Similarly, cardiac arrhythmias may also precipitate or exacerbate congestive heart failure. A prior history of cardiac disease is important to elicit. Patients with palpitations or syncope and a history of cardiomyopathy or prior MI frequently have ventricular tachyarrhythmias, whereas patients with valvular heart disease or hypertension frequently develop AF. A family history of cardiac disease (e.g., dilated or hypertrophic cardiomyopathy, bypass tracts, sudden cardiac death, LQTS) is important to note.

PHYSICAL EXAMINATION

In addition to noting the pulse rate and rhythm, a thorough examination is useful for identifying evidence of underlying cardiac disease. When patients are examined during an arrhythmic episode, several clues to the nature of the arrhythmia may be present. Evidence of AV dissociation suggests a ventricular arrhythmia and includes variable intensity of S_1 (because of variations in the PR interval), intermittent cannon waves in the jugular venous pulsation, and a cacophony of sounds (as a result of atrial systole occurring during various parts of the cardiac cycle, generating intermittent S_3 and S_4). The S_2 may become widely or paradoxically split if a bundle branch block develops during an arrhythmia. Nonetheless, these findings are not diagnostic of a ventricular source of the arrhythmia because bundle branch blocks and, rarely, AV dissociation may occur during supraventricular tachyarrhythmias as well.

USEFUL TESTS

Electrocardiogram

The ECG taken during the arrhythmia is usually diagnostic. If P waves are not obvious, moving the arm leads to a parasternal position (Lewis leads) or using an esophageal electrode (placed 40 cm into the esophagus by means of a

Figure 10-10 Carotid sinus massage during atrial flutter with resultant unmasking of the underlying flutter waves.

nasogastric tube) may help discern atrial activity. In patients who exhibit a hemodynamically stable supraventricular tachyarrhythmia, carotid sinus massage or pharmacologic therapy with adenosine or verapamil may slow or block conduction in the AV node, resulting in either tachycardia termination or the identification of the underlying rhythm. Carotid sinus massage is performed with the patient in the supine position by applying light pressure for 5 to 10 seconds over the carotid impulse at the angle of the jaw. A successful test should result in slowing of the ventricular rate (Fig. 10-10). If no effect is noted, massage can be performed over the contralateral carotid impulse. This test should not be performed if carotid bruits are present. Unfortunately, many patients are examined after the arrhythmia has resolved. Nonetheless, clues may be present on the resting ECG. A delta wave is diagnostic of WPW syndrome, which is associated with AV reentrant arrhythmias and AF. Evidence of prior MI raises the suspicion of ventricular tachyarrhythmias.

When a *wide-complex tachycardia* is present, determining whether it is VT or SVT with aberrancy is important because the therapeutic and prognostic implications differ significantly. When an SVT is associated with a narrow-complex QRS, the diagnosis is straightforward. However, when an SVT occurs in the setting of a preexisting bundle branch block or conducts aberrantly as a result of rate-related block in the His-Purkinje system, the resulting QRS complex is wide and may be difficult to distinguish from VT. Several features may be helpful in making this distinction. The presence of AV dissociation, capture beats, or fusion complexes is diagnostic of VT. However, the absence of these findings is not helpful because they are present in less than 50% of instances. A wide-complex tachycardia occurring in the presence of ischemia or in a patient with known ischemic heart disease is VT in more than 90% of instances. The heart rate, blood pressure, and presence or absence of symptoms do not differentiate these arrhythmias, whereas intermittent cannon waves in the jugular venous pulsations suggest VT. If an abnormal QRS complex is present when the patient is in normal sinus rhythm and the QRS complex during the tachycardia is identical to the one in normal sinus rhythm, the rhythm is likely SVT. Adenosine may be useful in determining the cause; with SVT, adenosine-induced blockade of the AV node will terminate the tachycardia in most instances, given that 90% of SVT involve the AV node (60% AVNRT, 30% AVRT). In the remainder of patients, adenosine-induced AV block will unmask the atrial activity and thus

help make the diagnosis. In rare instances, adenosine may terminate a VT when the tachycardia originates from the right ventricular outflow tract. Verapamil should never be used as a diagnostic test because it may precipitate ventricular fibrillation if the initial rhythm is VT. Table 10-1 lists the features that may help differentiate these arrhythmias from one another.

Recording Devices

Because of the intermittent nature of arrhythmias, prolonged recording devices are more effective than a single ECG in electrocardiographically capturing an arrhythmia. Ambulatory ECG (Holter) monitors continuously record the rhythm and are useful in patients who have frequent episodes of presumed arrhythmic symptoms. Patient-activated event monitors, or loop recorders, can be worn for weeks at a time and continuously monitor the patient's heart rhythm. If symptoms occur, the patient activates the device, which then permanently records the rhythm for several minutes before and after the event and transmits the recorded rhythm by telephone to a central monitoring

Table 10-1 Features that May Differentiate Ventricular Tachycardia from Supraventricular Tachycardia with Aberrancy

Helpful Features	Implications
Positive QRS concordance	Diagnostic of VT
Presence of AV dissociation, capture beats, or fusion beats	Diagnostic of VT
Atypical RBBB (monophasic R, QR, RS, or triphasic QRS in V ₁ ; R:S ratio < 1, QS or QR, monophasic R in V ₆)	Suggests VT
Atypical LBBB (R >30 min or R to S [nadir or notch] > 60 min in V ₁ or V ₂ ; R:S ratio < 1, QS or QR in V ₆)	Suggests VT
Shift of axis from baseline	Suggests VT
History of CAD	Suggests VT
QRS during tachycardia identical to QRS during sinus rhythm	Suggests SVT
Termination with adenosine	Suggests SVT

AV, atrioventricular; CAD, coronary artery disease; LBBB, left bundle branch block; RBBB, right bundle branch block; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

facility. This type of monitor is useful if the patient has infrequent symptoms. For patients with very infrequent symptoms, an implantable event monitor can be placed under the skin of the chest wall and can remain in place for up to 1 year. All these devices are useful in diagnosing arrhythmias, determining the relationship (if any) of the patient's symptoms to an arrhythmia, monitoring the efficacy of anti-arrhythmic therapy, and evaluating artificial pacemaker function. If a patient's symptoms are exertion related, formal exercise testing may be useful.

Head-Up Tilt-Table Testing

In patients with suggested neurocardiogenic syncope, *head-up tilt-table* testing may reproduce their symptoms. This procedure is performed by strapping a patient to the tilt table, then tilting the table 60 to 80 degrees vertically for 15 to 60 minutes. The presumed mechanism of tilt-induced syncope involves a postural decrease in ventricular filling, resulting in increased sympathetic activity and ventricular contraction. This increased contraction is believed to result in the activation of cardiac mechanoreceptors (C fibers), leading to reflex increase in vagal tone and withdrawal of peripheral sympathetic tone. The result is bradycardia-induced low cardiac output in addition to vasodilation leading to hypotension. The sensitivity of the test in detecting neurocardiogenic syncope can be up to 85% depending on the tilt protocol used, with a relatively low false-positive rate (<15%). The administration of intravenous isoproterenol or sublingual nitroglycerin increases the diagnostic yield of the test while decreasing its specificity.

Electrophysiologic Study

Invasive EP studies are performed by recording the electrical activity of the heart through catheters strategically positioned in the right atrial and ventricular chambers. This test may be useful in a group of patients in whom conduction disorders of the sinus or AV node are suggested. The results may help determine the mechanism of heart block and the need for permanent pacemaker implantation. More commonly, EP studies are used to evaluate patients with documented tachyarrhythmias or with syncope for which a tachyarrhythmia is suggested as the cause. Both supraventricular and ventricular tachyarrhythmias may be reproduced by programmed electrical stimulation. If a tachyarrhythmia is induced, the application of radiofrequency energy at the arrhythmia site of origin or targeting a critical component of the arrhythmia circuit often leads to tachycardia termination.

Syncope

Syncope is defined as sudden, transient loss of consciousness and may be the result of a variety of cardiac and noncardiac conditions (Table 10-2). Presyncope is a feeling of impending syncope without true loss of consciousness. Cardiovascular causes are responsible for most syncope episodes and produce loss of consciousness by means of a drop in blood pressure, with resultant bilateral cortical or brainstem hypoperfusion. Cerebrovascular disease is an uncommon cause of syncope, unless bilateral carotid artery disease or vertebrobasilar disease is present.

Table 10-2 Causes of Syncope

Cause	Features
Peripheral Vascular or Circulatory	
Vasovagal syncope (neurally mediated)	Prodrome of pallor, yawning, nausea, diaphoresis; precipitated by stress or pain; occurs when patient is upright, aborted by recumbency; fall in blood pressure with or without a decrease in heart rate
Micturition syncope	Syncope with urination (probably vagal)
Post-tussive syncope	Syncope after paroxysm of coughing
Hypersensitive carotid sinus syndrome	Vasodepressor and/or cardioinhibitory responses with light carotid sinus massage (see text)
Drugs	Orthostasis Occurs with antihypertensive drugs, tricyclic antidepressants, phenothiazines
Volume depletion	Orthostasis Occurs with hemorrhage, excessive vomiting or diarrhea, Addison disease
Autonomic dysfunction	Orthostasis Occurs in diabetes, alcoholism, Parkinson disease, deconditioning after a prolonged illness
Central Nervous System	
Cerebrovascular	Transient ischemic attacks and strokes are unusual causes of syncope; associated neurologic abnormalities are usually present
Seizures	Warning aura sometimes present, jerking of extremities, tongue biting, urinary incontinence, postictal confusion
Metabolic	
Hypoglycemia	Confusion, tachycardia, jitteriness before syncope; patient may be taking insulin
Cardiac	
Obstructive	Syncope is often exertional; physical findings consistent with aortic stenosis, hypertrophic obstructive cardiomyopathy, cardiac tamponade, atrial myxoma, prosthetic valve malfunction, Eisenmenger syndrome, tetralogy of Fallot, primary pulmonary hypertension, pulmonic stenosis, massive pulmonary embolism
Arrhythmias	Syncope may be sudden and occurs in any position; episodes of dizziness or palpitations; may be a history of heart disease; bradyarrhythmias or tachyarrhythmias may be responsible—check for hypersensitive carotid sinus

The most important aspect of the approach to the patient with syncope is obtaining a thorough history, both from the patient and from any witnesses to the episode. The conditions during which a syncopal episode occurs may suggest the cause. For instance, syncope that occurs on arising from a lying or sitting position suggests orthostasis. Exercise-induced syncope suggests obstructive cardiac disease, such as aortic or mitral valve stenosis or hypertrophic cardiomyopathy. Syncope during straining, coughing, or micturition is the result of Valsalva-induced decrease in venous return. A history of palpitations preceding the event suggests an arrhythmic cause. Syncope that occurs during emotional stress suggests a vasovagal episode. Certain features may suggest a noncardiac cause, including incontinence or tonic-clonic movements, which suggest seizure. Patients who suffer a cardiac syncopal episode usually regain consciousness rapidly (<5 minutes). Longer episodes of unresponsiveness suggest a noncardiac cause. Review of the patient's medications is important and may suggest drug-induced hypotension or arrhythmias as the cause of a syncopal episode.

The physical examination of a patient with syncope should include evaluation of orthostatic changes in the heart rate and blood pressure, a thorough cardiac examination to exclude significant murmurs, a neurologic examination, and carotid sinus massage when the history suggests carotid

sinus sensitivity as the diagnosis. A 12-lead ECG should be obtained and may be diagnostic of the cause of syncope (e.g., complete heart block) or reveal abnormalities that warrant further evaluation (e.g., prior myocardial infarction, conduction system disease, nonsustained VT, a delta wave of WPW syndrome).

Further cardiac testing is useful in select patients. An echocardiogram is helpful in patients in whom structural heart disease or an arrhythmic cause is suspected. A 24-hour Holter monitor or an event monitor may be helpful in evaluating for possible arrhythmias. In patients with recurrent syncope without evidence of a structural or arrhythmic cause and in patients in whom the history suggests vasovagal or neurocardiogenic syncope, tilt-table testing may be useful (see earlier discussion). In patients in whom the history, ECG, or Holter monitoring suggest a tachyarrhythmia or bradyarrhythmia as the cause of syncope, EP testing is indicated (see earlier discussion). However, in patients with a normal resting ECG and no structural heart disease, the diagnostic yield of EP testing is so low that it is rarely useful. Figure 10-11 offers a diagnostic approach to the patient with syncope. Despite all these diagnostic modalities, in more than 30% of all patients with syncope, the cause remains unknown. Fortunately, these patients can be reassured of a good prognosis.

Sudden Cardiac Death

Sudden cardiac death (SCD) is commonly defined as a natural, unexpected death occurring within 1 hour of the onset of symptoms. Sudden death may be the result of a variety of cardiac and noncardiac diseases (Table 10-3), although cardiac causes are by far the most common. SCD accounts for an estimated 300,000 deaths per year—more than 50% of all deaths from cardiac causes—and is the leading cause of death among men 20 to 60 years old. Ventricular tachyarrhythmias (VT and VF) occurring in the setting of ischemic heart disease account for the mechanism of death in most of these patients. Polymorphic VT occurring in the setting of LTQS (see later discussion), short QT syndrome (see later discussion), Brugada syndrome (see later discussion), and hypertrophic cardiomyopathy are also common causes of SCD, particularly in young patients. VT in the absence of underlying heart disease and rapid conduction of AF or AFL over an accessory bypass tract precipitating VT or VF account for other tachyarrhythmic causes of SCD. Bradyarrhythmias and pulseless electrical activity, a condition during which the electrical activity of the heart continues in the absence of mechanical contraction, account for only a small proportion of SCD.

Ischemic heart disease is present in at least 80% of patients who die suddenly of a cardiac cause, and as many as 75% of these patients have a prior history of a MI (Table 10-4). In the remainder, SCD is their first manifestation of ischemic heart disease. Nonetheless, only 20% of patients resuscitated from an episode of SCD have evidence of having had an acute transmural MI at the time of the event. This circumstance is of prognostic importance; survivors of SCD that occurred in the setting of an acute MI have a recurrence rate of less than 5% in the following year, compared with a 30% recurrence rate in survivors in whom SCD occurred in the absence of an acute infarction.

Table 10-3 Causes of Sudden Cardiac Death

Noncardiac

Central nervous system hemorrhage
Massive pulmonary embolus
Drug overdose
Hypoxia secondary to lung disease
Aortic dissection or rupture

Cardiac

Ventricular fibrillation
Myocardial ischemia/injury
Long QT syndrome
Short QT syndrome
Brugada syndrome
Arrhythmogenic right ventricular dysplasia
Ventricular tachycardia
Bradyarrhythmias, sick sinus syndrome
Aortic stenosis
Tetralogy of Fallot
Pericardial tamponade
Cardiac tumors
Complications of infective endocarditis
Hypertrophic cardiomyopathy (arrhythmia or obstruction)
Myocardial ischemia
Atherosclerosis
Prinzmetal angina
Kawasaki arteritis

Table 10-4 Predictors of Sudden Cardiac Death after Myocardial Infarction

Decreased left ventricular ejection fraction
Residual ischemia
Complex ventricular ectopy (nonsustained ventricular tachycardia) on ambulatory ECG monitoring
Late potentials on signal-averaged ECG
Decreased heart rate variability
Prolonged QT on ECG
Induction of sustained monomorphic ventricular tachycardia with programmed electrical stimulation
ECG, electrocardiogram.

The only effective treatment of an acute episode of SCD is immediate circulatory support with cardiopulmonary resuscitation and establishment of an effective cardiac rhythm with electrical defibrillation. Once a stable rhythm has been restored, intravenous anti-arrhythmic therapy, usually with amiodarone, should be instituted for the first 24 hours while determination of the precipitating cause is made. That VT or VF was the mechanism of SCD cannot be assumed, unless these rhythms were documented at the time of arrest. A thorough search for other possible causes is mandatory. In SCD survivors, a full cardiac evaluation should be performed to define cardiac function, identify the presence of reversible heart disease, and assess the risk for recurrent arrhythmias. Echocardiography can identify possible structural cardiac causes of SCD (e.g., aortic stenosis, hypertrophic cardiomyopathy) and allows assessment of left ventricular function. This identification is important prognostically; patients with depressed ventricular function have a higher likelihood of recurrent SCD, a poorer response to anti-arrhythmic drug therapy, and a higher mortality rate than do those with normal ventricular function. Ambulatory ECG monitoring and stress testing are useful in documenting the frequency and severity of recurrent ventricular arrhythmias and in assessing for residual ischemia.

Patients in whom acute MI precipitates SCD do not require anti-arrhythmic therapy. Cardiac catheterization and revascularization should be performed if possible. In SCD survivors in whom the event occurred in the absence of an acute MI, and in patients with recurrent ventricular tachyarrhythmias, the implantation of an ICD has been the mainstay of treatment.

Management of Cardiac Arrhythmias

When initiating treatment of an arrhythmia, several clinical factors should be considered, including the nature of the specific arrhythmia, the setting in which the arrhythmia occurred, the consequences of the arrhythmia, and the potential risks of therapy. Certain arrhythmias (e.g., VT) can cause hemodynamic instability or SCD and warrant aggressive treatment to prevent recurrences. Other arrhythmias are hemodynamically stable but produce intolerable symptoms (e.g., palpitations, dizziness) and should be similarly suppressed. Certain arrhythmias may not be a problem acutely but warrant treatment to prevent long-term complications

(e.g., stroke prevention in AF). The situation in which an arrhythmia occurs may dictate the need for therapy. For example, VF occurring in the setting of an acute MI is unlikely to recur if the underlying ischemic process is treated and warrants no specific therapy for the arrhythmia itself. Conversely, VF occurring in the absence of acute ischemia is likely to recur and requires aggressive therapy. Arrhythmias that are tolerated well and require no therapy in patients with structurally normal hearts may not be tolerated at all in patients with depressed left ventricular systolic function or valvular heart disease and may require aggressive therapy in these settings. Some arrhythmias are secondary to an underlying disease process. Metabolic abnormalities (e.g., hypokalemia, hypomagnesemia, hypoxia, hyperthyroidism) and acute illness (e.g., congestive heart failure, sepsis, anemia) may precipitate arrhythmias, as may emotional upset, certain foods or beverages (e.g., caffeine-containing products, alcohol), and both prescription (e.g., digoxin, theophylline, anti-arrhythmic agents) and nonprescription (e.g., decongestants, certain antibiotics, cocaine) drugs. Although treatment of arrhythmias associated with these factors may be warranted acutely, long-term therapy is not required, provided that the inciting factor is removed or controlled.

Asymptomatic arrhythmias are difficult clinical problems. Ventricular premature contractions and nonsustained VT may be markers of underlying heart disease and, although benign themselves, may progress to more malignant arrhythmias. Treatment with anti-arrhythmic medications in these instances has not been shown to decrease mortality, and, in fact, some agents are associated with increased mortality because of their pro-arrhythmic side effects. The presence of symptoms is clearly important in deciding whether to treat an arrhythmia. In patients who are asymptomatic, the risks of the arrhythmia must be compared with the risks of therapy before instituting an anti-arrhythmic agent.

Pharmacologic Therapy

Anti-arrhythmic medications work by interfering with various aspects of myocardial depolarization or repolarization and can be classified based on their particular mechanism of action. The most frequently used classification system is the Vaughn Williams classification, which categorizes these drugs based on their *in vitro* EP effects on normal Purkinje fibers (Table 10-5). This classification is a helpful construct; however, several limitations to its interpretation and use exist. First, whether the *in vivo* effects of a drug in a specific class are the same as those seen *in vitro* is unclear. Second, a given drug may have properties of more than one class. Third, drugs in the same class may differ somewhat in their modes of action, side-effect profile, and clinical effectiveness for treating a given arrhythmia. Nonetheless, the classification remains a useful communication tool.

Several general points are worth noting in the management with anti-arrhythmic agents. Many drugs are given as a standard dose, whereas others are titrated, depending on clinical effect. Therapeutic blood levels of many drugs have been established; however, the absolute concentration of the agent in the patient's blood is a much less useful guide to therapy than is the clinical effectiveness of the drug and the

Table 10-5 Vaughn Williams Classification of Anti-arrhythmic Drugs

Class	Physiologic Effect*	Examples
I	Blocks sodium channels; predominantly reduces the maximum velocity of the upstroke of the action potential (phase 0)	—
IA	Intermediate potency blockade	Quinidine, procainamide, disopyramide
IB	Least potent blockade	Lidocaine, tocainide, mexiletine, phenytoin
IC	Most potent blockade	Flecainide, propafenone, moricizine
II	β -Adrenergic receptor blockade	Propranolol, metoprolol, atenolol
III	Potassium channel blockade: predominantly prolongs action potential duration	Amiodarone, sotalol, bretylium, ibutilide, dofetilide
IV	Calcium channel blockade	Verapamil, diltiazem

*Several agents have physiologic effects characteristic of more than one class.

presence or absence of side effects. The therapeutic-to-toxic ratio of most anti-arrhythmic agents is small such that, at therapeutically effective doses, toxic side effects are common. Knowledge of the metabolism of these agents is important. Either the kidney or the liver metabolizes most anti-arrhythmic drugs (Table 10-6), and doses must be decreased in patients with renal or hepatic dysfunction to avoid toxicity. Many of these agents have negative inotropic effects, and, even at nontoxic levels, noncardiac side effects are common. These drugs frequently interact with other medications and may interfere with nonpharmacologic modes of therapy. For example, quinidine and amiodarone increase the serum digoxin level and augment the anticoagulant effect of warfarin. Flecainide and propafenone increase the amount of energy required for an artificial pacemaker to pace the heart effectively (pacing threshold), whereas amiodarone increases the amount of energy required to defibrillate the heart effectively (defibrillation threshold). For this reason, artificial pacemakers and ICDs need to be checked after instituting anti-arrhythmic agents.

Table 10-6 and Table 10-7 summarize the important characteristics of the most commonly used anti-arrhythmic agents. An in-depth discussion of each agent is beyond the scope of this chapter; however, several points warrant specific mention.

CLASS I ANTIARRHYTHMIC AGENTS

Class IA agents block sodium channels to a moderate degree and are useful for the long-term oral treatment of both supraventricular and ventricular arrhythmias. Procainamide is also available in an intravenous preparation and is useful for the acute management of these arrhythmias. These agents prolong the conduction time and the ERP of most cardiac tissues, including accessory pathways, and may be

Table 10-6 Select Characteristics of Anti-arrhythmic Drugs

Drug	Effect on Surface ECG	Effect on LV Function	Important Drug Interactions	Effect on Pacing and Defibrillation Thresholds	Major Route of Elimination
Quinidine	Prolongs QRS and QT	Negative inotropic effect	Increases digoxin level and warfarin effect Cimetidine increases quinidine level Phenobarbital, phenytoin, and rifampin decrease quinidine level	Increases PT and DT at high doses	Liver and kidney
Procainamide	Prolongs PR, QRS, and QT	Negative inotrope	Cimetidine, alcohol, and amiodarone increase procainamide level	Increases PT at high doses	Liver and kidney
Disopyramide	Prolongs QRS and QT	Negative inotrope	Phenobarbital, phenytoin, and rifampin all decrease disopyramide level	Increases PT at high doses	Liver and kidney
Lidocaine	Shortens QT	None	Propranolol, metoprolol, and cimetidine all increase lidocaine level	Increases DT	Liver
Mexiletine	Shortens QT	None	Increases theophylline level Phenobarbital, phenytoin, and rifampin all decrease mexiletine level	Variable effects	Liver
Flecainide	Prolongs PR and QRS	Negative inotrope	Increases digoxin level	Increases PT; variable effect on DT	Liver and kidney
Propafenone	Prolongs PR and QRS	Negative inotrope	Increases digoxin, theophylline, and cyclosporine levels; increases warfarin effect Phenobarbital, phenytoin, and rifampin decrease propafenone level Cimetidine and quinidine increase propafenone level	Increases PT; variable effect on DT	Liver
Moricizine	Prolongs PR and QRS	Negative inotrope	Decreases theophylline level Cimetidine increases moricizine level	—	Liver
Amiodarone	Prolongs PR and QT; slows sinus rate	None	Increases digoxin and cyclosporine levels; increases warfarin effect	Increases DT	Liver
Sotalol	Prolongs PR and QT; slows sinus rate	Negative inotrope	Additive effects with other β blockers	Decreases DT	Kidney
Bretylium	Prolongs PR and QT	None	—	—	Kidney
Ibutilide	Prolongs PR and QT	None	—	Decreases DT	Liver
Dofetilide	Prolongs QT	None	Verapamil, diltiazem, cimetidine, and ketoconazole all increase dofetilide level	Decreases DT	Liver and kidney

DT, defibrillation threshold; ECG, electrocardiogram; LV, left ventricle; PT, pacing threshold.

effective therapy for patients with AVNRT or AVRT. Because these agents slow the spontaneous sinoatrial rate and can enhance conduction through the AV node through vagolytic effects, they can induce more rapid ventricular rates in patients with AF and AFL. Therefore, care must be taken to ensure that the ventricular rate is controlled with a β blocker, calcium channel blocker, or digoxin before instituting a class IA agent in patients with atrial arrhythmias. Owing to its α -adrenergic blocking effects, quinidine may cause significant hypotension and may also produce syncope in 0.5% to 2% of patients as a result of QT prolongation and subse-

quent polymorphic VT. This pro-arrhythmic effect may also be seen with the other agents in this class. Between 60% and 70% of patients who receive procainamide develop antinuclear antibodies (specifically antihistone antibodies), whereas a clinical lupus-like syndrome occurs in only 20% to 30%; this rate is reversible on stopping the drug. Disopyramide has significant negative inotropic effects and should be used with extreme caution (if at all) in patients with left ventricular dysfunction.

Class IB agents are weak sodium channel blockers. They are useful for treating ventricular tachyarrhythmias, but,

Table 10-7 Common Side Effects of Select Anti-arrhythmic Drugs

Drug	Major Side Effects
Quinidine	Nausea, diarrhea, abdominal cramping Cinchonism: decreased hearing, tinnitus, blurred vision, delirium Rash, thrombocytopenia, hemolytic anemia Hypotension, torsades de pointes, quinidine syncope
Procainamide	Drug-induced lupus syndrome Nausea, vomiting Rash, fever, hypotension, psychosis, agranulocytosis Torsades de pointes
Disopyramide	Anticholinergic: dry mouth, blurred vision, constipation, urinary retention, closed-angle glaucoma Hypotension, worsening heart failure
Lidocaine	CNS: dizziness, peri-oral numbness, paresthesias, altered consciousness, coma, seizures
Mexiletine	Nausea, vomiting CNS: dizziness, tremor, paresthesias, ataxia, confusion
Flecainide	CNS: blurred vision, headache, ataxia Congestive heart failure, ventricular pro-arrhythmia
Propafenone	Nausea, vomiting, constipation, metallic taste to food Dizziness, headache, exacerbation of asthma, ventricular pro-arrhythmia
Moricizine	Nausea, dizziness, headache
β Blockers	Bronchospasm, bradycardia, fatigue, depression, impotence Congestive heart failure
Calcium channel blockers	Congestive heart failure, bradycardia, heart block, constipation
Amiodarone	Agranulocytosis, pulmonary fibrosis, hepatopathy, hyperthyroidism or hypothyroidism, corneal micro-deposits, bluish discoloration of the skin, nausea, constipation, bradycardia
Sotalol	Same as β blockers, torsades de pointes
Bretylum	Orthostatic hypotension Transient hypertension, tachycardia, and worsening of arrhythmia (initial catecholamine release)
Ibutilide	Torsades de pointes
Dofetilide	Torsades de pointes, headache, dizziness, diarrhea

CNS, central nervous system.

because they have minimal effects on the sinus or AV nodes, they are not effective for supraventricular arrhythmias. Lidocaine is the most clinically useful drug in this class and is the initial intravenous drug of choice in patients with ventricular tachyarrhythmias. Lidocaine appears particularly effective in ischemia-related arrhythmias; however, its prophylactic use during an acute infarction is not indicated and may increase mortality. Phenytoin is a potent anti-epileptic that also has

class IB anti-arrhythmic properties. It is particularly effective in treating atrial and ventricular arrhythmias caused by digoxin toxicity. These agents have relatively little effect on hemodynamics, and clinically important pro-arrhythmia is rare.

Class IC agents are potent blockers of sodium channels. They are effective therapy for both ventricular and supraventricular arrhythmias; however, the use of flecainide and moricizine to treat asymptomatic ventricular arrhythmias after MI has been proved to increase mortality, especially in patients with left ventricular dysfunction. Flecainide remains an effective and relatively safe therapy for supraventricular arrhythmias (especially paroxysmal AF) in patients with structurally normal hearts. Propafenone is similar to flecainide but with β -blocking effects and therefore may exacerbate bradycardia, heart block, heart failure, and bronchospasm. Both drugs can convert AF to AFL (class IC AFL), which usually conducts at faster rates. Therefore, similar to class IA agents, class IC agents should only be used after the initiation of an AV-nodal agent (β blockers, calcium channel blockers, digoxin) when treating patients with atrial arrhythmias.

CLASS II AND IV ANTIARRHYTHMIC AGENTS

The β blockers and *nondihydropyridine calcium channel blockers* constitute *class II* and *class IV* anti-arrhythmic agents, respectively. The anti-arrhythmic effectiveness of these drugs relates mainly to their ability to slow the rate of the sinus node and decrease conduction through the AV node. They are effective for controlling the rate of AF and AFL, although they are not effective for converting these arrhythmias to normal sinus rhythm. Intravenous administration of these agents may acutely terminate some supraventricular tachyarrhythmias, especially reentrant rhythms that use the AV node as one limb of the reentrant circuit (i.e., AVNRT, AVRT). By virtue of their ability to slow conduction in the AV node selectively, these agents may facilitate conduction down a bypass tract and are contraindicated in patients with WPW syndrome and atrial tachyarrhythmias. These agents also have a negative inotropic effect and thus must be used with caution in patients with left ventricular dysfunction or overt heart failure.

CLASS III ANTIARRHYTHMIC AGENTS

Amiodarone

Amiodarone is mainly a class III agent but has physiologic effects of all four classes. Similar to other class III anti-arrhythmic drugs, it prolongs the action potential duration. It is an effective therapy for a wide range of both supraventricular and ventricular arrhythmias and is safe to use in patients with left ventricular dysfunction. Amiodarone is the drug of choice for the treatment of AF in patients with heart failure and may decrease arrhythmic death after MI and in patients with nonischemic cardiomyopathy. It is more effective than other antiarrhythmic agents in preventing recurrences of VT or VF and is the drug of choice for treating these arrhythmias in the setting of cardiac arrest. In addition, amiodarone may be administered

intravenously for the acute treatment of refractory ventricular tachyarrhythmias. Its use has been somewhat limited by the fear of significant side effects; however, with maintenance doses of less than 300 mg/day, adverse effects are less common.

Drug Interactions

Before using amiodarone, it is important to make sure the patient is not taking other medicines that may interact with this drug. The effect of warfarin is increased with amiodarone, necessitating a reduction in the dosage. Similarly, the side effects of β blockers and calcium channel blockers are increased, often leading to bradycardia and AV block. The concomitant use of most antiarrhythmic agents is prohibited because of the risk for serious side effects, including malignant ventricular arrhythmias and bradycardia. Amiodarone stays in the body for weeks or months after drug discontinuation. Therefore, drug interactions should be monitored even after stopping the medication for at least few weeks.

Side Effects

Adverse effects are common, with prevalence as high as 15% in the first year and 50% during long-term use. Fortunately, many of these adverse effects are manageable, and the need to discontinue amiodarone therapy is relatively low, occurring in less than 20% of patients. The most serious side effect is pulmonary fibrosis, which shows as an interstitial pattern on chest radiographs and a restrictive pattern on pulmonary function tests. When this occurs, immediate discontinuation of the drug is recommended. Cases of optic neuropathy and optic neuritis, usually resulting in visual impairment, have been reported in patients treated with amiodarone. In some cases, visual impairment has progressed to permanent blindness. Optic neuropathy or neuritis may occur at any time following initiation of therapy. Although a causal relationship to the drug has not been clearly established, the presence of any visual impairment warrants prompt ophthalmic examination. Appearance of optic neuropathy or neuritis calls for re-evaluation of amiodarone therapy and frequently drug discontinuation. Elevations of hepatic enzyme levels are seen frequently in patients exposed to amiodarone and in most cases are asymptomatic. If the increase exceeds 3 times normal, or doubles in a patient with an elevated baseline, discontinuation of amiodarone or dosage reduction should be considered. Excess sinus bradycardia and AV block are also serious cardiovascular adverse effects, particularly when combined with class II and IV agents. Thyroid function abnormalities are relatively common; however, they are rarely a cause for drug discontinuation. Finally, long-term exposure may cause blue-gray discoloration of the skin, particularly the face and hands. This effect is not harmful and usually reverses after the medicine is stopped. Avoiding prolonged exposure to the sun may help to prevent this effect. A more comprehensive list of the potential side effects is available in Table 10-7.

Monitoring and Follow-Up

Initial assessment of patients started on amiodarone therapy should occur every 3 to 6 months for the first year and every 6 months thereafter. Patients receiving amiodarone

therapy should have liver and thyroid function tests performed at baseline and every 6 months. They also need to have a chest radiograph and pulmonary function tests at baseline and every year. High-resolution CT scan is indicated if there is a clinical suspicion of pulmonary toxicity. Similarly, ophthalmologic evaluation is indicated if visual symptoms develop.

Sotalol, Ibutilide, Dofetilide, and Bretylium

Sotalol has both class III and β -blocking effects. It is particularly effective for treating ventricular tachyarrhythmias, but it is also effective for a large number of supraventricular arrhythmias, including AF. *Ibutilide* is a parenteral class III agent that is effective for the acute termination of AF and AFL of recent onset (<90 days), and it enhances the success of electrical cardioversion of this arrhythmia. *Dofetilide* is a pure class III agent that is effective for the treatment of atrial arrhythmias; it is especially effective for the termination and prevention of AF and AFL. *Dofetilide* has no demonstrable negative inotropic effect, is more effective than sotalol for the acute conversion of AF, and is not associated with the risk for pulmonary and hepatic toxicity that is seen with amiodarone. At initiation, patients are routinely monitored for prolongation of the QT intervals and the increased risk for torsades de pointes. The incidence of this arrhythmia is low in patients given amiodarone but is as high as 2% and 5% in patients with impaired ventricular function who are given dofetilide or ibutilide, respectively. *Bretylium* causes an initial release of norepinephrine from nerve terminals and may result in transient hypertension and aggravation of arrhythmias. It subsequently prevents norepinephrine release and thus prevents arrhythmia recurrence. *Bretylium* is administered intravenously and is indicated for treating life-threatening ventricular tachyarrhythmias when other agents have failed.

Other Antiarrhythmic Agents

Several other anti-arrhythmic agents that do not fit into the Vaughn Williams classification are worthy of mention. *Adenosine* is an endogenous nucleoside that, when given intravenously in pharmacologic doses, results in profound, albeit transient, slowing of AV conduction and sinus node discharge rate. Flushing, chest pain, and dyspnea commonly occur after adenosine injection but are short lived because of the short half-life of this agent (about 6 seconds). The main use of adenosine is in the treatment of SVT; it terminates more than 95% of AVNRTs and AVRTs. During rapid atrial tachyarrhythmias, transient adenosine-induced heart block may help unmask the underlying rhythm. Theophylline blocks the effects of adenosine, and dipyridamole potentiates its effects. *Atropine* blocks the effects of the vagus nerve on the heart and results in an increased sinus rate and increased conduction through the AV node. It is indicated for the treatment of symptomatic bradycardia. *Digoxin* enhances vagal tone and results in slowing of the sinus node rate and conduction through the AV node. It is useful for controlling the ventricular response to a SVT when combined with a β blocker or a calcium channel blocker.

Nonpharmacologic Therapy of Bradyarrhythmias

CARDIAC PACEMAKERS

Artificial cardiac pacemakers are devices that deliver a small electrical impulse to a localized region of the heart, causing the affected myocytes to depolarize to the threshold potential, thus initiating an action potential that then spreads to the remainder of the heart. These devices can be used temporarily to treat a transient bradyarrhythmia resulting from a reversible cause, or they can be implanted permanently to treat irreversible disorders of impulse formation or conduction that result in recurrent or persistent bradyarrhythmias. Temporary pacemakers can deliver the electrical impulse indirectly through the chest wall (transcutaneous pacing), or they can be placed intravenously into the right side of the heart to deliver the impulse locally (transvenous pacing). Transcutaneous pacing requires higher energy to *capture* the heart electrically and therefore can be somewhat uncomfortable. In addition, some patients, especially obese individuals, cannot be effectively paced transcutaneously. Nonetheless, this type of pacemaker can be an effective mode of pacing in most patients, may help stabilize a patient who has an unstable bradyarrhythmia until a transvenous or permanent pacemaker can be inserted, and is useful to have as prophylaxis for acutely ill patients who are at high risk for developing significant bradyarrhythmias. Permanent pacemakers are usually inserted intravenously. The pulse generator is buried in a *pocket* created in the pectoral region of the chest wall, and the leads pass from the generator through the cephalic, axillary, or subclavian vein and into the right atrium or ventricle where they are anchored in place. Indications for permanent pacemaker insertion are listed in Table 10-8.

Current pacemakers allow for the tailoring of the pacemaker function to the specific needs of the patient. A code has been developed that describes these various functions. The first letter reflects the cardiac chamber being paced (V, ventricle; A, atrium; D, dual chamber—atrium and ventricle). The second letter reflects the chamber in which electrical activity is being sensed (V, ventricle; A, atrium; D, dual chamber—atrium and ventricle; O, none). The third letter reflects the response mode of the pacemaker. If the pacemaker senses the patient's own native beat, it may respond by being inhibited (I), triggered to fire (T), or triggered to fire after a sensed atrial event but inhibited by a sensed ventricular event (D). Newer pacemakers are also capable of sensing a patient's activity level (through temperature, vibration, or respiratory sensors) and changing their paced rate in response to a sensed increase in metabolic need. This mode is termed a *rate-responsive* mode and is indicated by an *R* after the first three letters. Examples of common pacing modes are listed in Table 10-9.

The choice of pacing mode depends on the needs of the individual patient. Dual-chamber pacing maintains AV synchrony, which is an advantage because the timing of atrial contraction is important for maximizing cardiac output. Therefore, AV synchronous pacing is useful for patients with left ventricular dysfunction in whom loss of AV synchrony may result in the precipitation of heart

Table 10-8 Indications for Pacemaker Insertion

Pacing is definitely indicated.	Acquired third-degree AVB with or without symptoms* Congenital third-degree AVB with symptoms Mobitz I (Wenckebach) second-degree AVB with symptomatic bradycardia Mobitz II second-degree AVB with or without symptomatic bradycardia Sinus bradycardia (heart rate < 40 beats/minute) with symptoms Alternating bundle branch block
Pacing is probably indicated.	Congenital AVB with moderate bradycardia Bifascicular block (RBBB + LAFB or RBBB + LPFB) with a history of syncope after ruling out other causes Incidental finding of significant His-Purkinje disease during invasive cardiac electrophysiologic evaluation Transient third-degree AVB or Mobitz II second-degree heart block after an AMI Neurocardiogenic syncope with a positive tilt-table test
Pacing is not indicated.	Asymptomatic sinus bradycardia Asymptomatic sinus node dysfunction Bradycardia during sleep First-degree AVB Asymptomatic Mobitz I (Wenckebach) second-degree AVB Transient asymptomatic pause during atrial fibrillation Asymptomatic, >3-second pause with CSM Recurrent syncope of undetermined cause

AMI, acute myocardial infarction; AVB, atrioventricular block; CSM, carotid sinus massage; LAFB, left anterior fascicular block; LBBB, left bundle branch block; LPFB, left posterior fascicular block; RBBB, right bundle branch block.

*Symptoms include syncope, dizziness, confusion, congestive heart failure, and decreased exercise tolerance.

failure. For patients who have structurally normal hearts or who have a pacemaker implanted for only occasional symptomatic bradyarrhythmias, maintaining AV synchrony is not as important, and a single ventricular pacing electrode is sufficient. In patients with chronic AF, AV synchrony is not possible, and a single ventricular pacing electrode is also adequate.

Safeguards have been programmed into the pacemakers that limit the upper pacing rate, thus preventing rapid ventricular pacing in response to a supraventricular tachyarrhythmia. Newer pacemakers can detect the onset of an atrial tachyarrhythmia and switch to an appropriate pacing mode (mode switching). Pacemaker malfunction may be demonstrated as failure of a pacemaker impulse to depolarize the heart (failure to capture), abnormalities of sensing (oversensing or undersensing), or pacing at an abnormal rate. Many pacemakers decrease their pacing rate or change their pacing mode as the battery life is depleted.

Table 10-9 Common Pacemaker Modes

Pacemaker Type	Code	Chamber Paced	Chamber Sensed	Mode
Ventricular asynchronous	VOO	V	None	Continuous ventricular pacing regardless of the presence of intrinsic QRS complexes
Ventricular demand	VVI	V	V	Ventricular pacing inhibited by spontaneous QRS complexes
Atrial demand	AAI	A	A	Atrial pacing inhibited by spontaneous P waves
Atrial synchronous, ventricular inhibited	VDD	V	AV	Ventricular pacing follows a sensed P wave after a preset AV delay; ventricular pacing inhibited by spontaneous QRS complexes; no atrial pacing
AV sequential	DVI	AV	V	Ventricular pacing follows atrial pacing after a preset AV delay; ventricular and atrial pacing inhibited by spontaneous QRS; no P-wave sensing
Optimal sequential	DDD	AV	AV	Ventricular pacing follows sensed P waves or atrial pacing after a preset AV delay; ventricular pacing inhibited by spontaneous QRS complexes; atrial pacing inhibited by spontaneous P waves
Rate responsive	VVIR DDDR	V AV	V AV	Same as VVI or DDD, but pacing rate increases with physiologic demand

A, atrial; AV, atrioventricular; V, ventricular.

Nonpharmacologic Therapy of Tachyarrhythmias

DIRECT CURRENT CARIOVERSION AND DEFIBRILLATION

Direct current cardioversion and electrical defibrillation are effective methods for treating atrial or ventricular tachyarrhythmias and are the methods of choice for terminating hemodynamically unstable tachyarrhythmias, as well as stable tachyarrhythmias that are refractory to pharmacologic therapy. Cardioversion refers to the synchronized application of an electrical shock to the heart in an attempt to terminate a tachyarrhythmia. Synchronization of the shock to the QRS complex is a critical feature because the inadvertent administration of an electrical shock during ventricular repolarization (i.e., during the T wave) may precipitate VF. Defibrillation refers to the asynchronous delivery of an electrical shock to terminate VF. Synchronization in this setting is not possible because no organized ventricular activity (QRS) occurs during VF.

Small, although real, risks are inherent with electrical cardioversion. For this reason, several factors need to be addressed before elective procedures. Hyperkalemia should be excluded, as should a supratherapeutic digoxin level; cardioversion in the setting of digoxin toxicity may precipitate refractory ventricular arrhythmias. Adequate sedation is important and can usually be accomplished by the intravenous administration of benzodiazepines (e.g., midazolam) or short-acting anesthetic agents (e.g., propofol). Aspiration of gastric contents can occur because patients are unable to protect their airways during this type of sedation; therefore, patients should have fasted for at least 6

hours before the procedure. Minor cutaneous burns at the site of application of the electrical current are common, especially if multiple shocks are delivered. Even with appropriate synchronization, electrical cardioversion may precipitate VF, in which case immediate defibrillation is required. In patients with AF, systemic embolization of atrial thrombus may occur after conversion to normal sinus rhythm. Therefore, patients who are undergoing elective cardioversion of AF must be adequately anticoagulated with warfarin for at least 3 weeks before and 4 weeks after electrical cardioversion.

The electrical shock is delivered through paddles applied to the patient's chest. These shocks can be arranged either with both paddles placed on the anterior chest (one paddle at the upper sternal border and the other at the cardiac apex) or with one paddle anteriorly located over the right upper sternal border and the other posteriorly over the left interscapular region. Lubrication with electrolyte gel or the use of electrolyte pads improves contact and decreases burns. AFL can frequently be converted to normal sinus rhythm with low-energy shocks (<50 joules), whereas AF frequently requires higher energy (100 to 360 joules). VT can be cardioverted with low-energy shocks (<50 joules), but VF should always be defibrillated with high-energy shocks (200 to 360 joules). If the initial shock is not successful, the energy should be titrated up and several paddle positions tried before accepting failure. Traditional defibrillators deliver monophasic electrical impulses, whereas newer devices deliver biphasic impulses. These biphasic defibrillators require significantly reduced energy for successful arrhythmia termination and are more effective than monophasic systems. Many tachyarrhythmias recur after initially successful cardioversion. Administering an antiarrhythmic agent may help maintain sinus rhythm in these patients.

RADIOFREQUENCY CATHETER ABLATION, AUTOMATIC IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS, AND SURGICAL THERAPY

Radiofrequency Catheter Ablation

Because of the frequent recurrence of tachyarrhythmias despite pharmacologic therapy and the risk for pro-arrhythmia with most anti-arrhythmic agents, several non-pharmacologic approaches to the chronic management of tachyarrhythmias have been developed. Radiofrequency catheter ablation involves the application of alternating current electrical energy in the radiofrequency range to a strategically chosen area of the endocardium. An arrhythmogenic focus or the pathway by which the arrhythmia is perpetuated can be identified (mapped), and a radiofrequency-induced lesion can be created at that site, thereby eliminating (i.e., ablating) the arrhythmia. Ablation is effective in eliminating AFL and supraventricular tachyarrhythmias caused by accessory pathways (e.g., WPW syndrome) and dual pathways in the AV node such as AVNRT. The success rate of this procedure in curing these arrhythmias is greater than 95%. In addition, radiofrequency ablation is effective in treating AF, although the success rate is less with this arrhythmia. Ablation is associated with a relatively low risk for complications that include tamponade, stroke, and inadvertent complete AV block in up to 2% of patients, depending on the site of ablation. In patients with AF or AFL that is refractory to pharmacologic rate control, production of iatrogenic complete heart block by ablation of the AV node and subsequent placement of a permanent ventricular pacemaker offers a definitive method of controlling the ventricular rate. Catheter ablation of VT is more difficult than it is for SVT but can be effective in select patients. Patients with monomorphic VT in the absence of structural heart disease (e.g., RVOT-VT and idiopathic left VT) and patients with bundle branch reentry VT are good candidates, and success can be expected in about 90% of these instances. VT related to prior MI is difficult to treat with ablation, and such therapy should be attempted only if affected patients have incessant or recurrent VT despite anti-arrhythmic therapy.

Automatic Implantable Cardioverter-Defibrillators

ICD therapy is the anti-tachycardic equivalent of a pacemaker and is used for treating ventricular tachyarrhythmias. Similar to the pacemaker, the ICD has a generator that is buried in the pectoral region and is connected to an electrode that is placed transvenously and anchored to the endocardium. The device monitors heart rate and identifies a tachyarrhythmia as any rhythm that is faster than the rate programmed into the device. Most ICDs have several possible therapeutic responses to a sensed tachyarrhythmic event. Pacing the ventricle at a faster rate (antitachycardia pacing) may successfully terminate a relatively slow VT. If this level is not successful, the device may then deliver a 20- to 36-joule electrical discharge, which may be repeated several times at escalating energy levels in an attempt to terminate the tachyarrhythmia. Fast VT and VF are usually treated with high-energy shock, although painless

antitachycardia pacing has been used with some success in treating fast VT. All current devices also have pacemaker capabilities in the event of a bradyarrhythmia.

Implantable Cardioverter-Defibrillator Indications for Secondary Prevention

ICDs have been shown to decrease mortality compared with anti-arrhythmic therapy in survivors of VF or hemodynamically unstable VT. Trials during the 1990s suggested that sotalol and amiodarone are effective anti-arrhythmic drugs in the treatment of patients with SCD or recurrent VT. Several secondary prevention trials including the Antiarrhythmics Versus Implantable Defibrillators (AVID) trial significantly changed the therapeutic approach to SCD survivors. This study was a randomized trial of anti-arrhythmic therapy (primarily amiodarone) versus ICD implantation in patients with depressed ventricular function who had survived an episode of life-threatening ventricular tachyarrhythmia, and it demonstrated a mortality benefit with ICD therapy. Therefore, in SCD survivors in whom the event occurred in the absence of an acute MI or a reversible cause, and in patients with hemodynamically unstable VT, the implantation of an ICD is indicated.

Implantable Cardioverter-Defibrillator Indications for Primary Prevention

Perhaps the most effective method of treating SCD is by identifying patients at highest risk and instituting therapy aimed at preventing its occurrence. In the patient who has had an MI, several factors have been shown to be associated with an increased risk for SCD (see Table 10-4). The occurrence of frequent complex ventricular ectopy in patients after an acute MI is associated with a near tripling of the risk for subsequent SCD; however, attempts at suppression of these arrhythmias with anti-arrhythmic agents have resulted in an increased mortality. Several studies have, however, demonstrated a decrease in overall mortality, as well as in SCD, in patients treated with β -blocking agents after a MI. Therefore, these agents should be instituted in these patients unless a contraindication to their use exists. Patients who have had an MI with moderate left ventricular dysfunction, nonsustained VT on ambulatory ECG monitoring, and inducible monomorphic VT during EP testing have been shown to have an improved survival with ICD implantation (according to the Multicenter Unsustained Tachycardia Trial [MUSTT] and Multicenter Automatic Defibrillator Implantation Trial [MADIT]). Recently, the MADIT-II and Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) demonstrated improved survival with ICD therapy regardless of the presence of spontaneous or inducible ventricular arrhythmias. The MADIT-II trial was designed to evaluate the effect of prophylactic ICD therapy on survival in patients with prior MI and left ventricular ejection fraction of 30% or less. The trial was stopped in November 2001 because ICD therapy was shown to save lives. The SCD-HeFT trial compared ICD therapy with amiodarone and placebo in patients with ischemic or nonischemic dilated cardiomyopathy with a left ventricular ejection fraction of 35% or less, New York Heart Association Functional Classification II-III, and no history or

suspicion of sustained VT or VF. Similar to the MADIT-II, ICD therapy was shown to improve all-cause mortality in this patient population. As a result of these multicenter trials, patients with moderate to severe left ventricular dysfunction should be referred for an ICD implant for primary prevention of SCD.

Surgical Therapy

Given the effectiveness of radiofrequency ablation and ICDs, surgical therapy of tachyarrhythmias is rarely necessary. Surgery is occasionally used after failed ablation in patients with accessory bypass tracts and those with recurrent or incessant VT that failed medical therapy and ablation. In addition, in patients with refractory VT in the setting of a ventricular aneurysm, surgical aneurysmectomy may eliminate the arrhythmia, with a success rate of about 70%, and improves pharmacologic control of the arrhythmia in an additional 20% of patients.

Clinical Syndromes

LONG QT SYNDROME

LQTS refers to specific congenital and acquired abnormalities of repolarization that result in prolongation of the QT interval on the surface ECG (Table 10-10). This circumstance is defined as a QTc longer than 440 minutes (QTc equals the QT interval divided by the square root of the RR interval). Acquired forms are the result of various drugs or metabolic abnormalities. At least four separate genetic mutations account for the congenital forms of this disorder and do so by alterations in potassium or sodium channels. Congenital forms may be associated with deafness (Jervell and Lange-Nielsen syndrome) or occur in isolation (Romano-Ward syndrome). The significance of the LQTS is its association with the development of a specific type of VT called *torsades de pointes*. This arrhythmia occurs in the setting of a prolonged QT interval, is usually initiated with a VPC, occurs during the susceptible period of repolarization (i.e., at the peak of the T wave), and is characterized by

a wide-complex tachyarrhythmia with QRS complexes of varying axis and morphology that appear to rotate around the isoelectric baseline. Frequently, these episodes are self-limited, although syncope and sudden death may occur.

The treatment of *torsades de pointes* differs from that of other forms of VT. Many anti-arrhythmic agents prolong the QT interval and exacerbate the arrhythmia. Intravenous magnesium (2 to 3 g) is effective in terminating this arrhythmia even in the presence of normal serum magnesium levels. Treatment with isoproterenol or temporary transvenous pacing at rates of 100 to 120 beats/minute can effectively help prevent the arrhythmia, presumably through tachycardia-induced shortening of the QT interval. Removing the inciting agent is of paramount importance in acquired cases. Chronic treatment in patients with the congenital syndromes is with β -blocker therapy at the highest doses tolerated. Chronic pacemaker or ICD implantation, or both, is indicated in patients with recurrent arrhythmia despite β -blocker therapy. Screening family members of these patients is also important to identify those at risk for this arrhythmia.

SHORT QT SYNDROME

Short QT syndrome is a new clinical entity that is associated with a high incidence SCD, AF, or both. The diagnosis is made when a patient exhibits syncope and a corrected QT interval shorter than 320 minutes. Missense mutations in *KCNH2* (*HERG*) linked to a gain of function of the rapidly activating delayed-rectifier current *I(Kr)* have been identified in the first two reported families with familial SCD. In addition, two more gain-of-function mutations in the *KCNJ2* gene encoding the strong inwardly rectifying channel protein *Kir2.1* and in the *KCNQ1* gene encoding the α subunit of the *KvLQT1* (*I(Ks)*) channel confirmed a genetically heterogeneous disease. The treatment of choice for syncope or SCD is the implantation of an ICD. In the asymptomatic patient, the treatment remains unclear.

BRUGADA SYNDROME

Brugada syndrome is characterized by the presence of an ST-segment elevation in V_1 to V_3 that is unrelated to ischemia, structural heart disease, or electrolyte abnormalities. This syndrome has been linked to mutations in *SCN5A*, the gene encoding for the α subunit of the sodium channel. Brugada syndrome is a familial disease with an autosomal dominant mode of transmission and incomplete penetrance and is found in 5 to 66 per 10,000 persons. Unfortunately, syncope and SCD caused by rapid polymorphic VT are often the first symptoms in patients with this disease. Unlike ischemia-induced polymorphic VT, the arrhythmia in patients with Brugada syndrome often occurs during sleep. Elevated parasympathetic activity and sodium channel blockers such as procainamide and flecainide exacerbate the occurrence of ventricular arrhythmias in patients with Brugada syndrome. On the other hand, high catecholamine states, isoproterenol (Isuprel), and potassium I_{to} blockers such as quinidine are effective in suppressing ventricular arrhythmias in patients with this syndrome. Similar to other clinical syndromes associated with SCD, ICD implantation is the preferred therapy in patients with Brugada

Table 10-10 Conditions Associated with Prolongation of the QT Interval

Condition	Examples
Congenital	Romano-Ward syndrome (without deafness) Jervell and Lange-Nielsen syndrome (with deafness)
Acquired: drugs	Class IA and class III anti-arrhythmic agents Tricyclic antidepressants Phenothiazines Antibiotics (macrolides, pentamidine, trimethoprim-sulfamethoxazole) Terfenadine (especially when combined with macrolides or antifungal agents)
Metabolic	Hypokalemia Hypocalcemia Hypomagnesemia
Other	Liquid protein diets

syndrome and a history of near syncope, syncope, or SCD. In the asymptomatic patient, the performance of a diagnostic EP study for further risk stratification has been suggested. In patients with inducible sustained ventricular

arrhythmias, the implantation of an ICD has been shown to improve long-term outcome. In the asymptomatic patient with a negative EP study, close follow-up is usually sufficient.

Prospectus for the Future

- Identification of specific populations of patients with paroxysmal AF who benefit from pulmonary vein isolation and ablation for maintenance of sinus rhythm
- Evaluation of atrial pacing as a modality to prevent recurrences of AF
- Further clarification of which patient populations benefit from implantation of a cardioverter-defibrillator
- Programming of cardioverter-defibrillators to provide therapy before arrhythmia onset by identifying electrical characteristics that may predict impending arrhythmias (e.g., long RR intervals, R-on-T phenomenon, T-wave alternans)
- Progress on the development of genetically engineered biologic pacemakers as alternatives to mechanical pacemakers

Pericardial and Myocardial Disease

Josef Stehlik and Ivor J. Benjamin

Pericardial Disease

The pericardium is a protective sac around the heart composed of two distinct layers: the *visceral* pericardium, an inner layer tightly attached to the heart muscle, and the parietal pericardium, a fibrous outer layer. The space between the two layers is called *pericardial space* and is lubricated by 5 to 15 mL of clear pericardial fluid produced by the visceral pericardium.

ACUTE PERICARDITIS

Acute pericarditis, inflammation of the visceral and parietal pericardium, can result from a number of different causes. Although a definitive cause is often not determined (and the condition is then called *idiopathic pericarditis*), viral infection is probably the most common cause. *Viral pericarditis* is usually self-limiting, although occasionally the symptoms may recur once or more before complete resolution. Although less common, pericarditis caused by bacterial infection or tuberculosis can be life-threatening. Pericardial inflammation can also result from direct pericardial injury (trauma, injury early after myocardial infarction or pericardiectomy) due to autoimmune mechanisms (late after myocardial infarction—Dressler syndrome, in connective tissue disease) or to uremia. A comprehensive list of conditions that can affect the pericardium is shown in Table 11-1.

The classic clinical presentation of pericarditis is chest pain, typically abrupt in onset, sharp, worse in supine position, and relieved by sitting upright and leaning forward. On heart auscultation, the presence of a *pericardial rub* indicates contact between two inflamed layers of the pericardium. Pericardial rub usually has a characteristic high-pitched, leathery quality, with three components that correspond to movement of the heart during the cardiac cycle (ventricular systole, early ventricular diastole, and atrial contraction; not all three components are always audible). Serial auscultation is advised because the rub may be intermittent and vary in

intensity. The absence of an audible rub does not exclude the diagnosis of pericarditis. Chest pain from myocardial ischemia or pulmonary embolism may mimic pericarditis, and these conditions should be considered in the differential diagnosis.

Electrocardiogram (ECG) changes are common. During the acute phase, depression of the PR segments and diffuse ST-segment elevations are typical and result from inflammation of the myocardium adjacent to visceral pericardium. Flattening and inversion of T waves may also be present. Most of the ECG abnormalities resolve over several days to weeks, but T-wave abnormalities may persist longer. ST-segment elevations in pericarditis may be mistaken for the current of injury seen in ST-elevation myocardial infarction. In pericarditis, however, multiple leads are affected, reciprocal ST-segment depressions are not seen, and ECG changes evolve much slower than in acute myocardial infarction.

Laboratory testing in pericarditis often shows elevated erythrocyte sedimentation rate, C-reactive protein, and white blood cell count. Testing directed at excluding specific causes of pericarditis may include tuberculin skin test, evaluation of thyroid and renal function, antinuclear antibody, complement levels, rheumatoid factor, and human immunodeficiency virus (HIV) serologic testing. Viral serologic studies have been insensitive and generally do not alter the therapeutic decision. Cardiac enzymes (serum levels of creatine kinase muscle band [CK-MB], troponin) may be elevated as a result of concomitant involvement of the myocardium. Chest radiographic and echocardiographic findings are normal unless pericardial effusion is also present.

The treatment of acute pericarditis is directed at managing the underlying cause and providing pain relief. For most patients, nonsteroidal anti-inflammatory drugs are effective in relieving the chest discomfort and facilitating the resolution of inflammation; colchicine can be an effective alternative. Glucocorticoids are used if the former therapy is not sufficiently effective. Although most cases of idiopathic and

viral pericarditis are self-limited, complications include recurrences, large pericardial effusion, cardiac tamponade, and pericardial constriction. These conditions are discussed later in more detail.

PERICARDIAL EFFUSION

Pericardial effusion is an abnormal accumulation of fluid within the pericardial space. Most causes of pericarditis can result in pericardial effusion (see Table 11-1). Additional causes include hypothyroidism, *chylopericardium* (accumulation of chylous from an injured thoracic duct) and *hemopericardium* (accumulation of blood in the pericardial space). *Hemopericardium* most often results from direct trauma (thoracic injury, pacemaker placement, coronary intervention, endomyocardial biopsy), cardiac rupture after myocardial infarction, or aortic dissection communicating with the pericardial space.

Symptoms of pericardial effusion depend on its size and rate of accumulation. Effusions that accumulate slowly are initially asymptomatic; significant accumulation of pericardial fluid may result in chest pressure as well as symptoms related to compression of adjacent structures. Pressure on the phrenic nerve, recurrent laryngeal nerve, lungs, or esophagus will cause cough, hoarseness, dyspnea and dysphagia. Maybe more importantly, pericardial effusion can result in hemodynamic compromise. When accumulation is

slow, the pericardial space can accommodate up to 2 liters of fluid without a significant increase in pericardial pressure. However, a rapidly accumulating effusion, such as in hemopericardium caused by trauma, may result in severe hemodynamic compromise with the collection of as little as 100 to 200 mL of fluid (see “Cardiac Tamponade”).

The physical examination in a patient with a small pericardial effusion is often normal. If the effusion is large, the apical impulse may be difficult to palpate, and the heart sounds may be muffled. On chest radiographic examination, the cardiac silhouette may be enlarged. On ECG, a large pericardial effusion will result in low voltage of QRS complexes; the amplitude of the QRS complexes may vary from beat to beat, an abnormality thought to be secondary to changes in the electrical axis resulting from the heart’s swinging motion within the pericardial sac (*QRS alternans*). Echocardiography is a sensitive test for detection of pericardial effusion and provides an accurate assessment of its size, location, and hemodynamic significance. Computed tomography (CT) and magnetic resonance imaging (MRI) also detect the presence of pericardial effusion with high accuracy and may determine the cause of the pericardial effusion through evaluation of surrounding structures and enhanced myocardial tissue characterization.

Drainage of the pericardial fluid by percutaneous fine-needle aspiration (*pericardiocentesis*) can be performed for diagnostic and therapeutic reasons. In general, diagnostic pericardiocentesis is usually of low yield and should be reserved for patients with persistent (>2 weeks) pericardial effusion or suspected purulent or tuberculous pericarditis. Pericardiocentesis is usually performed in the cardiac catheterization laboratory under fluoroscopic or echocardiographic guidance. Laboratory analysis of the fluid includes hematocrit and cell count determination; glucose, protein, cholesterol and triglyceride levels; Gram stain; and cultures. Examination for acid-fast bacilli is done when tuberculous disease is suspected. Tuberculous pericarditis is also associated with elevated levels of adenosine deaminase in the fluid. When appropriate, cytologic examination to rule out malignancy is done. Elevated triglyceride level suggests a chylous effusion seen in thoracic duct injury, and a high level of cholesterol suggests hypothyroidism as the cause. When the diagnosis remains unclear after fluid analysis, a sample of the pericardium can be obtained by surgical excision. Tissue examination is especially important when an effusion results from a chronic infectious process, such as tuberculosis, because pericardial fluid alone identifies the organism only in a minority of patients. Therapeutic pericardiocentesis is performed to remove pericardial fluid in patients with effusions resulting in significant symptoms or when there is evidence of hemodynamic compromise. For patients with recurrent effusions, pericardiectomy (pericardial window) may provide a longer-term continuous drainage into the pleural or peritoneal cavity.

The treatment for asymptomatic pericardial effusions is directed at the underlying illness, and, in turn, the prognosis depends on the underlying disease.

CARDIAC TAMPONADE

Cardiac tamponade occurs when pericardial effusion causes an increase in pericardial pressure that impairs proper

cardiac function. Hemodynamic compromise is a result of impaired filling of the cardiac chambers. The right atrium and right ventricle are first to be affected, and compression of left-sided chambers follows with further pericardial pressure increase. As a result, the cardiac stroke volume declines, and systemic blood pressure drops. Compensatory activation of the adrenergic system results in tachycardia and an increase in systemic vascular resistance. The amount of pericardial fluid necessary to cause tamponade depends on the rate of its accumulation. In addition, the state of intravascular volume will affect symptoms—decreased preload (e.g., in dehydration) exacerbates the hemodynamic changes, and high preload counteracts the effects of high pericardial pressures.

Fatigue, dyspnea, and lightheadedness are the main symptoms when pericardial fluid accumulates slowly. Rapid fluid accumulation leading to acute tamponade results in loss of consciousness and shock.

The classic diagnostic triad seen on physical examination includes hypotension, jugular venous distention (with absent y descent), and muffled heart sounds. Tachypnea, tachycardia, and hypotension are also present. *Pulsus paradoxus*, a decrease in the systemic systolic blood pressure of more than 10 mm Hg with inspiration, is an additional characteristic finding. Under normal conditions, intrathoracic pressures decrease during inspiration, which leads to an increase in venous blood return from the periphery and an increase of right ventricular filling. As a result, the right ventricle increases in size to accommodate the extra volume. In cardiac tamponade, the compressive effect of the pericardial fluid limits expansion of the right ventricle into the intrathoracic cavity, and instead the interventricular septum is displaced toward the left ventricle, impairing left ventricular filling. This results in lower left ventricular stroke volume and lower systemic blood pressure. In expiration, the interventricular septum returns to midline, and systemic pressure recovers. *Pulsus paradoxus* is not specific for cardiac tamponade. It may occur in chronic obstructive pulmonary disease, asthma, severe congestive heart failure, pulmonary embolism, and, in some instances, constrictive pericarditis.

If the effusion is large, the chest radiographic examination may reveal an enlarged globular (flask-shaped) cardiac silhouette. The ECG may show reduced voltage and electrical alternans (see explanation under “Effusive Constrictive Pericarditis”). Echocardiography is the gold standard for noninvasive assessment and demonstrates the pericardial effusion and its hemodynamic effects: compression of the right atrium, compression of the right ventricle in diastole, increased flow into the right ventricle, leftward bulging of the interventricular septum, and decreased left ventricular filling during inspiration. The inferior vena cava is typically distended. Right-sided heart catheterization can also be used to determine the hemodynamic significance of pericardial effusion. Typically, the pressure in the atria and diastolic pressure in the ventricles are elevated and equalized in all four chambers. This pressure is equal to the elevated pericardial pressure, which can be measured with a pericardial catheter.

Cardiac tamponade is a medical emergency and requires immediate treatment. Temporizing measures include immediate initiation of intravenous hydration, which increases

preload and aids in filling of the cardiac chambers. The effect of this therapy will only be temporary, however. Vasopressors may be necessary to support systemic blood pressure. The definitive treatment is pericardiocentesis, which usually leads to quick improvement of hemodynamics. If the effusion is recurrent or loculated, surgical drainage might be necessary. Treatment of the condition that leads to formation of the pericardial effusion is also necessary.

CONSTRICTIVE PERICARDITIS

Constrictive pericarditis results from scarring of the pericardium in response to various inflammatory conditions. It is characterized by a thickened, fibrotic (or calcified) pericardium that restricts diastolic filling of the heart. The disease process is often diffuse and symmetrical and results in elevated and equalized diastolic pressures in all four cardiac chambers. In contrast to pericardial tamponade, in which ventricular filling is impaired throughout diastole, early diastolic filling in constrictive pericarditis is not impaired but is slowed in mid and late diastole as the ventricles meet the resistance of the thickened pericardium.

Historically, the most common cause of pericardial constriction was tuberculous pericarditis that often leads to thickening and calcification of the pericardium. Currently, pericardial constriction is most often a sequel of nontuberculous pericarditis caused by viral infection, radiation exposure, connective tissue disorders, and thoracotomy, for example. Frequently, the exact cause will not be identified.

Symptoms of pericardial constriction are typically symptoms of right heart failure, and the onset is often insidious. Patients present with fatigue and dyspnea, abdominal pain, hepatic distension, ascites, and lower extremity swelling. On physical examination, the jugular veins are distended. Changes in intrathoracic pressure are not transmitted to the heart encased in thickened pericardium, and as a result, the jugular pressure during inspiration stays the same or increases (*Kussmaul sign*), rather than falling. There are prominent x and y descents in the jugular venous tracing. In contrast to pericardial tamponade, *pulsus paradoxus* is not typically present. On cardiac examination, an early diastolic sound (*pericardial knock*) that follows the aortic component of the second heart sound may be heard at the left sternal border. The pericardial knock corresponds to abrupt cessation of early, rapid diastolic filling.

Diagnosis of pericardial constriction may be difficult. Chest radiography may reveal pericardial calcification and pleural effusions. Echocardiographic examination may show thickened pericardium with reduced mobility, abnormalities of ventricular septal wall motion, and dilation of the inferior vena cava. Doppler echocardiography demonstrates abnormal flow velocities in the pulmonary and hepatic veins and an abnormal pattern of ventricular diastolic filling. CT and MRI can be used to measure pericardial thickness. MRI can also assess mobility of the pericardium and hemodynamic changes associated with constrictive pericarditis. Right-sided heart catheterization is used to confirm the diagnosis. Typical findings include prominent x and y descents in atrial tracings and elevation and equalization of atrial and ventricular diastolic pressures. The early diastolic pressure in the ventricles is normal; the early diastolic ventricular filling is rapid

Figure 11-1 Pressure recordings in a patient with constrictive pericarditis: simultaneous right ventricular and left ventricular pressure tracings with equalization of diastolic pressure, as well as *dip-and-plateau* morphology.

owing to elevated atrial pressure, and it slows abruptly in mid and late diastole as the ventricular volume reaches the limit set by the nondistensible pericardium. This characteristic appearance of the diastolic ventricular pressure curve—low early diastolic pressure that rises quickly and plateaus in late diastole, has been called the *dip-and-plateau sign* or the *square-root sign* (Fig. 11-1). Although many of the hemodynamic findings are similar to those seen in restrictive pericarditis, in pericardial constriction, the left and right ventricular diastolic pressure tracings are nearly superimposable and do not change with volume loading or exercise.

The treatment of constrictive pericarditis consists of salt restriction and use of diuretics to control the excess volume. If symptoms cannot be controlled by medical therapy, surgical removal of the pericardium (*pericardiectomy*) is recommended. In pure pericardial constriction, pericardiectomy is effective and leads to resolution of symptoms. Some patients, especially those with radiation heart injury, may have a combination of pericardial constriction and myocardial restriction. In these patients, pericardiectomy might lead only to partial improvement.

EFFUSIVE CONSTRICTIVE PERICARDITIS

Effusive constrictive pericarditis refers to a syndrome in which there is pericardial effusion as well as abnormally tense noncompliant visceral pericardium. It may represent an intermediate stage in the development of constrictive pericarditis. The clinical features resemble those of both tamponade and constriction. Drainage of the pericardial fluid leads to drop of the intrapericardial pressure; however, features of constrictive physiology remain. Effusive constrictive pericarditis can result from pericarditis of any cause but is more commonly seen with radiation-induced pericarditis.

The diagnosis of effusive constrictive pericarditis is generally made after successful pericardiocentesis does not lead to resolution of symptoms and hemodynamic abnormalities. If constriction is confirmed, pericardiectomy is the treatment of choice.

Diseases of the Myocardium

MYOCARDITIS

Myocarditis is an inflammatory process that affects the myocardium. Most cases of myocarditis are attributed to viral infection (*viral myocarditis*), but other infectious and noninfectious triggers also lead to myocardial inflammation.

Viruses most commonly associated with viral myocarditis are enteroviruses, specifically Coxsackie group B serotypes, adenoviruses, parvovirus B19, hepatitis C virus, cytomegalovirus, and HIV. The pathogenesis of viral myocarditis is believed to evolve in several phases. Initially, during the active viremia, the viruses infect the myocytes, and this is followed by cellular and antibody-mediated immune response. Although normal immune response will lead to viral clearing and myocardial healing, abnormal immune response can cause myocardial damage. This abnormal immune response leads to inflammatory cellular infiltration of the myocardium with T lymphocytes and macrophages, production of a wide range of pro-inflammatory cytokines (interleukins, tumor necrosis factor) that have negative inotropic effects, and production of autoantibodies directed against myocardial proteins. Although viral replication in the myocytes contributes to myocardial dysfunction, it is the immune response of the organism that is believed to result in the potentially permanent myocardial damage. In this last stage, which happens only in some patients, dilated cardiomyopathy and heart failure develop. The exact mechanisms of this process are not known, but it is believed that the cytokines, autoantibodies, and possibly other processes associated with persistent low-level viral replication in myocytes lead to myocyte atrophy, myocyte apoptosis, and adverse remodeling of the ventricles. It is believed that viral myocarditis accounts for more than one fifth of cases of nonischemic cardiomyopathy.

Many nonviral infectious agents also cause myocarditis. The most common bacterial infections in which myocarditis is seen are diphtheria, brucellosis, clostridial infections, legionnaires disease, meningococcal infections, streptococcal infection, and *Mycoplasma pneumoniae* infections. In many of these, the damage is attributed to the bacterial toxins, and myocardial function is expected to recover with treatment of the underlying infection. Rickettsial infections (Q fever, Rocky Mountain spotted fever), spirochetal infections (leptospirosis, Lyme disease), and fungal infections can also be complicated by myocarditis. In Central and South America, myocarditis caused by infection with protozoa *Trypanosoma cruzi* results in dilated cardiomyopathy (Chagas disease). Treatment with antiprotozoal therapy, if initiated early in the course of infection, may be beneficial; however, the myocardial damage seen in this parasitic infection is largely immune mediated.

Numerous noninfectious causes of myocarditis have also been described. Multiple chemicals and drugs can lead to myocardial inflammation by direct effect or as part of a hypersensitivity reaction. Some of the common causes include cocaine, chemotherapeutics (daunorubicin, doxorubicin), and antibiotics, among many others.

A distinct entity is *giant cell myocarditis*, which is usually associated with ventricular arrhythmias and progressive severe heart failure. The cause of this disease is not known, but it is believed to result from an autoimmune process. Multinucleated giant cells seen on myocardial biopsy are pathognomonic.

The clinical features of inflammatory myocarditis vary from asymptomatic to life-threatening presentations. The acute stage of viral myocarditis usually presents with symptoms of acute viral illness—fevers, muscle aches, fatigue. Patients usually seek medical attention once symptoms of heart failure develop, including exertion intolerance, shortness of breath, fluid retention, and persistent fatigue. In most cases, these symptoms develop several weeks after the acute viral illness has resolved. Presentation in patients with nonviral infectious myocarditis includes a combination of the primary infectious process and heart failure symptoms.

On physical examination, the patients are often tachycardic and hypotensive. Findings of heart failure—elevated jugular venous pressure, S₃ gallop, crackles, and peripheral edema, may be seen.

Elevated levels of serum cardiac enzymes (troponin, CK-MB) support the suspicion of myocardial injury in myocarditis. Testing aimed at determining the possible infectious etiology should be performed. Rising viral titers are often seen in viral myocarditis. Sinus tachycardia and nonspecific ST- and T-wave abnormalities are common ECG findings. When pericardium is also involved by the inflammatory process, diffuse ST-segment elevations typical for acute pericarditis are also seen. Ventricular ectopy is frequent, and atrioventricular conduction defects are seen in myocarditis associated with Lyme disease. Echocardiography will determine the presence of ventricular remodeling, including increasing chamber size and presence of ventricular systolic dysfunction. Increasingly, MRI has been used because it can detect focal changes in myocardial tissue that are highly suggestive of an inflammatory process. The role of transvenous endomyocardial biopsy in diagnosing acute myocarditis is evolving. The biopsy can detect the presence of infiltrating white cells (macrophages, lymphocytes, eosinophils), evidence of myocardial damage, and interstitial fibrosis. Although the presence of these histopathologic abnormalities is used to determine whether acute myocarditis is present, there is significant intraobserver and interobserver variability in evaluating these changes, and maybe more importantly, the biopsy findings often do not provide a conclusive diagnosis. A descriptive term of *acute lymphocytic myocarditis* is used when there is clear evidence of inflammation and the presence of infiltrating lymphocytes. There are some situations, however, in which endomyocardial biopsy will prove helpful, such as in giant cell myocarditis (multinucleated giant cells are seen) or hypersensitivity myocarditis (eosinophilic infiltrate is seen). Polymerase chain reaction to detect specific viral genomes in the myocardium can also be performed.

To date, no effective therapy for viral myocarditis has been established. Empiric trials in which specific antiviral agents are administered based on genomic diagnosis have for the most part enrolled only a small number of patients and lack long-term follow-up. Clinical trials of various forms of immunosuppressive therapy (prednisone, cyclosporine, azathioprine, intravenous immunoglobulin, interferon, immunoadsorption) have so far not resulted in conclusive evidence of benefit. The treatment of cardiomyopathy believed to have resulted from viral myocarditis is similar to that of nonischemic cardiomyopathy of other etiologies. β -adrenergic blockers, angiotensin-converting enzyme inhibitors, aldosterone receptor blockers, and diuretics are the mainstay of medical therapy; mechanical circulatory support and heart transplantation are considered for those who do not stabilize with medical therapy. The natural history of acute viral myocarditis is hard to determine because of the difficulties associated with establishing the diagnosis. It is believed, however, that roughly one third of the patients will recover fully, one third of the patients will have some sequelae in the form of left ventricular systolic dysfunction but be stable on medical therapy, and one third of patients may progress to advanced heart failure.

Treatment of nonviral infectious myocarditis is aimed at eradication of the specific infection. Hypersensitivity myocarditis and myocarditis associated with toxins responds to withdrawal of the offending agent. Immunosuppressive therapy has shown to be effective in giant cell myocarditis.

Patients with myocarditis should not participate in competitive sports for at least 6 months after the onset of clinical manifestations. Athletes may return to training and competition after this period if cardiac size and function return to normal, clinically relevant arrhythmias are absent, and serum markers of inflammation have normalized.

CARDIOMYOPATHIES

Cardiomyopathies are a heterogeneous group of diseases of the myocardium associated with structural and functional abnormalities. Different classifications of cardiomyopathies abound, and there are frequent changes to the classifications as a result of our better understanding of mechanisms of disease. The four main cardiomyopathic groups identified based on structural and functional characteristics are dilated, hypertrophic, restrictive, and arrhythmogenic right ventricular cardiomyopathy. Both familial (genetic) and nonfamilial (acquired) forms of the diseases have been described.

DILATED CARDIOMYOPATHY

Dilated cardiomyopathy (DCM) is characterized by enlargement and impaired systolic function of the left ventricle or both the left and right ventricles. Although abnormal loading conditions such as hypertension or valvular disease, as well as coronary artery disease, can lead to similar structural and functional changes (i.e., *hypertensive, valvular, or ischemic cardiomyopathy*), these conditions are not considered to be part of the DCM group and are discussed elsewhere. DCM can be familial (genetic) or acquired (Table 11-2).

Table 11-2 **Cardiomyopathies**

Disorder	Description, Cause
Dilated cardiomyopathy	Dilation and impaired systolic function of the left or both ventricles
Familial (genetic)	Known or unknown genetic mutations
Nonfamilial	Viral myocarditis, nonviral infective myocarditis, idiopathic (immune) myocarditis Toxins (drugs, alcohol) Pregnancy (peripartum cardiomyopathy) Nutritional (thiamine deficiency—beriberi, vitamin C deficiency—scurvy, selenium deficiency) Endocrine (diabetes mellitus, hyperthyroidism, hypothyroidism, hyperparathyroidism, pheochromocytoma, acromegaly) Autoimmune (rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis) Tachycardia induced
Hypertrophic cardiomyopathy	Left and/or right ventricular hypertrophy, often asymmetrical (usually more prominent hypertrophy of interventricular septum)
Familial (genetic)	Mutations of sarcomeric proteins (several hundred described so far) Metabolic storage diseases of the myocyte
Restrictive cardiomyopathy	Restrictive filling of the ventricles; ventricles are usually small, atria are markedly enlarged
Familial (genetic)	Mutations of sarcomeric proteins Familial amyloidosis (transthyretin, apolipoprotein) Hemochromatosis Desminopathy, pseudoxanthoma elasticum, glycogen storage diseases Unknown genetic mutations
Nonfamilial	Amyloidosis, sarcoidosis, carcinoid, scleroderma Endomyocardial fibrosis (hypereosinophilic syndrome, idiopathic, chromosomal cause, drugs) Radiation, metastatic cancer, anthracycline toxicity
Arrhythmogenic right ventricular	Progressive fibrofatty replacement of the right and, to lesser degree, left ventricular cardiomyopathy; familial, unknown gene
Familial	Unknown mutation Mutations of intercalated disk protein, cardiac ryanodine receptor, transforming growth factor- β 3
Unclassified Cardiomyopathies	
Takotsubo (stress-induced) cardiomyopathy	Transient dilation and dysfunction of the distal parts of the left ventricle (apical ballooning) seen in the setting of a stressful situation; usually resolves within weeks
Left ventricular noncompaction	Characterized by prominent left ventricular trabeculae and deep intertrabecular recesses; familial in most cases, caused by arrest in the normal embryogenesis of the heart; apex and periapical regions of the left ventricle most affected; some patients remain asymptomatic, others develop left ventricular dilation and systolic dysfunction
Cardiomyopathies associated with muscular dystrophies and neuromuscular disorders	Duchenne-Becker muscular dystrophy, Emery-Dreifuss muscular dystrophy, myotonic dystrophy, Friedreich ataxia, neurofibromatosis, tuberous sclerosis
Ion channelopathies	Disorders caused by mutations in genes encoding ionic channel proteins; not typically considered cardiomyopathies because they are not associated with typical structural changes of the heart but rather present with electrical dysfunction; some classifications now include these disorders as cardiomyopathies; long-QT syndrome, short-QT syndrome, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia

About one fourth of cases of DCM are familial, caused by genetic mutations. Some of the specific mutations that have been described involve genes that encode proteins of the sarcomere, cytoskeleton, nuclear membrane, and mitochondria; many mutations remain unknown. The mode of inheritance is typically autosomal dominant.

Nonfamilial DCM has different causes. Most cases are believed to be a result of acute viral myocarditis, a process described in detail earlier in this chapter. Exposure to cardiac

toxins can also lead to DCM. Anthracyclines, such as doxorubicin (Adriamycin), daunorubicin, and chemotherapeutic agents frequently used to treat hematologic malignancies, cause a dose-dependent cardiac toxicity. Despite the use of routine echocardiographic screening and discontinuation of anthracycline therapy when signs of ventricular dysfunction develop, this is still a frequent cause of DCM.

Long-term exposure to alcohol is an important preventable cause of DCM. The risk is seen when more than 90 g of

alcohol (about seven standard alcoholic drinks) is consumed daily for more than 5 years; lower exposure may lead to cardiomyopathy in women. Abstinence from alcohol may lead to sustained improvements in ventricular function.

Deficiency of certain nutrients—thiamine (beriberi), vitamin C (scurvy), carnitine, selenium, phosphate, and calcium—can also lead to DCM.

Peripartum cardiomyopathy is a form of idiopathic DCM that develops during the last month of pregnancy or within several months of delivery. The pathogenesis of this often life-threatening disease is not completely understood; autoimmunity, concurrent viral myocarditis, and hemodynamic stress of pregnancy have all been suggested as possible causes.

Prolonged periods of supraventricular or ventricular tachycardia can lead to idiopathic DCM (tachycardia-induced cardiomyopathy). The structural and functional changes usually reverse after the rapid heart rhythm is controlled.

The development of the structural and functional changes of DCM can be gradual, and many patients are asymptomatic for a significant amount of time. The first presentation of DCM is usually due to symptoms of heart failure, including fatigue, weakness, dyspnea, and edema. In some patients, the presenting episode is related to arrhythmia or an embolic event.

On physical examination, tachycardia is often present, with a narrow pulse pressure, as well as tachypnea and jugular venous distention. The cardiac examination reveals a laterally displaced apex. S_3 gallop is common; murmurs of mitral and tricuspid regurgitation are frequently heard because of dilation of the mitral and tricuspid annuli caused by ventricular enlargement. Crackles indicating pulmonary edema may be present over the lung fields, and breath sounds may be diminished if pleural effusions are present. In some patients, the clinical features of right ventricular heart failure may predominate, with hepatomegaly, ascites, lower extremity edema, and anasarca.

Diagnostic testing will show cardiomegaly, pulmonary venous congestion, and pleural effusions on chest radiography. Serum B-type natriuretic peptide (BNP) levels are elevated. ECG will determine the cardiac rhythm and will usually show only nonspecific ST- and T-wave abnormalities. Echocardiography provides a comprehensive evaluation of ventricular size and function, detects abnormalities of valvular function, and can also show the presence of a ventricular thrombus. Similar information can be now obtained with MRI. Complete work-up should rule out ischemic, valvular, and hypertensive heart disease as the etiology of myocardial dysfunction and should also include evaluation for potentially reversible causes of DCM (e.g., alcohol, nutritional deficiencies). Myocardial biopsy may be considered if the etiology of DCM is in question. In patients with a strong family history, a referral for genetic testing should be considered.

Management of patients with DCM will entail long-term therapy. First, potential reversible causes of DCM should be addressed (e.g., alcohol cessation, correction of nutritional deficiencies, removal of cardiotoxic agents). Loop diuretics are used to decongest patients who show signs of fluid overload. Although this therapy is clearly associated with symptom improvement, especially dyspnea, the effect of

diuretic on survival has not been well studied. A number of medication classes have been extensively studied in heart failure in respect to long-term morbidity and mortality. Vasodilators, such as angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and hydralazine, in combination with nitrates, have been shown to reduce both morbidity (hospital readmissions) and mortality of patients with systolic dysfunction of the left ventricle. Their effect is through decrease of left ventricular afterload. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers have additional beneficial effects associated with the blockade of the rennin-angiotensin-aldosterone axis. Blockade of the adrenergic system, which contributes to the detrimental remodeling of the left ventricle, has also been shown to decrease morbidity and mortality. The compounds studied in heart failure include carvedilol, metoprolol succinate, bisoprolol, and, in a subgroup of patients, bucindolol. β -adrenergic blockers should be avoided in cardiogenic shock and in patients with marked fluid overload. Aldosterone receptor blockade with spironolactone or eplerenone has also been shown to reduce long-term morbidity and mortality. Digitalis is used in patients with symptoms despite the use of therapies with proven mortality benefit. Although digitalis does not reduce mortality, it has been shown to reduce hospitalization for heart failure.

Patients with idiopathic DCM and persistent moderate to severe symptoms of heart failure, who also have a QRS duration longer than 120 milliseconds (evidence of dyssynchrony of left ventricular contraction), may benefit from cardiac resynchronization therapy with a biventricular pacemaker. The concurrent pacing of both left and right ventricle leads to a more efficient contraction, improvement of symptoms, and probably a survival benefit. Patients with idiopathic DCM are at an increased risk for possibly fatal ventricular tachycardia and ventricular fibrillation. Survival of patients with a left ventricular ejection fraction less than 35% despite maximal medical management has been shown to be improved with the use of implantable cardioverter-defibrillators (ICDs).

Patients with limiting heart failure symptoms despite the use of the previously described therapies may be considered for heart transplantation or support with a left ventricular assist device.

The prognosis of patients with DCM depends on the response to medical therapy. Although some patients will see a significant improvement in symptoms and cardiac function, in others, the disease will be progressive and associated with a high mortality rate.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) is characterized by left ventricular hypertrophy with nondilated or even small left ventricular cavity size and absence of an apparent cause for hypertrophy (e.g., hypertensive disease or aortic stenosis). This is a relatively common genetic disease (1 in 500 in the general population) with autosomal dominant inheritance. More than 400 individual mutations on 11 different genes encoding proteins of the cardiac sarcomere have been described, with mutations of the β -myosin heavy chain being the most frequent. Sporadic forms of the disease are believed to be a result of spontaneous mutations. The

microscopic phenotype includes cardiomyocyte hypertrophy, myofibrillar disarray, and interstitial fibrosis.

An additional group of diseases have recently been added to the category of HCM. These are metabolic storage diseases that result in changes in myocardial appearance that resemble changes caused by the classic sarcomeric mutations. These include glycogen storage diseases, lysosomal storage diseases, disorders of fatty acid metabolism, and mitochondrial cytopathies—all caused by mutations of nonsarcomeric proteins.

The phenotypical expression of the disease varies not only based on the specific mutation but also within families. This is probably due to different penetrance as a result of various largely unknown environmental factors.

The main pathophysiologic abnormalities seen in HCM are left ventricular outflow obstruction, diastolic dysfunction, mitral regurgitation, and arrhythmias. Obstruction of left ventricular outflow occurs in roughly half of the patients (hence the old terms *hypertrophic obstructive cardiomyopathy* and *idiopathic hypertrophic subaortic stenosis*). During systole, the hypertrophied septum bulges into the left ventricular outflow tract, creating a gradient between the lower part of the left ventricular cavity and the left ventricular outflow. This causes high-velocity turbulent flow through the narrowed path, which results in a suction force (Venturi effect) that pulls the anterior leaflet of the mitral valve into the outflow tract. This not only further worsens the obstruction but also causes mitral regurgitation. The relaxation properties of the abnormal myocardium are impaired, sufficient filling of the left ventricle requires higher than normal pressures, and the stroke volume is limited. This is called diastolic dysfunction. Patients with HCM are also predisposed to supraventricular and ventricular arrhythmias.

The symptomatic presentation of HCM varies as a result of the wide phenotypical spectrum. Some patients are asymptomatic, and HCM is diagnosed incidentally. Others present with symptoms resulting from the dynamic obstruction to left ventricular outflow and diastolic dysfunction. The most frequent symptom is dyspnea on exertion, which causes marked elevation of left ventricular filling pressures and pulmonary venous pressures, pulmonary congestion, and limitation in cardiac output. Ischemic chest pain can occur in the absence of epicardial coronary artery disease and is caused by increased oxygen demand by the hypertrophied ventricle and elevated wall tension that reduces blood flow to the subendocardium. Abnormalities of the structure of small myocardial arteries in HCM can also contribute to myocardial ischemia. Presyncope or syncope can be a result of outflow tract obstruction and inability to increase cardiac output during exertion, or a result of arrhythmias that can be triggered by exertion. In some, sudden death caused by ventricular arrhythmia is the initial manifestation of the disease.

A number of important findings can be found on physical examination. Patients with obstruction to flow have *pulsus bisferiens*—brisk initial upstroke in pulse followed by a mid-systolic dip corresponding to the development of left ventricular outflow tract obstruction, followed by another rise in late systole. Precordial examination shows a forceful and sustained apical impulse. Decreased compliance of the left ventricle during atrial contraction may lead to an audible S₄ gallop. Turbulent flow through the outflow tract causes a

harsh crescendo-decrescendo systolic murmur best heard along the left sternal border with radiation to the base of the heart. Patients may also have an apical holosystolic murmur of mitral regurgitation. The intensity of the murmur of HCM will change with changing degrees of obstruction. This can be observed with physiologic or pharmacologic maneuvers that change preload (left ventricular filling) or contractility. The intensity of the murmur will increase with Valsalva maneuver, with assuming a standing position, and after administration of nitroglycerin or inotropic drugs. The intensity of the murmur will decrease with squatting, volume loading, and administration of β -adrenergic blockers.

The ECG in HCM typically shows increased QRS voltage suggestive of left ventricular hypertrophy. Secondary ST depressions and deep T-wave inversions are also seen. In some patients, a pseudoinfarct pattern with Q waves in the inferior, lateral, or anterior leads is seen and reflects depolarization of the abnormally hypertrophic myocardium. Echocardiography and MRI are helpful in confirming the diagnosis and allow for evaluation of the degree and location of the hypertrophy, the presence and degree of outflow obstruction, and the presence of systolic anterior motion of the anterior mitral leaflet. Doppler echocardiography can be used to monitor for changes in the gradient during provocative maneuvers or for assessment of treatment effect. Echocardiography is also used for screening of family members of patients newly diagnosed with HCM. Cardiac catheterization can be used when echocardiography is inadequate in defining the severity of obstruction. It can confirm the presence of the intracavitary gradient and evaluate for changes in the gradient to the maneuvers described previously.

Management of HCM is aimed at reducing the left ventricular outflow obstruction, improving diastolic dysfunction, and reducing the risk for sudden cardiac death. β blockers and calcium channel blockers improve symptoms in many patients. The benefits are derived from a decrease in heart rate (which prolongs diastole and allows for improved ventricular filling) and decreased contractility (which relieves the severity of left ventricular outflow tract obstruction). Disopyramide, a medication with potent negative inotropic effects, has also been used. In some patients, significant symptoms due to persistent obstruction persist despite medical therapy, and in this situation, nonpharmacologic therapies should be considered. A dual-chamber pacemaker with intentional pacing of the right ventricle may decrease the obstruction by altering the sequence of ventricular contraction. A more predictable response is seen with surgical myectomy, in which resection of the basal anterior septum typically results in dramatic relief of the obstruction and improvement of symptoms (Fig. 11-2). Long-term follow-up studies after septal myectomy show lasting improvements in symptoms and exercise capacity without recurrence of outflow tract obstruction.

A less invasive alternative to septal myectomy is alcohol-induced septal ablation performed percutaneously in the cardiac catheterization laboratory. Alcohol is selectively injected into the septal perforator (a branch of the left anterior descending coronary artery), which provides blood supply to the proximal septum. This produces a controlled myocardial infarction and eventual thinning of the septum,

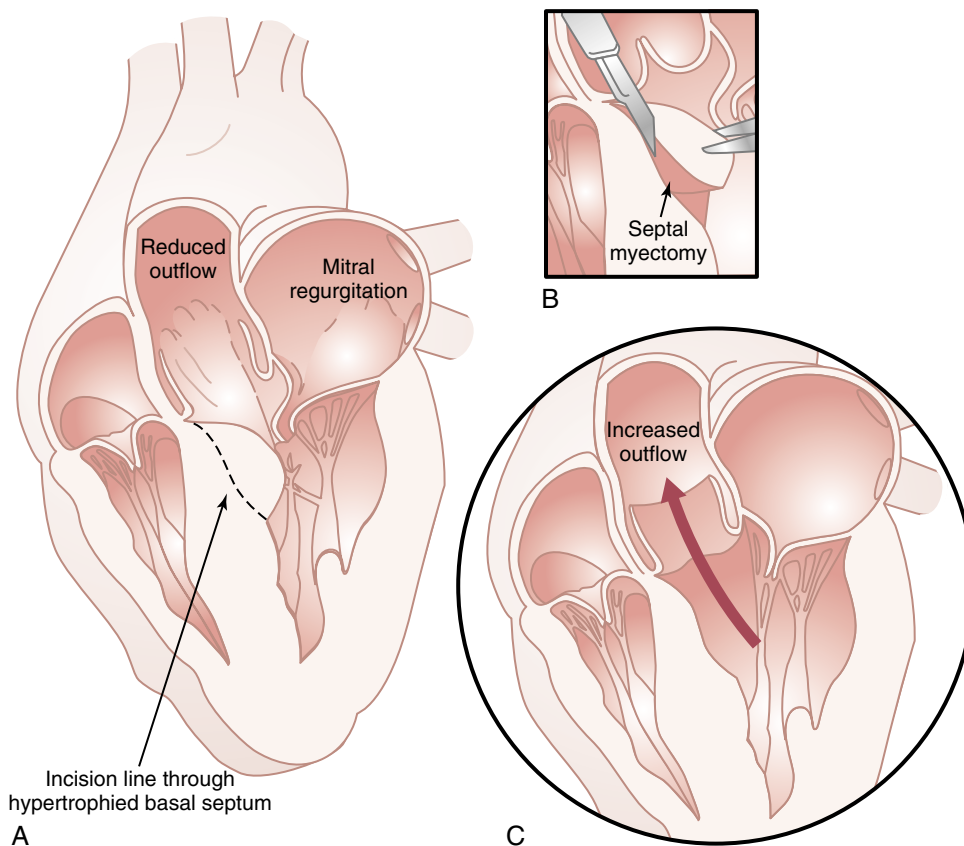

Figure 11-2 Schematic diagram of a patient undergoing surgical septal myectomy. (From Nishimura RA, Holmes DR Jr: Clinical practice: Hypertrophic obstructive cardiomyopathy. *N Engl J Med* 350:1320-1327, 2004.)

which widens the left ventricular outflow and decreases the outflow gradient. Both surgical septal myectomy and alcohol septal ablation are used in the management of HCM.

Supraventricular arrhythmias, such as atrial fibrillation, are seen frequently and are poorly tolerated. The loss of atrial contribution and shortening of the diastole due to tachycardia result in impaired ventricular filling and raise the outflow gradient. Thus, prompt restoration of sinus rhythm with cardioversion and antiarrhythmic therapy is recommended. Ventricular tachycardia and ventricular fibrillation are the primary mechanism of sudden death in patients with HCM. This can be prevented with ICD therapy. Use of ICD therapy is guided by the perceived risk for ventricular arrhythmias in individual patients. Some of the characteristics that have been associated with this risk are (1) prior cardiac arrest or sustained ventricular tachycardia, (2) high (>30 mm) ventricular wall thickness, (3) syncope, especially if exertional or recurrent, and (4) first-degree relative with sudden cardiac death. Certain genotypes also appear to convey an increased risk for sudden cardiac death.

Patients with HCM should be excluded from most competitive sports and avoid strenuous exercise.

The clinical course of HCM is varied. Sudden death is the leading cause of mortality. Heart failure symptoms may gradually progress, and some patients unresponsive to conventional therapy may require heart transplantation. Relatives of patients with HCM should have serial screening echocardiograms performed yearly during adolescence and less frequently throughout adulthood. Genetic testing can be

helpful in determining the presence of the HCM mutation in first-degree relatives of patients with HCM.

RESTRICTIVE CARDIOMYOPATHIES

Restrictive cardiomyopathy (RCM) is a relatively rare form of cardiomyopathy characterized by impaired ventricular filling with normal or decreased diastolic volume of either or both ventricles. Increased myocardial stiffness causes left ventricular pressure to rise significantly with only small changes in volume. Systolic function is usually preserved. Restrictive cardiomyopathies are familial (genetic) or acquired, and the exact causes for some idiopathic forms have not yet been established.

One of the more common genetic forms of RCM is familial amyloidosis, a result of known genetic mutations of transthyretin and apolipoprotein. Familial hemochromatosis is also associated with RCM. Certain sarcomeric protein mutations or mutations of the desmin gene can equally result in RCM.

Acquired forms of RCM result from different systemic disorders. Amyloidosis, sarcoidosis, carcinoid heart disease, and scleroderma have all been associated with RCM. Endocardial pathology that impairs ventricular filling also presents as RCM; examples are hypereosinophilic syndromes and endomyocardial fibrosis. The exact pathogenesis of these disorders is not well known, but parasitic infections and certain drugs (serotonin, methysergide, ergotamine) have been implicated. It is also likely that some nutritional factors

Table 11-3 Differentiation between Restrictive Cardiomyopathy and Constrictive Pericarditis

Type of Evaluation	Restrictive Cardiomyopathy	Constrictive Pericarditis
Physical examination	Kussmaul sign present Apical impulse may be prominent Regurgitant murmurs are common	Kussmaul sign may be present Apical impulse usually not palpable Pericardial knock may be present
Electrocardiography	Low QRS voltage (especially in amyloidosis) Pseudoinfarction pattern Bundle branch blocks AV conduction disturbances Atrial fibrillation	Low QRS voltage Repolarization abnormalities
Chest radiography		Calcification of the pericardium may be present
Echocardiography	Marked enlargement of the atria Increased wall thickness (especially in amyloidosis)	Atria usually of normal size Normal wall thickness Pericardial thickening may be seen
Doppler echocardiography	Restrictive mitral inflow (dominant E wave with short deceleration time) No significant variation of transvalvular velocities with respiration (<10%) Reversal of forward flow in hepatic veins during inspiration	Restrictive mitral inflow (dominant E wave with short deceleration time) Increased velocity of RV filling and decreased velocity of LV filling with inspiration; opposite with expiration; variation in velocity exceeds 15% Reversal of forward flow in hepatic veins during expiration
Cardiac catheterization	Prominent atrial x and y descents (w sign) Dip-and-plateau appearance of ventricular diastolic pressure Diastolic pressures increased but not equalized (LV diastolic pressure higher than RV diastolic pressure)	Prominent atrial x and y descents (w sign) Dip-and-plateau appearance of ventricular diastolic pressure Increase and equalization of diastolic pressures Discordance of RV and LV peak systolic pressures (with inspiration, RV systolic pressure increases and LV systolic pressure decreases)
Endomyocardial biopsy	May reveal specific cause of restrictive cardiomyopathy	No specific findings on endomyocardial biopsy Pericardial biopsy may reveal abnormality
Computed tomography, magnetic resonance imaging		Pericardial thickening

AV, atrioventricular, LV, left ventricular; RV, right ventricular.

play a role because there are significant geographic variations in the prevalence of the disease.

The diagnosis of restrictive cardiomyopathy should be considered in patients with predominantly right ventricular heart failure without evidence of either cardiomegaly or systolic dysfunction. Often, the correct diagnosis is not made until months or even years after symptom onset. Constrictive pericarditis can present similarly to RCM, and establishing the correct diagnosis can be challenging. Distinctive features of the two disorders are described in Table 11-3.

Treatment of restrictive cardiomyopathies is focused on alleviating the symptoms of heart failure and on the underlying disorder when treatment is available. Diuretics are used for decongestion, but intravascular depletion may compromise ventricular filling and lead to reduced cardiac output and hypotension. Supraventricular tachyarrhythmias are poorly tolerated. In patients with conduction system disease such as advanced atrioventricular block, a permanent pacemaker may be indicated. Some specific therapies include chemotherapy in amyloidosis, phlebotomy and iron chelation therapy in hemochromatosis, and steroids in sarcoidosis and endomyocardial fibrosis.

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

Arrhythmogenic right ventricular cardiomyopathy (ARVC), or arrhythmogenic right ventricular dysplasia, is an autosomal dominant disease with male predominance characterized by progressive replacement of right ventricular myocardium by fibrous and adipose tissue. This results in morphologic and functional changes in the right ventricle. In some patients, the fibrous and adipose infiltration also involves the left ventricle, and in these patients, the presentation may resemble DCM. The prevalence of ARVC is estimated at about 1 in 1000 to 5000, with significant regional variation.

The disease typically presents in young adults, and the presenting symptom is usually arrhythmia—palpitations, syncope, or sudden cardiac death (ARVC is a frequent cause of sudden death in young adults). Symptoms of right ventricular failure are rare, despite evidence of right ventricular dysfunction on imaging studies.

The clinical diagnosis of ARVC is suggested by integration of the information from clinical presentation (arrhythmias), resting ECG, family history, and imaging studies. Histologic examination of the right ventricle, when

available, confirms the diagnosis. Resting ECG may be normal, but some frequent abnormalities include incomplete or complete right bundle branch block, the so-called epsilon waves that follow the QRS complex, and inverted T waves in the precordial leads. Typical arrhythmia is a monomorphic sustained ventricular tachycardia originating in the right ventricle (left bundle branch block morphology). However, nonsustained ventricular tachycardias, frequent ventricular premature beats, and supraventricular tachycardias are also common. Right ventricular dilation and systolic dysfunction can be seen with echocardiography and MRI. The latter modality can also show presence of myocardial fat. Histologic examination of the right ventricular wall will demonstrate transmural fibrous and adipose infiltration.

Treatment consists of ICD therapy for patients with history of ventricular tachycardia and possibly even for primary prevention of sudden cardiac death. Antiarrhythmics and radiofrequency ablation of ventricular tachycardia are used in patients with frequent arrhythmias.

Patients with probable or definite diagnosis of ARVC should be excluded from competitive sports.

Unclassified Cardiomyopathies

Some cardiomyopathies, which do not fit into the current categories, are included and briefly described in Table 11-2.

Prospectus for the Future

Genetically engineered animal models have emerged as powerful tools for molecular and genetic studies of human diseases. Genetic testing for disease-causing genes of inherited cardiac disorders are available, but advances about the underlying pathogenesis are still needed to identify effective therapeutic targets. Emerging technologies such as proteomics and genomics might lend important insights into the pathogenesis of human viral myocarditis. Molecular aids using PCR and other serologic methods are likely to speed diagnosis with greater accuracy and specificity. In parallel, medical providers must be

alert to epidemiologic shifts in the prevalence of cardiotoxic agents such as hepatitis C that can contribute to new cases of viral myocarditis worldwide. Most importantly, future efforts are needed to forge consensus for the treatment of inflammatory phases and prevention of viral sequelae. Lastly, the global effort in basic and clinical research on AIDS is anticipated to yield spin-offs in pathogenesis, vaccine development, and other unforeseen benefits for the treatment and prevention of virus-mediated diseases in humans.

Cardiac Tumors

Primary cardiac tumors are extremely rare, with a prevalence of less than 0.3% in most pathologic series (Table 12-1). Myxoma is the most common primary tumor of the heart and is usually benign. These tumors are frequently isolated lesions, arising most often in the left atrium in the region of the fossa ovalis. Less commonly, myxomas may be detected in the right atrium, in the right or left ventricle, or in multiple sites within the heart. A familial pattern of myxomas can occur and is transmitted in an autosomal dominant manner. In these patients, multiple cardiac myxomas may be present in association with a constellation of extracardiac abnormalities, including pigmented nevi, cutaneous myxomas, breast fibroadenomas, and pituitary and adrenal gland disease. In addition, patients with familial myxoma may have recurrence of the tumor or tumors after surgical excision. Whether sporadic or familial, less than 10% of myxomas are malignant.

Symptoms associated with myxoma are usually related to embolization of tumor fragments and obstruction of the mitral valve. In addition, patients may exhibit a constellation of nonspecific symptoms and laboratory abnormalities, including fever, malaise, weight loss, anemia, and elevated erythrocyte sedimentation rate. The diagnosis is usually made with echocardiography; the transesophageal approach is the most sensitive method for detecting small left atrial tumors. Considering the propensity for embolization, most myxomas are surgically removed when diagnosed. Because tumors may recur, follow-up echocardiograms should be performed.

Other, less common benign tumors include papillary fibroelastomas, fibromas, and rhabdomyomas. Fibroelastomas are pedunculated tumors with frondlike attachments that usually arise from the surface of the mitral and aortic valve leaflets. These tumors do not result in valve dysfunction but may be a source of systemic embolization. Fibromas most often arise within the interventricular septum and may be associated with arrhythmias or conduction disturbances. Rhabdomyomas are the most common cardiac tumors

found in children and are often associated with tuberous sclerosis.

Cardiac lipomas may occur throughout the heart and pericardium. Pericardial lipomas can be large, whereas intramyocardial lipomas are small and often encapsulated. Surgical excision is the treatment of choice. Lipomatous hypertrophy of the interatrial septum should be considered in the differential of atrial masses. This lesion is a consequence of nonencapsulated adipose tissue hyperplasia and, although occasionally found incidentally at autopsy, may be associated with supraventricular arrhythmias, conduction disturbances, and, in rare cases, sudden cardiac death.

About one fourth of all primary cardiac tumors are malignant, and most are sarcomas. These tumors grow rapidly and often result in chamber obliteration and obstruction of blood flow. If there is involvement of the pericardium, a hemorrhagic effusion with pericardial tamponade may develop. The prognosis in affected individuals is poor; surgical excision is possible in rare cases. Irradiation and chemotherapy may provide palliative relief.

In contrast with primary cardiac tumors, metastatic disease involving the heart is common, occurring in up to one in five patients dying with malignancy. The most common tumors to metastasize to the heart are carcinomas of the lung, breast, and kidney; melanoma and lymphoma may also have cardiac involvement. Metastasis to the pericardium is common and often complicated by a hemorrhagic effusion and pericardial tamponade. Infiltration of the myocardium may result in conduction disturbances and arrhythmias. Intracavitary masses are unusual but may result from local tumor invasion or direct extension of the malignancy through the venous system (i.e., renal cell carcinoma may metastasize to the heart through the inferior vena cava). Treatment is directed at the underlying malignancy. If pericardial tamponade is present, immediate drainage will help stabilize the patient. A pericardotomy is often necessary to prevent reaccumulation of fluid within the pericardial sac. Surgical excision of an obstructing tumor mass is usually palliative.

Traumatic Heart Disease

NONPENETRATING CARDIAC INJURIES

Blunt cardiac trauma accounts for about 10% of all traumatic heart disease (Table 12-2). Motion-related injuries secondary to abrupt body deceleration (motor vehicle accidents) and chest wall compression (e.g., steering wheel impact, athletic blow, cardiac resuscitative maneuvers) are the most common causes of blunt injury to the heart. Changes in the myocardium range from small ecchymotic areas in the subepicardium to transmural injury with myocardial hemorrhage and necrosis. Pericarditis is present in most patients and may be complicated by a tear or rupture of the pericardium or cardiac tamponade. Less common

complications include rupture of a papillary muscle or chordae tendineae and coronary artery laceration.

Patients most often experience precordial pain that is similar to that associated with myocardial infarction. However, musculoskeletal pain secondary to chest wall injury may confuse the clinical presentation. Congestive heart failure is unusual unless myocardial injury has been extensive or valve dysfunction has occurred. Life-threatening ventricular arrhythmias may occur with severe trauma and are a frequent cause of death in such patients. The electrocardiogram most often demonstrates nonspecific repolarization abnormalities or ST-segment and T-wave changes consistent with acute pericarditis. If myocardial injury is extensive, localized ST-segment elevation and pathologic Q waves may be present. Elevation of the myocardial component of the creatine kinase muscle band (CK-MB) is supportive of a diagnosis of cardiac contusion but is of limited diagnostic use in patients with massive chest wall trauma because the CK-MB fraction may be elevated as a result of severe skeletal muscle injury. Newer markers of myocardial injury, such as troponins T and I, may be more specific for establishing a diagnosis of myocardial contusion. Echocardiography is a useful, noninvasive tool to assess for wall motion abnormalities, valve dysfunction, and the presence of hemodynamically significant pericardial effusion.

Treatment of patients with cardiac contusion is similar to that for myocardial infarction, with initial observation and monitoring, followed by a gradual increase in physical activity. Anticoagulants and thrombolytic agents are contraindicated given the risk for hemorrhage into the myocardium and pericardial sac. Most patients who survive the initial injury will have partial or complete recovery of myocardial function. However, patients should be monitored for late complications that include aneurysm formation, free-wall or papillary muscle rupture, and significant arrhythmias.

GREAT VESSEL INJURY

Rupture of the aorta is one of the most common cardiovascular injuries resulting from blunt chest wall trauma. In more than 90% of cases, rupture occurs in the descending thoracic aorta just distal to the origin of the subclavian artery. Most individuals die immediately of exsanguination. However, up to 20% of patients may survive the initial injury if the blood is confined within the aortic adventitia and surrounding mediastinal tissues (pseudoaneurysm). Characteristic symptoms and findings on presentation include chest and interscapular back pain, increased arterial pressure and pulse amplitude in the upper extremities, decreased pressure and pulse amplitude in the lower extremities, and mediastinal widening on the chest radiograph. Previously, aortography had been the standard for diagnosing blunt aortic injury. Aortography, however, is a relatively invasive, time-consuming procedure with the potential for additional morbidity in this critically ill group of patients. Although conventional chest computed tomography (CT) could not match the diagnostic accuracy of aortography, helical thin-cut CT angiography has emerged as a superior alternative to aortography for diagnosing blunt aortic injury. Helical CT scanning is an ideal diagnostic method for aortic injury because of its relatively low cost compared with aortography, its nearly uni-

versal availability in emergency departments, and its lack of operator dependence. In addition, at most trauma centers, CT scanning is already an integral part of the diagnosis and management of serious blunt injury, with patients typically undergoing simultaneous CT scanning of other areas of the body to evaluate potential injuries.

The overall diagnostic accuracy for helical CT scanning in the setting of blunt aortic injury exceeds 99%, with the positive and negative predictive values for helical CT scanning meeting or exceeding the same values for aortography. Patients without direct helical CT scan evidence of blunt aortic injury require no further evaluation. Aortography should be reserved for indeterminate helical CT scans. Such a strategy helps substantially reduce the morbidity and cost of unnecessary aortograms for blunt aortic injury.

The force from rapid deceleration necessary to tear the aorta often leads to injuries of other organs. Associated injuries may be present in more than 90% of patients with aortic transection, and 24% of these patients require a major surgical procedure before aortic repair. The extremely high death rate of acute blunt rupture of the thoracic aorta has led surgeons in the past to repair the tear as quickly as possible. This form of management, however, has resulted in high rates of death and complications, often because of associated injuries in other organs. Patients with traumatic rupture of the aorta fall into two broad categories: (1) About 5% are hemodynamically unstable or deteriorate within 6 hours of admission. These patients require emergent surgical correction because mortality without intervention exceeds 90%. (2) The other 95% of patients are hemodynamically stable at the time of presentation, allowing time for a work-up and staging of any intervention. Mortality in this group is as low as 25% and is rarely the result of free rupture if the blood pressure is controlled. In the past decade, the philosophy of managing traumatic rupture of the aorta in this subgroup of patients has changed to emphasizing blood pressure control and assessing the need for emergent repair against the risks of operation. Recent prospective studies have demonstrated the value of initial antihypertensive therapy to allow delayed repair of blunt aortic injury in patients with severe co-existent injuries to other organ systems. In a substantial number of cases, associated injuries or co-morbidities make the risks of immediate surgical repair prohibitive. The current indications for considering delayed aortic repair include trauma to the central nervous system, contaminated wounds, respiratory insufficiency from lung contusion or other causes, body surface burns, blunt cardiac injury, tears of solid organs that will undergo nonoperative management, and retroperitoneal hematoma, as well as patients 50 years or older and those with medical co-morbidities. Patients with significant neurologic, pulmonary, or cardiac injuries have better outcomes if their confounding pathologic condition can be ameliorated before thoracotomy.

PENETRATING CARDIAC INJURIES

Penetrating cardiac injuries are frequently the result of physical violence secondary to bullet and knife wounds. Similar wounds may result from the inward displacement of bone fragments or fractured ribs secondary to blunt chest wall injury. Iatrogenic injuries may occur during placement of central venous catheters and wires.

With traumatic perforations, the right ventricle is the most frequently involved chamber, considering its anterior location in the chest, and is often associated with pericardial laceration. Symptoms are related to the size of the wound and the nature of the concomitant pericardial injury. If the pericardium remains open, extravasated blood drains freely into the mediastinum and pleural cavity, and symptoms are related to the resulting hemothorax. If the pericardial sac limits blood loss, pericardial tamponade results. In this situation, treatment includes emergent pericardiocentesis followed by emergent surgical closure of the wound. Small penetrating wounds to the ventricles that are not associated with extensive cardiac damage have the highest rate of survival. Late complications include chronic pericarditis, arrhythmias, aneurysm formation, and ventricular septal defects.

Cardiac Surgery

CORONARY ARTERY BYPASS GRAFTING

Despite the effectiveness of current medical therapy for the treatment of coronary artery disease, many patients may require revascularization. Coronary artery bypass grafting (CABG) is an effective means of reducing or eliminating symptoms of angina pectoris. In addition, previous studies have shown that CABG may improve survival in certain subgroups of patients, including patients with angina refractory to medical therapy, patients with greater than 50% stenosis of the left main coronary artery, and patients with severe three-vessel coronary artery disease associated with left ventricular dysfunction. In addition, patients with two-vessel coronary artery disease in which a severe stenosis (>75%) is present in the proximal left anterior descending artery appear to benefit from CABG even if left ventricular function is normal.

Standard CABG is performed through a median sternotomy incision with cardiopulmonary bypass and cardioplegic arrest. Operative mortality is 1% or less in stable patients with normal left ventricular function; the incidences of perioperative myocardial infarction and stroke range from 1% to 4%. An increase in adverse events is associated with advancing age, female gender, short stature, diabetes, unstable angina or recent myocardial infarction, and severely reduced left ventricular function. Overall survival at 10 years is about 80%, with recurrent or progressive angina occurring in about 50% of patients.

Long-term success of surgery is dependent on the type of conduit used during surgery (saphenous vein grafts versus internal mammary artery) and the progression of atherosclerotic disease in the native and graft vessels. The internal mammary artery is particularly resistant to atherosclerotic disease and has a patency rate of about 90% at 10 years. In comparison, venous grafts are subject to closure both during the immediate postoperative period (usually secondary to technical factors) and months to years after surgery, secondary to intimal hyperplasia and progression of atherosclerosis. As a result, only 50% of venous grafts are patent 7 to 10 years after CABG. The major predictor of the subsequent development of atherosclerotic disease in the surgically placed bypass grafts is the ability of patients to control their risk

factors for the development of atherosclerotic disease generally after surgery, particularly cigarette smoking, hypertension, diabetes, hypercholesterolemia, and obesity. Aggressive lowering of low-density lipoprotein levels after CABG and the administration of a daily aspirin have been shown to reduce the incidence of venous graft occlusion. Most cases of recurrent angina can be managed successfully with medication (see Chapter 9). In many cases, percutaneous revascularization of a native vessel or graft will provide symptomatic relief and is the initial procedure of choice in this setting. In patients with refractory symptoms not amenable to percutaneous revascularization, repeat CABG is an option; however, in this setting, repeat CABG is associated with increased peri-operative mortality and less satisfactory long-term control of angina.

MINIMALLY INVASIVE CARDIAC SURGERY

Minimally invasive approaches for cardiac surgery can be broadly grouped into two categories: (1) those approaches that avoid the performance of a sternotomy, and (2) those approaches that avoid the use of cardiopulmonary bypass. During the past 15 years, progressive experience incorporating these approaches has led to the application of minimally invasive techniques to select patients undergoing cardiac surgery. Many of the approaches have significant limitations, however, and the development of minimally invasive techniques for the performance of cardiac surgery continues to evolve.

In highly select patients, minimally invasive direct coronary artery bypass (MIDCAB) can be performed through a limited thoracotomy, sparing the patient the peri-operative morbidity associated with a median sternotomy. This technique also avoids the use of cardiopulmonary bypass. The most common approach is through a small left anterior thoracotomy incision and allows for the harvesting of the left internal mammary artery under direct visualization. Therefore, this technique is most suitable for patients with proximal disease in the distribution of the left anterior descending coronary artery, although other coronary arteries can be bypassed using different thoracotomy approaches. The major limitation to this approach has been the lower patency rates in the left internal mammary grafts placed using this technique and a higher incidence of recurrent ischemia compared with conventional CABG. The MIDCAB procedure therefore is only applicable to highly select patients with disease in the distribution of the left anterior descending coronary artery and significant co-morbidities, which preclude the performance of a median sternotomy and use of cardiopulmonary bypass.

The initial experience with the MIDCAB approach and the subsequent demonstration of its limitations prompted the development of port-access cardiac surgery. This technique incorporates the MIDCAB approach of a limited lateral thoracotomy, thereby avoiding a median sternotomy, but uses cardiopulmonary bypass to facilitate performance of intracardiac procedures, including mitral valve repair or replacement, as well as the potential for access to other coronary artery distributions beyond the left anterior descending coronary artery for CABG. The port-access approach uses an endoaortic balloon through cannulas placed in the femoral vessels for cardiopulmonary bypass.

A few centers have successfully used the port-access platform for performance of select cardiac surgical procedures, particularly mitral valve repair or replacement. The widespread adoption of this platform has been limited by persistent difficulties with access to all areas of the heart for coronary revascularization and the potentially catastrophic complication of aortic dissection in a small number of patients.

The limitations encountered with both the MIDCAB and port-access platforms have spurred the development of performing coronary bypass surgery through a median sternotomy but without cardiopulmonary bypass (e.g., off-pump coronary artery bypass [OPCAB]), allowing for surgery on the beating heart. The advantages of OPCAB over other platforms for minimally invasive coronary surgery are that complete revascularization can be performed and both internal mammary arteries can be harvested. Compared with conventional CABG, OPCAB is associated with decreased blood loss, decreased need for transfusion, decreased myocardial enzyme release up to 24 hours after surgery, decreased renal dysfunction, and, typically, decreased number of grafts placed per patient. Also compared with conventional CABG, however, OPCAB is not associated with a decreased length of hospital stay, a decreased mortality rate, or improved long-term neurologic function. Although the OPCAB platform has become the most widely adopted approach for minimally invasive cardiac surgery, major questions remain regarding the intermediate and long-term patencies of the bypass grafts placed using this technique and whether the decreased number of grafts placed per patient compromises the long-term cardiac outcomes of patients undergoing this procedure, compared with conventional CABG. Large-scale prospective clinical trials need to be conducted to answer these questions definitively.

VALVULAR SURGERY

Surgical repair or replacement of a diseased valve is dependent on multiple factors, including the type and severity of the valve lesion, the presence of symptoms, and the functional status of the left and in some cases the right ventricle (see Chapter 8). In most adults, the diseased valve is usually replaced with a prosthesis, although some forms of valve disease, such as mitral valve regurgitation or mitral stenosis without significant valvular or chordal calcification, may be amenable to repair. Because prosthetic heart valves are associated with a number of complications, including thrombosis, endocarditis, and hemolysis, the decision to proceed with valve surgery should only be made after the risks of valve replacement are weighed against the potential benefits of symptom relief and improved survival.

Valve surgery is performed in a manner similar to CABG, with most cases requiring a median sternotomy, cardiopulmonary bypass, and cardioplegic arrest. Minimally invasive surgery through a modified sternotomy or thoracotomy incision may be possible in select patients with isolated aortic or mitral valve disease. Operative mortality for all techniques ranges from 1% to 8% for most patients with preserved left ventricular function and good exercise capacity. The risk of surgery increases further with advancing age, depressed left ventricular ejection fraction, presence of severe coronary artery disease, and replacement of multiple

valves. Symptomatic patients usually have significant clinical improvement after valve surgery; however, long-term survival is strongly dependent on the patient's preoperative functional status and ventricular function.

CARDIAC TRANSPLANTATION

During the past two decades, cardiac transplantation has become a life-saving treatment choice in patients with end-stage congestive heart failure. With advances in surgical techniques and immunosuppressive therapy, 1- and 5-year survival rates are about 90% and 75%, respectively. These rates are far superior to the 1-year survival rate in patients with advanced heart failure, which can be as low as 50%. Unfortunately, many patients suitable for cardiac transplantation die before surgery as a result of the limited number of donor hearts available each year. The development and widespread application of left ventricular assist devices has allowed many of these patients who would otherwise die awaiting transplantation to survive until a donor heart becomes available. In many cardiac transplant centers today, more than half of patients undergoing cardiac transplantation have previously undergone placement of a left ventricular assist device.

The major indications for cardiac transplantation are to prolong survival and improve the quality of life. Determining which patients are suitable for cardiac transplantation can be difficult because many patients may have clinical and hemodynamic improvement with intensification of medical therapy. In general, functional capacity, as assessed by exercise stress testing with measurement of maximal oxygen consumption at peak exercise, is the best predictor of which patients should be selected for cardiac transplantation. Individuals with severely impaired exercise capacity (e.g., peak oxygen consumption less than 10 to 12 mL/kg per minute, with the lower limit of normal 20 mL/kg per minute) are most likely to experience a survival benefit from transplantation. Exclusion criteria include irreversible pulmonary vascular hypertension, malignancy, active infection, diabetes mellitus with end-organ damage, and advanced liver or kidney disease. Although advanced age is associated with higher surgical and 1-year mortality rates, an age limit for cardiac transplantation is no longer strictly enforced at most centers, with patients instead being listed for transplantation based on an overall assessment of their physiologic status and potential for long-term survival after transplantation.

The procedure is performed through a median sternotomy incision. The posterior walls of the left and right atria with their venous connections are left in place and used to suture to the donor heart. The aorta and pulmonary artery are directly anastomosed to the recipient's great vessels. Immunosuppressive therapy is begun immediately after surgery and continued throughout the patient's life. Although new immunosuppressive agents are available, most regimens still include combinations of cyclosporine, azathioprine, and prednisone. Frequent complications during the first year include infection and rejection of the donor heart. In addition, hyperlipidemia and hypertension are common medical problems that may require treatment.

The major long-term complication is the development of coronary vasculopathy in the transplanted heart. In contrast

to coronary artery atherosclerosis, which tends to be a focal process affecting primarily the proximal vessels, this disease is characterized by diffuse myointimal proliferation involving primarily the medial and distal segments of the coronary arteries. Although the cause of this disease is not entirely known, coronary vasculopathy is thought to be secondary to an immune-mediated response directed against the donor vessels. Monitoring for this complication can be difficult because angina is not provoked in the denervated heart and standard exercise stress testing has a low sensitivity for detecting this disease. Coronary angiography is performed after transplantation and yearly thereafter to monitor for significant narrowing of the coronary arteries. Unfortunately, the diffuse nature of the vasculopathy makes coronary angiography less accurate for the detection of this disease. Intracoronary ultrasound, with measurements of the intimal layer and coronary artery lumen size, is a new technique that appears to be more sensitive than coronary angiography for the detection of this complication. Treatment options are limited, but aggressive management of hypercholesterolemia and the use of calcium channel blockers, specifically diltiazem, have been associated with a slowing of disease progression and a higher survival rate. Retransplantation is reserved for patients with severe, three-vessel coronary artery disease with reduced left ventricular function and symptoms of congestive heart failure.

NONCARDIAC SURGERY IN THE PATIENT WITH CARDIOVASCULAR DISEASE

Noncardiac surgery in patients with known cardiovascular disease may be associated with an increased risk for death or cardiac complications, such as myocardial infarction, congestive heart failure, and arrhythmias. To determine an individual patient's risk for a procedure, the consulting physician must have knowledge of the type and severity of the patient's cardiac disease, his or her co-morbid risk factors, and the type and urgency of surgery. In general, the preoperative evaluation and management of patients with cardiovascular disease are similar to those in the nonoperative setting, with additional noninvasive and invasive testing targeted toward those at-risk patients in whom the results would affect treatment or outcome.

Usually, estimation of a patient's peri-operative risk can be determined by a careful clinical evaluation, including a history, physical examination, and review of the electrocardiogram. Patients at highest risk for a peri-operative cardiac event are those with a recent myocardial infarction (defined as more than 7 days but less than 1 month earlier), unstable or severe angina, decompensated congestive heart failure, significant arrhythmias, or severe valvular disease (Table 12-3). Predictors of moderate or intermediate cardiac risk include a history of stable angina, compensated heart failure, prior myocardial infarction, or diabetes mellitus. Advanced age, an abnormal electrocardiogram, low-functional capacity, and poorly controlled hypertension are associated with cardiovascular disease but are not independent predictors of a peri-operative cardiac event.

Risks associated with the type of surgery are highest in patients undergoing major emergency procedures, especially when performed in the older adult population (Table 12-4). Cardiac complications are also common after vascular

Table 12-3 Clinical Predictors of Increased Perioperative Cardiovascular Risk (Myocardial Infarction, Congestive Heart Failure, Death)

Major

Unstable coronary syndromes
Recent myocardial infarction (e.g., >1 wk and ≤1 mo)
Unstable or severe angina (Canadian Cardiovascular Society angina class III or IV)
Decompensated heart failure
Significant arrhythmias
High-grade atrioventricular block
Symptomatic ventricular arrhythmias
Supraventricular arrhythmias with uncontrolled ventricular response
Severe valvular disease

Intermediate

Mild angina (Canadian Cardiovascular Society angina class I or II)
Prior myocardial infarction
Compensated or prior congestive heart failure
Diabetes mellitus

Minor

Advanced age
Abnormal electrocardiogram (e.g., left ventricular hypertrophy, left bundle branch block)
Rhythm other than sinus
Low functional capacity (i.e., unable to climb one flight of stairs with a bag of groceries)
History of a stroke
Uncontrolled systemic hypertension

Table 12-4 Cardiac Risk Stratification for Noncardiac Surgical Procedures

High (Reported Cardiac Risk > 5%)

Emergent major operations, particularly in the older adult population
Major vascular surgery, aortic aneurysm repair
Peripheral vascular surgery
Prolonged procedures associated with large fluid shifts or blood loss or both

Intermediate (Reported Cardiac Risk < 5%)

Carotid endarterectomy
Head and neck
Intraperitoneal and intrathoracic
Orthopedic
Prostate

Low (Reported Cardiac Risk < 1%)

Endoscopic procedures
Cataract extraction
Breast biopsy

Data from Eagle KA, Brundage BH, Chaitman BR, et al: Guidelines for perioperative cardiovascular evaluation for noncardiac surgery: Report of the ACC/AHA Task Force on Practice Guidelines. *J Am Coll Cardiol* 27:910-948, 1996.

surgery, considering that the prevalence of underlying coronary artery disease is high in this patient population. In addition, any surgery associated with large volume shifts or blood loss may place increased demands on an already diseased heart. Procedures associated with the lowest risk in the patient with cardiac disease are cataract extraction and endoscopy.

Once the clinical evaluation is complete and the type of surgery is known, the need for additional testing and treatment can be determined. If emergency surgery is contemplated, little in the way of cardiac assessment can be performed, and recommendations may be directed at perioperative medical management and surveillance. If surgery is not urgent, additional evaluation is based on the clinical assessments of the risk and type of surgery. Patients with major risk factors for cardiac complications should have surgery delayed until the cardiac condition is treated and stabilized. Patients with intermediate predictors of cardiac risk scheduled for high-risk surgery should undergo noninvasive testing, such as exercise or pharmacologic stress testing or echocardiography. The results of these tests will help determine future management, such as cardiac catheterization or intensification of medical therapy. Patients scheduled for low- or intermediate-risk surgery, especially if the patient has good exercise capacity, should proceed with surgery with appropriate medical management and postoperative surveillance. Noncardiac surgery is generally safe for patients with minor or no clinical risk factors for cardiac complications, although some patients with poor functional capacity scheduled for high-risk operations may benefit from additional cardiac evaluation.

Disease-Specific Approaches

CORONARY ARTERY DISEASE AND MYOCARDIAL INFARCTION

About 70% of postoperative myocardial infarctions occur within the first 6 days, with the peak incidence between 24 and 72 hours. Mortality associated with noncardiac surgery has been reported as high as 30% to 40%, especially if associated with congestive heart failure or significant arrhythmias. Multiple stresses associated with surgery can provoke ischemia. Physiologic tachycardia and hypertension secondary to volume shifts, anemia, infection, and the stress of wound healing increase myocardial oxygen demand and may provoke ischemia. In addition, increased platelet reactivity during the postoperative period may increase the risk for coronary thrombosis and subsequent infarction.

Despite the high mortality associated with perioperative myocardial infarction, few studies have examined the effects of anti-ischemic therapy on the prevention of this complication. Several small, uncontrolled trials have suggested that β blockers may reduce intraoperative ischemia. More recently, the use of atenolol before and after surgery was associated with a reduction in myocardial infarction and cardiac death, especially during the first 6 to 12 months after surgery. Although the data are limited, the use of a perioperative β blocker should be considered in all patients with suggested or known coronary artery disease unless a specific contraindication to its use is present. The data available on the usefulness of calcium channel blockers and nitrates are even more limited, but this approach may be appropriate for the treatment of symptomatic coronary disease in individuals who are not candidates for revascularization. Coronary angiography and revascularization should be reserved for individuals in whom this treatment would otherwise result

in significant improvement in symptoms or long-term survival. In rare cases, revascularization may be indicated in high-risk patients undergoing major noncardiac surgery.

All patients with suggested or known cardiac disease should have routine electrocardiograms the first 3 days after surgery to monitor for ischemia. When the electrocardiogram is inconclusive, measurement of troponin levels may be helpful to document an ischemic event. Treatment of a myocardial infarction in this setting is similar to that for the nonsurgical patient (see Chapter 9), although the use of anticoagulants and thrombolytic agents may be contraindicated in the immediate postoperative period. Special attention should be paid to correcting abnormalities that may provoke additional ischemia (e.g., hypoxia, anemia).

CONGESTIVE HEART FAILURE

Several studies have shown that decompensated heart failure is associated with increased peri-operative cardiac complications. In these patients, surgery should be postponed until appropriate treatment is instituted and symptoms have been stabilized. If planned surgery is associated with large blood loss or fluid shifts, a pulmonary artery catheter may be helpful in managing the patient.

During the postoperative period, congestive heart failure most commonly occurs during the first 24 to 48 hours when fluid administered during surgery is mobilized from the extravascular space. However, heart failure may also result from myocardial ischemia and new arrhythmias. Initial management includes identification and treatment of the underlying cause. In addition, intravenous diuretics usually provide rapid relief of pulmonary congestion. If heart failure is complicated by hypotension or poor urine output, insertion of a pulmonary artery catheter may be helpful to guide additional therapy (see Chapter 6).

VALVULAR HEART DISEASE

Aortic and mitral stenosis are associated with the greatest risk for complications after noncardiac surgery. Patients with symptomatic, severe aortic stenosis should have valve replacement before noncardiac surgery. In patients with mild to moderate mitral stenosis, careful attention to volume status and heart rate control are necessary to optimize left ventricular filling and to avoid pulmonary congestion. Patients with severe mitral stenosis should be considered for percutaneous valvuloplasty or mitral valve replacement before high-risk surgery. In patients with valve disease or prosthetic heart valves, prophylactic antibiotics are recommended when appropriate.

ARRHYTHMIAS AND CONDUCTION DEFECTS

Patients with symptomatic, high-grade conduction disturbances, such as third-degree atrioventricular (AV) block, have an increased peri-operative risk for cardiac complications and should have a temporary pacemaker inserted before surgery. Patients with first-degree AV block, Mobitz type I AV block, or bifascicular block (right bundle branch block and left anterior fascicular block) do not require prophylactic pacemaker insertion.

Atrial arrhythmias, such as atrial fibrillation, are common after surgery and are usually not associated with significant complications if the ventricular rate is well controlled. Ventricular premature beats and nonsustained ventricular tachycardia are also common after noncardiac surgery and do not require specific therapy unless associated with myocardial ischemia or heart failure. In most instances, treatment of the underlying cause (e.g., hypoxia, metabolic abnormalities, ischemia, volume overload) will result in significant improvement or resolution of the rhythm disturbance without specific anti-arrhythmic therapy.

CARDIAC DISEASE IN PREGNANCY

Pregnancy is associated with dramatic changes in the cardiovascular system that may result in significant hemodynamic stress to the patient with underlying heart disease. During a normal pregnancy, plasma volume increases an average of 50%, beginning in the first trimester and peaking between the 20th and 24th weeks of pregnancy. This change is accompanied by an increase in stroke volume, heart rate, and, accordingly, cardiac output. In addition, a concomitant fall in systemic vascular resistance and mean arterial pressure occurs because of the effects of gestational hormones on the vasculature and the creation of a low-resistance circulation in the pregnant uterus and placenta. During labor, uterine contractions result in a transient increase of up to 500 mL of blood in the central circulation, resulting in further increases in stroke volume and cardiac output. After delivery, intravascular volume and cardiac output increase further as compression of the inferior vena cava by the gravid uterus is relieved and extravascular fluid is mobilized. Symptoms and signs that may mimic cardiac disease often accompany these hemodynamic changes and include fatigue, reduced exercise tolerance, lower extremity edema, distention of the neck veins, S₃ gallop, and new systolic murmurs. Differentiating symptoms produced by cardiac disease versus those attributable to a normal pregnancy can be difficult. Under such circumstances, echocardiography can be a safe and helpful noninvasive test to assess cardiac structure and function in the pregnant patient.

Many pregnant patients with known cardiac disease can complete a normal pregnancy and delivery without significant harm to the mother or fetus. However, certain cardiac conditions, including irreversible pulmonary hypertension, cardiomyopathy associated with severe heart failure, and Marfan syndrome with a dilated aortic root, are associated with a high risk for cardiovascular complications and death. Under these circumstances, patients should be advised against having children. If pregnancy occurs, a first-trimester therapeutic abortion should be strongly recommended.

Specific Cardiac Conditions

MITRAL STENOSIS

Mitral stenosis secondary to rheumatic heart disease frequently occurs in young women of childbearing age. The physiologic increases in heart rate and cardiac output during pregnancy result in a significant increase in the gradient

across the mitral valve and a rise in left atrial and pulmonary venous pressures. Congestive heart failure may develop as the pregnancy progresses through the second and third trimesters or may occur more acutely with the onset of atrial fibrillation. The management of the patient with mitral stenosis depends on her prepregnant functional capacity and the severity of the valve obstruction. In general, patients with severely symptomatic mitral valve stenosis should have percutaneous or surgical correction of the valve before conception. Women with minimal symptoms (New York Heart Association functional classes I to II) usually tolerate pregnancy and vaginal delivery well even if moderate to severe stenosis is present. Management includes salt restriction, diuretic therapy, and aggressive treatment of pulmonary infections. Patients who develop atrial fibrillation with a rapid ventricular response should be treated with AV nodal blocking agents and cardioversion if possible. Patients who develop refractory heart failure during pregnancy should be considered for mitral balloon valvuloplasty because surgical commissurotomy or valve replacement may be associated with fetal demise.

AORTIC STENOSIS

Aortic stenosis in a pregnant woman is usually congenital in origin. Patients with significant outflow obstruction may develop angina or heart failure during the later portion of the pregnancy as cardiac output increases. Supportive therapy includes bed rest and prevention of hypovolemia. If these measures fail to control symptoms and the fetus is not near term, balloon valvuloplasty or aortic valve surgery should be considered to reduce the risk for maternal death.

MARFAN SYNDROME

Pregnant women with Marfan syndrome are at an increased risk for aortic dissection and rupture, especially during the third trimester and first postpartum month. Patients with an aortic root diameter greater than 40 mm are at greatest risk for this complication and should strongly consider therapeutic abortion during the first trimester. Women with an aortic root diameter less than 40 mm should have serial echocardiograms to monitor the size of the aortic root during pregnancy. In addition, restriction in physical activity and treatment with a β blocker may help prevent further dilation of the aorta.

CONGENITAL HEART DISEASE

Survival to reproductive age is common in patients with corrected congenital defects. The risk for pregnancy in these patients is related to the completeness of the repair and the mother's functional capacity. Uncomplicated atrial or ventricular septal defects not associated with symptoms or pulmonary hypertension are usually well tolerated during pregnancy. Intracardiac shunts associated with pulmonary vascular hypertension are associated with a high maternal mortality rate during pregnancy as a result of an increase in right-to-left shunting and worsening oxygen desaturation of the blood. In these women, pregnancy is contraindicated. If pregnancy occurs, a therapeutic abortion during the first trimester should be recommended. Women with uncor-

rected tetralogy of Fallot should undergo palliative or definitive repair before conception to improve maternal and fetal outcomes with pregnancy. Women with residual obstruction of the right ventricular outflow tract remain at high risk for right ventricular heart failure during pregnancy.

PROSTHETIC HEART VALVES

Most patients with a normal-functioning prosthetic valve tolerate pregnancy without complications. However, in patients with mechanical valves, special attention to the choice and dose of anticoagulant therapy is necessary to avoid thromboembolic complications in the mother and teratogenic effects in the fetus. Women should start subcutaneous heparin before conception to avoid the potential teratogenic effects of warfarin during the first several months of critical fetal organ development. This therapy can be continued throughout pregnancy, or, alternatively, warfarin can be reinstated late in the second trimester or during the third trimester. Heparin therapy, although reducing the risk for teratogenicity associated with warfarin use, is associated with a high risk for maternal bleeding complications. Low-molecular-weight heparin may be an acceptable alternative; however, no firm data are available to support these recommendations. At the time of delivery, anticoagulation therapy is interrupted to avoid bleeding complications. Antibiotic prophylaxis is generally not recommended at the time of delivery.

HEART DISEASE ARISING DURING PREGNANCY

Cardiovascular disease can develop during pregnancy and may pose a significant risk to the mother and fetus. Hypertension is not an uncommon problem during pregnancy and is defined as a consistent increase in blood pressure of 30/15 mm Hg or as an absolute blood pressure greater than 140/90 mm Hg. The three major forms of hypertension that may develop during pregnancy include chronic hypertension, gestational hypertension, and toxemia. Toxemia is a form of hypertension that develops during the second half of pregnancy and is associated with proteinuria, edema, and, in severe forms, seizures. This problem is primarily managed by the obstetrician and is not discussed in this text. Gestational hypertension is an elevation in blood pressure that occurs late in the pregnancy, during delivery, or in the first postpartum days. This disease entity is not associated with proteinuria or edema and resolves within 2 weeks of delivery. Chronic hypertension is presumed to be present if an elevation in blood pressure is detected before the 20th week of pregnancy. No matter what the cause, fetal mortality correlates with the severity of the hypertension and begins to rise when the diastolic pressure exceeds 75 mm Hg during the second trimester and 85 mm Hg during the third trimester. Initial treatments include a reduction in physical activity and salt restriction. If the blood pressure remains greater than 150/90 mm Hg, then antihypertensive treatment should be instituted. Agents that have been safely used in pregnancy include hydralazine, α -methyldopa, clonidine, β blockers, and labetalol. Diuretics should be used with caution because of the increased risk for placental hypoperfusion.

Peripartum cardiomyopathy (PCM) is a form of dilated cardiomyopathy that may begin during the last trimester of pregnancy or within the first 6 months after delivery in a woman without prior heart disease or other definable causes for cardiac dysfunction. The true incidence of the disease is unknown, but estimates conclude that one woman in 3000 to 4000 pregnancies is affected. Although the cause of PCM is unknown, myocardial injury is thought to be immunologically mediated. Women usually exhibit symptoms and signs of congestive heart failure. Echocardiography is useful to assess chamber size and degree of ventricular dysfunction. The outcome with PCM is variable, with death or progressive heart failure occurring in about one third of affected women. The prognosis is particularly poor if symptoms develop before delivery. Despite this risk, many patients will have complete recovery of ventricular function, although recurrence is possible, especially with subsequent pregnancies. Treatment is similar to that for congestive heart failure (see Chapter 6) and usually includes vasodilators, such as hydralazine, digoxin, and diuretics. Angiotensin-converting enzyme inhibitors have been associated with increased fetal wastage in pregnant animals and should be avoided. A

thorough evaluation of cardiac function should be performed before subsequent pregnancies. If a woman decides to proceed with another pregnancy, she should be monitored regularly for signs of cardiac decompensation.

About 50% of aortic dissections that occur in women younger than 40 years are associated with pregnancy. Although the cause of aortic dissection during pregnancy is unknown, it has been postulated that hemodynamic and hormonal changes associated with pregnancy may weaken the aortic wall. The highest incidence of dissection is during the third trimester, although it may occur at any time during the pregnancy and during the early postpartum period. The presenting symptoms and diagnostic work-up are similar to those for the nonpregnant patient (see Chapter 13). Transesophageal echocardiography is highly sensitive and specific for the detection of aortic dissection and offers the advantage of not exposing the fetus to ionizing radiation. Management includes aggressive blood pressure control and β -blocker therapy to reduce shear forces of the ejected blood. Recommendations for corrective surgery are similar to those for the nonpregnant patient and are discussed in Chapter 13.

Prospectus for the Future

CABG remains an important but less commonly used mode for revascularization of symptomatic coronary artery disease. Technical advances of percutaneous coronary angioplasty (PTCA), however, have emboldened such attempts for revascularization of unprotected left main disease, the established domain for CABG, even in octogenarians. Prospective studies are needed to evaluate the efficacy, health outcomes, and cost

benefits for combined approaches of CABG and PTCA with drug-eluting stents. Percutaneous and minimally invasive surgical options will gain greater widespread application in the management of heart disease. With the limited donor pool for cardiac transplantation, advanced heart failure will be managed with resynchronization therapy, left ventricular assist devices, and stem- and cell-based therapies.

Vascular Diseases and Hypertension

Wanpen Vongpatanasin and Ronald G. Victor

Diseases of the systemic and pulmonary vasculature are among the most common clinical problems encountered in internal medicine. Yet these important diseases are not often given the emphasis they deserve; they fall between the cracks of traditional medical subspecialties. Early clinical recognition is important because in many cases effective therapy can prevent or at least delay needless suffering and death. This chapter reviews the causes, clinical manifestations, diagnostic evaluations, and therapeutic approaches to the major forms of systemic and pulmonary vascular diseases, as well as arterial hypertension. New qualifying examinations are now available in both vascular medicine and hypertension, highlighting the increasing need for expertise in these fields.

Systemic Vascular Disease

PERIPHERAL ARTERIAL DISEASE

Peripheral arterial disease (PAD) refers to atherosclerotic vascular disease of mainly the lower extremities. Similar to other atherosclerotic vascular diseases, PAD is more prevalent in men than in women, particularly before the age of menopause. The prevalence increases with age, ranging from 2% to 6% for adults younger than 60 years to 20% to 30% for those older than 70 years. As with coronary atherosclerosis, the major reversible risk factors are cigarette smoking, diabetes mellitus, hyperlipidemia, and hypertension. Only 30% to 50% of patients with PAD become symptomatic. The classic syndrome of intermittent claudication refers to ischemic muscle pain or weakness that is brought on by exertion and promptly relieved by rest. Claudication is associated with a significant 10-year risk for morbidity and mortality. About 25% of patients develop worsening claudication, 5% require amputation, 10% to 20% require revascularization (e.g., surgery, angioplasty), and 30% die of a cardiovascular event (e.g., heart attack, stroke) as a result of

concomitant coronary or cerebrovascular atherosclerosis. To minimize the progression of PAD and avoid complications, risk factor modification is absolutely essential. This modification includes tight control of blood pressure (BP), plasma lipids, and blood glucose. Complete cessation of tobacco use is a must.

The diagnosis of PAD begins with a careful history and physical examination and is confirmed with noninvasive laboratory testing. Ischemic pain occurs in the leg muscles supplied by arterial segments that are distal to the site of stenosis. Thus, calf claudication is the hallmark of femoral-popliteal disease, whereas discomfort in the thigh, hip, or buttock associated with impotence indicates aortoiliac disease (Leriche syndrome). Depending on the severity of the stenosis, the pain is experienced at a predictable walking distance and is promptly relieved by rest. Claudication must be differentiated from the pseudoclaudication of lumbar degenerative spinal canal stenosis. In the latter condition, walking can also aggravate leg pain, but it is not relieved simply by the cessation of exercise. Rather, assuming positions that minimize lumbar extension such as stooping forward or sitting alleviates the pain. The characteristic physical findings of PAD are absent or diminished pulses distal to the stenosis, bruits over the diseased artery, hair loss, thin shiny skin, and muscle atrophy. Severe ischemia causes pallor, cyanosis, decreased skin temperature, ulceration, and gangrene.

Noninvasive techniques are effective. The *ankle-brachial index* (ABI) is the ratio of the highest systolic BP measured from either the dorsalis pedis or posterior tibialis artery to the highest systolic BP obtained from the brachial artery using a Doppler stethoscope. The normal ABI range is 0.9 to 1.3. An ABI of less than 0.9 indicates PAD. This simple noninvasive test has a sensitivity and a specificity of 95% and 99%, respectively. In some patients with diabetes mellitus or renal failure, the media of the affected leg vessels become so heavily calcified that they resist compression except during very high levels of cuff inflation. The result is a falsely elevated ankle BP and an artificially normal or supernormal ABI (Table 13-1).

Duplex ultrasonography is an important adjunct to the ABI, with a similar sensitivity and specificity. This test is particularly useful to diagnose PAD in patients with non-compressible vessels from medial wall calcification. The Doppler velocity waveform remains abnormal, despite a spuriously normal or elevated ABI. Magnetic resonance (MR) angiography and computed tomographic (CT) angiography are newer techniques that now permit excellent visualization of vascular stenosis and identification of runoff vessels. With these noninvasive imaging modalities, spatial resolution is comparable with that of traditional invasive angiography. Catheter-based angiography, the gold standard, now is reserved for patients undergoing revascularization.

The medical management of patients with PAD includes lifestyle and risk factor modification as well as antiplatelet therapy. Smoking cessation reduces the risk for limb loss, myocardial infarction, and death. Lipid-lowering therapy with a statin hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor should be initiated and intensified if low-density lipoprotein (LDL) cholesterol is greater than 100 mg/dL. Hypertension should be treated with appropriate medication, which should be intensified until BP is less

than 140/90 mm Hg. The target BP is even lower (<130/80 mm Hg) in PAD patients with diabetes or chronic kidney disease and in patients who have had a prior cardiovascular event or who have left ventricular hypertrophy (LVH) visualized by electrocardiography (ECG) or echocardiography. In contrast to traditional teaching, β -adrenergic blockers do not reduce walking capacity or worsen intermittent claudication in patients with PAD. Aspirin reduces the risk for myocardial infarction, death, and stroke. However, clopidogrel has proved more effective than aspirin in this setting. Each patient needs an exercise prescription because exercise training improves walking capacity and quality of life. Pentoxifylline is a methylxanthine derivative that may improve maximal walking distance, but the data are inconclusive. Better data is available with cilostazol, a phosphodiesterase III inhibitor, whereas sildenafil is a phosphodiesterase V inhibitor. In several studies of patients with symptomatic PAD, cilostazol consistently improved walking capacity and quality of life. It is one of the most effective agents for intermittent claudication. However, cilostazol must be avoided in patients with congestive heart failure because its use may increase mortality.

Revascularization (percutaneous or surgical) is indicated for patients with severe claudication that is resistant to medical therapy, limb-threatening ischemia, or vasculogenic impotence. Percutaneous revascularization offers a comparable patency rate with less morbidity and mortality than does surgery in patients with short focal stenoses in large arteries such as the distal aorta or iliac arteries (Fig. 13-1). Surgical revascularization is more suitable for longer areas of stenosis or obstructive lesions distal to the origin of the iliac arteries.

Acute limb ischemia (ALI) constitutes a vascular emergency. Sudden occlusion of a peripheral artery is caused by either arterial embolism or thrombosis in situ. Arterial emboli usually originate in the cardiac chambers in the

Table 13-1 Interpretation of Ankle-Brachial Index

Ankle-Brachial Index	Interpretation
0.90-1.30	Normal
0.70-0.89	Mild PAD
0.40-0.69	Moderate PAD
<0.40	Severe PAD
>1.30	Noncompressible vessels

PAD, peripheral arterial disease.

Figure 13-1 Angiogram of the distal abdominal aorta and iliac arteries demonstrates an occluded left common iliac artery with extensive collateral circulation from the contralateral internal iliac artery (*left panel*), which resolved after successful stent implantation (*right panel*). (Images courtesy of Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Texas.)

setting of preexisting cardiac disease such as myocardial infarction (e.g., left ventricular mural thrombus), congestive heart failure, or atrial arrhythmias (e.g., left atrial thrombus in a patient with atrial fibrillation). Thrombosis in situ usually occurs in arteries with a preexisting severe stenosis in the setting of longstanding PAD with or without previous vascular surgery. Patients with arterial embolism usually experience sudden onset of symptoms without a history of claudication, whereas those with thrombosis in situ typically have a history of claudication that has previously been stable and then suddenly assumes a crescendo pattern over a period of days. In either case, the physical examination reveals a cold, cyanotic (bluish) extremity with absent pulses distal to the site of arterial occlusion and diminished motor or sensory function. A hand-held Doppler device is used to assess signals at different arterial segments and confirms the diagnosis of acute vascular occlusion. Anticoagulation should be initiated immediately with intravenous heparin titrated to maintain the activated partial thromboplastin time equal to 2.0 to 2.5 times control. Patients with ALI who developed symptoms for more than 14 days or occlusion in the suprainguinal sites generally require surgical thromboembolectomy or bypass surgery. In contrast, patients with more recent onset of symptoms or infrainguinal occlusion should be treated with catheter-directed infusion of thrombolytic therapy or percutaneous thrombus extraction. Patients with irreversible tissue necrosis, regardless of the cause, should be treated with emergent amputation rather than revascularization to reduce the risk for kidney failure (myoglobinemia), sepsis, and multiple-organ failure.

AORTIC ANEURYSM

Abdominal aortic aneurysm (AAA) is a common vascular disease in older adults, affecting 4% to 8% of men and 0.5% to 1.5% of women older than 65 years. Thoracic aortic aneurysm is much less prevalent (0.4% to 0.5%). Besides age, the major risk factors for AAA are cigarette smoking, hypertension, and a family history of aortic aneurysms. Atherosclerosis is responsible for most cases of AAA, but other causes include cystic medial necrosis (Marfan syndrome, Ehlers-Danlos syndrome), vasculitis with connective tissue disease (Takayasu arteritis, giant cell arteritis), chronic infection (syphilitic aortitis), and trauma. Abdominal aortic aneurysms gradually grow in size over time at an average rate of 1 to 4 mm per year. The risk for rupture is low until the diameter reaches 5 cm, and then it increases exponentially. The risk for aortic rupture is 1% per year for aneurysms between 3.5 and 4.9 cm in diameter and 5% per year for aneurysms larger than 5 cm.

Most patients with AAA are asymptomatic, but some develop vascular complications such as aneurysm expansion with compression of adjacent structures. Occasionally, mural thrombi form within the aneurysm embolize, causing acute occlusion of distal arterial segments. Patients with iliac aneurysm may develop hydronephrosis or recurrent urinary tract infection from ureteral compression. Others develop neurologic symptoms from compression of sciatic or femoral nerves. The classic physical finding is a pulsatile nontender mass below the umbilicus (distal to the origin of the renal arteries). In thin patients, normal aortic pulsations are often

Figure 13-2 Computed tomographic angiogram of the distal abdominal aorta shows an abdominal aortic aneurysm with the largest diameter of 6.2 cm and severe stenosis at the origin of the right common iliac artery. (Image courtesy of Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Texas.)

Table 13-2 Indications for Surgical Treatment of Arterial Aneurysms

Symptoms from expansion of aneurysm or compression of adjacent structure
Rupture of aneurysm
Rapid aortic aneurysm expansion of ≥ 1 cm per year
Large aneurysm
Ascending aorta >4.5 cm for patients with Marfan syndrome and >5 cm for all others
Aortic arch >5.5 cm
Descending thoracic aorta >5 cm
Abdominal aorta >5.5 cm
Iliac aneurysm >3 cm

palpable but above the umbilicus. Hypotension and acute abdominal pain should prompt consideration of aneurysm rupture, which requires emergent operative repair. Duplex ultrasonography is an accurate and reliable diagnostic tool for abdominal aortic and iliac aneurysms. Routine screening for AAA with ultrasonography is recommended for all men between the ages of 65 and 75 years or men above the age of 60 with family history of AAA among first-degree relatives. Such screening has a proven mortality benefit. CT and MR angiography allow visualization of the thoracic and abdominal aorta as well as the iliac arteries and its branches (Fig. 13-2). Medical treatment for aortic aneurysm includes smoking cessation, tight BP control, and cholesterol reduction. β -Adrenergic blockade reduces the rate of aortic root enlargement in patients with Marfan syndrome but has not proved beneficial in patients with AAA from other causes. Patients with large aneurysms or rapid aneurysm expansion regardless of the size should undergo aneurysm repair (Table 13-2). Elective AAA repair carries a

peri-operative mortality rate of 2% to 6%. Furthermore, a large randomized study failed to demonstrate any benefit of surgery in patients with aneurysms 4 to 5.5 cm in diameter. For these reasons, patients with small aortic aneurysms should be treated medically with close monitoring of aneurysm size with periodic imaging studies every 6 to 12 months (see Table 13-2).

Percutaneous endovascular aneurysm repair (EVAR) is an alternative method to open surgical repair for treatment of AAA. EVAR offers lower perioperative death than surgical repair, but long-term survival rates are not different from surgery. EVAR has not been shown to improve mortality in patients with multiple co-morbidities, who are considered to be unfit for surgery, when compared with conservative management. Therefore, it should be offered only to selected patients with symptoms from compression of adjacent organs or vascular complications.

Aortic Dissection

In aortic dissection, the intimal layer is torn from the aortic wall, leading to the formation of a false lumen in parallel with the true lumen. Risk factors include hypertension, cocaine use, trauma, hereditary connective tissue disease (e.g., Marfan syndrome, Ehlers-Danlos syndrome), vasculitis (e.g., Takayasu arteritis, giant cell arteritis), Behçet disease, bicuspid aortic valve, and aortic coarctation. Aortic dissection can be classified as types A and B (Stanford system). Type A dissection involves the ascending aorta, whereas type B dissection involves the distal aorta. The DeBakey system subdivides aortic dissection into three subtypes: types I, II, and III. Type I dissection involves the entire aorta, whereas type II involves only the ascending aorta, and type III involves only the descending aorta. Aortic dissection involving the ascending aorta carries a high mortality rate of 1% to 2% per hour during the first 24 to 48 hours. Patients usually develop acute onset of severe chest or back pain. Abdominal pain, syncope, and stroke are common. Retrograde propagation of the dissection can cause pericardial tamponade or coronary artery dissection with acute myocardial infarction. Dissection involving the aortic valve causes acute severe aortic insufficiency with acute pulmonary edema. The dissection plane may propagate in an antegrade direction to compromise flow in the carotid and subclavian arteries, producing a stroke or acute upper limb ischemia. Patients with distal (type B) aortic dissection exhibit acute onset of back pain or chest pain often accompanied by lower extremity ischemia and ischemic neuropathy. The physical findings include pulse deficits, neurologic deficits, or a diastolic murmur of aortic regurgitation. However, acute aortic regurgitation into an unprepared ventricle produces only a short, soft diastolic murmur that is often missed. The widened pulse pressure and associated physical findings of chronic aortic regurgitation are absent, and the clinical picture is that of an acutely ill patient with tachypnea, tachycardia, and a narrow pulse pressure. Hypotension, jugular venous distention, and pulsus paradoxus should prompt the diagnosis of pericardial tamponade. Transesophageal echocardiography, MR angiography, or CT angiography confirms the diagnosis by demonstrating an intimal flap that separates the true lumen from the false lumen (Fig. 13-3). Type A aortic dissection is uniformly fatal without emergent surgical repair. With surgery, mortality is reduced to 10% at

Figure 13-3 Computed tomographic angiogram of the aorta shows type B aortic dissection. The intimal flap (arrow) separates the true lumen (T) from the false lumen (F) and compromises blood flow to the right kidney, causing renal atrophy and cortical thinning. (Image courtesy of Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Texas.)

24 hours and 20% at 30 days. Patients with type B aortic dissection should be treated medically because 1-year survival is higher with medical therapy than it is with surgery (75% versus 50%). However, surgery is indicated if type B dissection compromises blood flow to the legs, kidneys, or other viscera. Tight control of BP is essential because aortic aneurysm develops in 30% to 50% of patients with type B aortic dissection studied for 4 years.

Penetrating Aortic Ulcers and Intramural Hematoma

Penetrating aortic ulcers and intramural hematomas exhibit chest pain that is indistinguishable from that of aortic dissection. In contrast to aortic dissection, however, the pathologic condition is localized. No identifiable intimal flap and thus no branch vessel occlusion are produced. Disruption of the internal elastic lamina produces aortic ulcers that erode into the medial wall and protrude into the surrounding structures. Rupture of the vasa vasorum causes formation of localized hematoma underneath the adventitia with resultant asymmetrical thickening of the aortic wall. Patients with either condition typically are older than those with aortic dissection, have a larger aortic size, and have a higher prevalence of AAA. Aortic rupture is the major complication of both penetrating ulcers and intramural hematomas, particularly with those aneurysms located in the ascending aorta. The diagnosis is made with invasive angiography, CT angiography, or MR angiography (Fig. 13-4). Surgical intervention should be considered for ulcers and hematomas of the ascending aorta, deeply penetrating ulcers, or severely bulging hematomas, irrespective of their location. Ulcers and hematomas of the descending aorta may be managed successfully with β -adrenergic blockade and tight control of BP.

Figure 13-4 Computed tomographic angiogram of the descending thoracic aorta shows a large penetrating aortic ulcer above the diaphragm (arrow). (Image courtesy of Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Texas.)

Other Arterial Diseases

Buerger disease is a nonatherosclerotic disease of the arteries, veins, and nerves of the arms and legs affecting mostly young men before the age of 45 years. The cause is unknown, but all patients have a history of heavy tobacco addiction. The presenting symptom is claudication of the feet, legs, hands, or arms. Multiple-limb involvement and superficial thrombophlebitis are common. The C-reactive protein and Westergren sedimentation rate typically are normal, and a search for serologic markers for connective tissue disease (e.g., antinuclear antibody or rheumatoid factor, antiphospholipid antibody) is negative. The diagnosis is usually based on the typical clinical presentation. If the presentation is atypical, biopsy may be needed to make the diagnosis. The histologic hallmark is inflammatory intramural thrombi within the arteries and veins with sparing of internal elastic lamina and other arterial wall structures. The most effective treatment of Buerger disease is complete tobacco abstinence. The prostacyclin analogue iloprost constitutes adjunctive therapy to reduce limb ischemia and improve wound healing.

Raynaud phenomenon is a vasospastic disease of the small arteries of mainly the fingers and toes. Primary (idiopathic) Raynaud phenomenon occurs in the absence of underlying disorders. Secondary Raynaud phenomenon occurs in association with connective tissue diseases (e.g., scleroderma, polymyositis, rheumatoid arthritis, systemic lupus erythematosus) as well as with repeated mild physical trauma (e.g., use of jack hammers), certain drugs (e.g., antineoplastic chemotherapeutic agents, interferon, monoamine-reuptake inhibitors such as tricyclic antidepressants, serotonin agonists), and Buerger disease. Patients usually complain of recurrent episodes of digital ischemia, with a characteristic white-blue-red color sequence. Pallor is followed by cyanosis if ischemia is prolonged and then by erythema (reactive hyperemia) when the episode resolves. Episodes are precipitated by cold temperature or emotional stress. Physical examination can be entirely normal between

attacks with normal radial, ulnar, and pedal pulses. Some patients may have digital ulcers or thickening of fat pad (sclerodactyly). Patients should be instructed to avoid cold temperatures and dress warmly. Calcium channel blockers (CCBs) reduce the frequency and severity of vasospastic episodes.

Giant cell arteritis is an immune-mediated vasculitis predominantly involving medium-sized and large arteries such as the subclavian artery, axillary artery, and aorta of the older adult with a strong male predominance. About 40% of patients with giant cell arteritis also have polymyalgia rheumatica, a syndrome characterized by severe stiffness and pain originating in the muscles of the shoulders and pelvic girdle. Patients may exhibit headache from temporal arteritis, jaw claudication from ischemia of the masseter muscles, or visual loss from involvement of ophthalmic artery. Chest pain suggests the co-existence of aortic aneurysm or dissection. Physical findings include low-grade fever, scalp tenderness in the temporal area, pale and edematous fundi, or a diastolic murmur of aortic regurgitation. BP difference of more than 15 mm Hg between arms suggests subclavian artery stenosis. Laboratory findings include significantly elevated C-reactive protein and Westergren sedimentation rate plus anemia. The diagnosis is confirmed by histologic examination of the arterial tissue (frequently from temporal artery biopsy), showing infiltration of lymphocytes and macrophages (i.e., giant cells) in all layers of the vascular wall. High-dose corticosteroids are highly effective. To minimize complications from long-term corticosteroid administration, the steroid dose should be tapered to find the lowest dose needed to suppress symptoms, which often wane. Every attempt should be made to discontinue corticosteroids over time.

Takayasu arteritis is an idiopathic granulomatous vasculitis of the aorta, its main branches, and the pulmonary artery. This condition is particularly common in young women of Asian descent, but it also occurs in occidental women and men. The inflammatory process in the vascular wall can lead to stenosis and aneurysm formation. Hypertension, as a result of renal artery stenosis or aortic coarctation, is the most common manifestation and is present in as many as 80% of affected individuals. Because the vascular involvement is so widespread, patients may have symptoms and signs of coronary ischemia, congestive heart failure, stroke, vertebrobasilar insufficiency, or intermittent claudication. Physical findings include bruits over the subclavian arteries or aorta as well as diminished brachial pulses and thus a low brachial artery BP. The diagnosis is based primarily on this clinical presentation. First-line treatment is with corticosteroids. Other immunosuppressive agents such as methotrexate or cyclophosphamide are often added to prevent disease progression and relapse. Immunosuppressive therapy does not cause regression of preexisting vascular stenoses or aneurysms. For this reason, percutaneous or surgical revascularization is usually required.

Arteriovenous (AV) fistulas are abnormal vascular communications that shunt blood flow from the arterial system directly into the venous system, bypassing the capillary beds that normally ensure optimal tissue perfusion and nutrient exchange. AV fistulas may be congenital, as in AV malformation (AVM), or acquired. The main causes of acquired AV fistula are penetrating trauma (e.g., gunshot, knife

wound) and surgically created shunts for hemodialysis access. Patients may exhibit a pulsatile mass, symptoms related to compression of an adjacent organ, or bleeding from spontaneous rupture of an AVM. Systolic and diastolic bruits or thrills may be detectable over the fistula or AVM. An AVM in skeletal muscle may lead to bone malformation or a pathologic fracture, whereas AVM in the brain may result in neurologic deficits or seizures. High-output heart failure is another complication from a large AVM or fistula. MR angiography, CT angiography, or conventional angiography confirms the diagnosis. Depending on the size and location of the AVM, treatment options include surgical resection, transcatheter embolization, or pulse laser irradiation. Patients with acquired AV fistulas from trauma usually need surgical closure.

Pulmonary Vascular Disease

Pulmonary hypertension is characterized by elevated mean pulmonary pressure of greater than 25 mm Hg at rest or greater than 30 mm Hg during exercise. The many causes of pulmonary hypertension are summarized in Table 13-3.

Patients with pulmonary hypertension have not only an elevated pulmonary arterial pressure but also a low cardiac output, causing symptoms of exertional dyspnea, fatigue, and syncope. Pulmonary capillary wedge pressure is usually

normal except in patients with pulmonary venous hypertension and congenital heart disease.

PULMONARY ARTERIAL HYPERTENSION

Pulmonary arterial hypertension (PAH) is caused by a combination of pulmonary vasoconstriction, endothelial cell or smooth muscle proliferation, intimal fibrosis, and thrombosis in the pulmonary capillaries and arterioles. PAH is either idiopathic (primary pulmonary hypertension [PPH]) or secondary to connective tissue disease, congenital heart disease, portal hypertension, or human immunodeficiency virus (HIV) infection as well as anorexigenic drugs or toxins. Connective tissue diseases, particularly scleroderma, are the most common secondary causes of PAH.

Patients with mild PAH can be asymptomatic, but patients with more advanced disease complain of dyspnea, chest pain, syncope, or presyncope. Physical findings include a left parasternal lift, loud pulmonary component of the second heart sound, murmur of tricuspid or pulmonic regurgitation, hepatomegaly, peripheral edema, or ascites. Associated ECG abnormalities indicate right ventricular hypertrophy, right atrial enlargement, or right axis deviation. Echocardiography provides important information about the severity of the pulmonary hypertension (i.e., estimated pulmonary artery pressure, right ventricular dimensions and function) and its potential causes (e.g., left ventricular failure, valvular lesions, congenital heart disease with left-to-right shunts). Pulmonary function tests, ventilation-perfusion (\dot{V}/\dot{Q}) lung scans, polysomnography or overnight oximetry, autoantibody tests, HIV serology, and liver function tests also should be performed to determine other potential causes. Right ventricular catheterization should be performed in all patients with suggested PAH. Under basal conditions in the catheterization laboratory, an elevated mean pulmonary artery pressure exceeding 25 mm Hg, a pulmonary capillary wedge pressure below 15 mm Hg, and a pulmonary vascular resistance exceeding 3 units confirm the diagnosis. Acute vasodilator drug challenge should be performed during right ventricular catheterization to guide appropriate treatment.

Without treatment, the prognosis of PAH is poor, with a median survival of less than 3 years. Patients with severe symptoms should be treated with prostacyclin or epoprostenol (an intravenous prostacyclin analogue) because of their proven efficacy in improving exercise capacity, quality of life, and survival. Other prostacyclin analogues, such as treprostinil and iloprost, are also effective in reducing pulmonary artery pressure and improving exercise capacity. Other classes of drugs approved for treatment of PAH include endothelin receptor blockers and phosphodiesterase-5 inhibitors. Oral CCBs are indicated for the small subset of patients with mild to moderate symptoms who demonstrate significant reduction in pulmonary pressure with acute CCB challenge. Supplemental home oxygen is indicated for all patients with hypoxemia. Higher elevations exacerbate hypoxemia, and relocation to sea level improves symptoms. Oral anticoagulation is recommended for all patients with PAH. Diuretics should be prescribed for patients with peripheral edema or hepatic congestion. Lung transplantation is recommended only for patients in whom severe symptoms occur despite intensive medical therapy.

Table 13-3 Classification of Pulmonary Hypertension

Category 1: Pulmonary Arterial Hypertension

Primary pulmonary hypertension or idiopathic pulmonary hypertension:

- Sporadic
- Familial

PPH associated with:

- Connective tissue disease
- Congenital heart disease
- Portal hypertension
- Human immunodeficiency viral infection

Drugs and toxins:

- Anorexigens
- Cocaine

Category 2: Pulmonary Venous Hypertension

- Left ventricular heart failure
- Left ventricular valvular heart disease

Category 3: Pulmonary Hypertension associated with Chronic Respiratory Disease or Hypoxemia

- Chronic obstructive pulmonary disease
- Obstructive sleep apnea

Category 4: Pulmonary Hypertension associated with Chronic Venous Thromboembolism

- Left ventricular valvular heart disease

Category 5: Pulmonary Hypertension Due to Miscellaneous Disorders Directly Affecting the Pulmonary Vasculature

- Sarcoidosis
- Histiocytosis X
- Compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

Venous Thromboembolic Disease

Venous thromboembolism (VTE) encompasses both deep vein thrombosis (DVT) and pulmonary embolism (PE). Among the adult U.S. population, the overall combined annual incidence is as high as 1 new case per 1000 persons. The incidence of VTE is higher in men than in women and higher in African Americans and whites than in Asians and Hispanics. More than 150 years ago, Dr. Rudolf Virchow recognized three predisposing factors: (1) endothelial damage, (2) venous stasis, and (3) hypercoagulation (Virchow triad). Endothelial damage is common with surgery or trauma, venous stasis is common with prolonged bed rest or immobilization (leg cast), and hypercoagulation is common with cancer. Trousseau syndrome consists of migratory thrombophlebitis with noninfectious vegetations on the heart valves (marantic endocarditis) typically in the setting of mucin-secreting adenocarcinoma. Dr. Trousseau, a pathologist, diagnosed his own pancreatic carcinoma on the basis of the association that now bears his name. Hypercoagulable states include hereditary diseases such as deficiencies in antithrombin III, protein C, or protein S; mutation in factor V gene (factor V Leiden) or factor II gene (prothrombin G20210A); and hyperhomocysteinemia. However, a thorough search for identifiable risk factors will come up negative in 25% to 50% of patients with VTE.

DEEP VEIN THROMBOSIS

Most DVT starts in the calf veins. Without treatment, 15% to 30% of these clots propagate to the proximal calf veins. The risk for a subsequent PE is much higher with proximal DVT than those confined to the distal calf vessels (40% to 50% versus 5% to 10%, respectively). Involvement of the upper extremities is much less common, but subclavian and axillary vein thrombosis also can lead to PE in as many as 30% of affected individuals. The same risk factors that cause lower extremity DVT also cause upper extremity DVT. In addition, other specific causes of upper extremity DVT include traumatic damage of the vessel intima from heavy exertion such as rowing, wrestling, or weight lifting (Paget-Schroetter syndrome); from extrinsic compression at the level of thoracic inlet (thoracic outlet obstruction); or from insertion of central venous catheters or pacemakers. Pain and swelling are the major complaints from patients with DVT; however, a large number of patients with DVT are asymptomatic, particularly if the DVT is restricted to the calf. Patients with upper extremity DVT can develop the superior vena caval syndrome of facial swelling, blurred vision, and dyspnea. Thoracic outlet obstruction can compress the brachial plexus leading to unilateral arm pain associated with hand weakness. Physical examination frequently reveals tenderness, erythema, warmth, and swelling below the site of thrombosis. Pain with dorsiflexion of the foot (Homan sign) may be present, but the low sensitivity and the low specificity limit its usefulness in the diagnosis of lower extremity DVT. A palpable tender cord, dilated superficial veins, and low-grade fever occur in some patients. Upper extremity DVT can cause brachial plexus tenderness in the supraclavicular fossa and atrophic hand muscles. For

patients with probable thoracic outlet obstruction, several provocative tests should be performed. Adson test is positive if the radial pulses weaken during inspiration and during extension of the arm of the affected side while rotating the head to the same side. Wright test is positive if the radial pulses become weaker and painful symptoms are reproduced while abducting the shoulder of the affected side with the humerus externally rotated.

The laboratory diagnosis of DVT includes measurement of D-dimers, which are fibrin degradation products. D-dimer elevation is a highly sensitive indicator of DVT that can be performed rapidly in the emergency department. In a patient in whom the index of probability is low, a negative D-dimer test effectively excludes the diagnosis of DVT. However, the test is not specific and can be elevated in many other conditions frequently encountered in hospitalized patients (e.g., inflammation, recent surgery, malignancy). Duplex ultrasonography can be used to demonstrate the presence of a blood clot or noncompressibility of the affected veins proximal to the site of occlusion. Duplex ultrasonography has greater sensitivity in detecting proximal DVT (90% to 100%) than distal DVT (40% to 90%) of the lower extremities. With upper extremity DVT, acoustic shadowing of the clavicle may obscure detection of thrombosis in subclavian vein segments. MR angiography is particularly helpful in making the diagnosis of upper extremity DVT and pelvic vein thrombosis. Contrast venography is the conventional gold standard test, but it is invasive and technically difficult in patients with edematous extremities. Therefore, invasive venography should be reserved for patients in whom the clinical suggestion is high, despite negative or inconclusive results from noninvasive imaging.

Patients with proximal lower extremity DVT and those with upper extremity DVT should be treated initially with subcutaneous low-molecular-weight heparin (LMWH), intravenous or subcutaneous unfractionated heparin (UFH), or subcutaneous selective factor Xa inhibitor fondaparinux to prevent thrombus propagation and to maintain the patency of venous collaterals. Intravenous UFH should be given as a bolus, followed by continuous infusion to maintain an activated partial thromboplastin time of at least 1.5 times the control value. LMWH and fondaparinux has a longer half-life than UFH and can be given once or twice daily with similar efficacy. Oral warfarin should be initiated together with LMWH, UFH, or fondaparinux without delay and titrated until the international normalized ratio (INR) reaches a value between 2 and 3. When DVT is confined to the calf, the risk for PE is low, and the risk-to-benefit ratio of anticoagulation remains controversial.

When upper extremity DVT occurs in young patients who are otherwise healthy, two invasive approaches to thrombus removal should be considered: (1) infusion of a fibrinolytic drug through a catheter inserted directly into the affected vein, or (2) mechanical fragmentation of the thrombus through catheter-based technology. The purpose of these invasive procedures is to prevent or minimize the post-thrombotic syndrome, which includes chronic arm pain, swelling, hyperpigmentation, and ulceration from residual venous obstruction.

Catheter-based placement of a filter in the inferior vena cava should be considered for patients with proximal DVT who either have an absolute contraindication to anticoagula-

tion or develop recurrent PE despite an adequate trial of anticoagulation. Vena cava filters are effective in reducing the incidence of PE, but they increase the risk for recurrent DVT. Some proximal or distal migration of the filter occurs in up to 50% of cases; however, clinically evident filter embolization is limited to case reports.

PULMONARY EMBOLISM

PE occurs when a thrombus dislodges from the deep veins of the upper or lower extremities. Pulmonary vascular resistance and pulmonary arterial pressure increase from two mechanisms: (1) anatomic reduction in cross-sectional area of the pulmonary vascular bed, and (2) functional hypoxia-induced pulmonary vasoconstriction. The pressure overload on the right ventricle can lead to dilation, hypokinesis, and tricuspid regurgitation. When severe, elevated right ventricular end-diastolic pressure can compress the right coronary artery, causing subendocardial ischemia. In acute PE, areas of lung tissue are ventilated but underperfused. This \dot{V}/\dot{Q} mismatch and the resultant redistribution of pulmonary blood flow from obstructed pulmonary artery to other lung regions with lower \dot{V}/\dot{Q} cause arterial hypoxemia. In patients with a patent foramen ovale, hypoxemia worsens when the sudden elevation in right atrial pressure causes right-to-left shunting across the foramen.

The classic symptoms of acute PE are the sudden onset of dyspnea and pleuritic chest pain. Additional symptoms include anginal chest pain from right ventricular ischemia, hemoptysis from pulmonary infarction, and syncope or presyncope from massive PE with acute right ventricular failure (cor pulmonale). The most common physical findings are tachypnea and tachycardia. Additional physical findings include a right ventricular lift, inspiratory crackles, a loud pulmonary component of the second sound, expiratory wheezing, and a pleural rub. Symptoms and signs of proximal DVT are present in 10% to 20% of patients. Arterial blood gas analysis often reveals hypoxemia, respiratory alkalosis, and a high alveolar-to-arterial oxygen tension gradient. However, normal arterial blood gas values do not exclude the diagnosis. The most common finding with ECG analysis is sinus tachycardia. Atrial fibrillation, premature atrial contraction, and supraventricular tachycardia are less common. Other ECG changes suggest acute right ventricular strain. These include the $S_1-Q_3-T_3$ pattern, a new right bundle branch block or right axis deviation, and P-wave pulmonale. However, these findings are present in only 30% of patients with even massive PE. Common but nonspecific abnormalities with chest radiographic studies include atelectasis, pleural effusion, and pulmonary infiltrates. Less common but more specific radiographic findings include Hampton hump (i.e., wedge-shaped infiltrate in the peripheral lung field), which is indicative of pulmonary infarction, and Westermark sign (decreased vascularity). The plasma D-dimer test is elevated in most patients with PE as a result of activation of the endogenous fibrinolytic system, which is not sufficient to dissolve the clot. Commercially available D-dimer assays have a high sensitivity and negative predictive value but low specificity. Therefore, a normal D-dimer test effectively excludes the diagnosis of PE in patients in whom the clinical suggestion is low or intermediate. However, it should not be used to screen patients with a high

Figure 13-5 Spiral chest computed tomographic angiogram shows a large thrombus in the right main pulmonary artery (arrow). (Image provided by Michael Landay, MD, Department of Radiology, University of Texas Southwestern Medical Center, Dallas, Texas.)

index of suspicion because of low negative predictive value. Elevated levels of cardiac troponin I and troponin T and other markers of myocardial injury can be found in patients with PE and are indicative of right ventricular dysfunction and a poor prognosis.

In patients with suggested PE, a completely normal \dot{V}/\dot{Q} scan effectively excludes the diagnosis without further testing. However, less than 10% of \dot{V}/\dot{Q} scans are interpreted as definitively normal. In patients in whom a moderate or high level of clinical probability of PE exists, a high-probability \dot{V}/\dot{Q} scan has a diagnostic accuracy of 90% to 100%; however, a low or intermediate probability scan is no more helpful than a coin flip. More recently, multidetector CT angiography has become the imaging modality of choice in patients with acute PE because of its excellent visualization of the pulmonary artery (Fig. 13-5). The resolution of 1 mm or less rivals that of conventional invasive angiography. The speed of the newer-generation scanners allows acquisition of all images within a single breath-hold, avoiding respiratory motion artifacts. The overall negative predictive value of multidetector CT angiography exceeds 99%. A negative CT scan excludes the diagnosis of PE and eliminates the need for further diagnostic testing. CT also permits detection of other pathologic conditions involving the lung parenchyma, pleura, and mediastinal structures. Such pathologic findings may mimic PE and constitute alternative causes of chest pain and dyspnea. Multidetector CT angiography is not yet available at all centers. The requirement for intravenous injection of iodinated contrast material restricts applicability to those without a history of kidney disease or an allergic reaction to contrast dye. Figure 13-6 presents an algorithm for the work-up of PE based on current evidence. Echocardiography may directly detect thrombi in the right atrium, right ventricle, or pulmonary artery or indirectly demonstrate right ventricular dysfunction, signifying presence of hemodynamically significant emboli. Therefore, it is helpful in diagnosis of PE in patients with hypotension or shock, particularly when multidetector CT are not immediately available. Invasive pulmonary angiography should

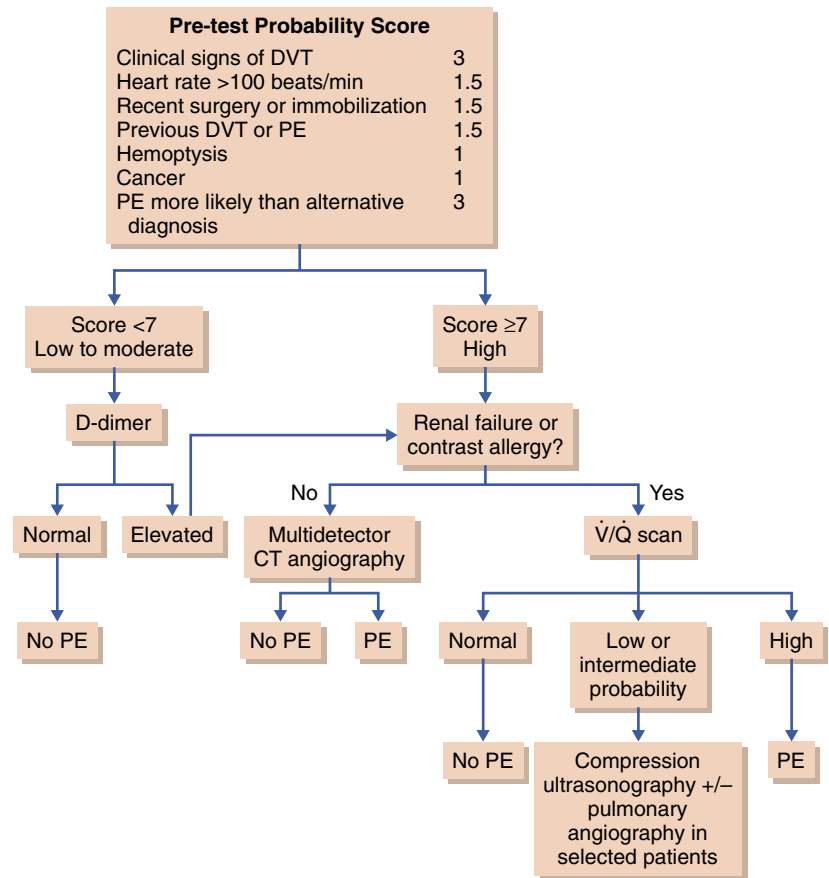

Figure 13-6 Diagnostic algorithm for patients with suggested pulmonary embolism (PE). DVT, deep vein thrombosis.

be reserved for patients in whom noninvasive testing is inconclusive.

Treatment of acute PE includes immediate anticoagulation with UFH, LMWH, or fondaparinux. LMWH and fondaparinux are preferred agents in patients with normal renal function due to the ease of subcutaneous administration and lower rates of thrombocytopenia. Because these drugs are excreted renally, they should be avoided in patients with renal failure and intravenous UFH should be used. Thrombolytic therapy with recombinant tissue plasminogen activator (rt-PA) is indicated for patients with hypotension or shock from massive PE. Surgical or percutaneous removal of emboli should be considered in patients with massive PE who have contraindications for thrombolytic therapy. Thrombolytic therapy should also be considered in patients with right ventricular enlargement or dysfunction, particularly when they have limited cardiovascular reserve or other predictors of poor outcomes such as elevated cardiac troponins. After initiation of heparins or fondaparinux, warfarin should be administered. Infusion of heparins or fondaparinux needs to be continued for at least the first 5 days of warfarin therapy until a therapeutic INR of 2 to 3 is reached.

The time necessary to continue anticoagulation after an acute PE or DVT episode depends on the presence or absence of reversible risk factors for recurrent VTE. Patients with a history of trauma or surgery generally have a low rate of recurrent VTE; therefore, warfarin can be discontinued after 3 to 6 months of administration. Patients with cancer and

VTE should be treated initially with subcutaneous fixed-dose LMWH for 3 to 6 months because of its greater efficacy than warfarin in preventing recurrent thromboembolism in this setting. After this period, treatment with LMWH or warfarin should be continued indefinitely unless the cancer is cured. Patients with idiopathic VTE with low risk for bleeding should be treated with warfarin indefinitely, whereas those with high bleeding risk should be treated for at least 3 months.

VENOUS THROMBOEMBOLISM PROPHYLAXIS

Patients who are at high risk for VTE should receive prophylaxis with subcutaneous UFH or LMWH. Patients at high risk include those who are hospitalized with acute medical illness, particularly congestive heart failure, acute respiratory illness, acute inflammatory diseases, those who are expected to be immobilized for 3 days or longer, or patients with previous VTE. Major surgery, either elective or emergent, is an important indication for VTE prophylaxis. Subcutaneous UFH is equally effective to LMWH and fondaparinux in preventing symptomatic DVT in patients undergoing general surgery, gynecologic surgery, or neurosurgery. However, LMWH, fondaparinux, or adjusted-dose warfarin to INR between 2 and 3 are preferred to UFH for prevention of DVT in orthopedic surgery such as hip surgery or total knee replacement because of superior efficacy. Patients undergoing major cancer surgery should receive continued prophylaxis.

laxis after discharge up to 28 days. Mechanical prophylaxis with intermittent pneumatic compression provides additional protection from VTE and should be administered in all surgical patients whenever possible.

Arterial Hypertension

Affecting nearly one third of the adult population (65 million in the United States and 1 billion people worldwide), arterial hypertension is the leading cause of death in the world, the most common cause for an outpatient visit to a physician, and the most easily recognized treatable risk factor for stroke, myocardial infarction, heart failure, peripheral vascular disease, aortic dissection, atrial fibrillation, and end-stage kidney disease. Despite this knowledge and unequivocal scientific proof that treating hypertension with medication dramatically reduces its attendant morbidity and mortality, hypertension remains untreated or undertreated in most affected individuals in all countries, including those with the most advanced systems of medical care (Fig. 13-7). Thus, hypertension remains one of the world's great public health problems. The asymptomatic nature of the condition impedes early detection, which requires regular BP measurement. Because most cases of hypertension cannot be cured, BP control requires lifelong treatment with prescription medications, which are costly and may cause more symptoms than the underlying disease process. Effective hypertension management requires continuity of care by a regular and knowledgeable medical provider as well as sustained active participation by an educated patient. This section reviews the most important principles in the early detection and effective treatment of hypertension.

Figure 13-7 Hypertension control rates in North America and Europe. (From Wang YR, Alexander GC, Stafford RS: Outpatient hypertension treatment, treatment intensification, and control in Western Europe and the United States. *Arch Intern Med* 141-147, 2007.)

INITIAL EVALUATION FOR HYPERTENSION

The initial evaluation for hypertension needs to accomplish three goals: (1) staging of BP, (2) assessing the patient's overall cardiovascular risk, and (3) detecting clues of secondary hypertension. The initial clinical data needed to accomplish these goals are obtained through a thorough history and physical examination, routine blood tests, a spot (preferably first morning) urine specimen, and a resting 12-lead ECG. In some patients, ambulatory BP monitoring and an echocardiogram provide helpful additional data about the time-integral burden of BP on the cardiovascular system.

GOAL 1: ACCURATE ASSESSMENT OF BLOOD PRESSURE

Across populations, the risks for heart disease and stroke increase continuously and logarithmically with increasing levels of systolic and diastolic BP at or above 115/75 mm Hg (Fig. 13-8). Thus, the dichotomous separation of *normal* from *high* BP is artificial. BP is currently staged as normal, prehypertension, or hypertension based on the average of two or more readings taken at two or more office visits. When a patient's average systolic and diastolic pressures fall into different stages, the higher stage applies (Table 13-4).

Prehypertension is designated as BPs in the 120 to 139 mm Hg systolic, 80 to 89 mm Hg diastolic ranges. Prehypertensive individuals are twice as likely to progress to hypertension as are those with lower values.

BP normally varies dramatically throughout a 24-hour period. To minimize variability in readings, BP should be measured at least twice after 5 minutes of rest with the patient seated, the back supported, and the arm bare and at heart level. The most common mistake in measuring BP is using a standard-issue cuff that is too small for a large arm, producing spuriously elevated readings. Most overweight adults require a large adult cuff. Tobacco and caffeine should be avoided for at least 30 minutes. To avoid underestimation of systolic pressure in older adults who may have an *auscultatory gap* as a result of arteriosclerosis, radial artery palpation should be performed to estimate systolic pressure; the cuff should then be inflated to a value 20 mm Hg higher than the level that obliterates the radial pulse and deflated at a rate of 3 to 5 mm Hg per second. BP should be measured in both arms and after 5 minutes of standing, the latter to exclude a significant postural fall in BP, particularly in older persons and in those with diabetes or other conditions (e.g., Parkinson disease) that predispose the patient to autonomic insufficiency.

Because of the anxiety of going to the physician, BPs often are higher in the physician's office than when measured at home or during normal daily life outside the home. Self-monitoring of BP outside of the physician's office actively engages a patient in his or her own health care and provides a better estimate of a person's usual BP for medical decision making. BP should be measured in early morning and evening times. Three BP readings should be obtained during each measurement, separated by at least 1 minute. Because the first BP tends to be the highest, average BP should be used to assess home BP. Many *electronic home monitors* are available, but only a handful of models have been rigorously

Figure 13-8 Absolute risk for coronary artery disease and stroke mortality by usual systolic blood pressure (BP) levels. (From Prospective Studies Collaboration: Age-specific relevance of usual BP to vascular mortality: A meta-analysis of individual data for one million adults in 61 prospective studies. *Lancet* 360:1903-1913, 2002.)

Blood Pressure Stage	Systolic Blood Pressure (mm Hg)	Diastolic Blood Pressure (mm Hg)
Normal	<120	<80
Prehypertension	120-139	80-89
Stage 1 hypertension	140-159	90-99
Stage 2 hypertension	≥160	≥100

*Calculation of seated blood pressure is based on the mean of two or more readings on two separate office visits.
 From Chobanian A, Bakris G, Black H, et al: The seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. The JNC 7 report. *JAMA* 289:2560-2572, 2003.

validated against mercury sphygmomanometry and can be recommended.

Ambulatory monitoring provides automated measurements of BP over a 24-hour period while patients are engaged in their usual activities, including sleep (Fig. 13-9). With ambulatory monitoring, current recommendations for *upper limits of normal* are a mean daytime BP of 135/85 mm Hg, mean nighttime BP of 120/70 mm Hg, and a mean 24-hour BP of 130/80 mm Hg. However, an *optimal* mean daytime ambulatory BP is less than 130/80 mm Hg. To avoid undertreating hypertension, these lower treatment thresholds must be used when incorporating ambulatory monitoring in medical decision making. With self-monitoring of BP at home, an average value of 130/80 mm Hg should be considered the upper limit of normal; BP should be lower in the patient’s own home than with daily activities outside the home.

Up to one third of patients with elevated office BPs have normal home or ambulatory BPs. If the 24-hour BP profile

is completely normal and no target organ damage has occurred despite consistently elevated office readings, the patient has *office-only*, or *white-coat*, hypertension, presumably the result of a transient adrenergic response to the measurement of BP in the physician’s office (see Fig. 13-9). In other patients, office readings underestimate ambulatory BPs, presumably because of sympathetic overactivity in daily life owing to job or home stress, tobacco abuse, or other adrenergic stimulation that dissipates when coming to the office (Fig. 13-10). Such documentation prevents underdiagnosing and undertreating this *masked hypertension*, which is also associated with high cardiovascular risks and identified in 10% of hypertensive patients in general and 60% to 70% of African American patients with hypertensive kidney disease.

GOAL 2: CARDIOVASCULAR RISK STRATIFICATION

Most patients with BPs in the prehypertensive or hypertensive range will have one or more additional modifiable risk factors for atherosclerosis (e.g., hypercholesterolemia, cigarette smoking, diabetes). Many patients already have evidence of target organ involvement at the time of the initial office evaluation for newly diagnosed hypertension. In addition to hypertensive stage, the other two components to cardiovascular risk are (1) co-morbidity, and (2) target organ damage (Table 13-5).

The current U.S. treatment guidelines recommend a usual BP of 140/90 mm Hg as the threshold for initiating a lifetime of antihypertensive medication in most patients and a lower threshold of 130/80 mm Hg for high-risk patients. The definition of *high-risk* patients has been expanded to include those with any of the following conditions: (1) diabetes mellitus; (2) chronic kidney disease (estimated glomerular filtration rate [GFR] < 60 mL/1.73 m² per minute or estimated urinary albumin excretion > 300 mg per 24 hours); (3) high Framingham risk score with estimated cardiovascular 10-year risk of 10% or greater; (4) unstable or stable angina;

Figure 13-9 Twenty-four-hour ambulatory blood pressure (BP) monitor tracings in two different patients. **A**, Optimal blood pressure (BP) in a healthy 37-year-old woman. The normal variability in BP, the nocturnal dip in BP during sleep, and the sharp increase in BP on awakening are noted. **B**, Pronounced white-coat effect in an 80-year-old woman referred for evaluation of medically refractory hypertension. Documentation of the white-coat effect prevented overtreatment of the patient's isolated systolic hypertension. (A, Courtesy of Meryem Tuncel, MD, Hypertension Division, Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, Texas. B, Tracing provided by Wanpen Vongpatanasin, MD, Hypertension Division, Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, Texas.)

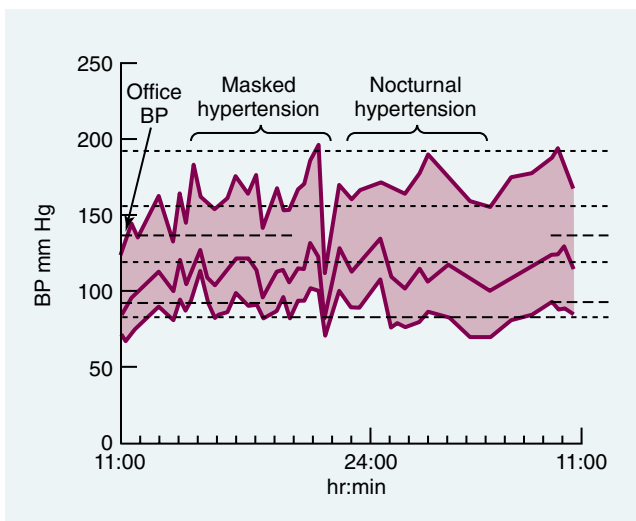

Figure 13-10 Twenty-four-hour ambulatory blood pressure (BP) monitor tracing shows both masked hypertension and nocturnal hypertension in a 55-year-old man with stage 3 chronic kidney disease. Treatment with three different antihypertensive medications in this patient produced an office BP of 125/75 mm Hg, which seems to be at goal. However, progressive hypertensive heart disease and deterioration of renal function suggested masked hypertension. Ambulatory monitoring revealed that the patient's treated BP was much higher out of the office, documenting both masked hypertension (ambulatory BP of 175/95 mm Hg and sustained nocturnal hypertension (BP of 175/90 mm Hg). Additional medication was added. (Tracing provided by Ronald G. Victor, MD, Hypertension Division, Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, Texas.)

Table 13-5 Components of Cardiovascular Risk Stratification in Patients with Hypertension or Prehypertension

Indications for BP < 130/80 mm Hg

- Diabetes mellitus
- Chronic kidney disease
- GFR < 60 mL/1.73 m²/min
- Urine albumin: Cr > 300 mg/24 hr
- Ten-year Framingham cardiovascular risk score ≥10%
- Stable or unstable angina
- ST-elevation or non-ST-elevation myocardial infarction
- Congestive heart failure or left ventricular ejection fraction < 40%
- Peripheral arterial disease, carotid disease, aortic aneurysm

BP, blood pressure; Cr, serum creatinine; GFR, glomerular filtration rate.

Data from Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Cholesterol in Adults (Adult Treatment Panel III). *JAMA* 285:2486-2497, 2001; and Scientific statement from the American Heart Association Council for High Blood Pressure Research and the Councils on Clinical Cardiology and Epidemiology and Prevention. *Circulation* 115:2761-2788, 2007.

(5) acute myocardial infarction (with or without ST elevation); (6) carotid artery disease, peripheral arterial disease, or AAA; and (7) congestive heart failure or left ventricular ejection fraction of less than 40%.

GOAL 3: IDENTIFICATION OF SECONDARY (IDENTIFIABLE) CAUSES OF HYPERTENSION

A thorough search for secondary causes is not cost-effective in most patients with hypertension, but it becomes critically important in two circumstances: (1) when a com-

Table 13-6 Guide to Evaluation of Secondary Hypertension

Probable Diagnosis	Clinical Clues	Diagnostic Testing
Renal parenchymal hypertension	Estimated GFR < 60 mL/1.73 m ² /min Urine albumin-to-creatinine ratio > 30 mg/g	Renal ultrasound
Renovascular disease	New elevation in serum creatinine, significant elevation in serum creatinine with initiation of ACEI or ARBs, refractory hypertension, flash pulmonary edema, abdominal bruit	MR or CT angiography, invasive angiogram
Coarctation of the aorta	Arm pulses > leg pulses, arm BP > leg BP, chest bruits, rib notching on chest radiograph	Chest MRI or CT, aortogram
Primary aldosteronism	Hypokalemia, refractory hypertension	Plasma renin and aldosterone, 24-hr urine potassium, 24-hr urine aldosterone and potassium after salt loading, adrenal CT, adrenal vein sampling
Cushing syndrome	Truncal obesity, wide and blanching purple striae, muscle weakness	24-hr urine cortisol, dexamethasone suppression test, adrenal CT
Pheochromocytoma	Spells of paroxysmal hypertension, palpitations, perspiration, pallor, pain in the head Diabetes	Plasma and 24-hr urine metanephrines and catecholamines, adrenal CT
Obstructive sleep apnea	Loud snoring, daytime somnolence, obesity, large neck	Sleep study

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; CT, computed tomography; GFR, glomerular filtration rate; MR, magnetic resonance; MRI, magnetic resonance imaging.
Data from Kaplan NM: Clinical Hypertension, 8th ed. Philadelphia, Williams & Wilkins, 2002.

elling cause is found on the initial evaluation, or (2) when the hypertensive process is so severe that it either is refractory to intensive multiple-drug therapy or requires hospitalization. Table 13-6 summarizes the major causes of secondary hypertension that should be suggested on the basis of a good history, physical examination, and routine laboratory tests.

Renal Parenchymal Hypertension

Chronic kidney disease is the most common cause of secondary hypertension. Hypertension is present in more than 85% of patients with chronic kidney disease and is a major factor causing their increased cardiovascular morbidity and mortality. The mechanisms causing the hypertension include an expanded plasma volume and peripheral vasoconstriction, with the latter caused by both activation of vasoconstrictor pathways (renin-angiotensin and sympathetic nervous systems) and inhibition of vasodilator pathways (nitric oxide). Renal insufficiency should be considered when proteinuria is found by dipstick or when the serum creatinine level is greater than 1.2 mg/dL in women with hypertension or greater than 1.4 mg/dL in men with hypertension.

Renovascular Hypertension

Unilateral or bilateral renal artery stenosis is present in less than 2% of patients with hypertension in a general medical practice but in up to 30% in patients with medically refractory hypertension. The main causes of renal artery stenosis are atherosclerosis (85% of patients), typically in older adults with other clinical manifestations of systemic atherosclerosis, and fibromuscular dysplasia (15% of patients), typically in women between the ages of 15 and 50 years. Unilateral renal artery stenosis leads to underperfusion of the juxta-

glomerular cells, thereby producing renin-dependent hypertension even though the contralateral kidney is able to maintain normal blood volume. In contrast, bilateral renal artery stenosis (or unilateral stenosis with a solitary kidney) constitutes a potentially reversible cause of progressive renal failure and volume-dependent hypertension. The following clinical clues increase the suggestion of renovascular hypertension: any hospitalization for urgent or emergent hypertension; recurrent *flash* pulmonary edema; recent worsening of longstanding, previously well-controlled hypertension; severe hypertension in a young adult or in an adult after 50 years of age; precipitously and progressively worsening of renal function in response to angiotensin-converting enzyme (ACE) inhibition or angiotensin receptor blockade (ARB); unilateral small kidney by any radiographic study; extensive peripheral arteriosclerosis; or a flank bruit. The diagnosis is confirmed by noninvasive testing with MR or spiral CT angiography (Fig. 13-11). Renal artery angioplasty often cures fibromuscular dysplasia. Atherosclerotic renal artery stenosis should be treated with intensive medical management of atherosclerotic risk factors (hypertension, lipids, smoking cessation). Revascularization should be considered for the following indications: (1) medically refractory hypertension, (2) progressive renal failure on medical therapy, and (3) bilateral renal artery stenosis or stenosis of a solitary functioning kidney.

Primary Aldosteronism

The most common causes of primary aldosteronism are (1) a unilateral aldosterone-producing adenoma and (2) bilateral adrenal hyperplasia. Because aldosterone is the principal ligand for the mineralocorticoid receptor in the distal nephron, excessive aldosterone production causes excessive renal Na⁺-K⁺ exchange, often resulting in hypokalemia. The

Figure 13-11 Computed tomographic angiogram with three-dimensional reconstruction. **A**, Classic *string-of-beads* lesion of fibromuscular dysplasia. **B**, Severe proximal atherosclerotic stenosis of the right renal artery. (Images courtesy of Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Texas.)

diagnosis should always be suggested when hypertension is accompanied by either unprovoked hypokalemia (serum K^+ < 3.5 mmol/L in the absence of diuretic therapy) or a tendency to develop excessive hypokalemia during diuretic therapy (serum K^+ < 3 mmol/L). However, more than one third of patients do not have hypokalemia on initial presentation, and the diagnosis should be considered in any patient with refractory hypertension. The diagnosis is confirmed by the demonstration of nonsuppressible hyperaldosteronism during salt loading, followed by adrenal vein sampling to distinguish between a unilateral adenoma and bilateral hyperplasia. Laparoscopic adrenalectomy is the treatment of choice for unilateral aldosterone-producing adenoma, whereas pharmacologic mineralocorticoid receptor blockade with eplerenone is the treatment for bilateral adrenal hyperplasia.

Mendelian Forms of Hypertension

Nine rare forms of severe early-onset hypertension are inherited as mendelian traits. In each case, the hypertension is mineralocorticoid induced and involves excessive activation of the epithelial sodium channel (*ENaC*), the final common pathway for reabsorption of sodium from the distal nephron. The resultant salt-dependent hypertension can be caused by gain-of-function mutations of *ENaC* (Liddle syndrome) or the mineralocorticoid receptor (i.e., a rare form of pregnancy-induced hypertension) and by increased production or decreased clearance of mineralocorticoids. These include aldosterone (glucocorticoid-remediable aldosteronism), deoxycorticosterone (17-hydroxylase deficiency), and cortisol (syndrome of apparent mineralocorticoid excess).

Pheochromocytoma

Pheochromocytomas are rare catecholamine-producing tumors of the adrenal (or sometimes extra-adrenal) chromaffin cells. The diagnosis should be suggested when hyperten-

sion is accompanied by paroxysms of headaches, palpitations, pallor, or diaphoresis. In some patients, pheochromocytoma is misdiagnosed as panic disorder. A family history of early-onset hypertension may suggest pheochromocytoma as part of the multiple endocrine neoplasia syndromes. If the diagnosis is missed, outpouring of catecholamines from the tumor can cause an unsuspected hypertensive crisis during unrelated radiologic or surgical procedures; the perioperative mortality rate exceeds 80% in such patients.

Laboratory confirmation of pheochromocytoma is made by demonstrating elevated levels of plasma or urinary metanephrines, catecholamines, or other metabolites such as vanillylmandelic acid. These are typically large tumors that can usually be localized by CT or magnetic resonance imaging (MRI), although nuclear scanning with specific isotopes that localize to chromaffin tissue is occasionally needed to identify smaller tumors.

Treatment of these tumors is surgical resection. Patients must receive adequate α blockade (phentolamine), β blockade, and volume expansion before surgery to prevent the hemodynamic swings that can occur during manual manipulation of the tumor peri-operatively. For unresectable tumors, chronic therapy with the α -adrenergic blocker phenoxybenzamine is usually effective.

The differential diagnosis includes other causes of neurogenic hypertension such as sympathomimetic agents (cocaine, methamphetamine), baroreflex failure, and obstructive sleep apnea. A history of surgery and radiation therapy for head-and-neck tumors suggests the possibility of baroreceptor damage. Loud snoring, obesity, and somnolence suggest obstructive sleep apnea. Weight loss, continuous positive airway pressure, and corrective surgery improve BP control in some patients with sleep apnea.

Other causes of secondary hypertension include hypothyroidism, hyperthyroidism, coarctation of the aorta, and immunosuppressive drugs, especially cyclosporine and tacrolimus.

TREATMENT OF HYPERTENSION

Prescription medication is the cornerstone of treating hypertension. Lifestyle modification should be used as an adjunct but not as an alternative to life-saving BP medication. Most dietary sodium comes from processed foods, and daily salt consumption can be reduced from 10 to 6 g by teaching patients to read food labels (6 g of NaCl = 2.4 g of Na⁺ = 100 mmol of Na⁺). The *Dietary Approaches to Stop Hypertension* (DASH) guidelines, which are rich in fresh fruits and vegetables (for high potassium content) and low-fat dairy products, has been shown to lower BP in feeding trials. Other lifestyle modifications that can lower BP include weight loss in overweight patients with hypertension, regular aerobic exercise, smoking cessation, and moderation in alcohol intake.

Currently, 92 prescription medications and many fixed-dose combinations are marketed for the treatment of hypertension in the United States (see Table 13-4).

WHICH DRUGS FOR WHICH PATIENTS?

Patients with Uncomplicated Hypertension

Choosing the best drugs to treat hypertension in a given patient comes down to two considerations: (1) effectively lowering BP and preventing hypertensive complications with minimal side effects and cost, and (2) concomitant treatment of co-morbid cardiovascular diseases (e.g., angina, heart failure). The seventh report of the U.S. Joint National Committee (JNC 7) recommends a thiazide-type diuretic as cost-effective first-line therapy for most patients with hypertension. It also recommends initiating therapy with two drugs—one being a thiazide—for stage 2 hypertension. In contrast, the European Society of Hypertension makes no specific drug class recommendation, arguing that the most effective drugs are those that the patient will tolerate and take. The British Hypertension Society advocates a treatment strategy that is based on the patient's age and ethnicity. It recommends initiating therapy with an ACE inhibitor or ARB or a β blocker (A or B drug) for young white patients (<55 years of age) who often have high-renin hypertension but a CCB or diuretic (C or D drug) for older and black patients who often have low-renin hypertension (Tables 13-7 and 13-8).

A growing body of evidence from clinical trials emphasizes the overriding importance of lowering BP with combinations of drugs rather than belaboring the choice of a single, best agent to begin therapy. Primary hypertension is multifactorial, and typically several medications (usually three or more) with different mechanisms of action (see Table 13-4) are required simultaneously to reach currently recommended BP levels (<140/90 mm Hg for most patients, <130/80 mm Hg for high-risk patients). In most patients with hypertension, low-dose combination drug therapy is the only way to control BP adequately and to minimize side effects. With many classes of antihypertensive medication, the dose-response relationship for BP is rather flat. Most of the BP lowering occurs at the lower end of the dose range. However, many of the side effects are steeply dose dependent, becoming problematic mainly at the high end of the

Table 13-7 Oral Antihypertensive Agents

Drug*	Dose Range, Total Doses per Day (mg/day)
Diuretics

HCTZ, hydrochlorothiazide.

clinical dose range. Thus, low-dose combinations achieve therapeutic synergy and minimize side effects. Fixed-dose combinations reduce pill burden and cost. Additional ways to facilitate patient adherence include (1) titrating medical therapy based on home readings, which engages the patient's active participation; (2) teaching the patient to know his or her goal BP values; and (3) prescribing long-acting preparations with once-daily dosing.

Along with antihypertensive medication and lifestyle modification, additional cardiovascular risk reduction with low-dose aspirin (81 mg per day) and lipid-lowering medication should be strongly considered as an integral part of most antihypertensive regimens. In patients who are treated for hypertension, low-dose aspirin has been shown to reduce the risk for myocardial infarction by 36% without increasing the risk for intracerebral hemorrhage. A sizeable cardiovascular benefit of adding 10 mg of the HMG-CoA reductase inhibitor atorvastatin to antihypertensive therapy has been demonstrated in patients older than 60 years with moderate hypertension and an average LDL cholesterol of only 130 mg/dL.

Patients with High Cardiovascular Risks

Aggressive BP reduction to reach target goal of less than 130/80 mm Hg is warranted in patients at high risk for cardiovascular events (see Table 13-5). In patients with very high cardiovascular risk profiles but without known left ventricular dysfunction, the ACE inhibitor ramipril (10 mg/day) reduces cardiovascular events, an effect that may or may not be beyond what can be explained by BP reduction alone. The ARB telmisartan similarly offers cardiovascular protection in these high-risk individuals with less side effects such as angioedema. In contrast, a combination of ARB and ACE inhibitor results in deterioration of renal function and increases risk for hypotension without added cardiovascular benefit. A recent clinical trial demonstrated a large benefit of combination therapy with dihydropyridine CCB and ACE inhibitor over the combination of thiazide diuretics and ACE inhibitor in reducing cardiovascular events. Thus, the former combination should be considered in high-risk patients who have an elevated BP of more than 20 mm Hg above target goal.

Hypertension in African Americans

Hypertension disproportionately affects African Americans. The explanation is unknown, but the dominant importance of environmental factors is indicated by a significant geographic variation in hypertension prevalence among African-origin and European-origin populations. Hypertension is rare in Africans living in Africa and is more prevalent in several European countries than it is in the United States. As monotherapy, an ACE inhibitor or ARB or a β blocker generally yields a smaller decrease in BP in an African American than it does in a white person with hypertension and thus affords less protection against stroke. However, when high doses of an ACE inhibitor or ARB are used in combination with a diuretic, antihypertensive efficacy is amplified, and ethnic differences seem to disappear. When used as part of an appropriate multidrug regimen, ACE inhibitor-based treatment can achieve excellent control of hypertension in African American patients with hypertensive nephrosclerosis, and it slows the deterioration in renal function.

Table 13-8 Major Contraindications and Side Effects of Antihypertensive Drugs

Drug Class	Major Contraindications	Side Effects
Diuretics		
Thiazides	Gout	Insulin resistance, new-onset type 2 diabetes (especially in combination with β blockers) Hypokalemia, hyponatremia Hypertriglyceridemia Hyperuricemia, precipitation of gout Erectile dysfunction (more than other drug classes) Potentiate nondepolarizing muscle relaxants Photosensitive dermatitis
Loop diuretics	Hepatic coma	Interstitial nephritis Hypokalemia Potentiate succinylcholine Potentiate aminoglycoside ototoxicity
Potassium-sparing diuretics	Serum K >5.5 mEq/L GFR <30 mg/mL/1.73 m ²	Fatal hyperkalemia if used with salt substitutes, ACE inhibitors, ARBs, high-potassium foods, NSAIDs
β blockers	Heart block Asthma Depression Cocaine and/or methamphetamine abuse	Insulin resistance, new-onset type 2 diabetes (especially in combination with thiazides) Heart block, acute decompensated CHF Bronchospasm Depression, nightmares, fatigue Cold extremities, claudication (β_2 effect) Stevens-Johnson syndrome Agranulocytosis
ACE inhibitors	Pregnancy Bilateral renal artery stenosis Hyperkalemia	Cough Hyperkalemia Angioedema Leukopenia Fetal toxicity Cholestatic jaundice (rare fulminant hepatic necrosis if the drug is not discontinued)
ARBs	Pregnancy Bilateral renal artery stenosis Hyperkalemia	Hyperkalemia Angioedema (very rare) Fetal toxicity
Direct renin inhibitors	Pregnancy Bilateral renal artery stenosis Hyperkalemia	Hyperkalemia diarrhea Fetal toxicity
Dihydropyridine CCBs	As monotherapy in chronic kidney disease with proteinuria	Headaches Flushing Ankle edema CHF Gingival hyperplasia Esophageal reflux
Nondihydropyridine CCBs	Heart block Systolic heart failure	Bradycardia, AV block (especially with verapamil) Constipation (often severe with verapamil) Worsening of systolic function, CHF Gingival edema and/or hypertrophy Increase cyclosporine blood levels Esophageal reflux
α blockers	Monotherapy for hypertension Orthostatic hypotension Systolic heart failure Left ventricular dysfunction	Orthostatic hypotension Drug tolerance (in the absence of diuretic therapy) Ankle edema CHF First-dose effect (acute hypotension) Potentiate hypotension with PDE-5 inhibitors (e.g., sildenafil)

Continued

Table 13-8 Major Contraindications and Side Effects of Antihypertensive Drugs—cont'd

Drug Class	Major Contraindications	Side Effects
Central sympatholytics	Orthostatic hypotension	Depression, dry mouth, lethargy Erectile dysfunction (dose dependent) Rebound hypertension with clonidine withdrawal Coombs-positive hemolytic anemia and elevated LFTs with α -methyldopa
Direct vasodilators	Orthostatic hypotension	Reflex tachycardia Fluid retention Hirsutism, pericardial effusion with minoxidil Lupus with hydralazine

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; AV, arteriovenous; CCB, calcium channel blocker, CHF, congestive heart failure; GFR, glomerular filtration rate; LFT, liver function test; NSAID, nonsteroidal anti-inflammatory drug; PDE-5, phosphodiesterase type 5.

Hypertensive Nephrosclerosis

Hypertension is the second most common cause of chronic kidney disease, accounting for more than 25% of cases. Hypertensive nephrosclerosis is the result of persistently uncontrolled hypertension, causing chronic glomerular ischemia. Typically, proteinuria is mild (<0.5 g per 24 hours). Nondiabetic chronic kidney disease is a compelling indication for ACE inhibitor-based or ARB-based antihypertensive therapy. ACE inhibitors cause greater dilation of the efferent renal arterioles, thereby minimizing intraglomerular hypertension. In contrast, arterial vasodilators such as dihydropyridine CCBs, when used without an ACE inhibitor or ARB, preferentially dilate the afferent arteriole and impair renal autoregulation. Glomerular hypertension can result if systemic BP is not sufficiently lowered. The ACE inhibitor should be withdrawn only if the rise in serum creatinine exceeds 30% of the baseline value or the serum K^+ increases to greater than 5.6 mmol/L.

Hypertensive Patients with Diabetes

Compared with its 25% prevalence in the general adult population, hypertension is present in 75% of patients with diabetes and is a major factor contributing to excessive risk for myocardial infarction, stroke, heart failure, microvascular complications, and diabetic nephropathy progressing to end-stage renal disease. To reduce these risks, BPs should be lowered to less than 130/80 mm Hg. The cardiovascular benefits of tight BP control in patients with diabetes cannot be overemphasized because they exceed and are additive to those of tight glucose control. To achieve such stringent BP goals typically requires three to five drugs. An ACE inhibitor or ARB should be the drug of first choice for the hypertensive patient with diabetes because of mounting evidence that these agents provide special renoprotective effects. However, an ACE inhibitor or ARB alone rarely achieves the stringent BP goals in patients with diabetic nephropathy. A loop diuretic is usually needed to shrink the expanded plasma volume. A dihydropyridine CCB is usually needed for antihypertensive synergy. The dihydropyridine CCB should not be started until antihypertensive therapy has been initiated with an ACE inhibitor or ARB. A β blocker should be added if the patient has coronary disease, which is prevalent in diabetes or heart failure. The α,β blocker carvedilol has a better metabolic profile than standard β blockers.

Hypertensive Patients with Coronary Artery Disease

To lower myocardial oxygen demands in patients with coronary disease, the antihypertensive regimen should reduce BP without causing reflex tachycardia. For this reason, a β blocker is often prescribed in conjunction with a dihydropyridine CCB. β blockers are indicated for patients with hypertension who have sustained a myocardial infarction and for most patients with chronic heart failure. ACE inhibitors are indicated for almost all patients with left ventricular systolic dysfunction and may be considered for patients after myocardial infarction even in the absence of ventricular dysfunction. In patients with stable coronary artery disease, a cardioprotective effect of ACE inhibition has also been demonstrated in patients with moderate cardiovascular risk profiles but not in those with lower risk profiles.

Isolated Systolic Hypertension in Older Adults

In developed countries, systolic pressure rises progressively with age; if individuals live long enough, almost all (>90%) develop hypertension. Diastolic pressure rises until the age of 50 years and decreases thereafter, producing a progressive rise in pulse pressure (i.e., systolic pressure minus diastolic pressure) (Fig. 13-12).

Different hemodynamic faults underlie hypertension in young and old persons. Patients who develop hypertension before 50 years of age typically have *combined systolic and diastolic hypertension*: systolic pressure greater than 140 mm Hg and diastolic pressure greater than 90 mm Hg. The main hemodynamic fault is vasoconstriction at the level of the resistance arterioles. In contrast, most patients who develop hypertension after 50 years of age have *isolated systolic hypertension*: systolic pressure greater than 140 mm Hg but diastolic pressure less than 90 mm Hg (often <80 mm Hg). In isolated systolic hypertension, the primary hemodynamic fault is decreased distensibility of the large conduit arteries (see Fig. 13-12). Collagen replaces elastin in the elastic lamina of the aorta, an age-dependent process that is accelerated by atherosclerosis and hypertension. The cardiovascular risk associated with isolated systolic hypertension is related to pulsatility, the repetitive pounding of the blood vessels with each cardiac cycle and a more rapid return of the arterial pulse wave from the periphery, both begetting more

Figure 13-12 Age-dependent changes in systolic and diastolic blood pressure (BP) in the United States (*left panel*). Schematic diagram explains the relation between aortic compliance and pulse pressure (*right panel*). (*Left panel*, From Burt V, Whelton P, Rocella EJ, et al: Prevalence of hypertension in the U.S. adult population: Results from the Third National Health and Nutrition Examination Survey, 1988-1991. *Hypertension* 25:305-313, 1995. *Right panel*, From Dr. Stanley Franklin University of California at Irvine.)

systolic hypertension. In the United States and Europe, most uncontrolled hypertension occurs in older patients with isolated systolic hypertension. A BP of 160/60 mm Hg (pulse pressure of 100 mm Hg) carries twice the risk for fatal coronary heart disease as 140/110 mm Hg (pulse pressure of 30 mm Hg) (Fig. 13-13)!

In older persons with isolated systolic hypertension, lowering systolic pressure from higher than 160 to lower than 150 mm Hg reduces the risks for stroke, myocardial infarction, and overall cardiovascular mortality; it also reduces heart failure admissions and slows the progression of dementia. Trial data do not yet exist in older persons to determine whether the treatment of isolated elevations in systolic pressure between 140 and 160 mm Hg is beneficial; however, in the absence of such data, most authorities recommend treatment to prevent progression of systolic hypertension. No studies have specifically tested for a mortality benefit of treating systolic hypertension in patients older than 80 years; however, post hoc analyses strongly suggest a large reduction in strokes and heart failure admissions.

Based on data from several large randomized trials, low-dose thiazide diuretics and dihydropyridine CCBs are the drugs of choice for isolated systolic hypertension. For many older patients with hypertension, especially those with diabetes, the addition of an ACE inhibitor or ARB will be necessary to achieve recommended BP goals. To prevent the development of orthostatic hypotension, medication should be titrated to standing BP.

Blood Pressure Lowering for Secondary Prevention of Stroke

Most neurologists do not recommend BP reduction during an acute stroke. After the acute phase, BP should be lowered with a thiazide diuretic, adding an ACE inhibitor or additional drugs as needed to achieve BP goals.

Figure 13-13 Joint influences of systolic blood pressure (SBP) and diastolic BP on coronary heart disease (CHD) risk in the Multiple Risk Factor Intervention Trial. (From Neaton JD, Wentworth D: Serum cholesterol, blood pressure, cigarette smoking, and death from coronary heart disease: Overall findings and differences by age for 316,099 white men. *Arch Intern Med* 152:56-64, 1992.)

Hypertensive Disorders of Women

Oral contraceptives cause a small increase in BP in most women but rarely cause a large increase into the hypertensive range. If hypertension develops, oral contraceptive therapy should be discontinued in favor of other methods of contraception. Oral estrogen replacement therapy appears to cause a small increase in BP. In contrast, transdermal

estrogen (which bypasses first-pass hepatic metabolism) appears to cause a small but consistent decrease in BP.

Hypertension, the most common nonobstetric complication of pregnancy, is present in 10% of all pregnancies. Of these cases, one third are caused by chronic hypertension, and two thirds are due to preeclampsia, which is defined as an increase in BP to 140/90 mm Hg or greater after the 20th week of gestation accompanied by proteinuria (>300 mg per 24 hours) and pathologic edema, sometimes accompanied by seizures (eclampsia) and the multisystem HELLP syndrome of hemolysis (H), elevated liver enzymes (EL), and low platelets (LP). Although the cause remains an enigma, preeclampsia is the most common cause of maternal mortality and perinatal mortality. α -Methyldopa remains the drug of choice for chronic hypertension in pregnancy, and hydralazine (plus bed rest) for preeclampsia.

Resistant Hypertension

Defined as persistence of usual BP above 140/90 mm Hg despite treatment with full doses of three or more different classes of medications in rational combination and including a diuretic, *resistant hypertension* is the most common reason for referral to a hypertension specialist. In practice, the problem usually falls into one of four categories: (1) pseudoresistance, (2) inadequate medical regimen, (3) non-adherence or ingestion of pressor substances, or (4) secondary hypertension. Pseudoresistant hypertension is caused by *white-coat aggravation*, a white-coat effect superimposed on chronic hypertension that is well-controlled with medication outside the physician's office. The most common cause of apparent drug resistance is the absence of appropriate diuretic therapy. Significant impairment in renal function can be present with serum creatinine in the 1.2 to 1.4 mg/dL range or even lower, particularly in older patients with little muscle mass. To avoid this pitfall, calculation of GFR by equations based on serum creatinine, age, and weight and measurement of the urinary albumin-to-creatinine ratio from a spot-urine specimen should be an essential part of the routine evaluation of every patient with hypertension. Other common shortcomings of the medical regimen include reliance on monotherapy and inadequate dosing. Several common causes of resistant hypertension are related to the patient's behavior: medication nonadherence, recidivism with lifestyle modification (e.g., obesity, a high-salt diet, excessive alcohol intake), or habitual use of pressor substances such as sympathomimetics (e.g., tobacco, cocaine, methamphetamine, phenylephrine-containing cold or herbal remedies) or nonsteroidal anti-inflammatory drugs, with the latter causing renal sodium retention. After these behavioral factors have been excluded, the search should begin for secondary hypertension. The most common unrecognized factors are chronic kidney disease and primary aldosteronism. An increasing body of evidence suggests addition of spironolactone as a highly effective treatment in patients with resistant hypertension even in the absence of aldosteronism. Therefore, it should be part of antihypertensive regimen unless contraindicated.

Acute Severe Hypertension

Of all the patients in the emergency department, 25% have an elevated BP. *Hypertensive emergencies* are acute, often severe elevations in BP that are accompanied by acute or

Figure 13-14 Hypertensive retinopathy is traditionally divided into four grades. **A**, Grade 1 shows very early and minor changes in a young patient; increased tortuosity of a retinal vessel and increased reflectiveness (silver wiring) of a retinal artery are seen at the 1-o'clock position in this view. Otherwise, the fundus is completely normal. **B**, Grade 2 also shows increased tortuosity and silver wiring (arrowheads). In addition, *nipping* of the venules at arteriovenous (AV) crossings is visualized (arrow). **C**, Grade 3 shows the same changes as grade 2 plus flame-shaped retinal hemorrhages and soft *cotton-wool* exudates. **D**, In grade 4, swelling of the optic disc (papilledema) is observed, retinal edema is present, and hard exudates may collect around the fovea, producing a typical *macular star*. (From Forbes CD, Jackson WF: *Color Atlas and Text of Clinical Medicine*, 3rd ed. London, Mosby, 2003.)

rapidly progressive target organ dysfunction such as myocardial or cerebral ischemia or infarction, pulmonary edema, or renal failure. *Hypertensive urgencies* are severe elevations in BP without severe symptoms and without evidence of acute or progressive target organ dysfunction. Thus the key distinction and approach to the patient depends on the state of the patient and the assessment of target organ damage, not simply the absolute level of BP. The full-blown clinical picture of a hypertensive emergency is a critically ill patient with a BP greater than 220/140 mm Hg, headaches, confusion, blurred vision, nausea and vomiting, seizures, heart failure, oliguria, and grade III or IV hypertensive retinopathy (Fig. 13-14). Hypertensive emergencies require immediate admission in an intensive care unit (ICU) for intravenous therapy and continuous BP monitoring, whereas hypertensive urgencies can often be managed with oral medications and appropriate outpatient follow-up in 24 to 72 hours. The most common hypertensive cardiac emergencies include acute aortic dissection, hypertension after coronary artery bypass graft surgery, acute myocardial infarction, and unstable angina. Other hypertensive emergencies include eclampsia, head trauma, severe body burns, postoperative bleeding

from vascular suture lines, and epistaxis that cannot be controlled with anterior and posterior nasal packing. Neurologic emergencies, which include acute ischemic stroke, hemorrhagic stroke, subarachnoid hemorrhage, and hypertensive encephalopathy, can be difficult to distinguish from one another. Hypertensive encephalopathy is characterized by severe hypertensive retinopathy (i.e., retinal hemorrhages and exudates, with or without papilledema) and a posterior leukoencephalopathy affecting mainly the white matter of the parieto-occipital regions as seen on cerebral MRI or CT. A new focal neurologic deficit suggests a stroke in evolution, which demands a much more conservative approach to correcting the elevated BP.

In most other hypertensive emergencies, the goal of parenteral therapy is to achieve a controlled and gradual lowering of BP. A good rule of thumb is to lower the initially elevated arterial pressure by 10% in the first hour and by an additional 15% over the next 3 to 12 hours to a BP of no less than 160/110 mm Hg. BP can be reduced further over the next 48 hours. Unnecessarily rapid correction of the elevated BP to completely normal values places the patient at high risk for worsening cerebral, cardiac, and renal ischemia. In chronic hypertension, cerebral autoregulation is reset to higher than normal BP. This compensatory adjustment prevents tissue overperfusion (i.e., increased intracranial pressure) at very high BP, but it also predisposes the patient to tissue underperfusion (i.e., cerebral ischemia) when an elevated BP is lowered too quickly. In patients with coronary disease, overly rapid or excessive reduction in diastolic BP in the ICU can precipitate an acute myocardial ischemia or infarction. Secondary causes of hypertension should be considered in every patient admitted to the ICU with hypertensive crisis.

Parenteral agents for the treatment of hypertensive emergency are summarized in Table 13-9. Sodium nitroprusside,

a nitric oxide donor, is the most popular agent because it can be titrated rapidly to control BP. Intravenous nitroglycerin, another nitric oxide donor, is indicated mainly for hypertension in the setting of acute coronary syndrome or decompensated heart failure. Nicardipine is a parenteral dihydropyridine CCB that is particularly useful in postoperative cardiac patients and in patients with renal failure to avoid the thiocyanate toxicity with nitroprusside. Fenoldopam is a selective dopamine-1 receptor agonist that causes both systemic and renal vasodilation as well as increased glomerular filtration, natriuresis, and diuresis. Intravenous labetalol is an effective treatment for hypertensive crisis, particularly in the setting of myocardial ischemia with preserved ventricular function.

Most patients in the emergency department with hypertensive urgencies are either nonadherent with their medical regimen or are being treated with an inadequate regimen. To expedite the necessary changes in medications, outpatient follow-up should be arranged within 72 hours. To manage the patient during the short interim period, effective oral medication includes labetalol, clonidine, or captopril, which is a short-acting ACE inhibitor.

BPs greater than 160/110 mm Hg are a common incidental finding among patients in emergency departments and other acute care settings for urgent medical or surgical care of symptoms that are unrelated to BP (e.g., musculoskeletal pain, orthopedic injury). In these settings, the elevated BP is more often the first indication of chronic hypertension than a simple physiologic stress reaction, providing an important opportunity to initiate primary care referral for formal evaluation and treatment of chronic hypertension. Home and ambulatory BP monitoring is indicated to determine whether the patient's BP normalizes completely once the acute illness has resolved.

Table 13-9 Parenteral Agents for Management of Hypertensive Emergencies

Agent	Dose	Onset of Action	Precautions
Parenteral Vasodilators			
Sodium nitroprusside	0.25-10 mcg/kg/min IV infusion	Immediate	Thiocyanate toxicity with prolonged use
Nitroglycerin	5-100 mcg/min IV infusion	2-5 min	Headache, tachycardia, tolerance
Nicardipine	5-15 mg/hr IV infusion	1-5 min	Protracted hypotension after prolonged use
Fenoldopam mesylate	0.1-0.3 mcg/kg/min IV infusion	1-5 min	Headache, tachycardia, increased intraocular pressure
Hydralazine	5-10 mg as IV bolus or 10-40 mg IM; repeat every 4-6 hr	10 min IV 20 min IM	Unpredictable and excessive falls in blood pressure; tachycardia; angina exacerbation
Enalaprilat	0.625-1.25 mg every 6 hr IV bolus	15-60 min blood pressure	Unpredictable and excessive falls in acute renal failure in patients with bilateral renal artery stenosis
Parenteral Adrenergic Inhibitors			
Labetalol	20-80 mg as slow IV injection every 10 min, or 0.5-2.0 mg/min IV as infusion	5-10 min	Bronchospasm, heart block, orthostatic hypotension
Metoprolol	5 mg IV every 10 min for three doses	5-10 min	Bronchospasm, heart block, heart failure, exacerbation of cocaine-induced myocardial ischemia
Esmolol	500 mcg/kg IV over 3 min; then 25-100 mg/kg/min as IV infusion	1-5 min	Bronchospasm, heart block, heart failure
Phentolamine	5-10 mg IV bolus every 5-15 min	1-2 min	Tachycardia, orthostatic hypotension

IM, intramuscular; IV, intravenous.

PROGNOSIS

One of the most important prognostic factors in hypertension is ECG or echocardiographic LVH, with the latter already present in as many as 25% of patients with newly diagnosed hypertension. LVH predisposes the patient to heart failure, atrial fibrillation, and sudden cardiac death. For these reasons, BP should be lowered to below 130/80 mm Hg in hypertensive patients with LVH.

Because of their relatively short duration (typically, <5 years), randomized trials underestimate the lifetime protection against premature disability and death afforded by several decades of antihypertensive therapy in clinical practice. In the Framingham Heart Study, treating hypertension for 20 years in middle-aged adults reduced total cardiovascular mortality by 60%, which is considerably greater than the results of most randomized trials despite the less intense treatment guidelines when therapy was initiated in the 1950s through the 1970s.

Prospectus for the Future

- Further delineation of genetic causes of hypertension and application of this research to the treatment and prevention of hypertension, including development of pharmacologic and nonpharmacologic therapy that target the various signaling pathways in hypertension and prehypertension
- Improvement of endovascular techniques (stent grafts) for the treatment of aortic aneurysms, aortic dissection, and peripheral vascular diseases and evaluation of the role of these techniques in patients who are unfit for surgery
- Evaluation of drug-eluting stents for the prevention of restenosis after percutaneous revascularization of infrainguinal vascular disease
- Further assessment of safety and efficacy of emerging antithrombotic therapy in patients with atrial fibrillation, venous thromboembolism, and vascular disease
- Improvements in noninvasive imaging techniques of the vasculature, including three-dimensional reconstruction using CT angiography, MR angiography, and duplex ultrasonography

The Lung in Health and Disease

Sharon Rounds and Matthew D. Jankowich

The lung is part of the respiratory system. The respiratory system includes the centers for respiratory control in the brain cortex and medulla, the spinal cord, and peripheral nerves that innervate the skeletal muscles of respiration and the airways and vessels. The upper airway, including the nose, pharynx, and larynx, are where inspired air is humidified and particulate matter is filtered. The chest wall bony structure serves to maintain the lungs in an inflated state. The skeletal muscles of respiration include the diaphragm and the accessory muscles; the latter are important when disease states result in diaphragm fatigue. The lung consists of conducting airways and blood vessels and the gas exchange unit with alveolar gas space and capillaries. The lung is a complex organ with an extensive array of airways and vessels arranged to efficiently transfer the gases necessary for sustaining life. This organ has an immense capacity for gas exchange; therefore, it is not a limiting factor in exercise tolerance in healthy individuals. However, gas exchange becomes compromised in lung disease, rendering the host unable to function properly. The most dramatic consequence of acute and chronic abnormalities in lung function is systemic hypoxemia, leading to tissue hypoxia. Thus, the sequelae of lung dysfunction involve detrimental effects to other organs.

In addition to gas exchange, it is increasingly recognized that the lungs have other functions, such as defense against inhaled infectious agents or environmental toxins. Also, the entire cardiac output passes through the pulmonary circulation that serves as a filter for blood-borne clots or infections. The massive surface area of endothelial cells lining the pulmonary circulation serves metabolic functions, such as conversion of angiotensin I to angiotensin II.

Lung disorders are common and range from well-known conditions such as asthma and chronic obstructive pulmonary disease (COPD) to rarely encountered disorders such as lymphangioliomyomatosis. This section discusses the diagnosis, evaluation, and treatment of disorders that develop in direct response to lung injury as well as disorders that develop indirectly through injuries to other organs. This chapter begins with a brief discussion of how the basic

structural-functional relationships of the lung are established during lung development, followed by a description of the classification of pulmonary disorders discussed in the chapters in this section.

Lung Development

The lung begins to develop during the first trimester of pregnancy through complex and overlapping processes that transform the embryonic lung bud into a functioning organ with an extensive airway network, two complete circulatory systems, and millions of alveoli responsible for the transfer of gases to and from the body. Lung development can be described in five consecutive stages: *embryonic*, *pseudoglandular*, *canalicular* or *vascular*, *saccular*, and *alveolar postnatal* (Table 14-1). During the embryonic stage, between 21 days and 7 weeks of gestation, the rudimentary lung emerges from the foregut as a single epithelial bud surrounded by mesenchymal tissue. This stage is followed by the pseudoglandular stage (between 5 and 17 weeks of gestation), during which repeated monochotomous and dichotomous branching forms rudimentary airways—a process termed *branching morphogenesis* (Fig. 14-1). Coinciding with airway formation, new bronchial arteries arise from the aorta. The canalicular stage is next (between 17 and 24 weeks of gestation) and is characterized by the formation of the acinus, the differentiation of the acinar epithelium, and the development of the distal pulmonary circulation. Through the process of *vasculogenesis*, capillary networks derived from endothelial cell precursors are formed, extend from and around the distal air spaces, and connect with the developing pulmonary arteries and veins. By the end of this stage, the thickness of the alveolar capillary membrane is similar to that in the adult. During the saccular or prenatal alveolar stage (between 24 and 38 weeks of gestation), vascularized crests emerging from the parenchyma divide the terminal airway structures termed *sacculi*. Thinning of the interstitium continues, bringing capillaries from adjacent alveolar structures into close apposition, leading to a double capillary

Table 14-1 Stages of Lung Development

Stage	Period	Comments
Embryonic	3-7 wk	Embryonic lung bud emerges from the foregut.
Pseudoglandular	5-17 wk	Airway tree is formed through a process of monochotomous and dichotomous branching accompanied by growth.
Canalicular	17-24 wk	Angiogenesis and vasculogenesis occur to form the developing vascular network.
Saccular	24-38 wk	Alveoli begin to form through thinning of the mesenchyme and apposition of vascular structures with the air spaces and maturation.
Alveolar (postnatal)	36 wk-2 yr	Further development of alveoli and maturation occurs.

Figure 14-1 Lung branching morphogenesis. Branching morphogenesis occurs during the pseudoglandular stage of lung development and is the process by which the embryonic lung develops the primitive airway system through monochotomous and dichotomous branching.

network. Near birth, capillaries from opposing networks fuse to form a single network, and capillary volume increases with continuing lung growth and expansion. After birth, the lung continues to grow through the first few years of childhood with the creation of more alveoli through the septation of the air sacs. By age 2 years, the lung contains double arterial supplies and venous drainage systems, a complex airway system designed to generate progressive decreases in resistance to airflow as the air travels distally, and a vast alveolar network that efficiently transfers gases to and from the blood.

The processes that drive lung development are tightly controlled, but mishaps do happen, leading to congenital lung disorders such as cystic adenomatoid malformation of the lung, lung hypoplasia or agenesis, bullous changes in the lung parenchyma, and abnormalities in the vasculature, including aberrant connections between systemic vessels and lung compartments (e.g., lung sequestration) and congenital absence of one or both pulmonary arteries. However, these conditions are rare when compared with the number of infants born annually with abnormal lung function as a result of prematurity. In premature infants, the type II pneumocytes of the lung are underdeveloped and produce insufficient quantities of surfactant, a surface-active substance produced by specific alveolar epithelial cells that helps decrease surface tension, thereby preventing alveolar collapse. This disorder is known as the *infant respiratory distress syndrome* (IRDS). The treatment of IRDS is administration

of exogenous surfactant and corticosteroids to enhance lung maturation. To sustain life while allowing maturation, mechanical ventilation and oxygen supplementation are required but may promote the development of bronchopulmonary dysplasia. In children without congenital abnormalities, lung disorders are relatively rare, except those caused by infection and accidents.

Pulmonary Disease

Diseases of the respiratory system in the adult are some of the most common clinical entities confronted by physicians. At least 4 of the top 10 causes of death by medical illnesses in the United States are related to pulmonary dysfunction in one way or another: cancer (of which lung cancer is the most common), COPD, pneumonia, and sepsis. COPDs, such as emphysema and chronic bronchitis, are the fourth leading cause of death and the second leading cause of disability in the United States. At a time when a decrease in the age-adjusted death rate by other common disorders such as coronary artery disease and stroke is occurring, death by COPD continues to increase and is projected to become the third leading cause of death in the United States by 2020. More than 16 million Americans are estimated to have COPD, but because COPD takes years to develop and the incidence of cigarette smoking (the most common etiologic factor for COPD) is staggering (in 2005, more than 44.5

million Americans were daily smokers), the true disease burden of COPD is much greater.

Asthma is also a common illness, affecting 6% to 8% of the population in the United States. Between the decades of 1960 and 1990, the prevalence, hospitalization rate, and mortality rate related to asthma increased dramatically. Sleep-disordered breathing is estimated to affect 7 to 18 million people in the United States, with 1.8 to 4 million of these having severe sleep apnea. Interstitial lung diseases are being increasingly recognized, and their true incidence appears to have been underestimated. For example, idiopathic pulmonary fibrosis, the most common of the idiopathic interstitial pneumonias, affects 85,000 to 100,000 Americans annually. Another interstitial lung disease, sarcoidosis, affects about 45,000 Americans each year. Acute respiratory conditions are also common. Viral upper respiratory infections account for 40% of all acute respiratory conditions. Pneumonia occurs in 6 million people per year and is one of the top leading causes of death in the United States.

These conditions affect individuals of all ages, races, and sex. However, a disproportionate increase in the incidence, morbidity, and mortality related to lung diseases exists in minority populations. This finding is true for COPD, asthma, and certain interstitial lung disorders, among others. Although these differences point to genetic differences among these populations, they also point to differences in culture, socioeconomic status, exposure to pollutants (e.g., inner-city living), and access to health care.

This section reviews the epidemiologic factors, pathophysiologic conditions, clinical presentation, evaluation, and management of the most common lung diseases. Lung diseases are often classified on the basis of the affected anatomic areas of the lung (e.g., interstitial lung diseases, pleural diseases, airways diseases) and the physiologic abnormalities detected by pulmonary function testing (e.g., obstructive lung diseases, restrictive lung diseases). In general, classification schemes based exclusively on physiologic factors are inaccurate because distinctly different disorders with different causes, consequences, and responses to therapy show similar physiologic abnormalities (Fig. 14-2).

The *obstructive lung diseases* share a common physiologic characterization of airflow limitation, as determined by

pulmonary function testing (referred to as an *obstructive pattern*). Obstructive lung diseases include emphysema, chronic bronchitis, asthma, and bronchiectasis, among others. The *interstitial lung diseases* are less common disorders but are more difficult to subclassify because this category includes more than 120 distinct entities, some that are inherited and most without an obvious cause. In general, a restrictive physiologic condition that is due to decreased lung compliance and small lung volumes characterizes these disorders, and this characterization is the reason they are often referred to as *restrictive lung disorders* (e.g., idiopathic pulmonary fibrosis). However, not all interstitial lung diseases exhibit a restrictive pattern on pulmonary function testing. They may have airflow limitation as a result of small airway involvement (e.g., sarcoidosis, bronchiolitis obliterans). The *pulmonary vascular diseases* are disorders in which involvement of the pulmonary vasculature causes increased intraluminal pressure or pulmonary hypertension. These range from disorders caused by obstruction to blood flow as a result of blood clots (e.g., pulmonary embolus) to disorders characterized by tissue remodeling and obliteration or compression of the vascular structures by connective tissue (e.g., primary pulmonary hypertension). The *disorders of respiratory control* include conditions in which extrapulmonary abnormalities are responsible for dysfunction of the respiratory system, causing abnormal ventilation. These include disorders of sleep such as obstructive sleep apnea. These also include disorders of the neuromuscular system in which ventilatory abnormalities are due to poor excursion of the respiratory muscles, as observed in myasthenia gravis and polymyositis. *Disorders of the pleura, chest wall, and mediastinum* are classified as such because they affect these specific structures. Infectious agents, of which viral and bacterial infections are the most frequent, cause conditions that include *infectious diseases of the lung*. *Neoplastic disorders* of the lung include both benign (e.g., hamartomas) and malignant (e.g., lung carcinoma) disorders, which can affect the lung parenchyma or its surrounding pleura (e.g., mesothelioma). This section also discusses illnesses requiring critical care such as acute lung injury and sepsis, which are often triggered by injuries to the lung and are frequently managed by pulmonologists and critical care specialists.

Figure 14-2 Lung diseases. Lung diseases are caused by abnormalities in the lung structure (e.g., airways, interstitium, vasculature), the chest wall, or external forces (e.g., infection). Disorders affecting the lung structure cause physiologic derangements (e.g., obstruction to airflow, restricted lung volumes, pulmonary hypertension, and hypoxia), but these derangements are not necessarily specific to any particular lung disease caused by the extensive overlap among the mechanisms responsible for their manifestation.

Prospectus for the Future

Important questions remain in lung development. What are the primary stimuli for branching morphogenesis? How does gene regulation alter lung development? How do lung airway and blood vessel development remain coordinated? What are the environment-gene interactions that cause abnormal lung development?

In addition, there are important fundamental questions in the epidemiology of lung diseases. For example, it is not clear

whether or how childhood asthma and adult COPD are related. In addition, the role of fine particulate matter air pollution in the pathogenesis of lung diseases is unclear.

Finally, the causes and pathogenesis of many lung diseases, such as sarcoidosis, are unclear.

General Approach to Patients with Respiratory Disorders

Brian Casserly and Sharon Rounds

History

A detailed history is necessary to assess effectively a patient who may have pulmonary disease. Patients with lung disorders often complain of one or more of the following symptoms: dyspnea or shortness of breath, fatigue, exercise intolerance, chest tightness, cough, sputum production, and chest pain, among others. Although individually these symptoms are not specific, the presence of certain symptoms coinciding in the same individual may point to a specific diagnosis.

Important to note, common symptoms of respiratory disease, such as dyspnea and cough, are frequently seen in diseases of other organ systems (Table 15-1). For example, dyspnea is also a cardinal symptom of heart disease, and cough may be caused by gastroesophageal reflux or chronic sinusitis. An organized approach to the patient, starting with a careful history and a detailed physical examination, will focus further investigation to determine the cause of the symptom.

Common Presenting Complaints

Dyspnea (shortness of breath) is a common complaint of patients with pulmonary disease (Table 15-2). Timing and acuity of onset, exacerbating and alleviating factors, and degree of functional impairment are key elements of the history. Associated symptoms such as cough, hemoptysis, chest pain, wheezing, orthopnea, and paroxysmal nocturnal dyspnea, as well as environmental triggers, should be elicited and are helpful in developing a differential diagnosis. If dyspnea is recent, of sudden onset, and accompanied by chest pain, then diseases such as pneumothorax, pulmonary

embolism, and pulmonary edema should come to mind. If the dyspnea is long-standing and is slowly progressive, then chronic conditions such as chronic obstructive pulmonary disease (COPD), pulmonary fibrosis, pulmonary arterial hypertension, and neuromuscular disorders are in the differential diagnosis. The progression of chronic dyspnea may be insidious. Asking specific questions to quantify changes in functional status over time is important. Dyspnea may occur during exertion or at rest and may be episodic or continuous. Episodic dyspnea associated with exertion suggests parenchymal lung disease or cardiac dysfunction. Dyspnea that is seasonal or triggered by environmental exposure suggests diseases such as asthma and hypersensitivity pneumonitis. Positional dyspnea can occur in patients with severe obstructive lung disease, diaphragmatic paralysis, or neuromuscular weakness.

Orthopnea is defined as dyspnea that occurs in the supine position. This condition may occur as a result of a decrease in vital capacity caused by abdominal contents exerting force against the diaphragm. *Paroxysmal nocturnal dyspnea* is dyspnea that occurs 1 to several hours after lying down and is associated with congestive heart failure. Increased venous return to the heart causes this condition, resulting in mild interstitial edema. Asthma can also be associated with nocturnal dyspnea and is thought to be due to decreased vital capacity, decreased production of endogenous agents with bronchodilator functions, and increased exposure to allergens present in beddings. Exercise-induced asthma causes dyspnea out of proportion to the degree of exertion, with dyspnea often being most severe in the 15 to 30 minutes after the cessation of exercise.

Wheezing, although associated with asthma, has many causes. The absence of wheezing does not rule out asthma in any setting, and the presence of wheezing does not establish the diagnosis. Other conditions that cause wheezing are congestive heart failure; endobronchial obstruction by

tumor, foreign body, or mucus; vocal cord abnormalities; and acute bronchitis.

Cough is a frustrating symptom for both the patient and the physician. The three most common causes of chronic cough are postnasal drip, asthma, and gastroesophageal reflux disease. Cough may be mild and infrequent, or it may be severe enough to induce emesis or syncope. Cough may be dry or may produce sputum or blood (*hemoptysis*). The symptom may begin months after initiation of a drug (e.g., angiotensin-converting enzyme [ACE] inhibitors) leading to a dry, hacking cough. *Bordetella pertussis* infection (whooping cough) and viral lower respiratory infections can produce a cough that may last for 3 months or longer. Patients with asthma often have a cough. On occasion, cough is their only symptom, a condition sometimes referred to as *cough-variant asthma*. Nocturnal cough should raise the suggestion of asthma, heart failure, or gastroesophageal reflux disease.

More than occasional production of *sputum* is abnormal and should be characterized with regard to quantity, color, presence or absence of blood, and timing. The physician should ask the patient to estimate the frequency and volume of sputum produced in 24 hours as well as any diurnal variation. *Chronic bronchitis* is defined as a persistent cough resulting in sputum production for more than 3 months in each of the last 3 years. Patients with asthma often have a productive cough resulting from excess mucus production. Colored sputum does not always signify a bacterial infection because the concentration of cellular debris, predominantly white cells present in any inflammatory process, influences sputum color. Patients with difficult to control asthma who report brown plugs or casts of the small bronchi in their sputum may have *allergic bronchopulmonary aspergillosis*.

Hemoptysis is a frightening symptom. The volume of blood may be scant or large enough to cause asphyxiation or exsanguination. The most common cause of hemoptysis in the United States is bronchitis, whereas the most common cause worldwide is pulmonary tuberculosis. Most cases of hemoptysis are small in volume and self-limited and resolve with the treatment of the underlying process. Massive hemoptysis, defined as more than 500 mL of blood in 24 hours, is rare and considered a medical emergency when it occurs. Causes of massive hemoptysis include lung cancer, lung cavities containing mycetomas, cavitary tuberculosis, pulmonary hemorrhage syndromes, pulmonary arteriovenous malformations, and bronchiectasis. The physician should distinguish among hemoptysis, epistaxis, and hematemesis. Because many patients have trouble identify-

ing the source of the bleeding, a careful upper airway physical examination is essential.

Chest pain attributable to the lungs usually results from pleural disease, pulmonary vascular disease, or musculoskeletal pain precipitated by coughing because no pain receptors exist in the lung parenchyma. Lung cancer, for example, does not cause pain until it invades the pleura, chest wall, vertebral bodies, or mediastinal structures. Disease or inflammation of the pleura causes pleuritic chest pain characterized as a sharp or stabbing pain with deep inspiration. Pain caused by pulmonary emboli, infection, pneumothorax, and collagen vascular disease is also usually pleuritic. Pulmonary hypertension may produce dull anterior chest pain unrelated to respiration caused by right ventricular strain and demand ischemia. Other examples of noncardiac causes of chest pain include esophageal disease, herpetic neuralgia, musculoskeletal pain, and trauma. Older patients or those with a history of chronic systemic steroid use may have thoracic pain resulting from vertebral compression or rib fractures. Adequate analgesia, including narcotics, is essential in the treatment of chest pain in patients with underlying lung disease to prevent the reduction in vital capacity caused by splinting of the chest in reaction to the pain. Musculoskeletal chest pain should be a diagnosis of exclusion after serious causes have been ruled out. This pain is usually reproducible with movement or palpation over the affected area.

Past History

One should always ask about previous respiratory illness including pneumonia, tuberculosis, or chronic bronchitis, or abnormalities of the chest radiograph that have been previously reported to the patient. Patients with the acquired immunodeficiency syndrome (AIDS) have a high risk for developing *Pneumocystis jirovecii* pneumonia and other chest infections including tuberculosis. Immunosuppression from long-standing steroid use may predispose to tuberculosis and other lung infections. Almost every class of drug can be associated with lung toxicity. Examples include pulmonary embolism from use of the oral contraceptive pill, interstitial lung disease from cytotoxic agents (e.g., methotrexate, cyclophosphamide, bleomycin), bronchospasm from β blockers or nonsteroidal anti-inflammatory drugs and cough from ACE inhibitors. Some medications known to cause lung disease may not be mentioned by the patient because they are illegal (e.g., cocaine, heroin).

An accurate history of tobacco use, as well as other *toxic* and *environmental exposures*, is essential in patients with respiratory complaints. Tobacco smoke is the most prevalent environmental toxin causing lung disease. Patients may be anxious about other inhaled toxins or irritants and yet may continue to smoke without concern. Asking about tobacco use and attempting to motivate patients to quit smoking is the physician's duty. The risk for lung disease from smoking is directly related to individual genetic susceptibility and the total pack-years of exposure, and it is inversely related to the age at onset of smoking and, in the case of lung cancer, the interval since smoking cessation.

A history of exposure to other inhaled toxins, irritants, or allergens should be elicited. A careful occupational history often uncovers exposure to inorganic dust or fibers such as asbestos, silica, or coal dust. Organic dusts may cause hypersensitivity pneumonitis and other interstitial lung diseases. Solvents and corrosive gases are also causes of pulmonary disease. The presence of household pets should be documented. Cats are the most allergenic for asthma, and birds may cause hypersensitivity or fungal lung disease. A travel history is important in evaluating infectious causes of pulmonary disease. For example, histoplasmosis is common in the Ohio and Mississippi River valleys, and coccidioidomycosis is found in the desert Southwest. Travel to developing countries increases the risk for exposure to tuberculosis. A family history is important in assessing the risk for genetic lung diseases such as cystic fibrosis and α_1 -antitrypsin deficiency as well as susceptibility to asthma, emphysema, or lung cancer.

Physical Examination

The physical examination should be complete, with emphasis on areas highlighted by the history. The first steps in the physical examination of the patient with pulmonary disease are observation and inspection, which must be done when the patient's chest is bare (Table 15-3). The physician should start by evaluating the general appearance of the patient. In particular, attention should be given to the presence or absence of respiratory distress. This observation will

not only help in diagnosis but also point to the urgency of the case.

Body habitus is important because morbid obesity in a patient with exercise intolerance and sleepiness might point to a diagnosis of sleep-disordered breathing, whereas dyspnea in a thin middle-aged man with pursed lips might suggest emphysema. Race and sex should also be noted because certain conditions are more frequently encountered in specific populations. For example, sarcoidosis is most common in African Americans in the Southeast, whereas lymphangioleiomyomatosis is a rare disorder that essentially affects young women of childbearing age. *Tachycardia and pulsus paradoxus* are important signs of severe asthma.

The physician should watch the patient breathe and note the effort required for breathing. Increased respiratory rate, use of accessory muscles of respiration, pursed-lip breathing, and paradoxical abdominal movement all indicate increased work of breathing. The patient's inability to speak in full sentences indicates severe airway obstruction or neuromuscular weakness. The physician should listen for cough during the history and physical examination and should note the strength of the cough because this may signal respiratory muscle weakness or severe obstructive lung disease. The patient's rib cage should expand symmetrically with inspiration. The shape of the thoracic cage should also be noted. Increased anteroposterior diameter is observed in those with lung hyperinflation due to obstructive lung disease. Severe kyphoscoliosis, pectus excavatum, ankylosing spondylitis, and morbid obesity can produce restrictive ventilatory disease as a consequence of distortion and restriction of the volume of the thoracic cavity.

The hands may reveal important signs of lung diseases. Look for *clubbing*, which is commonly associated with respiratory disease. An uncommon association with clubbing is hypertrophic pulmonary osteoarthropathy (HPO). HPO is characterized by the presence of periosteal inflammation at

the distal ends of long bones, the wrists, the ankles, and the metacarpal and metatarsal bones. There is swelling and tenderness over the wrists and other involved areas. Rarely HPO may occur without clubbing. The causes of HPO include primary lung carcinoma and pleural mesothelioma. Look for *staining* of the fingers (actually caused by tar because nicotine is colorless), a sign of cigarette smoking. The density of staining does not indicate the number of cigarettes smoked, but depends rather on the way the cigarette is held in the hand. Ask the patient to dorsiflex the wrists with the arms outstretched and to spread out the fingers. A flapping tremor (*asterixis*) may be seen with severe carbon dioxide retention. *Wasting and weakness* are signs of cachexia due to malignancy. In addition, compression and infiltration by a peripheral lung tumor of a lower trunk of the brachial plexus results in wasting of the small muscles of the hand and weakness of finger abduction.

Examination of the head and neck are also important. Inspect the eyes for evidence of *Horner syndrome* (a constricted pupil, partial ptosis, and loss of sweating), which can be due to an apical lung tumor compressing the sympathetic nerves in the neck. Listen to the voice for *hoarseness*, which may indicate recurrent laryngeal nerve palsy associated with carcinoma of the lung (usually left sided), or laryngeal carcinoma. However, the most common cause is laryngitis. Look for nasal polyps (associated with asthma), engorged turbinates (various allergic conditions), and a deviated septum (nasal obstruction). Look at the tongue for central cyanosis. The mouth may hold evidence of an upper respiratory tract infection (a reddened pharynx and tonsillar enlargement with or without a coating of pus). A broken tooth or gingivitis may predispose to lung abscess or pneumonia. Sinusitis is indicated by tenderness over the sinuses on palpation. There may be facial plethora or cyanosis if superior vena caval obstruction is present. Some patients with obstructive sleep apnea will be obese with a receding chin, a small pharynx, and a short, thick neck.

Palpation of the chest is performed by first palpating the accessory muscles of respiration in the patient's neck—the scalene and sternocleidomastoid muscles. Hypertrophy and contraction indicate increased respiratory effort. The trachea should be palpated and should lie in the midline of the neck. Deviation of the trachea may suggest lung collapse or a mass. Neck masses should be noted. The physician should place both hands on the lower half of the patient's posterior thorax with thumbs touching and fingers spread; the hands should be kept in place while the patient takes several deep inspirations. The physician's thumbs should separate slightly and the hands should move symmetrically apart during the patient's inspiration.

Fremitus is a faint vibration felt best with the edge of the hand against the patient's chest wall while the patient speaks. Fremitus is increased in areas with underlying lung consolidation, and it is decreased over a pleural effusion. Next, the patient's chest should be percussed. The level of the diaphragms on each side should be noted. The percussion note should be compared on the two sides starting at the apex and moving down, including the posterior, anterior, and lateral aspects. A pleural effusion, consolidation, mass, or elevated diaphragm can cause dullness to percussion; a pneumothorax or hyperinflation can cause hyperresonance.

Auscultation of the lungs is performed to evaluate the quality of the breath sounds and to detect the presence of extra (adventitious) sounds not heard in normal lungs. Normal breath sounds have two qualities, vesicular and bronchial. Bronchial breath sounds are heard over the central airways and are louder and coarser than vesicular breath sounds, which are heard at the periphery and base of the lungs. Bronchovesicular sounds are a combination of the two and are heard over medium-sized airways. Bronchial sounds have a longer inhaled component, whereas vesicular sounds have a much longer expiratory component and are much softer. Bronchial breath sounds and bronchovesicular breath sounds at the periphery of the lungs are abnormal and may be caused by underlying consolidation. In the presence of consolidation, increased transmission of vocal sounds, called *whispered pectoriloquy*, occurs; *egophony*, in which the spoken letter *e* sounds like an *a* over the area of consolidation, is heard and sometimes compared with the bleating of a goat.

Abnormal or extrapulmonary sounds are crackles, wheezes, and rubs. *Crackles* can be coarse rattles or fine, *Velcro-like* sounds. Mucus in the airways or the opening of large- and medium-sized airways often causes coarse crackles. Fine crackles, produced with inspiration by the opening of collapsed alveoli, are most common at the bases and are heard in pulmonary edema and interstitial fibrosis as well as in healthy older patients during deep inspiration. *Wheezing* is a higher-pitched sound and, when heard locally, suggests large airway obstruction. The wheezing of patients with asthma or congestive heart failure is lower in pitch and heard diffusely over all lung fields. Localized wheezing can be heard in conditions such as pulmonary embolism, obstruction of a bronchus by a tumor, and foreign-body aspiration. A *rub* is a pleural sound caused by inflamed pleural surfaces rubbing together. A rub has been described as the sound of pieces of leather rubbing against each other. Rubs are often evanescent and depend on the amount of fluid in the pleural space. Often, pleuritic chest pain and a rub develop after large-volume thoracentesis. A crunching sound timed with the cardiac cycle, called *Hamman crunch*, is heard in patients with a pneumomediastinum. The complete absence of breath sounds on one side should cause the examiner to think of pneumothorax, hydrothorax, or hemothorax; obstruction of a main stem bronchus; or surgical or congenital absence of the lung. The physical findings associated with various pulmonary disorders are outlined in Table 15-4.

Evaluation

The clinician should be able to develop a differential diagnosis based on a detailed history and a thorough physical examination. This preliminary differential diagnosis is the basis on which a battery of tests is ordered, recognizing that these tests might unveil disorders not considered in the initial assessment. The objective of this extended evaluation is twofold: (1) to confirm a diagnosis or discard other disorders, and (2) to assess the severity of the lung derangement. In general, patients with a suggested lung disorder should undergo pulmonary function testing. *Spirometry* evaluates airflows and helps distinguish between an obstructive pattern characteristic of COPD, asthma, and related

Table 15-4 Physical Findings in Common Pulmonary Disorders

Disorder	Mediastinal Displacement	Chest Wall Movement	Vocal Fremitus	Percussion Note	Breath Sounds	Added Sounds	Voice Sounds
Pleural effusion	Heart displaced to opposite side	Reduced over affected area	Absent or markedly decreased	Dull	Absent over fluid; bronchial breath at upper border	Absent; pleural rub may be found above effusion	Absent over effusion; increased with egophony at upper border
Consolidation	None	Reduced over affected area	Normal or increased	Dull	Bronchial	Crackles	Increased with egophony and whispered pectoriloquy
Pneumothorax	Tracheal deviation to opposite side if under tension	Decreased over affected area	Absent	Resonant	Absent or decreased	Absent	Absent
Atelectasis	Ipsilateral shift	Decreased over affected area	Variable	Dull	Absent or diminished	Crackles may be heard	Absent
Bronchospasm	None	Decreased symmetrically	Normal or decreased	Normal or decreased	Bronchovesicular	Wheezing	Normal or decreased
Interstitial fibrosis	None	Decreased symmetrically	Normal or increased	Normal	Bronchovesicular	End-inspiratory crackles unaffected by cough or posture	Normal

disorders, as well as a restrictive pattern observed in fibrosing lung disease. Spirometry will also provide information regarding the severity of the physiologic derangement. *Lung volume measurements* are helpful in assessing hyperinflation or confirming a restrictive process. Measuring diffusion capacity for carbon monoxide (D_LCO) will provide information about alterations in gas-exchanging capability. Further assessment of gas exchange can be obtained through the determination of oxygen saturation using pulse oximetry. Information regarding both oxygenation and acid-base status is obtained from *arterial blood gas* determination. A *6-minute walk test* will evaluate oxygenation during exertion; through this test, patients are often found to require supplemental oxygen for the first time. Other, more specialized tests (e.g., bronchoprovocation, cardiopulmonary stress testing, polysomnography) might be required, depending on the circumstances.

Imaging studies of the chest are extremely useful in evaluating lung structure. The *chest radiograph* will provide information about the lung parenchyma and pleura, the cardiac silhouette, mediastinal structures, and even body habitus. Frequently, examining old chest radiographic images is useful to assess progression of disease. *Computed tomography* will provide more accurate information about the pulmonary and mediastinal structures, and it is essential in the assessment of interstitial lung disease and lung masses, among other disorders. Together with *ventilation-perfusion scanning* and *pulmonary angiography*, the computed tomogram is one of the many tools available

to evaluate the lung vasculature. *Magnetic resonance imaging*, *positron-emission tomography*, and related tests are becoming more frequently used in the evaluation of patients with lung masses and other lung disorders. Standard blood tests such as the *blood counts* and *blood chemistry* point to specific disorders or may provide information about the severity of a lung disorder (e.g., polycythemia in chronic hypoxemia, leukocytosis in lung infection). Some specialized tests should be reserved when specific diagnoses such as *serologic conditions* (e.g., rheumatoid factor, antinuclear antibodies) are suggested in patients who may have connective tissue-related lung disease or *hypersensitivity profile* when the diagnosis of hypersensitivity pneumonitis is being entertained.

Together with the history and physical examination, these tests are useful at narrowing a diagnosis to establish a specific plan of treatment. This plan can often be created in a single visit. However, patients will frequently require several visits to a clinician. These follow-up visits serve to assess progression of disease, patient compliance with therapy, and response to management. If these noninvasive tests do not allow for diagnosing the problem, more invasive tests might be necessary. *Fiberoptic* or *rigid bronchoscopy* allows for direct visualization of the airways and for obtaining valuable clinical samples for study. *Transthoracic percutaneous needle aspiration* is useful in evaluating peripheral lung lesions. Ultimately, surgery might be required to obtain tissue through *open* or *video-assisted thoracoscopic-guided lung biopsy*.

Prospectus for the Future

The predictive values of various aspects of history and physical examination need to be clarified. The role of quantitative computed tomography analysis in diagnosis and assessment of dis-

ability of lung diseases needs to be clarified. The role of interventional pulmonary procedures must be ascertained for both diagnosis and treatment of lung diseases.

Evaluating Lung Structure and Function

F. Dennis McCool

The satisfactory functioning of all organ systems depends on their capacity to consume oxygen and eliminate carbon dioxide. The primary function of the lung is to deliver oxygen to the pulmonary capillary blood and to excrete carbon dioxide. To accomplish this, a volume of air must be delivered through numerous branching airways to small alveolar sacs. Oxygen can then diffuse across the thin alveolar membrane into the capillary blood, where it is bound to hemoglobin. As oxygen is removed from the alveolus, carbon dioxide diffuses from the pulmonary vasculature into the alveolar sacs. It is excreted from the body when air is exhaled from the lungs and airways. The remarkable matching of oxygen consumption and carbon dioxide production allows the human to maintain optimal oxygenation and acid-base balance over a wide range of activities that require enormous differences in ventilation. This chapter provides an overview of the anatomy and physiology that enable the respiratory system to perform its life-sustaining functions as well as a discussion of tests available to evaluate lung structure and function.

Anatomy

AIRWAY

Inspired air travels through the nose and mouth and then passes into the pharynx, larynx, and trachea. In the nose and nasopharynx, the air is heated, humidified, and filtered of airborne particles greater than 10 μm in diameter. Air then quickly enters the trachea and the left and right main stem bronchi. The bronchi separate into segmental and subsegmental airways. Cartilaginous rings help to maintain the patency of these large airways. In the main stem bronchi, the rings are circumferential, whereas in the trachea, the cartilaginous rings are U-shaped, with the posterior membrane of the trachea sharing a wall with the esophagus. The region of the lung that includes the first 18 branches of the airways is referred to as the *conducting zone*. This region consists of the trachea, bronchi, bronchioles, and alveolar ducts (Fig. 16-1). After about 18 subdivisions, the airways branch

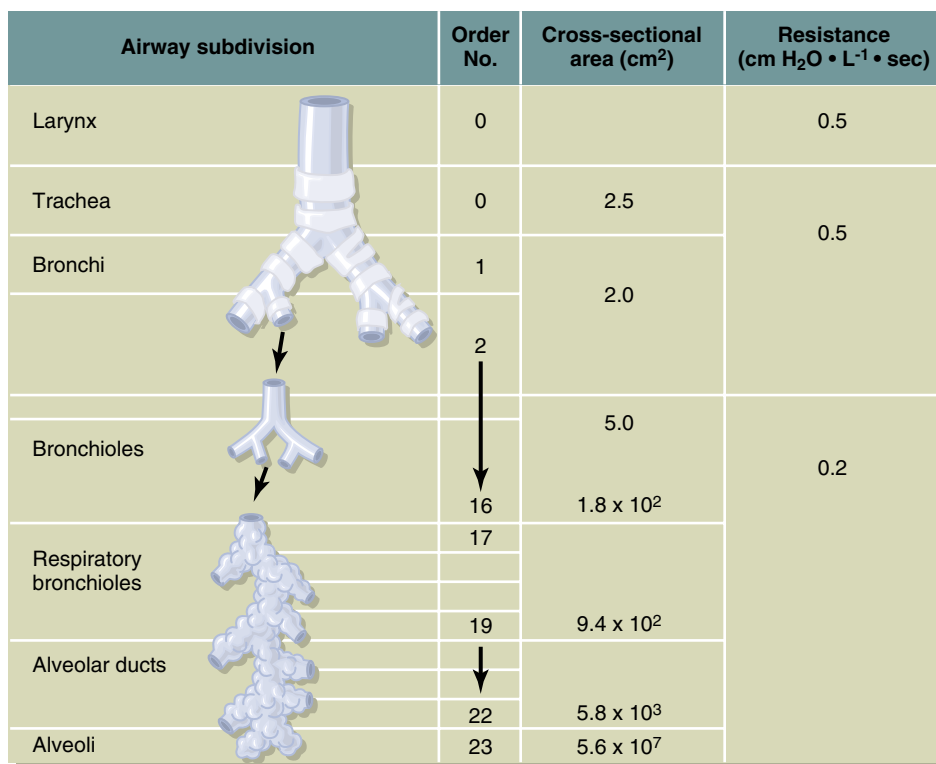

another 3 to 5 times until they become alveolar sacs. This area of the lung is referred to as the *respiratory zone* and consists of the terminal bronchioles and alveolar ducts. Gas exchange commences in the terminal bronchioles but primarily occurs in the alveoli. All totaled, there are about 27 subdivisions of the airway from the trachea to the alveolar ducts. The total cross-sectional area of this zone is far greater than the cross-sectional area of the more proximal airways. Thus, for a given airflow rate (Δ volume/time), air travels at a lower velocity (Δ distance/time) in the distal airways than in the larger proximal airways. This difference in velocity in concert with the difference in overall cross-sectional area results in low resistance to flow in the distal airways and greater resistance to airflow in the proximal airways.

ALVEOLI

The alveoli are the grapelike clusters of air sacs that interface with the pulmonary capillaries. There are about 300 million individual alveolar sacs. The alveoli are thin-walled structures with a total surface area of about 100 m^2 . This is roughly half the size of a tennis court. The surface of the alveoli is lined by two types of cells. The flat type I pneumocyte constitutes 95% of the cells. Type II pneumocytes account for about 5% of the alveolar lining cells and secrete surfactant; a complex lipoprotein whose role in lowering surface tension in the alveolar space is critical to reducing the forces needed to expand the lung. Surfactant is also important in preventing alveolar collapse at low lung volumes and thereby promoting normal gas exchange. The epithelial lining of the alveoli, the endothelial lining of the capillaries, and the intervening basement membrane present a barrier to gas exchange. Normally this barrier is less than 1 μm thick and does not significantly interfere with gas exchange.

BLOOD VESSELS

The pulmonary artery arises from the right ventricle and branches until it terminates in a meshwork of capillaries that

Airway subdivision	Order No.	Cross-sectional area (cm ²)	Resistance (cm H ₂ O • L ⁻¹ • sec)
Larynx	0		0.5

	17	1.8 x 10 ²	
Respiratory bronchioles	19	9.4 x 10 ²	
Alveolar ducts	22	5.8 x 10 ³	
Alveoli	23	5.6 x 10 ⁷	

Figure 16-1 The subdivision of the airways and their nomenclature. The cross-sectional area increases dramatically toward the peripheral, small airways. (Adapted from Weibel ER: *Morphometry of the Human Lung*. Berlin, Springer, 1963.)

surround the alveoli. This creates a large surface area that facilitates gas exchange. Blood returns to the heart through pulmonary veins that course through the lungs, coalesce into four main pulmonary veins, and empty into the left atrium. The pulmonary circulation is a low-resistance circuit with pulmonary vascular resistance about $\frac{1}{10}$ of the resistance in the systemic circulation. Pulmonary vessels can be easily recruited to accommodate increases in blood flow while maintaining low pressures and resistance. Accordingly, during exercise, any increase in cardiac output can be distributed through the lung without significantly increasing pulmonary arterial pressures. A separate vascular system, the bronchial system, also supplies the lung. The bronchial arteries originate from the aorta and, in contrast to the pulmonary arteries, are under systemic pressure. These vessels provide nutrients to lung structures proximal to the alveoli. Two thirds of the bronchial circulation drains into the pulmonary veins and then empties into the left atrium. This blood, which has low oxygen content, mixes with the freshly oxygenated blood from the pulmonary veins to lower the oxygen content of the blood that enters the systemic circulation.

Physiology

VENTILATION

Overall, gas exchange consists of a series of four steps. First is ventilation, second is diffusion of oxygen and carbon dioxide between alveolar sacs and alveolar capillaries, third is circulation, and the fourth is diffusion of oxygen

and carbon dioxide between systemic capillaries and cells. Ventilation refers to the bulk transport of air from the atmosphere to the alveolus. The product of tidal volume (V_T) and breathing frequency (f) represents the total volume of air delivered to the lung (minute ventilation, V_E). However, not all air entering the lung is in contact with gas-exchanging units. The portion of the inhaled breath that fills the respiratory zone is the alveolar volume (V_A), and the portion remaining in the conducting airways is the dead space volume (V_D) (Fig. 16-2). The fraction of the tidal breath that is dead space varies with the size of the breath. With larger breaths, the dead space is a smaller fraction of the total tidal volume. Thus, for a given tidal volume, slow, deep breathing results in greater V_A and improved gas exchange when compared with rapid, shallow breathing. The fraction of the tidal breath that is dead space can be calculated as follows:

$$V_D/V_T = (P_{aCO_2} - P_{eCO_2})/P_{aCO_2},$$

where P_{aCO_2} is arterial PCO_2 and P_{eCO_2} is the PCO_2 of mixed expired gas.

Normally, one third of a breath is dead space ($V_D / V_T = \frac{1}{3}$). At end-expiration, the V_D contains exhaled alveolar gas that had been in equilibrium with pulmonary capillary blood. The amount of fresh air reaching the alveoli on the next breath is the $V_A - V_D$.

Because every breath includes a portion that is dead space, minute ventilation (V_E) includes a portion of ventilation that is dead space and a portion that is alveolar ventilation. As the metabolic rate and CO_2 production increase, alveolar ventilation must increase to maintain an arterial PCO_2

Figure 16-2 Schematic of the inspired air that participates in gas exchange (350 mL) and the anatomic dead space (150 mL) for a tidal breath of 500 mL.

of 40 mm Hg. The relationship among these variables is described by the alveolar carbon dioxide equation.

$$P_{ACO_2} = CO_2 \text{ production} / V_A,$$

where P_{ACO_2} is alveolar ventilation and V_A is alveolar ventilation.

From the above equation, one appreciates that the partial pressure of carbon dioxide in the alveolus is indirectly proportional to alveolar ventilation. Similarly, as metabolic rate increases and O_2 consumption increases, alveolar ventilation must increase to maintain a normal arterial PO_2 . The relationship among these variables is described by the alveolar oxygen equation.

$$PAO_2 = \text{Oxygen consumption} / V_A$$

This relationship is somewhat more complicated because PAO_2 also is proportional to the fraction of inspired oxygen, water vapor pressure, and the partial pressure of CO_2 in the alveolus. The implications of these two relationships are that (1) the maintenance of a constant alveolar gas composition depends on a constant ratio of ventilation to metabolic rate; (2) if ventilation is too high (hyperventilation), alveolar P_{CO_2} will be low, and alveolar PO_2 will be high; and (3) if ventilation is too low (hypoventilation), alveolar P_{CO_2} will be high, and alveolar PO_2 will be low.

MECHANICS OF BREATHING

Respiratory mechanics is the study of forces needed to deliver air to the lung and how these forces govern the volume and flow of gases. Mechanically, the respiratory system consists of two structures: the lungs and the chest wall. The lungs are elastic (springlike) structures that are situated within another elastic structure, the chest wall. At end-expiration, with absent respiratory muscle activity, the inward recoil of the lung is exactly balanced by the outward recoil of the chest wall. Normally, the recoil of the lung is always inward (favoring lung deflation), and the recoil of the chest wall is outward (favoring inflation), except at high lung volumes, where the chest wall also recoils inward (Fig. 16-3). The inspiratory and expiratory muscles can disturb this balance and cause gas to flow in and out of the lung. The energy required to stretch the respiratory system above its equilibrium state (end-expiration during quiet breathing) is provided by the inspiratory muscles. With normal quiet

Figure 16-3 Schematic of the lung and chest wall at functional residual capacity. The *arrows* show that the expanding elastic force of the chest wall equals the collapsing elastic force of the lung. The intrapleural pressure is -5 because of both forces tugging on the pleural space in opposite directions.

breathing, gas flow out of the lung is usually accomplished by the passive recoil of the respiratory system.

During a typical breath, inspiratory muscle contraction lowers intrapleural pressure, which in turn lowers intralveolar pressure. Once alveolar pressure becomes subatmospheric, air can flow from the mouth through the airways to the alveoli. At the end of inspiration, the inspiratory muscles are turned off, and the lungs and chest wall recoil passively back to their equilibrium states. This passive respiratory system recoil causes alveolar pressure to become positive throughout expiration until the resting position of the lung and chest wall are reestablished and alveolar pressure once again equals atmospheric pressure. During quiet breathing, pleural pressure is always subatmospheric, whereas alveolar pressure oscillates above and below zero (atmospheric) pressure (Fig. 16-4). The major inspiratory muscle is the diaphragm. Others include the sternocleidomastoid muscles, the scalenus muscles, and the external intercostal muscles. Diaphragm contraction results in expansion of the lower rib cage and compression of the intra-abdominal contents. The latter action results in expansion of the abdominal wall. The expiratory muscles consist of the internal intercostal muscles and the abdominal muscles. Expiratory flows can be enhanced by recruiting the expiratory muscles, which occur during exercise or cough.

To inflate the respiratory system, the inspiratory muscles must overcome two types of forces; the elastic forces imposed by the lung and the chest wall (elastic loads) and resistive forces related to airflow (resistive loads). The elastic loads on the inspiratory muscles are due to the respiratory system's tendency to resist stretch. The elastic forces are volume dependent such that the respiratory system becomes more difficult to stretch at volumes above functional residual capacity (FRC) and more difficult to compress as volumes below FRC. The elastic forces can be characterized by examining the relationship between lung volume and recoil pressure (Fig. 16-5). When either deflated or inflated, the lung and chest wall have characteristic recoil pressures. The slope of the relationship between lung volume and recoil pressure of the chest wall or lung represents the compliance of each structure. The sum of the chest wall and lung recoil pressures represents the recoil pressure of the total respiratory system.

Figure 16-4 Volume, intrapleural pressure, and alveolar pressure during a normal breathing cycle. The letters A to D correspond to different phases of the cycle. Alveolar pressure is biphasic with zero crossings at times of no flow (end-expiration [A] and end-inspiration [C]). Intrapleural pressure remains subatmospheric throughout.

Figure 16-5 Volume-pressure (V-P) relationship of the respiratory system and its components: the lung and chest wall. Respiratory system recoil pressure at any volume is the sum of the lung and chest wall recoil pressures. The slope of the V-P curve represents the compliance of each structure. FRC, functional residual capacity.

The elastic properties of the lung are related to two factors: (1) the elastic behavior of fibrin and elastin in the lung parenchyma, and (2) the surface tension in the alveolus due to the air-liquid interface. Both factors contribute equally to lung elastic recoil. A surface active substance called *surfactant* is produced by type II alveolar cells and lines alveolar fluid. This substance consists of primarily phospholipids and lowers surface tension, making it easier to inflate the lung. The lungs are stiff and difficult to inflate in diseases charac-

Figure 16-6 Compliance curves for normal individuals and for patients with emphysema and pulmonary fibrosis. An elevation in the transpulmonary pressure required to achieve a given lung volume increases the work of breathing.

terized by a loss of surfactant such as infant respiratory distress syndrome. Diseases such as pulmonary fibrosis, which are characterized by excessive collagen in the lung, can make the lung stiff and difficult to inflate, whereas diseases such as emphysema, characterized by a loss of elastin and collagen, will decrease lung compliance (Fig. 16-6). Normally, at FRC, it takes about 1 cm of water pressure (cm H₂O) to inflate the lungs 200 mL and to inflate the chest wall 200 mL. Since the lung and chest wall both need to be inflated to the same volume during inspiration, it would take 2 cm H₂O of pressure to inflate both. Thus, normal respiratory system compliance is roughly 100 mL/cm H₂O, and lung and chest wall compliance 200 mL/cm H₂O, at volumes near FRC.

The second set of forces that the inspiratory muscles must overcome to inflate the lungs are flow-dependent forces; namely, tissue viscosity and airway flow resistance; the latter constituting the major component of the flow-dependent forces. Airway resistance during inspiration can be calculated by measuring inspiratory flow and the difference in pressure between the alveolus and the airway opening (ΔP_{A-ao}).

$$R = \Delta P_{A-ao} / \text{flow}$$

Airflow velocity, the type of airflow (laminar or turbulent), and the physical attributes of the airway (radius and length) are the key determinants of airway resistance. Of the physical properties, the radius of the airways is the major factor. Resistance increases to the fourth power as diameter decreases under conditions of laminar flow (streamline flow profile) and to the fifth power under conditions of turbulent flow (chaotic flow profile). Because airway diameter increases as lung volume increases, airway resistance decreases as lung

Figure 16-7 As lung volume increases, the airways are dilated, and resistance decreases. The reciprocal of resistance (conductance) increases as lung volume increases. AWR, airway resistance.

volume increases (Fig. 16-7). Airway diameter also contributes to regional differences in airway resistance. Although the peripheral airways are narrower than the central airways, their total cross-sectional area is much greater than that of the central airways. Consequently, resistance to airflow of the peripheral airways is low relative to the central airways (see Fig. 16-1). The velocity of airflow is another key determinant of airway resistance. Resistance is directly proportional to flow rate when flow is laminar and proportional to the square of flow rate when it is turbulent. In addition, the velocity of airflow determines, in part, whether the flow pattern is laminar or turbulent (higher resistance than laminar flow). Clinically, increased airway resistance can be seen in diseases associated with airway obstruction caused by an intrinsic mass, mucus within the airway, airway smooth muscle contraction, or dynamic compression of the airways. Lung elastic recoil also influences airflow. Decreased elastic recoil decreases airflow (**Web Fig. 16-1**). Normal resistance when breathing at FRC at low flow rates is in the range of 1 to 2 cm H₂O/L per second.

DISTRIBUTION OF VENTILATION

The distribution of inhaled volume throughout the lung is unequal. Generally more of the inhaled volume goes to the bases of the lung than to the apex when inhaling in the upright body position. This pattern of volume distribution leads to greater ventilation of the bases than the apices. This inhomogeneity of ventilation is due largely to regional differences in lung compliance. At the lung apex, the alveoli are relatively more inflated at FRC than at the lung base. The difference in alveolar distention from apex to base is related to pleural pressure differences from apex to base. The weight of the lung causes pleural pressure to be more negative at the apex and less negative at the base. The normal difference in pleural pressure from apex to base is about 8 cm H₂O (Fig.

Figure 16-8 Transpulmonary pressure (Ppl-Pal) and volume for lung units at the base and apex of the lung. Pleural pressure is more negative at the apex of the lung, thereby stretching the alveoli in this region and placing them on a less compliant part of the volume-pressure (V-P) curve. For a given change in transpulmonary pressure during inspiration, the more compliant base inflates to a greater degree than the apex.

16-8). Because the apical alveoli are more stretched at FRC, they are operating on a stiffer, less compliant region of their volume-pressure curve than the alveoli at the bases. Thus, at the beginning of inspiration, more volume is directed toward the base than to the apex of the lung.

CONTROL OF VENTILATION

Maintaining adequate oxygenation and acid-base balance is accomplished through the respiratory control system. This system consists of the neurologic respiratory control centers, the respiratory effectors (muscles that provide the power to inflate the lung), and the respiratory sensors. The respiratory center that automatically controls inspiration and expiration is located in the medulla of the brainstem. The respiratory center in the brainstem has an intrinsic rhythm generator (pacemaker) that drives breathing. The output of this center is modulated by inputs from peripheral and central chemoreceptors, mechanoreceptors in the lung, and higher centers in the brain, including conscious control from the cerebral cortex. The respiratory center in the medulla is primarily responsible for determining the level of ventilation.

Carbon dioxide is the primary factor controlling ventilation. CO₂ in the arterial blood diffuses across the blood-brain barrier, thereby reducing cerebral spinal fluid pH and stimulating the central chemoreceptors. A change in PaCO₂ above or below normal will increase or decrease ventilation, respectively. During quiet, restful breathing, the level of PaCO₂ is thought to be the major factor controlling breathing. Only when Pao₂ (partial pressure of oxygen dissolved in the blood and not bound to hemoglobin) falls substantially does ventilation respond significantly. Typically, Pao₂ needs to fall below 50 mm Hg before ventilation dramatically increases (Fig. 16-9). Low oxygen levels in the blood are not sensed by the respiratory center in the brain but are sensed by receptors located in the carotid body. This is a vascular

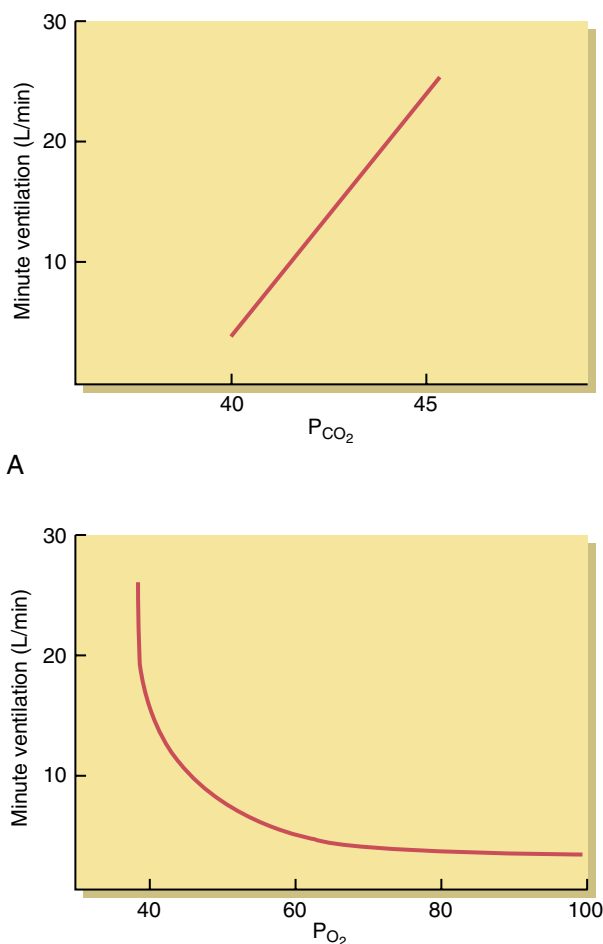

Figure 16-9 A rising P_{CO₂} leads to a linear increase in minute ventilation (A). The ventilatory response to hypoxemia (B) is less sensitive and is clinically relevant only when the P_{O₂} has dropped significantly.

receptor located between the internal and external branches of carotid artery. Changes in P_{aO₂} are sensed by the carotid sinus nerve. Neural traffic projects to the respiratory center through the glossopharyngeal nerve, which serves to modulate ventilation. The carotid body also senses changes in P_{aCO₂} and pH. Nonvolatile acids (i.e., ketoacids) stimulate ventilation through their effects on the carotid body.

The outcome of this complex respiratory control system is that variables such as P_{aO₂}, P_{aCO₂}, and pH are held within narrow limits under most circumstances. The respiratory control center also can adjust V_T and f to minimize the energetic cost of breathing and can adapt to special circumstances such as speaking, swimming, eating, and exercise. Breathing can be stimulated when P_{CO₂}, P_{O₂}, and pH are artificially manipulated. For example, rebreathing carbon dioxide, inhaling a concentration of low oxygen, or infusion of acid into the bloodstream will increase ventilation.

PERFUSION

The pulmonary vascular bed differs from the system circulation in several respects. The pulmonary vascular bed receives

Figure 16-10 Zonal model of blood flow in the lung. Because of the inter-relationship of vascular and alveolar pressures, the lung base receives the most flow (see text for explanation). (From West JB, Dollery CT, Naimark A: Distribution of blood flow in isolated lung: Relation to vascular and alveolar pressures. *J Appl Physiol* 19:713-724, 1964.)

the entire cardiac output of the right ventricle, whereas the cardiac output from the left ventricle is dispersed among several organ systems. Despite receiving the entire cardiac output, the pulmonary system is a low-resistance, low-pressure circuit. The normal mean systemic arterial pressure is about 100 mm Hg, whereas the normal mean pulmonary artery pressure is in the range of 15 mm Hg. The vasculature bed can passively accommodate an increase in blood flow without raising arterial pressure by recruiting more vessels in the lung. Thus, during exercise, there is little increase in pulmonary artery resistance despite a large increase in pulmonary blood flow. Hypoxic vasoconstriction also is a feature unique to the pulmonary vascular system and regulates regional blood flow. This regulation aids in matching blood flow to ventilation by reducing flow to poorly ventilated regions of the lung.

In the upright individual, there is greater perfusion of the lung bases than apices (Fig. 16-10). In a low-pressure system such as the pulmonary circulation, the effects of gravity on blood flow need to be considered. Usually the arterial-venous pressure difference provides the “driving” pressure for blood flow. Although this is true for the systemic circulation, it is true only for certain regions of the lung. With the respiratory system, pulmonary blood flow also needs to be considered in the context of alveolar pressure. Venous and arterial pressures are importantly affected by gravity, whereas alveolar pressure remains constant throughout the lung, assuming the airways are open. Thus, as one descends from the apex to the base of the lung, arterial and venous pressures increase because of gravity, but alveolar pressure remains constant. At the apex of the lung, alveolar pressure may be greater than arterial pressure. This region of the lung is referred to as *zone 1* and, in theory, receives no blood flow. Alveolar pressure may exceed arterial pressure under special circumstances such as hypovolemic shock, in which pulmonary arterial pressure may fall below alveolar pressure, and with very high levels of positive end-expiratory pressure

(PEEP), which may increase alveolar pressure to the extent at which it becomes greater than arterial pressure. As one descends from the apex toward the midzone of the lung, arterial and venous pressures increase, and alveolar pressure remains constant. At some point, arterial pressure becomes greater than alveolar pressure. In this region, the driving pressure for blood flow is the arterial-alveolar pressure difference. This region is referred to as *zone 2* of the lung. Normally, there is very little zone 2 because alveolar pressure is less than venous pressure in most of the lung. However, with high levels of PEEP, alveolar pressure will become greater than venous pressure in more lung regions. When further approaching the base of the lung, the effects of gravity on arterial and venous pressures are more pronounced, venous pressure becomes greater than alveolar pressure, and the arterial-venous pressure difference provides the driving pressure for blood flow. This region is referred to as *zone 3* of the lung. Normally, most of the lung is in zone 3, and most of the perfusion is to the lung base. This inequality in perfusion from apex to base is qualitatively similar to the inequality of ventilation from apex to base, thereby optimizing the matching of ventilation and perfusion.

GAS TRANSFER

Oxygen and carbon dioxide are easily dissolved in plasma. Nitrogen is much less soluble and is not significantly exchanged across the alveolar-capillary interface. The pressure gradient for oxygen between the alveolus and capillary promotes diffusion of oxygen from the alveolus to the capillary (P_{AO_2} of 150 mm Hg versus P_{AO_2} of 40 mm Hg). This pressure difference is greater than that driving carbon dioxide from the mixed venous blood to the alveolus (P_{MVCO_2} of 45 mm Hg versus P_{ACO_2} of 40 mm Hg). Despite the lower driving pressure, the greater solubility of carbon dioxide allows complete equilibration between the alveolus and plasma during each respiratory cycle (Fig. 16-11).

Most of the oxygen contained in the blood is bound to hemoglobin, with a small fraction dissolved and measured as the P_{AO_2} . The amount of oxygen dissolved is about 3 mL/L in arterial blood, whereas the amount of oxygen bound to hemoglobin is about 197 mL/L in arterial blood, assuming a normal hematocrit. Each molecule of hemoglobin is capable of carrying four molecules of oxygen. The shape of the oxyhemoglobin association curve reflects the cooperative binding of oxygen to hemoglobin (Fig. 16-12). In general, the percent hemoglobin saturation is between 80% and 100% with P_{AO_2} above 60 mm Hg and drops dramatically when the P_{AO_2} is less than 60 mm Hg. Factors that decrease the affinity of hemoglobin for oxygen include a reduction in blood pH, an increase in temperature, an increase in P_{CO_2} , and an increase in 2,3-diphosphoglyceric acid (2,3-DPG). These factors facilitate unloading of oxygen into tissues. This is seen as a shift of the oxyhemoglobin dissociation curve to the right. The oxygen carrying capacity of hemoglobin is also affected by competitive inhibitors for binding sites such as carbon monoxide. Carbon monoxide has an affinity for hemoglobin that is 240 times greater than oxygen. Thus, it will preferentially bind to hemoglobin. However, it does not affect the amount of oxygen dissolved in the blood. Someone with carbon monoxide poisoning

Figure 16-11 Changes in P_{O_2} and P_{CO_2} as blood courses from the pulmonary artery through the capillaries and into the pulmonary veins. The diffusion gradient is greater for O_2 than CO_2 . However, equilibration of capillary and alveolar gas occurs for both molecules within the 0.75 second it takes for blood to traverse the capillaries.

may have a normal P_{AO_2} but very low blood oxygen content due to the desaturated hemoglobin.

About 5% of carbon dioxide is dissolved in plasma, and the remainder is transported in other forms. A small amount of carbon dioxide also binds to hemoglobin. However, carbon dioxide does not exhibit cooperative binding; therefore, the shape of the carbon dioxide-hemoglobin dissociation curve is linear (see Fig. 16-12). Carbon dioxide binds to the protein component of the hemoglobin molecule and to the amino groups of the polypeptide chains of plasma proteins to form carbamino compounds. About 10% of carbon dioxide is transported in this fashion. Most of the carbon dioxide is transported as bicarbonate ion. As carbon dioxide diffuses from metabolically active tissue into the blood, it reacts with water to form carbonic acid. This reaction primarily occurs in the red blood cell because it is catalyzed by the enzyme carbonic anhydrase, which resides in the red blood cell. Carbonic acid then dissociates to bicarbonate and hydrogen ion. Although there is more carbon dioxide dissolved in blood than oxygen, it is still a small fraction of the total carbon dioxide transported by blood.

ABNORMALITIES OF PULMONARY GAS EXCHANGE

The P_{aO_2} and P_{aCO_2} are determined by the degree of equilibration between the alveolar gas and capillary blood. The degree of equilibration depends on four major factors: (1) ventilation, (2) matching of ventilation with perfusion, (3) shunt, and (4) diffusion. A fifth cause of hypoxemia is a low inspired P_{O_2} . *Hypoxemia* refers to a reduction in the oxygen content in the blood. Specifically, hypoxemia is determined by measuring the P_{O_2} of arterial blood. In contrast, *hypoxia*

Figure 16-12 **A**, The oxyhemoglobin dissociation curve. The bulk of the oxygen is combined with hemoglobin. The various factors that decrease the hemoglobin oxygen affinity are shown. Opposite changes increase hemoglobin oxygen affinity, shifting the curve to the left. **B**, The carbon dioxide dissociation curve is more linear than the oxyhemoglobin curve throughout the physiologic range. Increased P_{aO_2} shifts the curve to the right, which decreases carbon dioxide content for any given P_{aCO_2} and thus facilitates carbon dioxide off-loading in the lungs. The shift to the left at a lower P_{aO_2} facilitates carbon dioxide on-loading at the tissues. DPG, diphosphoglycerate.

refers to a decrease in oxygen content of an organ, for example, myocardial hypoxemia.

Hypoventilation is defined as ventilation inadequate to keep P_{CO_2} from increasing above normal. In this situation, hypoxemia may occur when increased carbon dioxide in alveoli displaces alveolar oxygen. The reciprocal relationship between alveolar carbon dioxide and alveolar oxygen is described by the alveolar gas equation.

$$P_{AO_2} = [(P_B - P_{H_2O}) \times F_{IO_2}] - (P_{aCO_2}/R),$$

where P_{AO_2} is the partial pressure of oxygen in the alveolus; P_B is barometric pressure; P_{H_2O} is water vapor pressure; F_{IO_2} is the fraction of inspired oxygen; and R is the respiratory exchange ratio.

From this equation, it is apparent that as alveolar ventilation falls and P_{aCO_2} rises, P_{AO_2} will have to fall. Administering supplemental oxygen (increasing the F_{IO_2}) can reverse hypoventilation-induced hypoxemia. When breathing room air, the difference between alveolar oxygen and arterial oxygen (P_{A-a} gradient) is normally about 20 mm Hg. Generally, this difference increases when hypoxemia is present. However, when hypoxemia is due to hypoventilation, the O_2 gradient is within normal limits. Causes of hypoventilation are varied and range from diseases or drugs that depress the respiratory control center to disorders of the chest wall or respiratory muscles that impair respiratory pump function. Disorders associated with hypoventilation include inflammation trauma or hemorrhage in the brainstem, spinal cord pathology, anterior horn cell disease, peripheral neuropathies, myopathies, abnormalities of the chest wall such as kyphoscoliosis, and upper airway obstruction. Administering a higher F_{IO_2} will alleviate the hypoxemia but will do little to improve the elevated P_{aCO_2} .

A second cause of hypoxemia is ventilation-perfusion ratio (\dot{V}/\dot{Q}) mismatch. This is the most common cause of hypoxemia in disease states. In the ideal lung, ventilation and perfusion would be perfectly matched. Although both ventilation and perfusion are greater at the base relative to the apex of the lung, the \dot{V}/\dot{Q} is lower at the base than at the apex of the lung. In the normal lung, the \dot{V}/\dot{Q} ranges from 0.5 at the base to 3 at the apex. The overall \dot{V}/\dot{Q} for the normal lung is 0.8. If lung disease develops, \dot{V}/\dot{Q} inequality may develop. If the \dot{V}/\dot{Q} is less than 0.8, the P_{A-a} gradient is increased, and hypoxia ensues. The P_{aCO_2} is usually within the normal range but will increase slightly at extremely low ratios (Fig. 16-13). Typically, hypoxemia seen in diseases that affect the airways, such as chronic obstructive pulmonary disease (COPD), is due to \dot{V}/\dot{Q} mismatch. As with hypoxemia due to hypoventilation, administering a higher F_{IO_2} improves hypoxemia due to \dot{V}/\dot{Q} mismatch.

Figure 16-13 **A**, The effect of increasing ventilation-perfusion (\dot{V}/\dot{Q}) inequality on P_{aO_2} and P_{aCO_2} when cardiac output and minute ventilation are held constant. **B**, The gas tensions change when ventilation is allowed to increase. Increased ventilation can maintain a normal P_{aCO_2} but can only partially correct the hypoxemia. (Adapted from Dantzker DR: Gas exchange abnormalities. In Montenegro H [ed]: Chronic Obstructive Pulmonary Disease. New York, Churchill Livingstone, 1984, pp 141-160.)

The third cause of hypoxemia is shunt. A right-to-left shunt occurs when a portion of blood travels from the right side to the left side of the heart without the opportunity to exchange oxygen and carbon dioxide in the lung. Right to left shunts can be classified as anatomic or physiologic. With an anatomic shunt, a portion of the blood bypasses the lung by traversing through an anatomic canal. In all healthy individuals, there is a small fraction of blood in the bronchial circulation that passes to the pulmonary veins and empties into the left atrium, thereby reducing P_{aO_2} of the systemic circulation. A smaller portion of the normal shunt is related to the coronary circulation draining through the thebesian veins into the left ventricle. Anatomic shunts found in disease states can be classified as intracardiac or intrapulmonary shunts. Intracardiac shunts occur when right atrial pressures are elevated and deoxygenated blood travels from the right atrium to the left atrium through an atrial septal defect or patent foramen ovale. Intrapulmonary anatomic shunts consist primarily of arteriovenous malformations or telangiectasias. A physiologic right-to-left shunt consists of a portion of the pulmonary arterial blood passing through normal vasculature but not coming into contact with alveolar air. This is an extreme example of ventilation-perfusion mismatch ($\dot{V}/\dot{Q} = 0$). Physiologic shunt can be due to diffuse flooding of the alveoli with fluid, as seen with congestive heart failure or acute respiratory distress syndrome. Alveolar flooding with inflammatory exudates as seen in lobar pneumonia also causes a shunt. The fraction of blood shunted can be calculated when the F_{iO_2} is 100% by using the following equation.

$$QS/Qt = (C_{CO_2} - C_{aO_2}) / (C_{CO_2} - C_{vO_2}),$$

where QS is the shunted blood flow, Qt is the total blood flow, C_{CO_2} is the end pulmonary capillary oxygen content; C_{aO_2} is the arterial oxygen content; and C_{vO_2} is the mixed venous oxygen content.

If the shunt is severe enough, patients will require mechanical ventilation and the application of positive end expiratory pressure to improve arterial oxygenation. At values less than 50% of the cardiac output, a shunt has very little effect on P_{aCO_2} (Fig. 16-14). With shunt, the P_A - a gradient is elevated, and the P_{aCO_2} is within normal range or may be low. Unlike hypoxemia due to hypoventilation or \dot{V}/\dot{Q} mismatch, administering a high F_{iO_2} does not improve hypoxemia due to shunt.

The fourth cause of hypoxemia is diffusion impairment. With normal cardiopulmonary function, the blood spends on average 0.75 second in the pulmonary capillaries. Typically, it only takes 0.25 second for the alveolar oxygen to diffuse across the thin alveolar capillary membrane and equilibrate with pulmonary arterial blood. However, if there is impairment to diffusion across this membrane (thickening of the alveolar capillary membrane by fluid, fibrous tissue, cellular debris, or inflammatory cells), it will take longer for the oxygen in the alveoli to equilibrate with pulmonary arterial blood. If the impediment to diffusion is such that it takes longer than 0.75 second for oxygen to diffuse, hypoxemia ensues. Alternatively, if the time the red cell spends traversing the pulmonary capillary decreases to 0.25 second or less, hypoxemia may develop. Hypoxemia may only be evident during exercise in individuals with diffusion

Figure 16-14 The effect of increasing shunt on the arterial P_{aO_2} and P_{aCO_2} . The minute ventilation has been held constant in this example. Under usual circumstances, the hypoxemia would lead to increased minute ventilation and a fall in the P_{aCO_2} as the shunt increases. (From Dantzker DR: Gas exchange abnormalities. In Montenegro H [ed]: Chronic Obstructive Pulmonary Disease. New York, Churchill Livingstone, 1984, pp 141-160.)

impairment because of the shortened red cell transit time. In this instance, the O_2 gradient may be normal at rest but increases with exercise. With diffusion impairment, the P_{aCO_2} generally is within the normal range. As with hypoxemia due to hypoventilation and \dot{V}/\dot{Q} mismatch, administering a higher F_{iO_2} improves hypoxemia due to impaired diffusion.

A fifth cause of hypoxemia is due to low inspired oxygen. This is seen at an altitude at which the fraction of inspired oxygen is normal, but the partial pressure of oxygen is low because barometric pressure is low (P_{atm}). Rarely, circumstances occur in which the F_{iO_2} is low (e.g., rebreathing air). Hypoxemia due to low inspired oxygen is associated with a normal O_2 gradient and is usually accompanied by a low P_{aCO_2} . Providing supplemental oxygen will correct this form of hypoxemia. Finally, a low mixed venous P_{O_2} will predispose individuals to hypoxia (Fig. 16-15).

Evaluation of Lung Function

Pulmonary function tests evaluate one or more major aspects of the respiratory systems. Accurate measurements of lung volumes, airway function, and gas exchange require a pulmonary function testing laboratory. Pulmonary function tests are commonly used to aid in the diagnosis of disease and assess disease severity. In addition, they are helpful in monitoring the course of the disease, assessing risk for surgical procedures, and measuring the effects of varied environmental exposures. Assessment of bronchodilator response or other forms of treatment also can be evaluated with serial pulmonary function tests (Table 16-1). Accurate interpretation of pulmonary function tests requires the appropriate reference standards. Variables that affect the predicted

Figure 16-15 The effect of altering mixed venous P_{VO_2} on the arterial oxygen content under three assumed conditions: a normal lung, severe ventilation-perfusion (V/Q) inequality, and the presence of a 40% shunt. For each situation, the patient is breathing 50% oxygen and the P_{VO_2} or mixed venous P_{O_2} is altered, keeping all other variables constant. (From Dantzker DR: Gas exchange in the adult respiratory distress syndrome. Clin Chest Med 3:57-67, 1982.)

Figure 16-16 Lung volumes and capacities. Although spirometry can measure vital capacity and its subdivisions, calculation of residual volume requires measurement of functional residual capacity by body plethysmography, helium dilution technique, or nitrogen washout.

Table 16-1 Indications for Pulmonary Function Testing	
• Evaluation of signs and symptoms	• Shortness of breath, exertional dyspnea, chronic cough
• Screening at-risk populations	• Monitoring pulmonary drug toxicity
• Follow-up abnormal study	• Chest radiograph, electrocardiogram, arterial blood gases, hemoglobin
• Preoperative assessment	• Assess severity
	• Follow response to therapy
	• Determine further treatment goals
	• Assess disability

standards for pulmonary function tests include age, height, gender, race, and hemoglobin concentration.

Spirometry is the simplest means of measuring lung function and can be performed in an office practice. A spirometer is an apparatus that measures inspiratory and expiratory volumes. Flow rates can be calculated from tracings of volume versus time. Typically, vital capacity (VC) is measured as the difference between a full inspiration to total lung capacity (TLC) and a full exhalation to residual volume (RV) (Fig. 16-16). Flow rates are measured after instructing someone to forcefully exhale from TLC to RV. Such a forced expiratory maneuver allows one to calculate the forced expired volume in 1 second (FEV_1) and the forced vital capacity (FVC) (Fig. 16-17). A value of 80% to 120% predicted is considered normal for FVC. Normally, people can exhale more than 75% to 80% of their FVC in the first second, and the majority of FVC can be exhaled in 3 seconds. The ratio of these two variables is normally more than 0.8.

Figure 16-17 Spirometry in a normal individual and in a patient with obstructive lung disease. FEV_1 represents the forced expired volume in 1 second, and FVC represents the forced vital capacity. The slope of the line connecting the points at 25% and 75% of the FVC represents the forced expired flow (FEF at 25% to 75%) or maximum mid-expiratory flow (MMEF). The FEF at 25% to 75% is less reproducible and less specific than the FEV_1 .

Spirometry can reveal abnormalities that are classified into two patterns—obstructive and restrictive. Obstructive impairments are defined by a low FEV_1/FVC ratio. Diseases characterized by an obstructive pattern include asthma, chronic bronchitis, emphysema, bronchiectasis, cystic fibrosis, and some central airway lesions. The reduction in FEV_1 (expressed as % predicted FEV_1) is used to determine the severity of airflow obstruction (**Web Fig. 16-2**). Peak expiratory flow rate (PEFR) can be measured as the maximal expired flow rate obtained during spirometry or when using a hand-held peak flow meter. The lower the peak expiratory flow rate, the more significant the obstruction. The peak flow meter can be used at home or in the emergency department and to evaluate the presence of obstruction. Severe attacks of asthma, for example, are usually associated with peak expiratory flow rates of less than 200 L per minute (normal is 500 to 600 L per minute). A restrictive pattern is characterized by loss of lung volume. With spirometry, both the FVC and FEV_1 are reduced with a normal FEV_1/FVC ratio. The restrictive pattern must be confirmed by measurements of lung volumes.

Lung volumes are measured using body plethysmography or by dilution of an inert gas such as helium. Lung volumes that can be measured with these techniques include FRC, TLC, and RV (see Fig. 16-16). As mentioned previously, FRC is the lung volume at which the inward elastic recoil of the lung equals the outward elastic recoil of the chest wall. Changes in FRC reflect abnormalities in lung elastic recoil. Diseases associated with increased elastic recoil such as pulmonary fibrosis are associated with a reduction in FRC, whereas those with decreased recoil such as emphysema are associated with an increase in FRC. TLC is the amount of air in the thorax after a maximal inspiration and is determined by the balance of the forces generated by the respiratory muscles to expand the respiratory system and the elastic

recoil of the respiratory system. Restrictive lung disease is defined as a TLC less than 80% predicted, whereas values of TLC greater than 120% predicted are consistent with hyperinflation. The lower the percent predicted TLC, the more severe the restrictive impairment. Restriction may be due to disorders of the lung, chest wall, respiratory muscles, or pleural space. Lung diseases that cause pulmonary fibrosis will cause a restrictive pattern because of the increased elastic recoil of the respiratory system. Diseases of the chest wall, such as kyphoscoliosis, obesity, and ankylosing spondylitis can also cause restriction by reducing the elasticity of the chest wall. Weakness of the respiratory muscles causes restriction by reducing the force available to inflate the respiratory system. Myasthenia gravis, amyotrophic lateral sclerosis, diaphragm paralysis, and Guillain-Barré syndrome can be associated with weakness sufficient to cause restrictive lung disease. Finally, space-occupying lesions involving the pleural space such as pleural effusions, pneumothorax, or pleural tumors can cause restriction. Occasionally, RV and FRC may be elevated with no increase in total lung capacity. This pattern is referred to *air trapping* and can be seen with COPD or asthma.

The forced expiratory maneuver can be analyzed in terms of flow and volume, that is, a flow-volume loop (Fig. 16-18). Flow-volume loops are useful when identifying obstructive and restrictive patterns. The characteristic appearance of obstructive impairment is concavity (“scooping”) of the expiratory loop (**Web Fig. 16-3**). With restrictive impairments, the loops are similar in appearance to normal but reduced in size. In addition, flow-volume loops are the primary means of identifying upper airway obstruction. Upper airway obstruction is characterized by a truncated (clipped) inspiratory or expiratory loop. A fixed obstruction has clipping of both inspiratory and expiratory loops. Variable intrathoracic upper airway obstruction exhibits

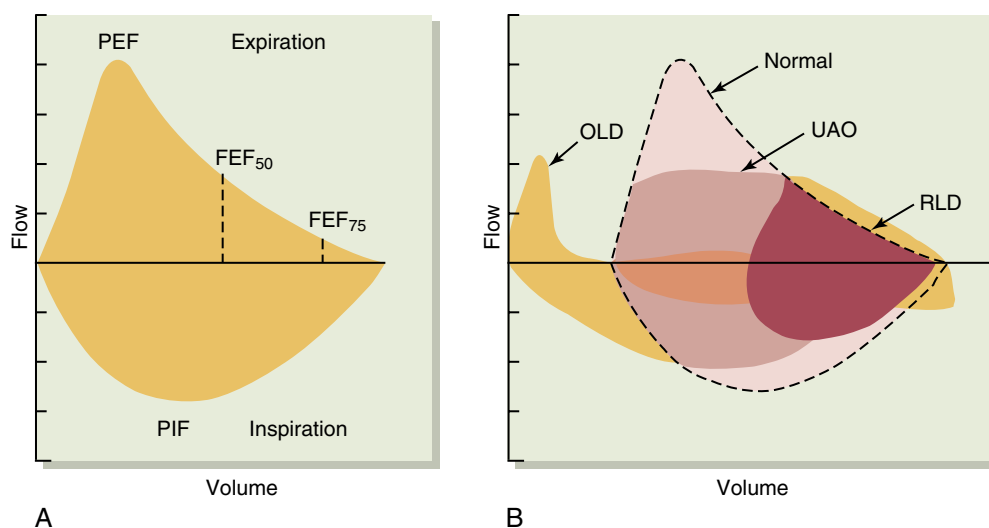

Figure 16-18 **A**, The maximum expired flow and volume curve in a normal individual. The peak expiratory flow (PEF) and forced expiratory flows at 50% and 75% of the exhaled vital capacity (FEF at 50% and 75%) are indicated. PIF, peak inspiratory flow. **B**, In obstructive lung disease (OLD), hyperinflation pushes the position of the curve to the left, and characteristic scalloping on expiration develops. In restrictive lung disease (RLD), lung volumes are reduced, but flow for any point in volume is normal. The flow-volume curve displays different patterns with various forms of upper airway obstruction (UAO), with reduction in respiratory flow if the obstruction is outside the thoracic cavity and, in addition, in expiratory flow if the obstruction is caused by a fixed deformity.

clipping of the expiratory loop, whereas variable extrathoracic obstruction exhibits clipping of the inspiratory loop (see Fig. 16-18).

BRONCHOPROVOCATION TESTING

Bronchoprovocation testing is typically used to determine the presence or absence of hyperreactive airways disease. Some individuals in whom there is a clinical suspicion of asthma may have normal expiratory flow rates and lung volumes. Bronchoprovocation testing in these individuals can be important in identifying hyperreactive airways disease and supporting the diagnosis of asthma. Methacholine is a cholinergic agonist that causes bronchoconstriction. Individuals with hyperreactive airways exhibit airflow limitation after inhaling low concentrations of methacholine. During the bronchoprovocation test, the subject inhales increasing concentrations of methacholine. Measurements of FEV₁ and FVC, as well as specific airways conductance, are obtained after the inhalation of each concentration. If the FEV₁ is reduced by 20% or more or the specific airways conductance is reduced by 40% or more, a diagnosis of hyperreactive airways disease can be ascertained. Patients with asthma demonstrate a fall in FEV₁ of 20% from baseline at doses considerably smaller than normal individuals (Fig. 16-19).

LUNG DIFFUSION CAPACITY

The diffusion of oxygen from the alveolus into the capillary can be assessed by measuring the diffusion capacity for carbon monoxide. To calculate diffusion capacity for oxygen, one needs to know the alveolar volume and the partial pressure of oxygen in the alveolus and in the pulmonary capillary.

Because it is not practical to measure the oxygen tension of pulmonary capillary blood, carbon monoxide is used rather than oxygen to assess diffusion capacity. Carbon monoxide diffuses across the alveolar capillary membranes much as oxygen does. However, carbon monoxide has the advantage of completely binding to hemoglobin. Therefore, the partial pressure of carbon monoxide in the pulmonary venous blood is negligible. Diffusion capacity for carbon monoxide (DLCO) is then measured as the rate of disappearance of carbon monoxide from the alveolus and is used as a surrogate for oxygen diffusion capacity. This measurement provides an overall assessment of gas exchange and depends on factors including the surface area of the lung, the physical properties of the gas, perfusion of ventilated areas, hemoglobin concentration, and the thickness of the alveolar-capillary membrane. Thus, an abnormal DLCO may not only signify disruption of the alveolar-capillary membrane but may also be related to a reduction in surface area of the lung (pneumectomy), poor perfusion (pulmonary embolus), or poor ventilation of alveolar units. An increased DLCO may be associated with engorgement of the pulmonary circulation with red blood cells or polycythemia. A low DLCO may be seen in interstitial lung diseases that alter the alveolar-capillary membrane or diseases such as emphysema that destroy both alveolar septa and capillaries (Web Fig. 16-4). Anemia lowers the DLCO. Most laboratories provide a hemoglobin correction for diffusion capacity.

ARTERIAL BLOOD GASES

The measurement of Pao₂ and Paco₂ provides information about the adequacy of oxygenation and ventilation. This requires arterial blood sampling through arterial puncture or indwelling cannula (Table 16-2). Oxygenation can also be measured through noninvasive devices including the pulse oximeter, which measures hemoglobin oxygen saturation, and through transcutaneous devices that measure Pao₂ and Paco₂. These devices are particularly useful for measuring oxygenation during exertion in the office setting. Often, alterations in oxygenation are not detected at rest, but they are unveiled during exertion. The 6-minute walk test is a standardized test in which the patient walks for 6 minutes while the oxygen hemoglobin saturation is measured. A decrease in the oxygen hemoglobin saturation is abnormal and suggests impaired gas exchange capabilities.

In summary, pulmonary function tests, in conjunction with history and physical examination, can be used to diagnose pulmonary disorders and assess severity and response to therapy, as illustrated in the flow diagram (Web Fig. 16-5).

Figure 16-19 Bronchoprovocation challenge. Patients are exposed to increasing concentrations of an inhaled challenge (e.g., methacholine, histamine) followed by evaluation of FEV₁ (percent control, PC). The FEV₁ falls at lower concentrations of the challenge drug in a patient with asthma (blue circles) when compared with an individual without asthma (red circles).

Table 16-2 Normal Values for Arterial Blood Gases

PO ₂ : 104 – (0.27 × age)
PCO ₂ : 36–44
pH: 7.35–7.45
Alveolar-arterial O ₂ difference = 2.5 + 0.21 × age

Evaluation of Lung Structure

CHEST RADIOGRAPH

Generally, the evaluation of a patient with lung disease begins with routine chest radiography and then proceeds to more specialized techniques such as computed tomography (CT) or magnetic resonance imaging (MRI). Ideally, the chest radiograph consists of two different films, a postero-anterior (PA) radiograph and a lateral radiograph (**Web Fig. 16-6**). Many pathologic processes can be identified on a PA chest radiograph; however, the lateral view adds valuable information about areas that are not well seen on the PA projection. In particular, the retrocardiac region, the posterior bases of the lung, and the bony structure of the thorax such as the vertebral column are visualized better on the lateral radiograph. The PA chest radiograph is obtained with the patient standing with his or her back to the x-ray beam and the anterior chest wall placed against the film cassette. The chest radiograph should be obtained while the patient takes the deepest breath possible. When the patient is too weak to stand or too sick to travel to the radiology department, the cassette is placed behind the patient's back, and the x-ray beam travels from anterior to posterior (AP film). The quality of a portable film is not that of a standard PA film, but it still provides valuable information.

The approach to examining a chest radiograph should be systematic so that subtle abnormalities are not missed. An examination of a chest radiograph includes evaluating the lungs and pulmonary vasculature, the bony thorax, the heart and great vessels, the diaphragm and pleura, the mediastinum, the soft tissues, and the subdiaphragmatic areas. Abnormalities seen on a chest radiograph include pulmonary infiltrates, nodules, interstitial disease, vascular disease, masses, pleural effusions and thickening, cavitory lung disease, cardiac enlargement, some airway diseases, and vertebral or rib fractures. In addition to the PA and lateral chest radiographs, the lateral decubitus projection is often used to identify the presence or absence of pleural effusion. The decubitus view is particularly useful in determining whether blunting of the costal phrenic sulcus is due to freely flowing pleural fluid or related to pleural thickening. The chest radiograph in concert with a good history and physical examination allows the clinician to diagnose chest disease in many circumstances.

FLUOROSCOPY

Fluoroscopic examination of the chest is useful in evaluating motion of the diaphragm. This technique is particularly helpful in diagnosing unilateral diaphragm paralysis. A paralyzed hemidiaphragm moves paradoxically when the patient is instructed to inhale or forcefully sniff. However, fluoroscopy is limited when evaluating for bilateral diaphragm paralysis. Because of compensatory respiratory strategies in the setting of bilateral diaphragm paralysis, apparent normal descent of the diaphragm may be seen during inspiration, leading to a false-negative result by fluoroscopy. Furthermore, paradoxical hemidiaphragm motion is seen in as many as 6% of normal subjects during the sniff maneuver. This observation leads to a false-positive interpretation.

Alternatively, two-dimensional B-mode ultrasound of the diaphragm can be used to visualize diaphragm contraction during inspiration. With this technique, the diaphragm muscle is visualized in the zone of apposition of the diaphragm to the rib cage. Absence of contraction correlates with the absence of active transdiaphragmatic pressure and indicates diaphragm paralysis. This technique can be used to diagnose bilateral and unilateral diaphragm paralysis.

COMPUTED TOMOGRAPHY

CT has many applications in pulmonary medicine and provides more detailed information about lung structure than chest radiography. Using this technique, cross sections of the entire thorax can be obtained, usually at 1-cm intervals. Image contrast can be adjusted to optimize visualization of the lung parenchyma or pleural and mediastinal structures. The use of intravenous contrast material as part of the examination permits separation of vascular from nonvascular mediastinal structures. CT of the chest adds tremendous anatomic detail when compared with chest radiography. Its increased resolution permits elucidation of many findings. It helps to characterize pulmonary nodules and masses, distinguish between pleural thickening and pleural fluid, estimate the size of the heart and presence of pericardial fluid, identify patterns of involvement of interstitial lung disease, detect cavities, identify intracavitary processes such as mycetomas, quantify the extent and distribution of emphysema, detect and measure mediastinal adenopathy for staging of lung cancer, and identify vascular invasion by neoplasm. Newer generations of CT scanners are able to use multiple x-ray beams so that 4 to 64 images are created simultaneously at a much faster rate than the older models, which used only a single x-ray beam and detector.

CT angiography allows for construction of three-dimensional images of the pulmonary vascular system. This imaging technique has emerged as the procedure of choice for identifying pulmonary embolism supplanting pulmonary ventilation-perfusion scintigraphic lung scanning. The technique also can be used to identify pulmonary vascular abnormalities such as aortic dissection, pulmonary venous malformations, and aortic aneurism.

High-resolution CT is a technique that generates thin anatomic slices (1 mm) to provide a high-contrast image of the pulmonary parenchyma. With high-resolution CT, a special reconstruction algorithm sharpens the soft tissue interfaces to provide superior visualization of the pulmonary parenchyma. This technique primarily is used to identify interstitial lung disease and bronchiectasis. It is extremely useful in identifying interstitial lung disease that may not be apparent on a plain chest radiograph and has supplanted bronchography in the diagnosis of bronchiectasis.

MAGNETIC RESONANCE IMAGING

MRI is a tomographic technique that uses radio waves modified by a strong magnetic field to produce an image. It provides images that are similar to those produced with CT but with better definition of vascular structures. MRIs can be constructed in one of several anatomic planes. Although the standard image is usually an axial view, sagittal and coronal images can be easily created from the information obtained

at the time of the study. Intravenous administration of gadolinium acts as a contrast agent and allows better visualization of vascular structures. MRI can be used to study aortic dissection and may have a role in the evaluation of pulmonary emboli.

PULMONARY ANGIOGRAPHY

Pulmonary angiography entails placement of a catheter in the pulmonary artery followed by rapid injection of contrast. Angiography was the gold-standard for diagnosing pulmonary thromboembolic disease. Pulmonary angiography can be useful in detecting congenital abnormalities of the pulmonary vascular tree, but CT and MRI have largely supplanted pulmonary angiography.

POSITRON-EMISSION TOMOGRAPHY

Positron-emission tomography (PET) detects metabolically active masses greater than 1 cm in diameter. It is helpful in assessing whether a pulmonary nodule is benign or malignant. However, it does not distinguish between inflammation and malignancy. Thus, assessment of multiple pulmonary nodules using PET scanning is limited because of false-positive findings due to active granulomatous disease such as tuberculosis, sarcoidosis, or fungal infections. Dual-modality integrated PET-CT combines morphologic and functional imaging. The combination of PET and CT is helpful in localizing solitary metastatic lymph nodes in the hilum, which allows better staging of lung cancer. In addition, PET-CT is helpful in planning radiation therapy for patients with lung cancer associated with atelectasis.

BRONCHOSCOPY

Fiberoptic bronchoscopy is used for diagnostic or therapeutic indications. It is most commonly performed to directly visualize the nasopharynx, larynx, vocal cords, and proximal tracheobronchial tree for diagnostic purposes. The procedure is performed by sedating the patient and providing

local anesthesia with inhaled and bronchoscopically instilled lidocaine. The bronchial mucosa is assessed for endobronchial masses, mucosal integrity, extrinsic compression, dynamic compression, and hemorrhage. The bronchoscope is equipped with a channel for passage of biopsy forceps, bronchial brushes, or needles for aspiration and tissue biopsy. Saline also can be instilled through the channel for bronchial washings or bronchoalveolar lavage. Bronchial washings can be analyzed for cytology, culture, and special stains. A bronchial brush is used to scrape the bronchial mucosa and harvest cells for cytology. Bronchoscopes can also be adapted to provide ultrasound images of the airways and neighboring tissues. Endobronchial ultrasound (EBUS) uses high acoustic frequencies, in the range of 20 MHz, which provide high-resolution images of proximal tissue. EBUS can provide guidance for needle aspiration of mediastinal lymph nodes.

Common therapeutic indications for bronchoscopy include the retrieval of foreign bodies, suctioning of secretions, re-expansion of atelectatic lung, and assistance with difficult endotracheal intubations. In special centers, bronchoscopy is used to perform YAG laser therapy of endobronchial lesions, guide placements of catheters for brachytherapy of lung cancer, or guide placement of stents. Lasers produce a beam of light that can induce tissue vaporization, coagulation, and necrosis. Cryotherapy probes induce tissue necrosis through hypothermic cellular crystallization and microthrombosis. Cryotherapy and electrocautery have been used to treat and relieve airway obstruction caused by benign tracheal bronchial tumors, polyps, and granulation tissue. The goal of endobronchial brachytherapy is to relieve airway obstruction from central tumors. This is generally used as an adjunct to conventional external-beam irradiation. Tracheobronchial stenting can be performed to manage airway compression associated with malignant tumors, tracheoesophageal fistulas, and tracheobronchomalacia. Bronchoscopy is generally a safe procedure, with major complications, including significant bleeding, pneumothorax, and respiratory failure, occurring in 0.1% to 1.7% of patients.

Prospectus for the Future

Continued refinement and evolution of techniques and methods currently used to assess pulmonary structure and function will enhance our ability to diagnose and treat individuals with lung disease. Although pulmonary function testing has been performed for decades, advances in equipment design and better standardization of methods will improve accuracy and reproducibility. Further development of noninvasive techniques used to measure changes in lung volume from body surface displacements may allow for assessment of pulmonary function in settings outside of the pulmonary function laboratory. Great strides in assessing lung structure will evolve from advances in CT, PET, and MRI technology. CT volume-rendering techniques will provide images of the central airways enabling “virtual bronchoscopy.” This technique may be useful to guide biopsy location for conventional bronchoscopy and allow visualization of airways distal to an endobronchial obstruction. Volumetric measurements of pulmonary nodules using CT seg-

mentation techniques will allow more accurate calculation of nodule volume and better assessment of tumor doubling times. This, in concert with PET-CT, may provide more accurate means of determining malignant potential of solitary pulmonary nodules. MRI may evolve into the preferred method for evaluating pulmonary emboli and mediastinal disease. Velocity-encoded MRI is a promising modality for assessing pulmonary vascular blood flow and pressures, which may prove to be more accurate than current noninvasive methods. Lymph node specific magnetic resonance contrast agents and the development of PET molecular tracers targeting tumor proteins and receptors may better differentiate enlarged lymph nodes due to hyperplasia from those due to neoplasia. Finally, new insights into function of the respiratory control centers in the cortex and brainstem may be attained from studies using functional MRI of the brain.

Obstructive Lung Diseases

Matthew D. Jankowich

The obstructive lung diseases are a group of common pulmonary disorders resulting in dyspnea characterized by an obstructive pattern of expiratory airflow limitation on spirometry. These disorders include *chronic obstructive pulmonary disease* (COPD), *asthma*, *cystic fibrosis*, *bronchiectasis*, and the *bronchiolar disorders*. COPD is a clinical term encompassing varied pathophysiologic processes, including *emphysema*, *chronic bronchitis*, and *small airways disease*, one or more of which may be prominent in a given patient with this disorder. COPD is characterized in general by abnormal airway inflammation and abnormal lung structure in response to an inhaled irritant, typically cigarette smoke, resulting in irreversible or incompletely reversible airflow limitation. Asthma is distinguished from COPD by characteristic bronchial smooth muscle hyperreactivity and reversible airflow limitation and by its frequent association with atopy (Fig. 17-1). These disorders are epidemic in the general population and account for a significant proportion of the morbidity and mortality associated with the obstructive lung diseases.

All the obstructive lung disorders cause an obstructive pattern of expiratory airflow limitation, although the basis for airflow obstruction varies among disorders. The flow of air through the bronchial tree is directly proportional to the driving pressure and is inversely proportional to the resistance. In obstructive lung disease, alterations in one or both of these processes might be present. For example, in emphysema, airflow limitation is caused by decreased elastic recoil resulting in decreased driving pressure. By contrast, in asthma, airflow limitation is due to bronchoconstriction that increases airway resistance. Airway obstruction to flow causes characteristic changes in lung volumes. The residual volume and functional residual capacity are increased, whereas the total lung capacity remains normal or is increased. Vital capacity is reduced by the increase in residual volume. Several factors may contribute to the increase in functional residual capacity and residual volume in obstructive lung disease. Decreased lung elastic recoil in emphysema increases the functional residual capacity because of reduced opposition to the outward force exerted by the chest wall. Loss of airway tone and decreased tethering by surrounding lung in COPD, as well as bronchoconstriction and mucus plugging in acute asthma, allow airways to collapse at higher

lung volumes and trap excessive air. Finally, under demands for increased minute ventilation such as during exercise, the increased resistance to airflow may not allow the lungs to empty completely during the time available for expiration, leading to so-called dynamic hyperinflation of the lungs as the volume of trapped air progressively increases while the inspiratory capacity is progressively limited.

The three major consequences of the changes in lung volume seen with obstructive lung disease are as follows: (1) Breathing at higher lung volumes requires a higher change in pressure for the same change in lung volume, and this requirement increases the work of breathing. (2) Larger lung volumes place the inspiratory muscles at a mechanical disadvantage. The diaphragm is flattened, thereby decreasing its ability to change intrathoracic volume, and all the inspiratory muscle fibers are shortened, decreasing the tension they are able to exert to effect changes in lung volume. (3) Lung volumes are larger, resulting in tethering of the narrowed and collapsing airways by the surrounding lung parenchyma, tending to retain airway patency and reduce airway resistance and air trapping; this consequence is beneficial. These three physiologic derangements explain many of the clinical features of obstructive lung diseases (Table 17-1).

Although the consequences to lung function are relatively similar in the obstructive lung diseases, their pathogenesis, treatment, and prognosis are different. Therefore, a careful evaluation is needed to reach a definitive diagnosis that will guide targeted therapy.

Chronic Obstructive Pulmonary Disease

COPD results in slowly progressive dyspnea and is characterized by abnormalities of airway and lung structure occurring in response to noxious inhaled substances, especially cigarette smoke. The abnormalities of airway and lung structure in COPD result in irreversible airflow limitation, the physiologic hallmark of COPD. The term COPD encompasses emphysema, chronic bronchitis, and small airways disease, pulmonary disorders that have common clinical

manifestations and often co-exist in the same patient. The term excludes other causes of airflow obstruction, such as asthma, although in practice these diseases may at times overlap.

COPD is one of the most common disorders seen by physicians, and it is the fourth leading cause of death in the United States. There are an estimated 1,500,000 emergency department visits related to COPD annually, and about 700,000 patients with COPD are hospitalized each year. From 1997 to 2001, about 90,000 deaths per year attributable to COPD occurred in the United States. Although COPD has historically been more prevalent in males than females, the prevalence of COPD in females has been increasing, and annual death rates for COPD have been steadily rising in

both white and black women. Prevalence rates for COPD are correlated with increasing age, lower socioeconomic status, and smoking.

Cigarette smoking is by far the most common cause of COPD; however, other factors such as inhalation of cooking fire smoke, air pollution, occupational exposures to dust and fumes, and infections contribute to the occurrence, severity, and progression of the disease. Although cigarette smoking is the most common cause, it is important to note that only 20% of smokers are thought to develop clinically significant COPD (although many more may experience some loss of lung function). This finding suggests that COPD results from a susceptibility to environmental factors (e.g., tobacco) as a result of a genetic predisposition. A genetic predisposition is also implied by the documentation of familial clusters of COPD.

Several longitudinal studies have defined patterns of age-related decline in lung function and have documented the concept of susceptibility to COPD. These studies show that most adult nonsmoking men exhibit a decline in forced expiratory volume in 1 second (FEV₁) of 35 to 40 mL per year. This rate is increased to 45 to 60 mL per year in most cigarette smokers. However, the susceptible smoker may demonstrate losses of 70 to 120 mL per year (Fig. 17-2). This information allows the physician to project the rate of decrease of lung function in patients with COPD and assess the effects of therapeutic interventions.

Although COPD results in chronic, progressive dyspnea, periodic acute exacerbations are characteristic of COPD. Exacerbations are characterized by a rapidly developing worsening of pulmonary function respiratory symptoms such as cough and sputum production. Acute exacerbations are associated with various triggers, including viral or bacterial respiratory infections, air pollution, and cardiac failure. Exacerbations vary widely in severity, but severe exacerbations may lead to hospitalization, acute respiratory failure, and death. Following an exacerbation, a patient may take weeks to return to a baseline level of function. Patients with

Figure 17-1 Classification of obstructive lung diseases. COPD, chronic obstructive lung disease.

Table 17-1 Features of Obstructive Lung Diseases

Disorder	Clinical Features	Laboratory Findings
Chronic obstructive pulmonary disease	Chronic progressive dyspnea	Decreased expiratory flow rates, hypoxia and hypercapnia in end-stage disease
Emphysema	Little or no sputum, end-stage cachexia	Hyperinflation, increased compliance, low D _L CO, rarely α ₁ -antitrypsin deficiency
Chronic bronchitis	Sputum, history of smoking, industrial exposure	Nonspecific; rarely occurs in isolation without varying degrees of emphysema
Asthma	Episodic dyspnea, cough, wheezing, with or without environmental triggers	Airway hyperreactivity, response to bronchodilators
Bronchiectasis	Usually large volume of sputum	Chest radiograph: dilated bronchi, thick-walled, tram track shadows, obstruction with or without restriction on pulmonary function tests
Immotile cilia syndrome	Situs inversus, dextrocardia, sinusitis, infertility	Abnormal dynein in ciliated cells
Hypogammaglobulinemia		Decrease in one or more immunoglobulins
Cystic fibrosis	Sinusitis, bronchiectasis, meconium ileus, malabsorption, infertility	Increased sweat chloride, mutation in CFTR chloride channel, elevated fecal fat, abnormal nasal mucosal potential difference

CFTR, cystic fibrosis transmembrane conductance regulator; D_LCO, diffusion capacity for carbon monoxide.

Figure 17-2 Pattern of decline in forced expiratory volume in 1 second (FEV_1) with risks for morbidity and mortality from respiration disease in a susceptible smoker in comparison with a normal patient and with a nonsusceptible smoker. Although cessation of smoking does not replenish the lung function already lost in a susceptible smoker, it decreases the rate of further decline. (Data from Fletcher C, Peto R: The natural history of chronic airflow obstruction. *BMJ* 1:1645-1648, 1977.)

frequent exacerbations of COPD appear to experience an accelerated rate of decline in FEV_1 .

The only genetic disorder thus far definitively linked to COPD is α_1 -antitrypsin deficiency, which accounts for less than 1% of all cases. The deficient enzyme, α_1 -antitrypsin, an acute-phase reactant, is produced primarily in the liver, from which it travels to the lung, where it deactivates elastases released by inflammatory cells that are capable of degrading connective tissue matrices. In doing so, α_1 -antitrypsin prevents the uncontrolled degradation of elastin in the lung parenchyma and protects against the development of emphysema. Individuals with the ZZ genotype of α_1 -antitrypsin deficiency produce mutant forms of α_1 -antitrypsin that have a tendency to inappropriately polymerize within the hepatocyte, leading to a deficiency in secreted α_1 -antitrypsin and in some cases to collateral damage to the liver caused by accumulation of intracellular misfolded, mutant α_1 -antitrypsin. Patients who develop emphysema at a young age (<40 years) should be evaluated for this condition whether or not they smoke. Polymorphisms in various other candidate genes that may be relevant to susceptibility to COPD are under investigation.

As noted previously, the main pathophysiologic abnormalities potentially present in COPD are emphysema, chronic bronchitis, and small airways disease. These disorders are individually discussed next.

Emphysema

Emphysema is defined as a permanent enlargement of the air spaces distal to the terminal bronchiole (**Web Fig. 17-1**). This occurs as a result of destruction of lung parenchyma, but in the absence of significant fibrosis. These changes result in an abnormal acinus with limited capabilities for gas exchange. Based on thin gross lung sections, emphysema can be classified into *centrilobular* and *panlobular* types (**Web Figs. 17-2 and 17-3**). In centrilobular emphysema, the proximal part of the lobule (the respiratory bronchiole) is affected, which represents the most common

histologic feature observed in emphysema related to smoking, whereas panlobular emphysema is typically seen in α_1 -antitrypsin deficiency.

The observation that α_1 -antitrypsin deficiency was associated with emphysema, and that emphysema could be reproduced in experimental models by the instillation of papain, a protease, into the lungs, led to the hypothesis that emphysema is caused by an imbalance between protease and anti-protease systems in the lung. This theorized imbalance would favor proteolytic destruction of lung connective tissue, resulting in emphysema (the *protease-antiprotease hypothesis*). Research has focused on neutrophil elastase and its role in the destruction of lung elastin. Neutrophil elastase is the main target for inactivation by α_1 -antitrypsin and has relatively unopposed effects. However, evidence of a primary role of this enzyme in cigarette smoke-induced emphysema is less clear, so the focus has since broadened to include examination of the role of the matrix metalloproteinases (MMPs), produced by macrophages and other cells, in emphysema. Transgenic mice deficient in the *MMP-12* gene are resistant to the development of emphysema, supporting a role for this enzyme in mediating lung connective tissue loss leading to emphysema.

The *inflammation* induced by cigarette smoke is a trigger of the cycle of protease release and lung destruction resulting in emphysema (**Web Fig. 17-4**). Macrophages are activated by cigarette smoke and recruit neutrophils and other inflammatory cells to the lung, leading to the release of elastase and MMPs. The destruction of elastin and other connective tissue elements in the lungs over time by these proteases leads in turn to the loss of elastic recoil and the destruction of alveolar structures characteristic of emphysema.

Cigarette smoke contains many oxidant molecules, capable of inducing *oxidative stress* in the lung. Oxidative stress has diverse effects, including the oxidative inactivation of antiproteases in the lung as well as acetylation of specific histones in the chromatin of lung cells and macrophages, allowing the expression of various pro-inflammatory genes. Histone deacetylase activity is reduced in COPD, which in turn may result in an inability to control the pro-inflammatory response in this condition. Pro-inflammatory gene expression promotes cytokine production and release, contributing to further inflammatory cell recruitment and activation. Systemic inflammation, triggered by ongoing pulmonary inflammation, may lead to nonpulmonary abnormalities associated with emphysema, including cachexia and skeletal muscle alterations. Finally, increased *apoptosis* of pneumocytes and endothelial cells has been observed in lungs with emphysema and could contribute to the loss of alveoli.

Understanding of emphysema pathogenesis has improved, with the recognition that inflammation, oxidative stress, protease-antiprotease balance, and apoptosis are linked in a complex interaction induced by cigarette smoke. This improved understanding has broadened the range of therapeutic possibilities that may be effective in ameliorating the destructive process. To date, however, specific therapies targeted at molecular pathways involved in emphysema pathogenesis have not been successful at altering disease progression, with the possible exception of α_1 -antitrypsin replacement therapy in α_1 -antitrypsin deficiency.

Chronic Bronchitis

Chronic bronchitis often coincides with emphysema in the patient with COPD, and it is defined in clinical terms as a persistent cough resulting in sputum production for more than 3 months in each of the past 2 years. Cigarette smoking is the major cause, although exposure to pollutants such as dusts may also play a role. Pathologic findings are goblet cell hyperplasia, mucus hypersecretion and plugging, and airway inflammation and fibrosis.

The disease mechanisms involved in the development of emphysema are also important in the pathogenesis of chronic bronchitis. However, in contrast to emphysema, chronic bronchitis is a disease of the large airways and not the lung parenchyma. Therefore, the relationship of chronic bronchitis to airflow obstruction is less robust than for emphysema, and airflow limitation in a patient with chronic bronchitis may be more reflective of concomitant emphysema and small airways disease. Inflammation in chronic bronchitis leads to effects on the airway epithelium, including *excess mucus production* and *impairment in mucociliary clearance*. *Neurogenic stimuli* are also important in the pathogenesis of airway obstruction in chronic bronchitis. The conducting airways are surrounded by smooth muscle, which contains adrenergic and cholinergic receptors. Stimulation of β_2 -adrenergic receptors by circulating catecholamines dilates airways, whereas stimulation of airway irritant receptors constricts airways through a cholinergic mechanism by means of the vagus nerve. The irritant bronchoconstrictive pathways are normally present to protect against inhalation of noxious agents, but in pathologic states, these pathways may contribute to airway hyperreactivity. A host of endogenous chemical mediators such as proteases, growth factors, and cytokines can also affect airway tone.

By definition, the predominant symptom in chronic bronchitis is sputum production. Bronchospasm may also be prominent. Recurrent bacterial airway infections are typical. As with all patients with COPD, the evaluation of patients with chronic bronchitis should include pulmonary function tests and a chest radiograph in addition to standard laboratory testing.

Small Airways Disease

The role of small airways (<2 mm in diameter) in the pathogenesis of COPD continues to be elucidated. The small airways are thought to be a major site of resistance to airflow in COPD. *Respiratory bronchiolitis*, with an accumulation of pigmented macrophages in and around the bronchioles (Web Fig. 17-5), may be an incidental finding in asymptomatic smokers without COPD. However, as COPD develops, other inflammatory cells are recruited to the small conducting airways, presumably in reaction to ongoing irritation from cigarette smoke or inhaled particles. With inflammation, the small airways in COPD can be affected by remodeling, leading to airway wall thickening and fibrosis, smooth muscle hypertrophy, and airway luminal narrowing, contributing to airflow obstruction. Small airways can be occluded by mucus plugs and inflammatory exudates, leading to an overall loss of cross-sectional area and increased resistance to airflow. Lymphoid follicles may form around the airways in response to ongoing antigenic stimulation and

bacterial infection, with a prominence of B cells and CD8⁺ cells in more advanced COPD. Emphysema contributes to airflow obstruction at the small airway level by destruction of the alveoli tethered to the airways, which normally provide a force opposing airway closure. These changes at the small airway level contribute to the physiologic abnormalities and altered local immune response in COPD.

CLINICAL MANIFESTATIONS

COPD related to chronic tobacco exposure is characterized by slowly progressive dyspnea that is first noted during exertion but that progresses over years until it is evident at rest. Affected individuals complain of exercise intolerance and fatigue, and the disease eventually leads to weight loss, depression, and anxiety as a result of increased work of breathing. Chronic cough can be present and is productive or dry, depending on the degree of airway involvement (e.g., chronic bronchitis). In general, emphysema caused by chronic cigarette smoking is almost never observed in patients before 40 years of age. If it is, consideration should be given to genetic disorders, such as α_1 -antitrypsin deficiency.

During the early stages of COPD, the physical examination may be normal. A normal examination and the absence of symptoms often delay diagnosis. Inspection of the thorax and palpation may fail to reveal findings. As the disease progresses, the lungs may be hyperresonant to percussion, and auscultation may show diminished breath sounds with rhonchi, wheezes, or faint crackles. The chest wall may begin to remodel, giving the patient the appearance of a “barrel chest.” During the late stages of COPD, patients show evidence of increased work of breathing with use of accessory muscles, pursed-lip breathing, and weight loss. Skeletal muscle wasting may also become evident. Despite their respiratory insufficiency, some patients are able to sustain relatively normal oxygen levels in blood until very late in the disease, leading to the classic clinical presentation of the “pink puffer.” Other patients tend to retain CO₂ and diminish their work of breathing, resulting in chronic respiratory acidosis and, in extreme cases, polycythemia and cyanosis; this is the prototypical “blue bloater” phenotype.

As the disease progresses, the lung volumes increase (hyperinflation) and the diaphragms flatten, which renders inspiratory excursions inefficient. Tidal volume decreases and respiratory rate increases in an effort to decrease work of breathing. In advanced disease, the cardiovascular system becomes affected as a result of loss of vasculature in destroyed alveolar walls and vascular remodeling due to chronic hypoxia. With limited area for blood flow, pulmonary vascular resistance is increased, leading to increased right ventricular afterload and development of pulmonary hypertension. This accelerates the development of right ventricular failure, which is referred to as *cor pulmonale* in the setting of lung disease. Right heart gallop, distended neck veins, hepatojugular reflux, and leg edema characterize *cor pulmonale*.

EVALUATION

Airway narrowing, which increases resistance to airflow, and a loss of elastic recoil of the lung, which decreases

driving pressure, decrease airflow in the lungs. Both these physiologic abnormalities are often present in COPD. They can be detected by pulmonary function tests, which are essential for the diagnosis of obstructive pulmonary disease, for assessing its severity, and for evaluating response to therapy. COPD is characterized by airflow obstruction, with decreased FEV₁. The decrease in FEV₁ predominates when compared with that of the forced vital capacity (FVC), leading to reduction of the FEV₁/FVC ratio; a reduced FEV₁ and FEV₁/FVC ratio is pathognomonic of airflow obstruction.

Although some degree of reversibility can be detected with bronchodilators, and hyper-reactivity can be unveiled by bronchoprovocation challenge, the obstructive defect is not entirely reversible in COPD. This characteristic and the progressive nature of the obstruction represent key features that help distinguish COPD from asthma. The severity of disease and prognosis can be estimated by the FEV₁; an FEV₁ of about 1 L (usually 50% of predicted levels) suggests severe obstruction and, in the case of COPD, predicts a mean survival of 50% at 5 years. FEV₁ can be incorporated into a validated prognostic scoring system, the BODE index, that is a better predictor of mortality than FEV₁ alone. The BODE index includes the assessment of body mass index (B); degree of obstruction (O) as assessed by FEV₁, modified Medical Research Council dyspnea (D) score, and exercise (E) capacity as denoted by 6-minute walk distance.

Lung volumes should be measured with pulmonary function testing because the limitation to expired airflow and decreased elastic recoil lead to lung hyperinflation, evidenced by increased residual volume, functional residual capacity, and, ultimately, total lung capacity. Increased lung volume causes flattening of the diaphragm, which causes shortening of its muscle fibers, thereby reducing contractile efficiency.

Destruction of alveoli decreases the surface area for gas exchange in emphysema. This loss of surface area, coupled with bronchial obstruction and altered distribution of ventilated air, results in ventilation-perfusion ratio (\dot{V}/\dot{Q}) inequality or mismatch, a cause of hypoxemia. Hyperinflation of the lungs increases zone 1 conditions, in which alveolar pressure exceeds pulmonary arterial pressure, a process that decreases perfusion and increases physiologic dead space. Hypercarbia, but not hypoxemia, can be avoided by hyperventilation, even with substantial \dot{V}/\dot{Q} mismatching. However, eventually, the metabolic costs of breathing become excessive, and respiratory muscles fatigue. Over time, chemoreceptors *reset*, allowing the level of partial pressure of carbon dioxide in arterial blood (Paco₂) to rise, which increases the efficiency of ventilation by eliminating a higher concentration of carbon dioxide per breath, and thereby lowering the metabolic cost of breathing. Significant individual variation is observed in the degree of mechanical impairment and in the magnitude of increase in Paco₂. Derangements in gas exchange can be detected by performing arterial blood gases. They can also be detected by showing a decrease in lung *diffusion capacity for carbon monoxide* (D_{1,CO}) or by evaluating hemoglobin oxygen desaturation during exertion. The degree of decrease in D_{1,CO} correlates well with the radiologic extent of emphysema in COPD.

Chest radiographs may fail to reveal abnormalities during the early stages of COPD, but in later stages, radiographic

studies show hyperinflation, hyperlucency, flattening of the diaphragms, and bullous changes in lung parenchyma (**Web Fig. 17-6**). Pleural abnormalities, lymphadenopathy, and mediastinal widening are not characteristic of emphysema and should point to other diagnoses, such as lung cancer. *Computed tomography* (CT) is more sensitive than plain radiographs because CT allows for a more detailed evaluation of the lung parenchyma and surrounding structures. CT is useful in assessing the distribution of emphysema (**Web Fig. 17-7**) in patients for whom operative interventions such as lung volume reduction surgery are being contemplated. High-resolution computed tomography (HRCT) is highly sensitive for the detection of occult emphysema and can reveal the pattern of emphysematous changes. The *electrocardiogram* might show evidence of right ventricular strain. *Echocardiography* can reveal evidence of right ventricular hypertrophy or dilation and can often provide an estimate of pulmonary arterial pressures in patients with advanced COPD. Blood hemoglobin might reveal erythrocytosis in the setting of chronic hypoxemia, whereas increased white blood cell counts might suggest infection. The *arterial blood gas* may show hypoxemia, hypercarbia, or both, whereas acidemia due to acute hypercarbia may be present during an exacerbation.

MANAGEMENT

Because a cure for COPD does not exist, the best approach to this condition resides in its prevention. Most cases of COPD in the United States are due to cigarette smoking. Thus, an appropriate major emphasis has been placed on the development of community education programs that emphasize smoking prevention and promote smoking cessation. Legislative measures banning smoking in various public settings and levying increased taxes on cigarettes have been used to diminish the effects of environmental or second-hand tobacco smoke exposure and to discourage smoking. Although smoking cessation interventions are only effective in a minority of patients, smoking cessation will decrease mortality in patients with COPD who do succeed at quitting. Most patients who are successful at smoking cessation have had at least one prior failed attempt, so physicians should encourage smoking cessation with at least brief interventions at every opportunity, even in patients who have tried but failed to quit in the past. Long-term physician and group support increases the success of cessation attempts, and pharmacologic smoking cessation aides, including nicotine replacement with gum or transdermal patches, bupropion, and varenicline, may provide additional benefit.

After COPD is established, therapy is directed at avoiding complications such as exacerbations, relieving airflow obstruction through use of bronchodilators, and providing supplemental oxygen to patients with hypoxemia. Commonly used inhaled bronchodilators include sympathomimetic agents (β_2 -adrenoreceptor agonists) and anticholinergic agents. Ipratropium bromide, a short-acting anticholinergic agent, is efficacious at decreasing dyspnea and improving FEV₁ in COPD. Albuterol is the most commonly used β_2 agonist; its bronchodilator effect is rapid in onset and is also relatively short lived. In practice, a combination of albuterol and ipratropium is frequently prescribed

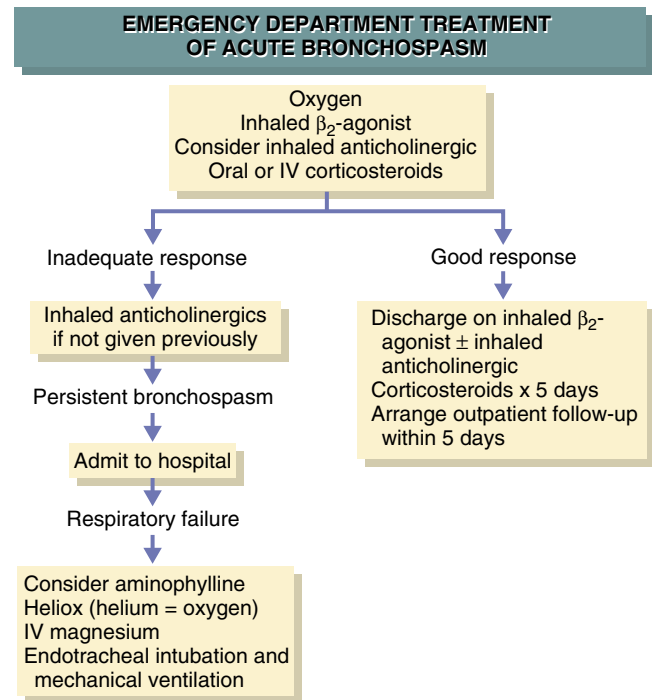

because these agents produce greater benefits when used in combination than individually. Short-acting agents are typically initiated in patients with mild disease or intermittent symptoms on an as-needed basis. Long-acting bronchodilators are effective for maintenance therapy in patients with persistent symptoms and may improve compliance. The long-acting β_2 agonists formoterol and salmeterol can be administered twice daily. Tiotropium is a long-acting anticholinergic that has been found to improve symptoms and lung function and to reduce the frequency of exacerbations in patients with COPD.

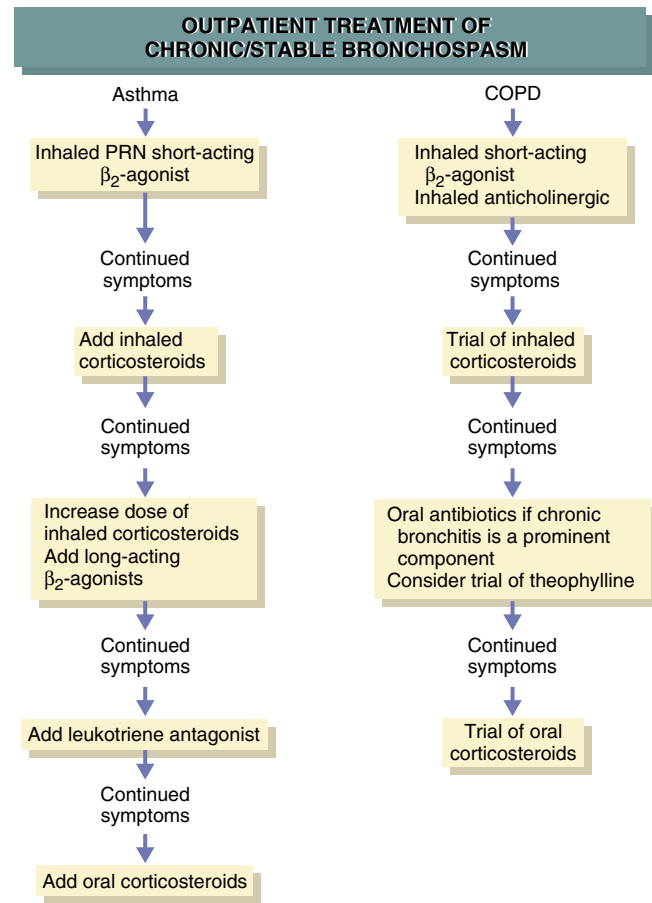

Short-acting bronchodilators can be delivered either by a metered-dose inhaler (MDI) or nebulizer. The MDI offers advantages of portability and ease of administration and convenience. When used correctly with a spacer, MDIs are as effective as nebulizers in delivering the drug. Nebulization has no advantage over the use of MDIs in the long-term management of obstructive lung disease except in patients unable to use an MDI properly.

Theophylline, a methylxanthine, is a weak systemic sympathomimetic agent with a narrow therapeutic window. It is not a first-line drug in the treatment of obstructive lung disease, although long-acting derivatives with improved safety profiles have been developed. Theophylline preparations have some anti-inflammatory activity and may provide additional bronchodilation in patients with COPD who do not respond adequately to inhaled β agonists. When these preparations are used, blood concentrations should be maintained in the lower end of the therapeutic range (between 8 and 12 mcg/mL). Toxicity is common at concentrations higher than 20 mcg/mL. The metabolism of theophylline is decreased by many commonly used drugs (e.g., erythromycin), and toxic serum concentrations of theophylline can be reached quickly when these other drugs are administered unless the theophylline dose is adjusted appropriately. Toxic effects of theophylline may be observed in the gastrointestinal, cardiac, and neurologic systems. Severe theophylline toxicity could be fatal and may require treatment with charcoal hemoperfusion.

Current data suggest that the chronic use of inhaled corticosteroids improves symptoms and decreases the frequency of exacerbations. For this reason, inhaled long-acting corticosteroids (e.g., fluticasone propionate, budesonide) are frequently used in the treatment of COPD. Inhaled corticosteroids are less clearly effective in COPD than in asthma, and pneumonia may occur more frequently in patients with COPD treated with inhaled corticosteroids. Inhaled corticosteroids can be combined with long-acting β agonists. Combination of a long-acting β agonist, salmeterol, with an inhaled corticosteroid, fluticasone, in patients with moderate to severe COPD improved health-related quality of life and reduced exacerbations to a greater extent than either component alone. Systemic use of corticosteroids is indicated during acute exacerbations, and intravenous corticosteroids have been proved useful in the acute setting. Intravenous corticosteroids have also proved effective for the management of acute exacerbations of most obstructive lung diseases, including cases of asthma (Fig. 17-3). Patients with acute exacerbations are generally transitioned from intravenous to oral steroids within 72 hours, with a subsequent tapering of the oral steroid dose over 2 weeks. Other agents with anti-inflammatory capabilities, such

A

B

Figure 17-3 Algorithms for the treatment of bronchospasm in the emergency department (A) and in outpatients with stable disease (B).

as leukotriene inhibitors, are not indicated for treatment of COPD.

Continuous oxygen therapy has been shown to improve survival in patients with COPD and hypoxemia. Oxygen supplementation is recommended once the partial pressure of oxygen in arterial blood (P_{aO_2}) drops below 55 mm Hg or the hemoglobin oxygen saturation decreases to 88%. Oxygen supplementation is indicated at higher levels of P_{aO_2} if end-organ damage is present.

Oxygen therapy is frequently necessary for treatment of acute exacerbations of obstructive lung disease. In patients who hypoventilate chronically and therefore have an elevated P_{aCO_2} , elevating the inspired oxygen content may acutely worsen hypercarbia by inhibiting the hypoxic ventilatory drive and by promoting the dissociation of carbon dioxide from oxygenated hemoglobin (the *Haldane effect*). Nonetheless, arterial oxygen must be maintained in a range compatible with life even at the expense of precipitating respiratory failure requiring mechanical ventilation. During exacerbations of COPD leading to hypercarbic respiratory failure, noninvasive positive airway pressure ventilation has proved useful in reducing the work of breathing, alleviating diaphragm fatigue, and reducing the need for endotracheal intubation and mechanical ventilation.

Exacerbations of airway obstruction may result from viral or bacterial infection. The most common bacterial pathogens in COPD are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Management of acute exacerbations should include empiric antibiotics. Immunization with influenza vaccines directed at specific epidemic strains reduces exacerbations of COPD. Pneumococcal vaccination is also recommended in patients with COPD.

Multiple airway clearance techniques aid in clearing of airway secretions, but their effectiveness in the management of emphysema and other obstructive lung diseases in adults is questionable. If needed, chest physiotherapy and postural drainage might be useful in patients with chronic bronchitis and increased sputum production. Few data support the use of specific mucolytics or expectorant agents for patients with COPD.

Patients with pulmonary disease of sufficient severity to compromise normal activities of daily living commonly demonstrate improved quality of life and less subjective dyspnea when enrolled in a comprehensive, high-quality *pulmonary rehabilitation program*. Pulmonary rehabilitation has not been shown to improve objective measures of pulmonary function, to affect the rate of decline in lung function, or to improve survival. However, it has been shown to improve the quality of life in motivated patients. An important part of pulmonary rehabilitation is nutritional assessment and careful attention to maintaining adequate nutrition. Malnutrition and cachexia are common in later stages of obstructive lung disease and result in decreased respiratory muscle strength and compromised immune function.

In certain patients with advanced emphysema, surgical interventions might prove beneficial. Of these, bullectomy, lung volume reduction surgery (LVRS), and lung transplantation are all potentially effective surgical options for select patients. Resection of nonfunctional areas of lung (e.g., bullectomy) may allow for compressed functional areas to expand and may improve symptoms, airflow, and oxygena-

tion by improving \dot{V}/\dot{Q} matching in a subgroup of patients. In addition, resection of bullae can decrease lung volumes, resulting in enhanced diaphragmatic function and decreased work of breathing. The best candidates for LVRS are those with predominantly upper lobe disease with a low exercise tolerance despite rehabilitation and without other major co-morbidities. In general, a high surgical mortality risk exists in patients with an FEV_1 or D_LCO of less than 20% predicted and in those with more homogeneous distribution of emphysema. Endoscopic placement of one-way endobronchial valves to deflate regions of lung with emphysema is under active investigation.

Single or bilateral lung transplantation is an option for patients with end-stage airflow obstruction. In general, the average survival after lung transplantation is 4 to 5 years. Chronic rejection, viral infections, transplant-associated lymphoproliferative disease, and late occurrence of obliterative bronchiolitis remain significant problems of lung transplantation, but the procedure can clearly improve the quality of life and can extend productive life in properly selected patients.

Although the disease course can be unpredictable, discussion of end-of-life issues with the patient is an important component of longitudinal care as COPD progresses to an advanced stage. Developing advance directives regarding use of intensive care measures at the end of life may be desirable. Opioid narcotics can be highly effective at relieving dyspnea in patients with terminal complications of COPD.

Bronchiolar Disorders

The bronchiolar disorders are known for patchy inflammation and epithelial injury, fibrosis, or obliteration of the noncartilaginous small airways, the bronchioles (**Web Fig. 17-8**). This results in airflow limitation that is due to increased airway resistance. Bronchiolitis contributes to the syndrome of COPD, as discussed previously under “Small Airways Disease,” but isolated bronchiolar disorders with different etiologies than cigarette smoking also exist. These disorders may be self-limited, as in *acute bronchiolitis* caused by viral infections including respiratory syncytial virus (RSV), or relentlessly progressive, as in the *bronchiolitis obliterans syndrome* occurring after lung transplantation. Acute bronchiolitis is most common in infants, occurring in epidemic form during wintertime in association with RSV, and can complicate adult viral respiratory infections or can result from aspiration injury. Wheezing and dyspnea are typical symptoms of acute bronchiolitis. *Diffuse panbronchiolitis* is an idiopathic disorder most common in Japan and is characterized by cough with purulent sputum, sinusitis, and dyspnea. Recurrent respiratory infections with bacterial organisms such as *Pseudomonas aeruginosa* complicate the course of diffuse panbronchiolitis. *Bronchiolitis obliterans* is seen with connective tissue diseases, the bronchiolitis obliterans syndrome of chronic allograft rejection after lung transplantation, as well as after occupational toxin exposures. For example, occupational clusters of bronchiolitis obliterans have recently been described following exposure to diacetyl, a flavoring chemical used in the manufacture of microwave popcorn.

In general, the bronchiolar disorders cause an obstructive pattern of expiratory airflow limitation on pulmonary function testing without evidence of reversibility. The bronchiolitis obliterans syndrome is diagnosed clinically by a decline in FEV₁ of 20% from a stable baseline value on serial testing after lung transplantation. HRCT is valuable in the diagnosis and assessment of the bronchiolar disorders. Characteristic findings on HRCT include centrilobular nodules or *tree-in-bud opacities*, reflecting impacted inflammatory exudates or sloughed epithelial cells in the bronchioles. A “mosaic” pattern, with decreased attenuation in geographic regions of lung reflecting areas of air trapping distal to obstructed bronchioles, is often seen, and CT scanning during the expiratory phase can confirm that this finding is caused by air trapping as opposed to decreased perfusion from pulmonary vascular disease. Lung biopsy is often of limited value because of the scattered, patchy nature of the abnormalities present in the bronchiolar disorders.

Treatment of the bronchiolar disorders is challenging. Acute bronchiolitis typically resolves without treatment; bronchodilators and steroids are not clearly beneficial, although they are often prescribed. The bronchiolitis obliterans syndrome responds poorly to increased immunosuppression and is a frequent cause of death after transplantation. Azithromycin, a macrolide antibiotic, has been reported to increase FEV₁ in the bronchiolitis obliterans syndrome. Macrolide antibiotics have also been reported to positively affect the clinical course of diffuse panbronchiolitis, possibly reflecting immunomodulatory or antifibrotic effects of these medications. Lung transplantation may be necessary in progressive bronchiolitis obliterans, and retransplantation has sometimes been performed in patients affected by the bronchiolitis obliterans syndrome after transplant rejection.

Bronchiectasis

⊕ Bronchiectasis is abnormal dilation of the bronchi (**Web Fig. 17-9**) resulting from inflammation and permanent destructive changes in the elastic and muscular layers of the bronchial walls. Bronchiectasis may be localized to a certain bronchus or may be diffuse. This disorder is usually caused by recurrent or chronic severe infections such as necrotizing pneumonias (e.g., *Staphylococcus aureus* pneumonia), tuberculosis, or infection with atypical mycobacteria (e.g., *Mycobacterium avium-intracellulare*). Viral (e.g., *measles*) and fungal (e.g., *histoplasmosis* and *coccidioidomycosis*) infections may cause bronchiectasis as well. *Allergic bronchopulmonary aspergillosis* is a condition associated with hypersensitivity to aspergillus fungi that is usually exhibited as severe intractable asthma, central bronchiectasis, high levels of immunoglobulin E (IgE), and precipitins for *Aspergillus* species.

Localized bronchiectasis may result from anatomic obstruction, either by an endobronchial foreign body, tumor, or broncholith, or as a result of extrinsic compression by lymphadenopathy. The *right middle lobe syndrome* results from narrowing of the right middle lobe bronchial orifice, often by lymph nodes, leading to localized bronchiectasis distal to the site of obstruction. Anatomic obstruction results in chronic or recurrent infection and inflammation leading to bronchial distortion and destruction over time.

Bronchiectasis is more frequent in middle-aged to older individuals. In addition to infections and anatomic obstruction, bronchiectasis may be related to connective tissue diseases including rheumatoid arthritis. Bronchiectasis may occur in younger patients when associated with congenital defects like *cystic fibrosis* or *primary ciliary dyskinesia*, a rare inherited abnormality of the ciliary microtubules that impairs airway clearance and is associated with recurrent infections. The classic triad of sinusitis, *situs inversus*, and infertility is diagnostic of *Kartagener syndrome*, a form of primary ciliary dyskinesia. Other congenital syndromes associated with bronchiectasis include α_1 -antitrypsin deficiency and immunodeficiency states related to hypogammaglobulinemia.

Patients with bronchiectasis exhibit chronic cough and foul-smelling sputum, shortness of breath, abnormal chest sounds, and fatigue. Blood-streaked sputum is common, and massive hemoptysis may occur. Clubbing may be present. Periodic exacerbations due to infection with bacterial pathogens, including *P. aeruginosa*, *S. pneumoniae*, and *H. influenzae*, are common. Pulmonary function tests may show varying degrees of obstruction. Evidence of bronchial hyperresponsiveness is not infrequent. Chest radiographs may be normal or may show increased interstitial markings. The classic finding is parallel lines in peripheral lung fields described as *tram tracks*, which represent thickened bronchial walls that do not taper from proximal to distal sites. HRCT is more sensitive for the detection of dilated airways and is the test of choice in the diagnosis of suspected bronchiectasis. Bronchiectasis on HRCT is suggested by lack of airway tapering at the lung periphery and by airways that are larger in diameter than their accompanying blood vessel. Bronchoscopy may be indicated in localized bronchiectasis to assess for endobronchial abnormalities. Sputum can be cultured to assess for fungal or mycobacterial organisms that may be causative of the bronchiectasis, or for identification of specific bacterial pathogens during exacerbations.

Treatment of the underlying cause of the bronchiectasis should be undertaken if possible. An anatomic obstruction, such as from a foreign body or benign tumor, should be relieved. Atypical mycobacterial infection should be treated with an appropriate multidrug regimen in symptomatic patients following confirmation of the diagnosis with multiple smears and cultures. Allergic bronchopulmonary aspergillosis is typically treated with corticosteroids; addition of azole antifungals may also be beneficial. Bacterial exacerbations of bronchiectasis should be treated with a broad-spectrum antibiotic effective against the likely pathogens, such as a quinolone. Aerosolized antibiotics are of benefit in the suppression of bacterial growth in bronchiectasis associated with cystic fibrosis but are less clearly beneficial in noncystic fibrosis bronchiectasis. Immunoglobulin supplementation may aid in the host defense against bacterial infection in individuals with hypogammaglobulinemia. Airway clearance and postural drainage are frequently employed in bronchiectasis but are of uncertain benefit. Bronchodilators may provide symptomatic relief. Massive hemoptysis should be managed with airway protection and identification of the bleeding site; bronchial artery angiography with embolization of the causative bleeding vessels may be life-saving. The role of surgery is mainly

in the removal of a badly damaged isolated segment of bronchiectatic lung, for the resection of obstructing lesions causing distal bronchiectasis, and on occasion as a salvage therapy in resection of a site with uncontrolled hemorrhage.

Cystic Fibrosis

Cystic fibrosis is an autosomal recessive genetic disorder that affects about 30,000 children and adults in the United States. This disorder affects many organs, including the lungs, pancreas, and reproductive organs, although most mortality related to cystic fibrosis is due to lung disease. It is the most common lethal genetic disorder in the white population, with a carrier frequency of about 1 in 29, affecting 1 in 3300 live births. About 1000 new patients with cystic fibrosis are diagnosed each year. Cystic fibrosis results from a mutation in a single gene that encodes the cystic fibrosis transmembrane conductance regulator (CFTR), which is a cyclic adenosine monophosphate-regulated chloride channel present on the apical surface of epithelial cells (**Web Fig. 17-10**). The most common mutation is the $\Delta F508$ mutation, a 3 base-pair deletion that results in absence of the phenylalanine residue at the 508 position of the protein. However, more than 1600 mutations have been identified to date. The abnormal CFTR protein results in defective chloride transport and increased sodium reabsorption in airway and ductal epithelia, creating abnormally thick and viscous secretions in the respiratory, hepatobiliary, gastrointestinal, and reproductive tracts. The thick secretions do not easily clear from the airways, resulting in respiratory symptoms, and cause luminal obstruction and destruction of exocrine ducts in other organs, leading to exocrine organ dysfunction.

Infants with cystic fibrosis may present with meconium ileus or failure to thrive with steatorrhea. Salty-tasting skin may be noted by caregivers. Patients with cystic fibrosis typically have chronic cough with thick sputum production, wheezing, and dyspnea. Pancreatic insufficiency and diabetes are common, and male patients have azoospermia (Table 17-2). Nasal polyps are often present, and clubbing is typical. Cystic fibrosis should be considered in the differential diagnosis of patients with unexplained chronic sinus disease, bronchiectasis, male infertility associated with absence of the vas deferens, pancreatitis, or malabsorption. Pulmonary function tests demonstrate hyperinflation and obstruction; a bronchodilator response may be present. Chest imaging studies show hyperinflation, bronchial wall thickening, and bronchiectasis.

In patients with cystic fibrosis, the airways become colonized initially with *S. aureus* or *H. influenzae*, followed by *P. aeruginosa* in ensuing years. Persistent inflammation and infection cause bronchial wall destruction and bronchiectasis. Mucus plugging of small airways results in postobstructive cystic dilations and parenchymal destruction, and progressive airflow obstruction and eventually hypoxemia ensue. The course of cystic fibrosis may additionally be complicated by the development of allergic bronchopulmonary aspergillosis and by nontuberculous mycobacterial infection. Colonization and infection with multidrug resistant *Burkholderia cepacia* complex may occur in advanced cystic

Table 17-2 Organ Involvement in Cystic Fibrosis

Pulmonary

- Cough and sputum production
- Recurrent pneumonias
- Bronchial hyperreactivity
- Hemoptysis
- Pneumothorax
- Significant digital clubbing
- Cor pulmonale

Upper Respiratory Tract

- Nasal polyps
- Chronic sinusitis

Gastrointestinal

- Meconium ileus in the neonate
- Distal intestinal obstruction
- Rectal prolapse
- Hernias
- Exocrine pancreatic dysfunction causing steatorrhea, malnutrition, and vitamin deficiency
- Acute pancreatitis (rare)
- Diabetes mellitus
- Cirrhosis and portal hypertension
- Salivary gland inflammation
- Cholelithiasis

Genitourinary

- Azoospermia
- Decreased fertility rate in women
- Nephrolithiasis

fibrosis, creating challenging management issues. Most patients die of respiratory failure.

The diagnosis of cystic fibrosis is made by measuring the concentration of chloride in sweat (*sweat test*). The diagnosis is considered definitive if the clinical picture is consistent with cystic fibrosis and if the chloride concentration performed in a certified laboratory is greater than 60 mEq/L on at least two occasions. Genotyping can also confirm the diagnosis if known mutations are identified in both gene alleles and can be used if sweat testing is equivocal.

Although most patients are diagnosed in childhood, some patients are not diagnosed until adulthood. About 45% of the population with cystic fibrosis in the United States is older than 18 years. Before 1940, infants with cystic fibrosis rarely lived to their first birthday. Currently, the median predicted life span for a person with cystic fibrosis is about 37 years of age.

The treatment of cystic fibrosis relies on aggressive airway hygiene, nutritional support including pancreatic enzyme replacement, antibiotics, and bronchodilators. Aerosolized recombinant human DNase (dornase alfa) decreases sputum viscosity, improves lung function, and reduces exacerbations in cystic fibrosis. Inhaled hypertonic saline helps to hydrate secretions, allowing them to be coughed out more easily, and also improves pulmonary function, although likely to a lesser extent than dornase alfa. Inhaled tobramycin provided twice daily every other month is indicated in moderate to severe cystic fibrosis patients with pseudomonas infections. Anti-inflammatory therapy with ibuprofen and azithromycin may be helpful in certain patients with cystic fibrosis. However, inhaled corticosteroids are not clearly beneficial. As is the case for other obstructive lung diseases, the ultimate therapy for patients with cystic fibrosis with end-stage lung

disease is lung transplantation; bilateral lung transplantation is preferred in this condition.

Asthma

Asthma is a common pulmonary disorder characterized by airway inflammation, airway hyper-reactivity, and reversible airflow obstruction. The incidence of asthma is highest in children, but it affects all ages and occurs worldwide, with a preponderance of the disease in developed industrialized countries. Asthma results in a large burden of morbidity as well as economic cost in the United States. From 2001 to 2003, about 20 million persons per year reported having asthma in the United States. The prevalence of asthma has increased markedly over a period of decades. Asthma prevalence more than doubled among children from 1980 to 1995 alone, and the overall prevalence of asthma increased from 3.1% to 5.6% of the population during that time. Although asthma prevalence continued to increase up to 2001, it has recently appeared to plateau, and about 7% of the United States population is estimated to have asthma. Disturbingly, despite modern therapies and improved understanding of asthma, the number of deaths caused by asthma in the United States increased from 2891 in 1980 to 5637 deaths in 1995. Since then, the number of asthma deaths has appeared to decline, although about 4000 deaths per year still occur as a result of asthma. The reasons for the increase in asthma-related deaths in the late 20th century remain uncertain.

The cause of asthma is unknown, but it is likely to be a polygenic disease influenced by environmental factors. Atopy is strongly linked to asthma. Asthma is generally associated with an allergic-type activation of the immune system typified by a helper T-cell subtype 2 (T_H2)-predominant T-cell response to inhaled antigens, with consequent IgE production and allergic airway inflammation. Exposure to indoor allergens like dust mites, cockroaches, furry pets, and fungi is a significant factor, as are outdoor pollution and other irritants, including cigarette smoke. Current concepts of asthma pathogenesis include a focus on impairment of the shift from T_H2 -predominant immunity to a T_H1 immune response early in life. Paradoxically, the perpetuation of T_H2 immune responses and the development of inappropriate allergic responses may be related to the relative lack of exposure of the immune system to appropriate infectious antigenic stimuli in childhood in the developed world, the so-called *hygiene hypothesis*. Farming, for example, appears to be protective against the development of asthma and allergic disease, possibly in part because of the increased exposure to microbial antigens eliciting a T_H1 response. Increased exposure to other children, as in daycare settings, and less frequent use of antibiotics may also decrease asthma risk, supporting this hypothesis. On the other hand, asthma is common in poor urban settings in which there is heavy exposure to allergic antigens from dust mites and cockroaches. The timing and role of particular environmental exposures in utero and in early life in the pathogenesis of asthma and allergic diseases remains to be fully elucidated, and there is no current theory that completely explains asthma pathogenesis or the recent increased incidence of asthma. The interplay of other aspects of modern life, such

as diet, with regards to asthma propensity continues to be explored.

Several genetic polymorphisms have been associated with asthma, including variations in the β -adrenergic receptor leading to diminished responsiveness to β agonists. Identifying other genetic polymorphisms important in asthma is a subject of ongoing research. Although asthma is more common in male children than female children, the prevalence of asthma changes following puberty, and asthma is more common in adult women than men, suggesting possible hormonal influences on asthma pathogenesis. Asthma can also be induced by workplace exposures in persons having no previous history of asthma (*occupational asthma*). Certain substances, like isocyanates, used in spray paints, and Western red cedar wood dust, are strongly provocative agents for the development of occupational asthma. Obesity has been linked to a higher incidence of asthma, a disturbing observation in view of the increasing prevalence of obesity. The mechanisms by which obesity may influence asthma development are unclear. Certain infectious agents and other conditions can cause acute bronchospasm even in patients without the diagnosis of asthma. Such is the case for viral infections, gastroesophageal reflux disease, and exposure to gases or fumes, and these disorders may play a role in the development or control of some cases of asthma.

The hallmark of asthma is *airway hyperresponsiveness*, a tendency of the airway smooth muscle to constrict in response to levels of inhaled allergens or irritants that would not typically elicit such a response in normal hosts. Inhaled allergens provoke airway mast cell degranulation by binding to and cross-linking IgE on the mast cell surface. Mast cell degranulation leads to the release of chemical mediators, which cause acute bronchoconstriction and thus increased airway resistance and wheezing, as well as mucus hypersecretion (**Web Fig. 17-11**). In addition, disruption of the continuity of the ciliated columnar epithelium and increased vascularity and edema of the airway wall follow antigen exposure. In addition to allergens, factors such as stimulation of irritant receptors, respiratory tract infections, and airway cooling can provoke bronchoconstriction in asthmatic individuals. Airway cooling appears to be responsible for exercise-induced bronchoconstriction as well as some wintertime asthma attacks. Underlying chronic *airway inflammation* is considered a major pathogenetic mechanism responsible for asthma. Patients with asthma have higher numbers of activated inflammatory cells within the airway wall, and the epithelium is typically infiltrated with eosinophils, mast cells, macrophages, and T lymphocytes, which produce multiple soluble mediators (e.g., cytokines, leukotrienes, bradykinins). However, although airway inflammation in asthma is generally typified by a T_H2 -type response with predominantly eosinophilic inflammation, some patients with severe asthma exhibit neutrophilic airway inflammation and cytokine production more characteristic of T_H1 inflammation, suggesting asthma may be a common clinical phenotype resulting from heterogeneous forms of airway inflammation.

Asthma is associated with *airway wall remodeling*, which is characterized by hyperplasia and hypertrophy of smooth muscle cells (**Web Fig. 17-12**), edema, inflammatory infiltration, angiogenesis, and increased deposition of connective tissue components such as types I and III collagens. The

latter leads to not only a thickening of the subepithelial lamina reticularis (Web Fig. 17-13) but also an expansion of the entire airway wall. Airway remodeling may begin fairly early in the course of the disease. Whether inflammation leads to remodeling or these processes represent two independent manifestations of the disease is unknown. Pulmonary function does seem to decline at an accelerated rate over time in patients with asthma, and airway wall remodeling may play a role in this functional loss. Over time, airway wall remodeling may lead to irreversible airflow limitation, which can worsen the disease by rendering bronchodilator drugs less effective; airway wall remodeling may make the distinction between asthma and COPD difficult.

CLINICAL MANIFESTATIONS

The classic triad of symptoms is wheezing, chronic episodic dyspnea, and chronic cough. However, the clinical manifestations of asthma may vary widely from mild intermittent symptoms to catastrophic attacks resulting in asphyxiation and death. Although wheezing is not a pathognomonic feature of asthma, in the setting of a compatible clinical picture, asthma is the most common diagnosis. Asthma can develop at any age as episodic cough, shortness of breath, and chest tightness. Often these symptoms worsen at night or during the early hours of the morning. Other associated symptoms are sputum production and chest pain or tightness. Patients may exhibit only one or a combination of the foregoing symptoms. Physical examination may be normal or may show evidence of wheezing. Rhinitis or nasal polyps may be present. In the case of an acute exacerbation, the clinician may find that the patient has difficulty talking, is using accessory muscles of inspiration, has *pulsus paradoxus*, is diaphoretic, and has mental status changes ranging from agitation to somnolence. In patients with these findings, treatment should be immediate and aggressive.

EVALUATION

A diagnosis of asthma requires documentation of hyperactivity and reversible airway obstruction to flow. The history might be sufficient to assess this because most patients complain of repeated but reversible episodes of wheezing. Airflow limitation is easily detected by spirometry when present. However, because asthma is episodic, patients might exhibit symptoms at a time when this cannot be documented. Depending on the circumstances, it might be necessary to test for airway hyperactivity by bronchoprovocation challenge (Table 17-3). The patient is given an airway application of a stimulant with bronchoconstrictor activity; histamine, methacholine, and cold air are among the most commonly used stimulants. Methacholine, a synthetic form of acetylcholine, is generally preferred to histamine because there are less systemic side effects. Exercise can also be used to trigger an attack. Although most patients with or without asthma may develop some degree of airflow limitation during bronchoprovocation testing, the diagnosis depends on the dose of the stimulus needed to elicit an effect; those with asthma develop airflow limitation at much lower doses than patients without. For methacholine challenges, the concentration of methacholine required to produce a 20% decline in FEV₁ from baseline is reported. Although a posi-

Table 17-3 Diagnostic Studies in Asthma

Routine pulmonary function test	Decreased FEV ₁ ; hyperinflation; improvement with bronchodilator
Special pulmonary function test	
Methacholine or cold-air challenge	Indicates the presence of nonspecific bronchial hyperreactivity; bronchoconstriction occurs at lower doses in asthma
Challenge with specific agents: occupational, drugs	Occasionally performed
Chest radiograph	Fleeting infiltrates and central bronchiectasis in ABPA
Skin tests	Demonstrate atopy; little value except prick test to <i>Aspergillus fumigatus</i> positive in ABPA
Blood tests	Eosinophils and IgE are usually increased in atopy; levels may be very high in ABPA; <i>Aspergillus precipitins</i> increased in many, but not all, patients with ABPA

ABPA, allergic bronchopulmonary aspergillosis; FEV₁, forced expiratory volume in 1 second; IgE, immunoglobulin E.

tive bronchoprovocation challenge is not by itself diagnostic of asthma, a negative bronchoprovocation challenge is generally helpful in ruling out asthma as a diagnosis.

Lung volume measurements may show hyperinflation during active disease, but D_LCO is typically normal because asthma is an airways disease and does not cause destruction of the acinus. Decreased D_LCO may be due to artifacts created by the measurement, which is highly sensitive to distribution of the gas (as is the case in mucus plugging). In this setting, the D_LCO value normalizes when corrected for gas volume distribution. During acute exacerbations of asthma, arterial blood gases are useful to determine gas-exchange status. A chest radiograph should be obtained if a concern for pulmonary infection exists. Fleeting or migratory infiltrates on chest radiograph in a patient with difficult asthma should suggest the possibility of allergic bronchopulmonary aspergillosis. Blood tests in asthma might reveal eosinophilia and increased levels of IgE. Skin tests might be useful to identify household and other antigens that may precipitate asthma attacks in a particular patient (see Table 17-3).

MANAGEMENT

The management of asthma requires education and cooperation on the part of the patient. Simple, inexpensive peak expiratory flow meters can be used at home to monitor airflow obstruction. A diary should be maintained, and a clear written plan should be in place for using symptoms and peak flow information to intervene early in exacerbations and to alter long-term therapy for optimal control of symptoms. Short-acting β agonists are used for the acute relief of symptoms such as wheezing. However, the cornerstone of maintenance therapy in all but mild intermittent asthma is scheduled administration of inhaled corticosteroids. Long-acting β agonists may be added for additional

symptomatic control as needed. Long-acting β agonists should not be employed as a monotherapy for asthma control, especially in African American patients, because there has been an increased mortality demonstrated in this patient population using this therapeutic approach. Leukotriene inhibitors can be used as adjuncts in maintenance therapy, although they generally appear to be less effective than inhaled corticosteroids. Theophylline preparations may have additional beneficial effects in some patients, but the narrow therapeutic window and modest efficacy of these preparations limit their value. Oral or intravenous corticosteroids are used during acute asthma exacerbations, although long-term use of oral corticosteroids should be avoided if possible given the various side effects associated with chronic glucocorticoid administration.

Allergen avoidance is a reasonable measure in asthma, although the effects of specific interventions, such as mattress barrier protection to reduce dust mite exposure, appear limited. Treatment of associated conditions that may exacerbate asthma, such as allergic rhinitis and gastroesophageal reflux disease, may be clinically beneficial and aid in achieving asthma control. Use of recombinant human anti-IgE monoclonal antibody may be effective at reducing exacerbations in patients with allergic asthma.

Acute severe asthma, or *status asthmaticus*, is an attack of severe bronchospasm that is unresponsive to routine therapy. Such attacks may be sudden (*hyperacute asthma*) and may be rapidly fatal, often before medical care can be obtained. In most cases, however, patients have a history of progressive dyspnea over hours to days, with increasing bronchodilator use. Treatment of status asthmaticus should be aggressive, with the administration of nebulized bronchodilators and intravenous steroids and with continuous monitoring of blood oxygen saturation by pulse oximetry, often supplemented by arterial blood gas analysis to evaluate for hypercarbia. A rising PaCO_2 in a patient with asthma is an ominous sign and may portend a need for ventilatory support. Non-invasive ventilation has been used successfully to decrease the work of breathing and avoid the need for endotracheal intubation in patients with exacerbations of asthma. However, in some cases, intubation and mechanical ventilation is necessary for the management of respiratory failure in status asthmaticus. Mechanical ventilation of the patient with status asthmaticus can be extremely challenging and may require the use of paralytic agents to control the breathing pattern and even use of inhaled general anesthesia to relieve bronchospasm.

Prospectus for the Future

The obstructive lung diseases are common and account for a tremendous burden of morbidity and mortality in the general population. Public health strategies to discourage smoking, the major cause of COPD, have shown promise in developed countries, but more attention to strategies aimed at discouraging smoking in developing countries is needed. In addition, more effective treatments for tobacco addiction are needed. Our understanding of the causes of the asthma epidemic remain limited, a crucial hindrance to developing effective methods to prevent the development of this disease. Improved understanding of the genetic and environmental risk factors for asthma development may allow the implementation of novel forms of immune modulation in susceptible individuals early in life. Therapies that are effective at altering the natural course of COPD or asthma once disease is established using disease-modifying agents are currently lacking, despite improved understanding of the molecular pathogenesis of these disorders. New approaches to counter histone acetylation-deacetyla-

tion balance may generate more effective anti-inflammatory agents for use in COPD, whereas an understanding of the role of chitinases in asthma may result in novel treatments for this chronic condition. Clinicians caring for patients with cystic fibrosis now have an effective array of tools capable of allowing the supportive care of patients for decades of life. Molecular approaches to the treatment of cystic fibrosis aimed at improving the intracellular trafficking and function of the cystic fibrosis transmembrane receptor, attacking the disease at its root cause, are also underway. Finally, the increasing recognition of the pathogenetic heterogeneity of individuals with obstructive lung disease displaying asthma or COPD phenotypes means that current one-size-fits-all approaches to therapy using agents such as inhaled steroids or β agonists will be abandoned in favor of sophisticated personalized therapeutic regimens and perhaps regenerative medical approaches. The significant economic costs of such personalized medicine, however, demand a greater focus on disease prevention.

Interstitial Lung Diseases

Jason M. Aliotta and Matthew D. Jankowich

The interstitial lung diseases (ILDs) form a complex group of dozens of disorders with heterogeneous clinical courses and prognoses that are characterized by diffuse, typically chronic, lung injury, occurring in the setting of variable amounts of inflammation, which often leads to lung fibrosis. These diseases are daunting for the clinician because the differential diagnosis may be broad, and the work-up required to make the appropriate diagnosis may be extensive. Understanding of these disorders has been hampered in the past by use of confusing and nonspecific terminology, especially with regard to the idiopathic interstitial pneumonias. Current classifications use histopathology and clinical syndromes to divide these disorders into more understandable groupings. This text uses a classification that divides ILDs into the following categories: *idiopathic interstitial pneumonitides*, *granulomatous disorders*, *connective tissue-related ILDs*, *drug-induced ILDs*, *pulmonary vasculitic disorders*, and *distinct entities of unknown origin that exhibit well-defined syndromes* such as *pulmonary Langerhans cell histiocytosis* and *lymphangioleiomyomatosis*.

The presentation of ILD is often nonspecific, with common clinical symptoms including dyspnea on exertion, dry cough, and sometimes constitutional symptoms. Pulmonary function tests generally show restriction and gas-exchange abnormalities. Imaging demonstrating *diffuse lung disease* often leads to the consideration of ILD as a diagnosis. However, early radiographic changes may be subtle, and other clinical entities such as congestive heart failure or lymphangitic carcinomatosis may cause similar clinical, physiologic, and radiographic findings. Therefore, diagnosis may be delayed in some circumstances until other clinical entities are excluded and biopsy is undertaken. High-resolution computed tomography (HRCT) has contributed greatly to the diagnostic work-up of patients with suspected ILD because typical HRCT patterns in appropriate clinical settings may be sufficient for diagnosis.

Most ILDs, including more common entities like idiopathic pulmonary fibrosis (IPF), often present with chronic progressive symptoms. However, some ILDs can present in an acute fashion. Such entities include acute pneumonitis due to systemic lupus erythematosus, acute hypersensitivity pneumonitis, some drug reactions, and acute interstitial pneumonia. In such cases, infection often needs to be ruled

out, and diagnosis may be challenging in critically ill individuals.

When ILD is suspected in a patient with typical symptoms and diffuse lung disease on imaging, the epidemiologic background, including the age, race, and sex of the patient, is helpful in formulating the diagnostic possibilities. For example, IPF typically occurs in middle-aged or elderly individuals, whereas sarcoidosis often presents in young individuals and is most common in those of African American background in the United States. Sex is also a consideration because lymphangioleiomyomatosis presents almost exclusively in women of childbearing age, whereas pulmonary Langerhans cell histiocytosis most often occurs in young male smokers. This background data can help to focus the initial differential diagnosis.

History can further narrow the differential in the setting of suspected ILD. Important factors to elicit are a history of rash, dysphagia, arthritis, or Raynaud phenomenon that may suggest an underlying connective tissue disorder. If the patient carries a diagnosis of connective tissue disease, this may be helpful in limiting the work-up if imaging findings typical of the usual pulmonary manifestations of the particular connective tissue disease are present. Other past medical history is informative; a history of severe or poorly controlled asthma in a patient with radiographic infiltrates and constitutional symptoms should lead to consideration of *Churg-Strauss syndrome*, whereas a history of severe sinus disease should raise the possibility of *Wegener granulomatosis*. Drug-induced ILD should be considered in all patients presenting with diffuse lung disease on imaging, and a careful medication usage history is critical. The smoking history is also important because a number of ILDs are associated with cigarette smoking, including *respiratory bronchiolitis interstitial lung disease*, *desquamative interstitial pneumonitis*, and pulmonary Langerhans cell histiocytosis.

Environmental exposures should be elicited because a typical exposure to, for example, pet birds or hot tubs may be suggestive of *hypersensitivity pneumonitis*. Home visits can be very informative. The occupational history is also important. Although the pneumoconioses due to asbestos and silica exposure are becoming much less common with modern safeguards and restrictions, these diseases continue to present long after exposure. High-technology

manufacturing has particular hazards, for example, with beryllium exposure leading to berylliosis in susceptible individuals. Nonindustrial professions still carry occupational risks; for example, outbreaks of granulomatous pneumonitis have been described in indoor lifeguards exposed to molds.

The physical examination may reveal only oxygen desaturation with exertion in early ILD. Patients may show evidence of decreased chest expansion during inspection. Auscultation of the lungs typically reveals Velcro-like crackles at the lung bases. Clubbing may be present. Skin rashes, arthritis and joint deformities, Raynaud phenomenon, and dysphagia may point to a connective tissue–related ILD such as *dermatomyositis* or *polymyositis*, *progressive systemic sclerosis*, or *mixed connective tissue disorder*. Evidence of right ventricular heart failure with jugular vein distention, a cardiac gallop, loud P₂ sound, and leg edema suggests pulmonary hypertension; right ventricular heart failure is usually the result of chronic hypoxemia and is often related to end-stage lung disease. Laboratory studies may be of benefit; for example, eosinophilia will suggest the particular group of disorders associated with pulmonary infiltrates and peripheral blood eosinophilia.

A chest radiograph can narrow the possible diagnosis based on the distribution of the typical reticulonodular changes found in ILD. For example, sarcoidosis, lymphangiomyomatosis, silicosis, hypersensitivity pneumonitis, eosinophilic granuloma, and ankylosing spondylitis most often affect the upper- and mid-level lung fields, whereas IPF, asbestosis, and many connective tissue-related ILDs typically involve the lower-level lung fields. These patterns are best analyzed through the use of HRCT of the chest, a test considered essential in the evaluation of patients suggested as having ILD. HRCT can reveal patterns of disease that allow the diagnostic considerations to be significantly narrowed. For example, upper lobe–predominant cystic lung disease on HRCT suggests a group of entities including Langerhans cell histiocytosis, sarcoidosis, and lymphangiomyomatosis. Lower lobe and peripheral reticular opacities with associated traction bronchiectasis and honeycombing suggest idiopathic pulmonary fibrosis, asbestosis, or certain connective tissue disease–related ILDs. Visualization of abnormalities of the mediastinum or pleura occurring in association with parenchymal lung disease is also helpful. Sarcoidosis, for example, typically exhibits hilar and mediastinal lymphadenopathy in association with beadlike septal nodules, whereas pleural plaques in association with lower lobe fibrosis is consistent with asbestosis. Incorporation of HRCT imaging data with clinical history may in some circumstances be sufficient for diagnosis.

Pulmonary function tests in ILD typically reveal a restrictive pattern characterized by proportionately decreased airflows with preserved forced expiratory volume in 1 second–to–forced vital capacity (FEV₁/FVC) ratio (no obstruction to airflow) and decreased lung volumes as highlighted by decreased total lung capacity and functional residual capacity. The diffusion capacity for carbon dioxide (DLCO) of the lung is often decreased and may be the earliest change present in drug-induced ILD or connective tissue disease-related ILD. The restrictive abnormality found in most forms of ILD is due to the decreased compliance of the lung in the setting of fibrosis. Histologically, ILD affects the interstitium of the lung, the space located between the base-

ment membrane of the vascular structures within the distal air spaces and the basement membranes of the epithelial cells that line the alveoli (Fig. 18-1). This space also extends proximally toward the alveolar ducts and respiratory bronchioles. Normally, the interstitium of the lung contains a few fibroblasts and connective tissue components within a very thin wall that allows for the efficient diffusion of gases. In ILD, however, this space expands with the accumulation of fibroblasts or other cells and the deposition of an aberrant matrix that increases the distance between the alveolar space and vascular structures, thereby delaying and sometimes preventing gas exchange. This thickened interstitium accounts for the poor oxygenation and increased lung stiffness exhibited as decreased compliance, small lung volumes, and increased work of breathing. Because lung involvement by ILD may be sporadic, with areas of normal lung adjacent to areas of fibrosis, local differences in compliance may result in abnormal V/Q matching, contributing to hypoxemia. The processes outlined above account for the physiologic manifestations seen in disorders like *idiopathic pulmonary fibrosis* (IPF) and *asbestosis*.

In some ILDs, an obstructive rather than restrictive abnormality or mixed findings are present on pulmonary function testing, and lung volumes are relatively preserved on physiologic testing and imaging (Fig. 18-2). In such diseases as lymphangiomyomatosis, pulmonary Langerhans cell histiocytosis, and hypersensitivity pneumonitis, as well as in some cases of sarcoidosis, obstructive or mixed patterns on pulmonary function testing with preservation of lung volumes are typical. This pattern of disease is due to proximal extension of the interstitial disease in the lung parenchyma with consequent involvement of the small airways. For example, in lymphangiomyomatosis, the small airways are narrowed by the proliferation of surrounding abnormal smooth muscle–like cells. This leads to increased airways resistance and airflow obstruction. Endobronchial disease with direct narrowing of the airways can occur in sarcoidosis, leading to similar effects. Therefore, the presence of airflow obstruction does not rule out a diagnosis of interstitial lung disease but may help to focus the differential diagnosis on particular entities.

As outlined earlier, in ILD, a synthesis of clinical, functional, and imaging data, often in the context of a multidisciplinary approach, is crucial to arriving at an appropriate diagnosis. In many circumstances, however, clinical and imaging data are insufficiently specific, and lung biopsy must be undertaken. In general, surgical lung biopsy, typically through a thoracoscopic approach, is the preferred method of obtaining tissue for examination. Transbronchial lung biopsy through the bronchoscope yields small fragments of tissue, typically too small to allow for appropriate examination of the lung architecture, and is not recommended for the assessment of suspected IPF. However, transbronchial biopsies may be useful in the setting of certain ILDs, including sarcoidosis, cryptogenic organizing pneumonia, and hypersensitivity pneumonitis. In general, the lung's response to injury is relatively stereotyped, with particular biopsy patterns of injury such as usual interstitial pneumonitis or granulomatous inflammation, being seen in a variety of disorders. Interpretation of lung biopsy results must therefore be done in the appropriate context, with incorporation of clinical and imaging data, because a biopsy

Preserved lung volumes

Idiopathic pulmonary fibrosis
Asbestosis

Figure 18-1 Radiographic manifestations of interstitial lung diseases. *Left image* shows well-preserved lung volumes with bilateral interstitial reticulonodular infiltrates as seen in diseases similar to sarcoidosis and hypersensitivity pneumonitis. *Right image* shows reduced lung volumes with bilateral basilar infiltrates as seen in idiopathic pulmonary fibrosis.

Figure 18-2 Interstitial lung disease (ILD) affects the interstitium of the lung at different locations. Depending on the site of disease activity, its consequences may vary. Specifically, diseases that affect the interstitium that surrounds the distal part of the alveoli lead to physiologic restrictions with reduced lung volumes. In contrast, diseases that preferentially affect the interstitium located near the more proximal parts of the acinus near the distal bronchioles may exhibit predominantly with well-preserved lung volumes and physiologic obstruction.

result of, for example, usual interstitial pneumonitis may carry a different prognosis in the setting of rheumatoid arthritis–associated ILD than in the setting of IPF. The summary of the typical manifestations of several ILDs is included in Table 18-1.

The management of ILD varies depending on the underlying cause, and treatments appropriate to specific entities are discussed later. Exposure avoidance is critical in the setting of hypersensitivity pneumonitis, smoking-related ILD, and drug-induced ILD. Immunosuppressants are employed in a variety of the ILDs with variable results depending on the specific entity. Supplemental oxygen and pulmonary rehabilitation may be helpful in advanced disease. Lung transplantation is performed in patients with limited life expectancy; early referral is suggested for patients with poor prognosis, as in IPF.

Idiopathic Interstitial Pneumonias

The idiopathic interstitial pneumonias (IIPs) are a group of ILDs of unknown origins. In the 1970s, these conditions were generally considered different variations of *IPF*. However, the distinct clinical presentations, natural courses,

Table 18-1 Manifestations of Interstitial Lung Disease

Disease	Physical Examination	Radiographs	Laboratory Findings	Histologic Findings
Pneumoconioses Coal worker's pneumoconiosis	Variable findings Normal Crackles	Diffuse reticulonodular infiltrates	Nonspecific except beryllium: lymphocyte transformation test	Fibrosis Coal: anthracotic pigment
Asbestosis Silica-induced ILD Beryllium exposure	Clubbing	Large nodules Eggshell calcification of hilar nodes Pleural plaques	Obstructive and/or restrictive PFTs	Silica: inflammation, bi-refringent crystals, alveolar proteinosis Asbestos: mesothelioma
Hypersensitivity pneumonitis	Fever Cough Crackles	Waxing and waning reticulonodular infiltrates Fibrosis	Serum precipitins to specific proteins Obstructive and/or restrictive PFTs	Obliterative bronchiolitis without granulomas Desquamative interstitial pneumonitis and diffuse alveolar damage Diffuse or patchy, intra-alveolar Macrophages
IPF DIP and/or RB-ILD	Variable findings Normal Crackles Clubbing	Normal to end-stage honeycombing Abnormalities usually diffuse	Nonspecific Restrictive PFTs	
UIP AIP NSIP				Patchy, fibroblasts, fibrosis Uniform, fibroblasts, no fibrosis Patchy or diffuse, prominent interstitial inflammation, fibrosis
Collagen vascular	Collagen vascular disease Crackles Pleural rub	Pleural effusions Diffuse interstitial infiltrates Nodular infiltrates Occasional cavities	Serologic findings for specific disease Occasionally obstructive, usually restrictive PFTs	Interstitial inflammation Vasculitis Bronchiolar obstruction Organizing pneumonia Fibrosis
Drug-induced ILD	Fever Crackles Pleural rub	Fibrosis Migratory infiltrates Diffuse interstitial infiltrates Pulmonary edema	Restrictive PFTs Anti-RNP antibodies	Alveolar macrophages with lamellar bodies in amiodarone Interstitial inflammation Fibrosis Eosinophilic infiltration

Sarcoidosis	Fever Malaise Weight loss Erythema nodosum Lupus pernio and skin plaques Salivary and lacrimal gland enlargement Iritis, uveitis, chorioretinitis; keratoconjunctivitis Cranial nerve palsies Arthritis Occasional rales or wheezes	Reticulonodular infiltrates Nodules Hilar adenopathy Mediastinal adenopathy Fibrosis	Lymphocytic bronchoalveolar lavage, T4 > T8 subsets Obstructive and/or restrictive PFTs Elevated transaminases with liver involvement Occasional hypercalcemia	Noncaseating granuloma with giant cells and negative acid-fast bacilli and fungal stains Fibrosis
Radiation exposure	Crackles Fever	Focal interstitial infiltrates corresponding to radiation port Occasional diffuse infiltrates Fibrosis	None	Acute: endothelial and alveolar lining cell damage Chronic: fibrosis
Pulmonary Langerhans cell histiocytosis	None to cough Dyspnea Chest pain Fatigue Weight loss Occasional fever	Spontaneous pneumothorax Nodules Reticulonodular infiltrates Middle and upper lobe predominance Honeycombing Sparing of costophrenic angle Cysts and nodules on HRCT	Normal lung volumes with decreased DLCO	OKT-6 (CD1) and S100-positive immunostaining Few eosinophils Peribronchiolar inflammation Macrophages filling lumen of bronchioles and intraluminal fibrosis
Lymphangioliomyomatosis	Dyspnea Cough Chest pain Decreased breath sounds or rales Hemoptysis Ascites	Spontaneous pneumothorax Pleural effusions Reticulonodular infiltrate Miliary pattern Honeycombing Hyperinflation Diffuse, small, thin-walled cysts on HRCT	Obstructive and/or restrictive PFTs Chylous pleural effusions Chylous ascites	HMB-45–positive immunostaining Atypical smooth muscle cell proliferation around bronchovascular bundles
COP	Fever Chills Malaise Fatigue Cough Dyspnea on exertion Weight loss	Peripheral patchy infiltrates, occasionally migratory CT scan: patchy consolidation, ground glass opacities, small nodules	Restrictive and occasionally obstructive PFTs in smokers	Patchy peri-bronchiolar distribution Foamy macrophages in alveolar spaces Intraluminal buds of granulation tissue

AIP, acute interstitial pneumonia; BOOP, bronchiolitis obliterans and organizing pneumonia; COP, cryptogenic organizing pneumonia; CT, computed tomography; DIP, desquamate interstitial pneumonia; HRCT, high-resolution computed tomography; ILD, interstitial lung disease; IPF, idiopathic pulmonary fibrosis; NSIP, nonspecific interstitial pneumonia; PFT, pulmonary function test; RB, respiratory bronchiolitis; RNP, antiribonucleoprotein antibodies; UIP, usual interstitial.

and responses to treatment observed in these patients led to their reclassification into a group of idiopathic interstitial disorders. The latest classification scheme was suggested in a 2002 consensus statement by the American Thoracic and the European Respiratory Societies. These disorders are recognized as distinct clinicopathologic entities and can be classified based on their *histologic pattern* as well as their *clinical course*. Those with an *acute clinical course* include *acute interstitial pneumonia (AIP)*; a *subacute clinical course* include *nonspecific interstitial pneumonia (NSIP)*, *cryptogenic organizing pneumonia (COP)*, *respiratory bronchiolitis-associated interstitial lung disease (RB-ILD)*, *desquamative interstitial pneumonia (DIP)*, and *lymphoid interstitial pneumonia (LIP)*; or a *chronic clinical course* as seen in *usual interstitial pneumonia (UIP)*.

Of the IIPs, IPF, also known as *cryptogenic fibrosing alveolitis*, is the most common, affecting 85,000 to 100,000 individuals in the United States. Although initially thought to be a relatively rare disease, IPF is now considered to be one of the most common ILDs with prevalence in some populations of 29 cases per 100,000; the prevalence is much higher in patients older than 70 years. In most patients with IPF, the disease is sporadic; however, IPF has been found in members of certain families (termed *familial IPF*), indicating that genetic alterations might predispose patients to this illness. The disease is idiopathic, but gamma herpesviruses have been detected in the lungs of a large proportion of patients with IPF, and an animal model resembling this condition has been reported. Many environmental, occupational, and infectious agents can cause lung fibrosis, including asbestos, silica, and tuberculosis. Therefore, distinguishing IPF from these other lung disorders is important because of the implications for prognosis and therapy.

IPF is characterized by progressive fibrosis of the lungs resulting in nonproductive cough and shortness of breath that worsens with exertion and, ultimately, causes hypoxemic respiratory failure. A typical patient with IPF is between 50 and 70 years of age, and the symptoms frequently develop 1 to 2 years before a diagnosis is confirmed. Physical examination often reveals crackles in the bases of both lungs, indicating the predominant site of scarring. With increased connective tissue deposition, the lung becomes stiff as evidenced by decreased compliance. Pulmonary function tests show decreased lung volumes consistent with a restrictive process. Poor oxygenation in IPF often requires long-term oxygen supplementation. The chest radiograph shows infiltrates that are most predominant at the bases and periphery of the lungs. HRCT allows for better visualization of the lung and is useful in evaluating the extent of disease. It delineates the areas of fibrosis and provides information about other structures in the chest. The classic HRCT findings of IPF are bilateral reticulonodular infiltrates with peripheral distribution and the presence of honeycombing and traction bronchiectasis in the absence of ground-glass opacification, lymphadenopathy, and pleural disease (Fig. 18-3; **Web Fig. 18-1**). In the setting of a typical clinical presentation and classic HRCT findings, a lung biopsy may not be necessary. Unfortunately, a lung biopsy is required for confirmation in many patients.

The histologic patterns of IPF show areas of scar tissue interspersed with normal alveolar structures. An interesting pathologic feature is the presence of *fibroblastic foci*, which

Figure 18-3 Computer tomography of the chest in a patient with idiopathic pulmonary fibrosis.

are areas in which fibroblasts accumulate and are believed to be the site of disease activity. This overall pattern of tissue organization is UIP, which can accompany other disorders (e.g., connective tissue-related ILD); thus, the diagnosis of IPF depends on a clinical, radiographic, and histologic picture that includes the syndrome of ILD in the absence of an obvious cause and a histologic manifestation consistent with UIP.

There is insufficient clinical evidence to suggest that any pharmacologic treatment improves survival or the quality of life for patients with IPF. As a result, clinicians typically consider offering treatment on a case-by-case basis after carefully weighing the benefits against the risks of treatment. Younger patients (<50 years of age) with significant ground-glass opacification, little fibrosis by HRCT, and minimal loss of lung function who have no contraindications to therapy are reasonable candidates for offering pharmacologic treatment. Combination therapy, using corticosteroids along with azathioprine, is generally recommended. The addition of *N*-acetylcysteine may offer additional benefit when added to this regimen. Other medications, including cyclophosphamide, cyclosporine, colchicine, penicillamine, and interferon- γ do little to stop the progression of IPF and may be more harmful than beneficial. More recently, it has been recognized that some patients with IPF experience acute respiratory deterioration in the absence of any clinically apparent cause (heart failure, pulmonary embolism, pneumonia). These episodes of idiopathic acute deterioration have been termed *acute exacerbations of IPF* and are associated with a poor prognosis. HRCT findings include new ground-glass opacities and consolidation superimposed on a background reticular or honeycomb pattern consistent with UIP. Histologically, evidence of acute lung injury (diffuse alveolar damage) can be found on the background of UIP. Acute exacerbations of IPF are typically treated with high doses of corticosteroids. Because survival on the lung transplantation waiting list for patients with IPF is worse than for patients with other indications for lung transplantation, early referral for transplantation evaluation should be initiated. Unfortunately, the 5-year survival rate for lung transplantation in patients with IPF is only 40% to 50%.

The second most common IIP is *NSIP*. As the term suggests, this condition exhibits a histologic picture that is nonspecific and characterized by diffuse interstitial inflammation. It is often associated with other conditions such as connective tissue disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis, polymyositis) or hypersensitivity pneumonitis. The association with these disorders is so strong that histologic confirmation of *NSIP* should prompt a search for these conditions. As in *IPF*, patients with *NSIP* exhibit slowly progressive dyspnea and bilateral interstitial infiltrates. Ground-glass opacification is often noted by *HRCT*. *NSIP* is more responsive to immunosuppressants than is *IPF*, and a 3-month trial period with these agents should be considered. However, occasionally, *NSIP* is associated with significant fibrosis (*fibrosing NSIP*), and lung transplantation should be considered in these patients, if possible.

DIP is usually seen in young individuals and is associated with a history of cigarette smoking. Patients exhibit a progressive shortness of breath and bilateral infiltrates on chest radiograph. The *HRCT* pattern is nonspecific, and a biopsy may be required for diagnosis. Tissue histologic findings show the accumulation of activated macrophages in the alveolar spaces. Treatment relies on immunosuppressant therapy and the avoidance of tobacco exposure. *DIP* is often confused with (and is considered by some experts to be identical to) *RB-ILD*, which has a similar clinical presentation and is associated with tobacco exposure.

AIP is another IIP that is not commonly seen. There is no sex predominance in *AIP* and no association with smoking. Its presentation differs from other IIPs in that it is more acute, with dyspnea progressing from days to a few weeks, invariably leading to respiratory failure. Patients often have a prior illness suggestive of a viral upper respiratory infection with constitutional symptoms such as myalgias, arthralgias, fever, chills, and malaise. The histologic pattern shows diffuse alveolar damage. Although a trial with immunosuppressants is recommended, this condition is often fatal, independent of treatment.

COP is often considered within the group of IIPs because it mimics these disorders clinically. Patients with *COP* exhibit subacute or chronic dyspnea first noted on exertion and sometimes triggered after an acute illness like an upper respiratory viral infection. Connective tissue disorders, inhaled irritants, and drugs (e.g., methotrexate) can cause *COP*. Histologically, *COP* is characterized by distal airway and interstitial inflammation and obliteration of distal air spaces with fibroblasts and fibrosis. Similar to *NSIP* and *DIP*, this condition is likely to respond to immunosuppressant therapy.

LIP is still classified by many groups as being one of the pulmonary lymphoproliferative disorders because many cases were thought to develop into lymphoma. However, with recent advances in immunohistochemistry and molecular analysis techniques, it would appear that only a small number of cases of *LIP* are found to actually undergo malignant transformation. *LIP* is an uncommon disease that is seen predominantly in women. Patients present with gradual-onset dyspnea and cough and occasionally fever, weight loss, chest pain, and arthralgias. Clinically, cases of *LIP* must be investigated for any known cause or associations, such as collagen vascular diseases (i.e., Sjögren syn-

drome), rheumatologic diseases (i.e., rheumatoid arthritis), and immunodeficiency diseases (i.e., AIDS). Histologically, infiltration of cells, including lymphocytes, plasma cells, and histiocytes, can be seen within alveolar septae. In addition, type II pneumocyte hyperplasia and an increase in the number of alveolar macrophages can be seen in *LIP*. Lymphoid follicles are often present, usually in the distribution of pulmonary lymphatics. Corticosteroids are used to treat *LIP* with variable success; however, more than one third of patients progress to develop diffuse fibrosis. It is unclear whether treatment influences the course of the disease or has a significant effect on lung physiology.

Granulomatous Disorders

A variety of noninfectious *ILDs* are characterized by granuloma formation within the lungs, including Wegener granulomatosis, hypersensitivity pneumonitis, and chronic beryllium disease. These disorders are discussed elsewhere in this chapter. Of the *ILDs* characterized by granulomatous lung inflammation, *sarcoidosis* is the most common. *Sarcoidosis* is a multisystem illness with frequent lung involvement with a prevalence of 1 to 40 cases per 100,000 worldwide. A higher incidence of *sarcoidosis* is reported among Scandinavian, German, and Irish individuals residing in northern Europe. In the United States, the prevalence rates of *sarcoidosis* are 10.9 per 100,000 for whites and 35.5 per 100,000 for African Americans, with women being more frequently affected. *Sarcoidosis* typically occurs in young individuals between 10 and 40 years of age, with women being affected more often than men.

Sarcoidosis is characterized by the formation in tissues of noncaseating granulomas that organize in an inner core of epithelioid cells, macrophages, and giant cells, surrounded by a rim of lymphocytes, fibroblasts, and connective tissue. Granulomas are present in the airways or lung parenchyma in more than 90% of patients with *sarcoidosis*. Granulomatous angiitis may also be found in the lungs. The upper respiratory system, lymph nodes, skin, and eyes are commonly involved. Virtually any other organ may be affected, including the liver, bone marrow, spleen, musculoskeletal system, heart, salivary glands, and nervous system (Table 18-2). The granulomas may be clinically silent, or, if extensive, may result in a disruption of normal organ structure and function. The cause of these lesions is unknown, but given the frequency of lung involvement, inhaled antigens, ranging from bacteria to environmental substances, have been hypothesized to trigger the onset of granulomatous inflammation. This inflammation may be self-limited or may be propagated, possibly by repeated exposure to the unknown antigen or because of the development of an autoimmune cross-reaction. Familial susceptibility to *sarcoidosis* seems to exist. To date, however, neither genetic factors nor specific environmental triggers have been firmly established. A single causative antigen may not exist, and *sarcoidosis* instead may represent a stereotypical inflammatory reaction to various possible antigens in a genetically susceptible host.

Sarcoidosis is associated with abnormal immune function as evidenced by cutaneous anergy and as exhibited in lung by an increased ratio of $CD4^+$ to $CD8^+$ T lymphocytes and

Table 18-2 Clinical Manifestations of Sarcoidosis

Organ Systems	
Pulmonary	Dyspnea, cough, wheezing, hemoptysis, endobronchial lesions
Dermatologic	Erythema nodosum, papules, plaques
Otolaryngologic	Saddle nose deformity, sinusitis, laryngeal lesions, parotitis
Ocular	Uveitis, chorioretinitis, keratoconjunctivitis, lacrimal gland enlargement, chronic tearing, optic neuritis
Neurologic	Cranial nerve palsy, headache, diabetes insipidus, mass lesions, seizures, meningitis, encephalitis
Rheumatologic	Arthralgias, arthropathy, myopathy
Gastrointestinal	Elevated transaminases, abdominal pain, jaundice
Cardiologic	Arrhythmias, conduction abnormalities, sudden cardiac death, pulmonary hypertension, congestive heart failure
Hematologic	Lymphadenopathy (especially hilar), hypersplenism
Endocrine	Hypercalcemia, hypercalciuria, epididymitis
Renal	Renal calculi, interstitial nephritis, renal failure
Syndromes	
Löfgren syndrome	Fever, arthralgias, bilateral hilar adenopathy, erythema nodosum
Heerfordt syndrome (uveoparotid fever)	Fever, swelling of parotid gland and uveal tracts, cranial nerve VII palsy

increased concentrations of pro-inflammatory cytokines such as interferon- γ , interleukin-12, and tumor necrosis factor- α (TNF- α). These derangements can be detected in the bronchoalveolar lavage fluid and are consistent with an imbalance in the production of T_h1 versus T_h2 cytokines, favoring the production of the former and promoting persistent inflammation. Sarcoidosis may occur in the setting of immunomodulatory therapy, especially with interferon alfa, highlighting the role of immune imbalances in the disorder.

The clinical presentation of sarcoidosis is variable. The disease is frequently detected incidentally on routine chest radiograph in asymptomatic individuals. Others may present with diverse acute or chronic symptoms. Patients may develop well-described acute syndromes such as *Löfgren syndrome*, which includes erythema nodosum, arthritis, and hilar adenopathy, or *uveoparotid fever*, also known as Heerfordt syndrome, which exhibits the triad of uveitis, parotitis, and facial nerve palsy. Both syndromes are associated with better outcomes when compared with other clinical presentations of sarcoidosis. In many cases, symptoms are vague and chronic and may include systemic symptoms such as low-grade fevers, night sweats, or joint pains. Respiratory manifestations, including shortness of breath, dry cough, and chest pain, occur in one third to one half of patients.

Table 18-3 Radiographic Staging of Sarcoidosis

Stage	Radiographic Findings
0	Normal radiograph
I	Adenopathy without parenchymal abnormality
II	Adenopathy and parenchymal disease
III	Parenchymal disease without lymphadenopathy
IV	End-stage fibrosis

Skin manifestations include erythema nodosum; plaques; nodules; and lupus pernio, a violaceous, often disfiguring, nodular lesion of the nose and cheeks. Ocular symptoms are also common, and the onset of uveitis may eventually lead to the diagnosis of sarcoidosis when granulomatous extraocular organ involvement is uncovered. Neurosarcoidosis may present with cranial nerve palsies or with headache in the setting of lymphocytic meningitis. Sarcoidosis can involve the heart, resulting in a cardiomyopathy. Arrhythmias and sudden cardiac death can occur as a result of the disruption of the conducting system by granulomatous infiltration. Pulmonary hypertension may result from pulmonary fibrosis or directly from granulomatous vasculitis.

In 90% of patients, the chest radiograph shows abnormalities that include bilateral hilar adenopathy (**Web Fig. 18-2**), infiltrates (**Web Fig. 18-3**), and fibrosis. The radiographic changes characteristic of sarcoidosis have been classified in stages 0 through IV (Table 18-3), but this staging system does not imply a typical chronologic progression. As in other ILDs, computed tomography (CT) is more sensitive for the detection of parenchymal abnormalities, and also more clearly demonstrates the extent of mediastinal adenopathy. Parenchymal HRCT findings include nodularity along the bronchovascular bundles emanating from the hila (**Web Fig. 18-4**). Positron-emission tomography (PET) scans may reveal other sites of organ involvement. Pulmonary function tests typically show restriction or obstruction. Liver involvement may cause mild elevation of transaminases, and cirrhosis and liver failure have been reported, although they are rare. Hypercalcemia and hypercalciuria may be detected and are due to increased intestinal absorption of calcium as a result of increased conversion of vitamin D to its active form in sarcoid granulomas. Kidney stones may result from the abnormal calcium metabolism. Elevated levels of angiotensin-converting enzyme (ACE) are common but are not specific. The use of ACE levels in the diagnosis or management of sarcoidosis is controversial.

The diagnosis of sarcoidosis is dependent on a typical clinical, radiographic, and histologic picture and is a diagnosis of exclusion. Tissue samples will show noncaseating granulomas, but because this finding is nonspecific, careful attention should be given to ruling out infectious causes of granulomatous inflammation, such as mycobacterial infection, through stains and cultures. Necrotizing granulomas have rarely been reported in sarcoidosis, but this finding should prompt an intense search for infection. In contrast to most ILDs, in which tissue diagnosis requires open-lung biopsy, the granulomas in sarcoidosis can be identified in skin nodules or in lymph nodes. A transbronchial lung biopsy is positive in 50% to 60% of patients with normal

parenchyma and close to 90% of patients with parenchymal abnormalities detected by chest radiograph. Because airway involvement is common, endobronchial biopsies may also demonstrate granulomas. After the diagnosis is made, all patients should have an ophthalmologic evaluation as well as a 24-hour collection of urine to evaluate for hypercalciuria. Electrocardiographic (ECG) examination and sometimes Holter monitoring should be performed to assess for conduction system abnormalities or arrhythmias resulting from involvement of the heart by sarcoidosis.

The course of sarcoidosis is variable. Spontaneous remission is common, and death and disability are relatively rare, making decisions regarding treatment initiation difficult. The acute sarcoidosis syndromes tend to remit and not recur. However, about one third of all patients with sarcoidosis will have chronic progressive disease, and some patients will develop pulmonary fibrosis or other end-organ damage. Corticosteroids are the standard therapy but should not be used indiscriminately in all patients with the diagnosis of sarcoidosis. Whether corticosteroids alter the disease course is uncertain. However, corticosteroid therapy should be considered in patients with extrapulmonary organ involvement or progressive pulmonary dysfunction. Patients with erythema nodosum in the setting of Löfgren syndrome may be managed with nonsteroidal anti-inflammatory medications alone. Other skin involvement may respond to hydroxychloroquine or corticosteroids, although the treatment of lupus pernio is challenging. Anterior uveitis may be treated with topical steroids, but other eye involvement may require systemic corticosteroids. Systemic corticosteroids are also generally used for the treatment of cardiac sarcoidosis. Conduction system disease and arrhythmias may necessitate placement of pacemakers or automatic implantable cardioverter-defibrillators. Neurosarcoidosis and hypercalcemia, as well as progressive pulmonary disease, are among the other indications for systemic steroid treatment (Table 18-4). Methotrexate has been used as a steroid-sparing agent. Anti-tumor necrosis factor- α agents, minocycline, hydroxychloroquine (Plaquenil), and thalidomide have been tested, although efficacy data are relatively sparse.

Interstitial Lung Diseases Related to Connective Tissue Disorders

In patients with ILD, a thorough history and physical examination may reveal abnormalities, such as arthritis and hand deformities, rashes, esophageal dysmotility, Raynaud syndrome, or skin changes suggestive of an underlying connective tissue disease. Connective tissue disorders, such as *systemic lupus erythematosus*, *rheumatoid arthritis (RA)*, *mixed connective tissue disorder*, *systemic sclerosis (scleroderma)*, *polymyositis* or *dermatomyositis*, and *Sjögren syndrome*, can cause ILD as well as a wide variety of other pulmonary manifestations (Table 18-5). Lung disease is a major cause of morbidity and mortality in some of these conditions, especially systemic sclerosis. Although not typical, an ILD related to connective tissue disorders (CTD-ILD) can even develop before other symptoms such as arthritis manifest, making the diagnosis more difficult.

Table 18-4 Indications for Use of Corticosteroids in Sarcoidosis

Disorder	Treatment
Iridocyclitis	Corticosteroid eye drops Local subconjunctival deposit of cortisone
Posterior uveitis	Oral prednisone
Pulmonary involvement	Steroids rarely recommended for stage 1; usually used if infiltrate remains static or worsens over 3-month period or if patient is symptomatic
Upper airway obstruction	Rare indication for intravenous steroids
Lupus pernio	Oral prednisone shrinks the disfiguring lesions
Hypercalcemia	Responds well to corticosteroids
Cardiac involvement	Corticosteroids usually recommended if patient has arrhythmias or conduction disturbances
Central nervous system involvement	Response is best in patients with acute symptoms
Lacrimal and salivary gland involvement	Corticosteroids recommended for disordered function, <i>not</i> gland swelling
Bone cysts	Corticosteroids recommended if symptomatic

Clinical manifestations of CTD-ILD are nonspecific and include exertional dyspnea and dry cough. Exertional dyspnea may be obscured by disabilities caused by the underlying CTD. CTD-ILD may also be relatively asymptomatic, manifesting as an incidental finding on imaging. Lung examination in patients with CTD-ILD may reveal bibasilar crackles, and pulmonary function tests often show a restrictive pattern with decreased diffusion capacity. If obstruction is present on pulmonary function testing, airway manifestations of the CTD, such as obliterative bronchiolitis in the setting of RA, must be considered. Chest imaging studies are useful because they may reveal typical patterns associated with the underlying CTD, often obviating the need for biopsy. Such patterns include apical fibrocavitary disease in ankylosing spondylitis and basilar fibrotic changes in RA, polymyositis, and systemic sclerosis. Imaging may also reveal pulmonary nodules in RA, or pleural disease in the setting of RA or systemic lupus erythematosus. Pulmonary hypertension in the absence of fibrosis can occur in these patients, especially with limited scleroderma (CREST syndrome) and systemic lupus erythematosus, so echocardiography may be helpful in patients with these disorders and otherwise unexplained dyspnea. Drug-induced lung disorders related to immunosuppressant therapy should always be considered in patients with CTD. Although CTD-ILD typically is chronic in nature, acute or fulminant pneumonitis that may be difficult to distinguish from opportunistic infection can be seen in systemic lupus erythematosus, Sjögren syndrome, polymyositis, and dermatomyositis.

Bronchoscopy with bronchoalveolar lavage is often used to rule out infection in acute presentations or if imaging reveals areas of consolidation as may occur with organizing

Table 18-5 Pulmonary Involvement in Connective Tissue Disorders

DM, dermatomyositis; PM, polymyositis; RA, rheumatoid arthritis; SS, Sjögren syndrome.

pneumonia in RA. Lung biopsy may be necessary if the clinical presentation or imaging findings are atypical. Biopsies of areas of typical basilar fibrosis in CTD frequently reveal patterns consistent with NSIP or UIP. In Sjögren syndrome with ILD, lymphocytic interstitial pneumonia or even lymphoma may be found on biopsy. Diffuse alveolar damage is found in the setting of acute lupus pneumonitis. Immunosuppressants are the mainstay of treatment for CTD-ILD, and, in general, these disorders are more responsive to this therapy than is IPF.

Drug-Induced Lung Disorders

A large number and variety of drugs can induce adverse reactions in the lung, often in the form of an ILD (Table 18-6). These reactions can vary in severity from self-limited hypersensitivity reactions (Web Fig. 18-5) to diffuse alveolar damage resulting in respiratory failure and death. In general, a high index of suspicion is needed to make the association between a drug and a pulmonary reaction, and a careful review of medications and other pharmacologic substances used by a patient is necessary in the setting of diffuse lung disease. Other pharmacologic substances that commonly produce adverse pulmonary reactions include illicit drugs such as heroin and cocaine. Substances like talc may also be injected inadvertently during the use of illicit drugs, resulting in pulmonary vascular or interstitial disease.

The clinical presentation of drug-induced ILD is often nonspecific, with fever, cough, and dyspnea accompanied by radiographic infiltrates. Eosinophilia may sometimes be present. Antinuclear antibodies are positive, but anti-double-stranded DNA antibodies are negative, in the setting of *drug-induced lupus*. Pulmonary function tests, if performed, generally reveal decreases in diffusion capacity and often a restrictive pattern. ILD caused by medications generally does not produce a unique radiographic or histologic pattern of lung injury but may result in a variety of nonspecific reactions, including pulmonary infiltrates with peripheral eosinophilia, a hypersensitivity pneumonitis pattern, and interstitial fibrosis. Alveolar filling may also occur in the

setting of drug-induced organizing pneumonia and acute lung injury or diffuse alveolar damage. Pleural and pericardial effusions may be present in lupus-like drug reactions. Because the presentation of drug-induced ILDs lacks specificity, ILDs are typically diagnoses of exclusion.

There are particular settings in which drug-induced lung disease may be especially relevant and should be strongly considered in the differential diagnosis. These settings include the use of chemotherapeutic agents, the use of illicit drugs, patients presenting with lupus-like illness, and patients using particular agents well-known to produce pulmonary toxicity such as *amiodarone* or *nitrofurantoin*. Many chemotherapeutic agents, ranging from the newer tyrosine kinase inhibitors to older agents such as *bleomycin* and *methotrexate*, may produce lung injury and ILD. Diagnosis of a drug-induced ILD may be challenging in patients treated with chemotherapy because atypical infections and chemotherapy-induced heart failure may result in similar symptoms and radiographic findings.

Heroin use typically results in pulmonary edema or aspiration injury and not ILD per se. Cocaine use can produce a variety of pulmonary effects, including organizing pneumonia, alveolar hemorrhage, and diffuse alveolar damage. “Crack lung” is a clinical diagnosis typified by dyspnea, hemoptysis, and pulmonary infiltrates occurring in the setting of crack cocaine use. Drug-induced lupus occurs with particular drugs, such as *procainamide* or *hydralazine*. Amiodarone lung toxicity is a classic drug-induced lung disorder that results in alveolar or interstitial infiltrates accompanied by dyspnea on exertion; foamy macrophages can be detected by bronchoalveolar lavage, but only indicate amiodarone use, not toxicity. Nitrofurantoin may cause an acute pulmonary syndrome with fever, dyspnea, and cough soon after initiation of the drug, or a chronic pulmonary fibrosis with long-standing use. Amiodarone and nitrofurantoin reactions necessitate drug withdrawal and often corticosteroids for resolution.

Pulmonary toxicity from drugs may be dose-dependent, as with bleomycin, in which the risk of lung toxicity increases with cumulative doses exceeding 450 U. Amiodarone lung disease typically occurs with doses over 400 mg/day. Synergistic lung toxicities may occur. For example, exposure to

Table 18-6 Common Drug-Induced Lung Diseases

Drug	Dose Relation	Manifestation
Chemotherapeutic		
Bevacizumab	Acute	Hemoptysis, pulmonary hemorrhage
Bleomycin	Acute or delayed, >450 U increased risk	Pneumonitis, fibrosis, BOOP, lung nodules
Busulfan	Chronic	Fibrosis, alveolar proteinosis
Cyclophosphamide	Chronic	Fibrosis, BOOP
Cytosine arabinoside	Acute	Pulmonary edema, ARDS
Gefitinib	Acute	Pulmonary fibrosis, interstitial pneumonitis, diffuse alveolar damage
Gemcitabine	Acute	Dyspnea, bronchospasm, capillary leak syndrome with pulmonary edema, ARDS, alveolar hemorrhage
Imatinib	Acute, chronic	Pulmonary edema, pneumonitis
Interferon alfa	Chronic	Sarcoidosis
Irinotecan	Acute	Pneumonitis
Methotrexate	Acute or chronic	Hypersensitivity pneumonitis, resolves with discontinuation, BOOP
Mitomycin C	Acute or delayed	Pneumonitis, ARDS, BOOP, hemolytic uremic syndrome
Paclitaxel and docetaxel	Acute	Interstitial and hypersensitivity pneumonitis
Antimicrobial		
Nitrofurantoin	Acute or chronic	Acute pneumonitis, chronic fibrosis
Sulfasalazine	Acute or chronic	Pulmonary infiltrates with eosinophilia, BOOP
Cardiovascular		
Amiodarone	Acute or chronic, >400 mg/day	Pneumonitis, fibrosis
Flecainide	Acute	ARDS, LIP
Tocainide	Weeks or months	Pneumonitis
Procainamide	Subacute or chronic	Drug-induced systemic lupus erythematosus, pleural effusions, pulmonary infiltrates
Anti-inflammatory		
Aspirin	Acute	Pulmonary edema, bronchospasm
Illicit		
Opiates	Acute	Pulmonary edema
Cocaine	Acute	Pulmonary edema, diffuse alveolar damage, pulmonary hemorrhage, BOOP
Talc (in intravenous and inhaled illicit drugs)	Acute or chronic	Granulomatous interstitial fibrosis, granulomatous pulmonary artery occlusion, particulate embolization
Tocolytics		
Terbutaline, albuterol, ritodrine	Acute	Pulmonary edema

ARDS, acute respiratory distress syndrome; BOOP, bronchiolitis obliterans and organizing pneumonia; LIP, lymphoid interstitial pneumonia.

high levels of inspired oxygen may precipitate bleomycin lung injury and should be avoided if possible in exposed patients.

The website <http://www.pneumotox.com> is an online reference site tabulating the reported pulmonary toxicities of various drugs that is searchable by drug name as well as by pattern of lung involvement.

Pulmonary Vasculitis and Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage (DAH) syndromes encompass diverse group of specific entities that are all characterized by the disruption of the alveolar-capillary membrane, resulting in bleeding into the alveolar spaces. Unfortunately, patients with DAH do not always present with signs, symptoms, and

laboratory and radiographic findings that support a specific underlying diagnosis. Often, DAH is found without features that identify a specific etiology.

All DAH syndromes are characterized by the abrupt onset of cough, fever, and dyspnea. Hemoptysis is common but not universal because it may be absent in up to one third of patients with DAH. Physical findings are generally nonspecific, although ocular, nasopharyngeal, or cutaneous abnormalities may suggest systemic vasculitis or collagen vascular disease as an etiology. The cardiopulmonary examination is often normal but may reveal inspiratory crackles, a systolic murmur suggestive of mitral stenosis or evidence of pulmonary hypertension. Falling hemoglobin levels, the presence of increasingly hemorrhagic fluid on sequential bronchoalveolar lavage and new patchy alveolar infiltrates (**Web Fig 18-6**) by chest imaging favor the diagnosis of DAH. Other laboratory abnormalities may include the presence of azotemia, suggesting a pulmonary-renal syndrome. In this setting, an abnormal urinalysis with proteinuria, hematuria, and red

blood cell casts is usually seen. The erythrocyte sedimentation rate (ESR) may be increased, particularly in those with an underlying systemic disease. Some lung disorders characterized by DAH are associated with the production of antineutrophil cytoplasmic antibodies (ANCA) directed against neutrophil cytoplasmic antigens or antibodies directed at the glomerular basement membrane. ANCA testing, in particular, can play an important role in the workup of DAH because it is used in the diagnosis and classification of various pulmonary vasculitides that cause DAH. Two major immunofluorescent patterns can be seen in ANCA testing: diffuse staining throughout the cytoplasm (c-ANCA) or staining around the nucleus (p-ANCA). Specific antigens that ANCA are directed against include proteinase-3 (PR-3), typically causing the c-ANCA pattern, and myeloperoxidase (MPO), which typically causes the p-ANCA pattern.

All DAH syndromes are characterized by three distinct histologic patterns. *Bland pulmonary hemorrhage* is due to alveolar hemorrhage without inflammation or destruction of the alveolar structures. This pattern is seen in conditions where there is elevated pulmonary capillary hydrostatic pressure, such as congestive heart failure or mitral stenosis, or with the use of certain anticoagulation medications. *Diffuse alveolar damage* (DAD) is caused by a variety of pulmonary infections, connective tissue diseases, and medications. DAD is also seen in acute respiratory distress syndrome (ARDS) from any etiology. Histologically, alveolar walls appear edematous and are lined with hyaline membranes. The most common histologic pattern seen on lung biopsy obtained from patients with DAH is *pulmonary capillaritis*, which is characterized by neutrophilic infiltration of the alveolar septa. This sequentially leads to necrosis, loss of capillary structural integrity, and extravasation of red blood cells into the interstitium and alveolar spaces. This finding is seen in a variety of connective tissue diseases and is the most common histologic pattern of the pulmonary vasculitides.

The pulmonary vasculitides represent a group of specific entities, many of which are associated with elevated serum ANCA levels. These entities include *Wegener granulomatosis*, *microscopic polyangiitis*, *Churg-Strauss syndrome*, and certain drug-induced vasculitis syndromes. *Pauci-immune glomerulonephritis without evidence of extrarenal disease* is a disorder that is considered to be on the spectrum of Wegener granulomatosis and microscopic polyangiitis because its histologic features are indistinguishable from these disorders and some patients eventually develop extrarenal (pulmonary) manifestations. *Wegener granulomatosis* is a systemic necrotizing granulomatous vasculitis that often involves the small and medium-sized vessels of the upper airway, the lower respiratory tract, and the kidney. Although this triad is not always seen at initial presentation, as only 40% of those affected have renal disease at that time, 80% to 90% of patients eventually develop glomerulonephritis. The most frequent manifestations of this illness are pulmonary, as highlighted by cough, chest pain, hemoptysis, and dyspnea. Constitutional symptoms, such as fever and weight loss, as well as symptoms due to involvement of the skin, eye, heart, nervous system, and musculoskeletal system, are also common. The diagnosis of Wegener granulomatosis is supported by clinical findings and by the presence of circulating ANCAs, which are seen in 90% of all patients. The remaining 10% are ANCA negative. In ANCA-positive patients, antibodies are

usually directed against PR-3; however, 10% to 20% may have anti-MPO antibodies. Chest imaging may show bilateral disease and infiltrates that evolve over the course of the illness. Lung nodules are common and may cavitate. Effusions and adenopathy are not common. Sinus films or CT scans serve to diagnose upper airway involvement. Tissue biopsy at a site of active disease is generally needed to confirm Wegener's granulomatosis. The presence of granulomatous inflammation is common, but actual vasculitis is seen in only 35% of patients. A renal biopsy is preferred because it is easier to perform and more often diagnostic. In the absence of renal involvement, a lung biopsy should be considered. Pathologically, Wegener granulomatosis is characterized by small and medium vessel necrotizing vasculitis and granulomatous inflammation. Special stains and cultures should be performed to exclude the presence of infections that can produce similar findings.

Microscopic polyangiitis is a form of systemic necrotizing small vessel vasculitis that universally affects the kidneys, whereas pulmonary involvement occurs in only a minority of patients (10% to 30%). This rare condition has a prevalence of 1 to 3 cases per 100,000, but it is the most common cause of pulmonary-renal syndrome. It is often heralded by a long prodromal phase, characterized by constitutional symptoms followed by the development of rapidly progressive glomerulonephritis (RPGN). In those patients who do develop lung involvement, DAH secondary to capillaritis is the most common manifestation. Joint, skin, peripheral nervous system, and gastrointestinal involvement can be seen as well. Seventy percent of patients with microscopic polyangiitis are ANCA positive, most of whom have anti-MPO antibodies. Because anti-MPO and anti-PR3 antibodies can be present in both microscopic polyangiitis and Wegener granulomatosis, these diseases cannot be distinguished based on their ANCA pattern. However, the two diseases can be distinguished pathologically because microscopic polyangiitis is characterized by a focal, segmental necrotizing vasculitis affecting venules, capillaries, arterioles, and small arteries *without* clinical or pathologic evidence of necrotizing granulomatous inflammation. The absence or paucity of immunoglobulin localization in vessel walls distinguishes microscopic polyangiitis from immune complex-mediated small vessel vasculitis such as *Henoch-Schönlein purpura* and *cryoglobulinemic vasculitis*.

Treatments of Wegener granulomatosis and microscopic polyangiitis are similar. Combination therapy with corticosteroids and cyclophosphamide is the standard of care. Azathioprine can be substituted for cyclophosphamide if remission is achieved. Intravenous immunoglobulin may be effective for those with persistent disease. Novel therapies, including trimethoprim-sulfamethoxazole, antilymphocyte monoclonal antibodies, and tumor necrosis factor inhibitors, have been tried with some success.

Allergic granulomatosis or *Churg-Strauss syndrome* is characterized by the triad of asthma, hypereosinophilia, and necrotizing vasculitis. Many other organ systems, including the nervous system, skin, heart, and gastrointestinal tract, may be involved as well. The vasculitis can be associated with skin nodules and purpura. Although DAH and glomerulonephritis may occur, they are much less common than in the other small vessel vasculitides. Morbidity and mortality are often due to cardiac or gastrointestinal complications or

to status asthmaticus and respiratory failure. ANCA are less helpful in Churg-Strauss syndrome because only 50% of patients are ANCA positive. Anti-MPO antibodies are more commonly seen in these patients. Pathologically, both a necrotizing, small vessel vasculitis and an eosinophil-rich inflammatory infiltrate with necrotizing granulomas are seen. Most patients respond well to corticosteroids, but other immunosuppressants similar to cyclophosphamide may be required in patients with refractory disorders.

Other well-known causes of pulmonary capillaritis include the systemic vasculitides, collagen vascular disorders, anti-glomerular membrane antibody syndrome (*Goodpasture syndrome*), and *Henoch-Schönlein purpura*. Goodpasture syndrome causes DAH associated with glomerulonephritis caused by anti-glomerular basement membrane antibodies to the α_3 chain of type IV collagen that is also found in the lung basement membrane. More than 90% of patients with Goodpasture syndrome have anti-glomerular basement membrane antibodies detectable in the serum. In those without circulating antibodies, the diagnosis may be confirmed by lung biopsy, although the kidney is the preferred site. Up to 40% may also be ANCA positive, primarily with anti-MPO antibodies. Pathologically, linear deposition of antibody along the alveolar or glomerular basement membrane that is visible by direct immunofluorescence occurs. The treatment of Goodpasture syndrome is plasmapheresis and immunosuppression. The disease is fatal if left untreated.

Idiopathic pulmonary hemorrhage or *hemosiderosis* is a diagnosis of exclusion. Patients with this syndrome have recurrent DAH without associated renal or systemic disease. Histologically, the lung shows hemorrhage and hemosiderin accumulation without inflammation. Treatment includes supportive care, immunosuppression, and occasionally plasmapheresis, but response to therapy is varied. This syndrome is most common in children, who have a worse prognosis than adults.

Environmental and Occupational Interstitial Lung Diseases

Several environmental and occupational exposures may cause ILDs. These include the *pneumoconioses*, *drug-induced ILD* (discussed earlier), and *hypersensitivity pneumonitis*. Pneumoconiosis and hypersensitivity pneumonitis are discussed later. The pneumoconioses are lung diseases resulting from the inhalation of mineral dusts, including silica, coal dust, or asbestos. Hypersensitivity pneumonitis is caused by the inhalation of organic dusts.

PNEUMOCONIOSIS

The pneumoconioses result from the effects of accumulation of mineral dusts in the lungs, with the typical reaction being fibrosis. In general, the risk and extent of these diseases are related to the intensity and cumulative amount of exposure over time. Prevention of the pneumoconioses through occupational safeguards or, in the case of asbestos, legislative bans on use, is most important because there are not effective treatments for these diseases once established.

Silicosis is a lung disease caused by exposure to crystalline-free silica, which results in an inflammatory and fibrotic reaction resulting in the characteristic silicotic nodule. Certain occupations that have a higher propensity for exposure to silica include mining, stone cutting, carving, polishing, foundry work, and abrasive clearing (sandblasting). Although exposure is usually chronic (over years), accelerated and acute disease manifestations have been described in the setting of heavier short-term exposures. Acute silicosis causes a pulmonary alveolar proteinosis, with an accumulation of surfactant in the alveolar spaces. Chronic silicosis results in *simple nodular silicosis*, which is usually asymptomatic unless the patient is also exposed to tobacco, and *progressive massive fibrosis* (PMF), which is characterized by extensive bilateral apical fibrosis resulting from the confluence of many silicotic nodules. Patients with silicosis may present with dyspnea or may be relatively asymptomatic but present for evaluation of an abnormal chest radiograph. Chest radiographs in uncomplicated silicosis show upper lobe nodular opacities, which may be subtle, whereas PMF results in marked architectural distortion of the upper lobes (**Web Fig 18-7**). Hilar node enlargement may be seen accompanied by *eggshell* nodal calcification (**Web Fig 18-8**). Pulmonary function tests in simple nodular silicosis may be normal or show a mixed obstructive or restrictive pattern, whereas PMF is typically associated with severe restriction and hypoxemia. Patients with silicosis are at elevated risk for tuberculosis and should be screened for latent tuberculosis infection; there is also an association between silicosis and rheumatoid arthritis.

Coal worker's pneumoconiosis is an uncommon cause of pulmonary fibrosis, occurring in workers exposed to coal dust and graphite. Usually, the patients are exposed while working in underground mines. Coal worker's pneumoconiosis results in the formation of pigmented lesions in the lung, surrounded by emphysema, known as *coal macules*. PMF may subsequently occur. Most patients show chronic cough, which is usually productive, because of bronchitis related to coal exposure or to tobacco. The chest radiograph shows diffuse small rounded opacities. As with silicosis, there is an association with rheumatoid arthritis; Caplan syndrome is the occurrence of multiple large, sometimes cavitory, lung nodules in association with rheumatoid arthritis following coal dust exposure.

Asbestosis is due to chronic exposure to asbestos, which is a fibrous silicate used for insulation, for friction-bearing surfaces, and to strengthen materials. The inhaled asbestos fibers are deposited in the lungs, where small fibers may be phagocytosed and cleared through lymphatics to the pleural space, but longer fibers are often retained. Typically, asbestos exposure may lead to pleural disease characterized by pleural plaques, effusion, and fibrosis, but it does not necessarily affect the lung parenchyma. If it does, it is called *asbestosis* and is associated with interstitial lung fibrosis. Asbestosis is characterized by a gradual onset of dyspnea. As with other pneumoconioses, the risk and severity of disease are related to the extent and duration of cumulative exposure. Asbestosis is often diagnosed after exposure has ceased, and disease progression may continue to occur in the absence of ongoing exposure, owing to the reaction to retained asbestos fibers in the lung. The clinical presentation, pulmonary function tests, and imaging studies are similar to those

found in restrictive lung diseases like IPF. However, the detection of significant pleural disease is useful in distinguishing this illness from other ILDs. The diagnosis is made from the history and demonstration of concomitant pleural plaques and lower lobe–predominant fibrotic changes on chest radiographs or CT scan. In uncertain cases, the demonstration of asbestos in tissue specimens may be necessary; asbestos bodies are the characteristic finding and consist of asbestos fibers coated by iron-containing (ferruginous) material. Asbestos exposure results in an elevated incidence of malignancy, including lung carcinoma and mesothelioma, especially in persons who also smoke. Whether the presence of asbestosis itself confers a heightened risk for malignancy, independent of the effects of asbestos exposure alone, is uncertain. No specific treatment for asbestosis exists.

Berylliosis results from exposure to beryllium, a rare metal useful in modern, high-technology industries. Exposure to beryllium can lead to an acute chemical bronchitis and pneumonitis or chronic beryllium disease. Chronic beryllium disease is characterized by a multisystemic granulomatosis that is difficult to distinguish from sarcoidosis. The diagnosis is made by history of exposure, histologic examination, and laboratory confirmation through the beryllium lymphocyte proliferation test that is available at specialized centers. Corticosteroids may be useful in the treatment of berylliosis, but patients should avoid further exposure to beryllium.

HYPERSENSITIVITY PNEUMONITIS

Hypersensitivity pneumonitis (also termed *extrinsic allergic alveolitis*) is a relatively common ILD resulting from an exaggerated immune reaction to various inhaled organic antigens in sensitized individuals. Potential sensitizing antigens are diverse, ranging from bacterial, fungal, and animal proteins to low-molecular-weight chemicals (Table 18-7). Although evocative descriptions have been given to occupational forms of this disease (“paprika splitter’s lung” resulting from sensitivity to *Mucor stolonifer*), more prosaic exposures may occur in everyday life, for example, to contaminated hot tub water or to pet birds. The disease may present in an acute fashion several hours after intense exposure to a provocative antigen, with fever, chills, cough, dyspnea, and malaise that last for up to 24 hours. Subacute or chronic disease may occur with repeated or prolonged antigen exposure and may result in chronic dyspnea and cough, with eventual progression to pulmonary fibrosis.

Diffuse crackles and wheezes are common physical findings. Hypoxemia may be present. In general, hypersensitivity pneumonitis is characterized by nonspecific infiltrates in the mid and upper lung fields on chest radiographs. CT scanning is more sensitive than chest radiography, revealing ground-glass opacities, centrilobular nodules, and mosaic attenuation patterns resulting from airway obstruction. In chronic hypersensitivity pneumonitis, emphysema and lower lobe honeycombing may be present. Restrictive or mixed obstructive-restrictive patterns may be seen on pulmonary function testing, along with abnormalities of gas exchange. Bronchoalveolar lavage may demonstrate a lymphocytic alveolitis, with CD8 T-lymphocyte predominance. Patients with hypersensitivity pneumonitis may have pre-

Table 18-7 Hypersensitivity Pneumonitis

Antigen	Source	Disease Examples
Thermophilic bacteria	Moldy hay, sugar cane, compost	Farmer’s lung, bagassosis, mushroom worker’s disease
Other bacteria	Contaminated water, wood dust, fertilizer, paprika dust	Humidifier, detergent worker’s disease, and familial hypersensitivity pneumonitis
Fungi	Moldy cork, contaminated wood dust, barley, maple logs	Suberosis, sequoiosis, and maple bark stripper’s disease, malt worker’s disease, and paprika splitter’s lung
Animal protein	Bird droppings, animal urine, bovine and porcine pituitary powder	Pigeon breeder’s lung, duck fever, turkey handler’s disease, pituitary snuff taker’s disease, laboratory worker’s hypersensitivity pneumonitis
Chemically altered human proteins (albumin and others)	Toluene diisocyanate Trimellitic anhydride Diphenylmethane diisocyanate	Hypersensitivity pneumonitis
Phthalic anhydride	Heated epoxy resin	Epoxy resin lung

cipitating antibodies to the offending antigen, but serum precipitins are not sufficiently sensitive or specific for diagnosis, and the specific antigen may not be known or may not be tested for with standard test panels.

An appropriate exposure, clinical history, and imaging findings can suggest the diagnosis, but lung biopsy may be necessary for confirmation. Transbronchial biopsy is often sufficient. Typical biopsy findings include poorly formed granulomas containing foreign body giant cells and interstitial chronic inflammation with a bronchiolocentric component. Clinical improvement often occurs in the hospital setting when patients are isolated from the offending antigen, and relapse may occur after discharge. Corticosteroids can relieve symptoms in the acute phase, but their efficacy in chronic forms of the disease is less clear. Identification of the cause of hypersensitivity pneumonitis is important because chronic disease management requires avoidance of exposure to the antigen, which can be financially or psychologically challenging for patients in the setting of occupational, pet, or residential exposures.

Specific Entities

PULMONARY LANGERHANS CELL HISTIOCYTOSIS (EOSINOPHILIC GRANULOMA)

Pulmonary Langerhans cell histiocytosis (LCH), also called *eosinophilic granuloma*, is a disease of young- to middle-aged adults. Nearly all cases occur in white men who smoke. The

disorder results from the infiltration of Langerhans cells, which are dendritic cells, into the lung parenchyma. Smoking may alter local immune signaling, attracting the Langerhans cells to the lungs. Patients typically exhibit constitutional symptoms, dyspnea on exertion, and cough, possibly with hemoptysis. Pneumothorax may also occur. Imaging shows micronodular lesions and cysts that predominate in the mid and upper lung zones. Pulmonary function tests show an obstructive pattern and impaired diffusion capacity. Specific diagnosis can be made with open lung biopsy, which demonstrates multiple stellate lung nodules that may be cellular or fibrotic, containing Langerhans cells that stain for Cd1a and S100. Electron microscopy may reveal Birbeck granules, distinctive racquet-shaped structures within the cells. In the right clinical setting and with a typical HRCT, a biopsy might not be needed for diagnosis. In contrast to systemic LCH, pulmonary LCH is not a neoplastic disorder, and spontaneous regression may occur. The main treatment is tobacco cessation. Corticosteroids and other immunosuppressants are sometimes employed as adjunctive therapy.

LYMPHANGIOLEIOMYOMATOSIS

Lymphangiomyomatosis (LAM) is a rare disorder that may occur in association with the tuberous sclerosis complex or sporadically in women of childbearing age. The disease is characterized by extensive nodular infiltration of the lungs and lymphatics with growths of smooth muscle–like cells. Mutations in the *TSC-1* or *TSC-2* gene, encoding for tumor suppressor proteins that normally act as inhibitors of protein synthesis and cell growth, may result in tuberous sclerosis or LAM, with mutations in *TSC-2* being associated with greater disease severity. Dyspnea and pneumothorax are the most common presentations, with chylous pleural effusions and hemoptysis also occurring. These clinical presentations result from the lung parenchymal destruction, airway narrowing, and lymphatic obstruction caused by the abnormal proliferation of the smooth muscle–like cells. Imaging studies show an interstitial pattern with mid and upper lung predominance, multiple thin-walled cystic lesions, and characteristically preserved lung volumes. Pleural effusion or pneumothorax may also be present on imaging. CT of the abdomen may reveal fat-containing kidney lesions consistent with angiomyolipomas. Pulmonary function tests typically show a progressive obstructive pattern, although mixed obstruction and restriction may also be seen.

Although the clinical features coupled with characteristic imaging are often diagnostic, lung biopsy might be necessary in some cases. This demonstrates interstitial nodules composed centrally of spindle-shaped cells that stain for smooth muscle cell actin as well as with HMB-45, an antibody to the melanocytic glycoprotein gp-100, involving the alveolar walls, lobular septa, venules, small airways, and pleura. Treatment involves management of pleural complications, including use of pleurodesis to prevent recurrent pneumothorax or effusion; bronchodilator and oxygen therapy; and avoidance of pharmacologic estrogens, which may exacerbate the disease. Progesterones have been used in an attempt to modulate disease progression, although efficacy data are limited. Because the products of the *TSC-1* and *TSC-2* genes normally act as inhibitors of the mammalian target of rapamycin (m-TOR), use of inhibitors of m-TOR activity

like sirolimus is under investigation in LAM, with sirolimus being shown in one small study to improve lung function in LAM. Lung transplantation can be performed in patients with severe pulmonary dysfunction.

EOSINOPHILIC LUNG DISEASE

Eosinophilic lung diseases are characterized by the presence of pulmonary infiltrates and eosinophilia of the peripheral blood or lung. Because eosinophilia is a feature of many diseases, it is important to distinguish primary pulmonary eosinophilic lung disorders from lung disorders in which eosinophilia is secondary to a specific cause. Eosinophilic lung diseases can be categorized as follows: *primary pulmonary eosinophilic disorders* (including *acute* and *chronic eosinophilic pneumonia*, *hypereosinophilic syndrome*), *pulmonary disorders of known cause associated with eosinophilia* (including *asthma*, *allergic bronchopulmonary aspergillosis*, *drug reactions*, *parasitic infections*), *lung diseases associated with eosinophilia* (including *hypersensitivity pneumonitis*, *COP*, *IPF*), *malignancies associated with eosinophilia* (including *lung cancer*, *leukemia*, *lymphoma*), and *systemic disease associated with eosinophilia* (including *rheumatoid arthritis*, *sarcoidosis*, and *Sjögren syndrome*).

Acute eosinophilic pneumonia is characterized by fever, a nonproductive cough, and dyspnea of less than 7 days' duration, often leading to respiratory failure. This disease typically affects men between the ages of 20 and 40 years who are otherwise healthy. Chest imaging reveals diffuse bilateral pulmonary infiltrates. Eosinophilia is not present in the peripheral blood initially but may occur 7 to 30 days after onset. However, abundant eosinophils can be found in bronchoalveolar lavage fluid, and a level of greater than 25% of all nucleated cells is helpful in making the correct diagnosis. Although lung biopsy is typically not required to make the diagnosis, it can show eosinophilic infiltration with acute and organizing diffuse alveolar damage. Treatment with corticosteroids typically offers complete clinical and radiographic resolution without recurrence or residual sequelae.

Chronic eosinophilic pneumonia is an idiopathic disease predominantly of middle-aged women. Also termed *prolonged pulmonary eosinophilia*, this illness is characterized by a productive cough, dyspnea, malaise, weight loss, night sweats, and fever associated with progressive peripheral lung infiltrates that, on chest radiography, have been described as resembling the “photographic negative of pulmonary edema” (Web Fig 18-9). On presentation, most patients have a peripheral eosinophilia of greater than 30% and bronchoalveolar lavage fluid eosinophilia as well. Histologic examination shows eosinophils and histiocytes in the lung parenchyma and interstitium, areas of COP, but minimal fibrosis. Spontaneous remissions have been reported, but respiratory failure can also develop. Typically, treatment with corticosteroids is rapidly effective. Prolonged therapy is recommended because unlike with acute eosinophilic pneumonia, relapses are common.

Simple pulmonary eosinophilia, also known as *Löffler syndrome*, is characterized by transient migratory infiltrates that last less than 1 month. In some cases, no symptoms are present, but dyspnea and dry cough may occur. Pathologic examination of tissues reveals interstitial and intra-alveolar

accumulation of eosinophils, macrophages, and edema. The syndrome might be idiopathic or caused by parasitic infections (e.g., *Ascaris* species, *Strongyloides* species, hookworms) or drugs (e.g., nitrofurantoin, minocycline, sulfonamides, penicillin, nonsteroidal anti-inflammatory drugs). Treatment requires removal of the offending agent or treatment of the parasitic infection. In idiopathic cases, corticosteroids may be used.

Allergic bronchopulmonary aspergillosis (ABPA) is a hypersensitivity reaction that occurs when *Aspergillus* species colonizes the airways in patients with asthma or cystic fibrosis. Patients may present with fever, malaise, a cough productive of thick brown mucus plugs, and occasionally hemoptysis. On chest radiograph, pulmonary infiltrates, which are often transient and migratory, and central bronchiectasis may be seen. Peripheral eosinophilia of greater than 10%, elevated IgE levels (as well as the presence of aspergillus-specific IgE), and precipitating antibodies to aspergillus are among the laboratory abnormalities seen in ABPA. Response to corticosteroids is good. Itraconazole can be added to the treatment regimen as well.

PULMONARY ALVEOLAR PROTEINOSIS

Pulmonary alveolar proteinosis (PAP) is a rare disorder in which lipoproteinaceous material, similar to surfactant, accumulates within the alveoli. PAP has a congenital form,

characterized by mutations of the genes encoding surfactant protein B or C or for the receptor for granulocyte-macrophage colony-stimulating factor (GM-CSF). Secondary PAP occurs in conditions in which there is a functional impairment or decrease in the number of alveolar macrophages, as seen in various hematologic malignancies (leukemia), infections (pneumocystis pneumonia), and inhalation of toxic dusts (silica, aluminum) or following allogeneic bone marrow transplantation. Acquired or idiopathic forms of PAP may represent an autoimmune disease, with neutralizing antibodies directly targeting GM-CSF playing a role in its pathogenesis. Patients with PAP present with progressive dyspnea on exertion, malaise, low-grade fever, and cough. Chest radiograph typically reveals bilateral perihilar opacities. CT scan may show thickening of the intralobular and interlobular septae, creating a pattern referred to as *crazy paving*, which is a nonspecific finding because it is seen in many other diseases of the lung. Bronchoalveolar lavage fluid can establish the diagnosis because the lavage fluid has a milky, opaque appearance that contains large “foamy” alveolar macrophages with few inflammatory cells. Asymptomatic patients and those with mild symptoms require no immediate treatment. Whole-lung lavage is indicated for patients with hypoxemia or severe dyspnea and, in up to 40% of patients, may be required only one time. GM-CSF administration in patients with acquired PAP may be beneficial, but less so than whole-lung lavage.

Prospectus for the Future

Sensitive and specific noninvasive methods are needed for the early identification of ILDs when attempts at preventing progression of lung fibrosis are likely to be more effective. IPF, the most common of the IIPs, is almost invariably fatal, and current treatment strategies are ineffective. Several clinical trials are examining the effectiveness of novel drugs in its treatment, including anti-TNF- α agents, endothelin receptor antagonists, and antioxidants. The National Institutes of Health have established the *Idiopathic Pulmonary Fibrosis Clinical Research Network* to accelerate discovery. However, much confusion about this disease remains in the community, and educational strategies will be needed to accelerate diagnosis. Sarcoidosis is another enigmatic disease that, when progressive, is largely unresponsive to current treatment strategies. Small studies suggest agents capable of immunomodulation might be useful, but further work is needed in this area. The advent of new technology able to evaluate genetic abnormalities related to

disease has unveiled gene polymorphisms associated with IPF and sarcoidosis, among other ILDs. However, the true role of these abnormalities in causing the disease remains unclear, and the ability to exploit this information for early detection of disease is still limited. Interesting research is ongoing related to less common ILDs such as lymphangioleiomyomatosis, which affects women of childbearing age, and is focusing on the intracellular pathways that lead to cellular dysfunction in these disorders. Further work in this area and in the detection of the environmental hazards responsible for ILD is desperately needed. Until new and effective treatment strategies are generated, lung transplantation represents the only hope for an increasing number of patients with fibrosing ILDs. Therefore, efforts to extend life in lung transplant recipients are underway, particularly those targeting chronic rejection and bronchiolitis obliterans, the main cause of death in this population.

Pulmonary Vascular Disease

Sharon Rounds

Pulmonary vascular diseases are a heterogeneous group of disorders with multiple causes. Pulmonary vascular disorders are caused by conditions that directly affect the pulmonary vessels, as in idiopathic pulmonary arterial hypertension (IPAH), or by disorders outside of the lung, as in pulmonary hypertension associated with lung disease and hypoxemia. The World Health Organization classification of pulmonary hypertensive disorders is presented in Table 19-1. The main complication of these disorders is the development of pulmonary hypertension, which is defined as mean pulmonary artery pressure over 25 mm Hg at rest or over 30 mm Hg with exercise. Factors that increase pulmonary arterial pressure include cardiac output, left atrial pressure, blood viscosity, and (most importantly) loss of cross-sectional area of the vascular bed, which increases vascular resistance. The loss of a cross-sectional area may be the result of mechanical occlusion, loss of vessels, vascular remodeling, or vasoconstriction. Clinical manifestations of the disease may not be exhibited until late in the course of the disease. This delayed onset occurs because the pulmonary vasculature is a high-flow, low-resistance, highly compliant system with very high capacitance such that it can accept the entire output of the right ventricle with only slight increases in pressure—even when one half of the pulmonary vasculature is removed.

Pulmonary Thromboembolic Disease

Pulmonary thromboembolic disease is a relatively common entity with an incidence ranging from 400,000 to 650,000 patients per year in the United States. Pulmonary thromboembolic disease is usually a complication of venous thrombosis. The deep veins of the femoral and popliteal systems of the lower extremities are most often affected, but right atrial, right ventricular, and upper extremity thromboses can also embolize to the lung. In view of this, predisposing factors for pulmonary embolism are the same as those

for venous thrombosis and include venous stasis, hypercoagulability, and endothelial injury. Congenital or acquired procoagulant disorders (e.g., activated protein C deficiency) are also considered predisposing factors.

After a clot dislodges from the lower extremity circulation, it travels to the pulmonary circulation, where it can obstruct a branch of the pulmonary artery. The affected lung segment develops an increased ventilation-perfusion ratio (\dot{V}/\dot{Q}). This increases overall dead space ventilation, which leads to an inefficient excretion of partial pressure of carbon dioxide in arterial blood (P_{aCO_2}). In addition, blood flow is shifted from the obstructed site to other areas, which may include areas of low \dot{V}/\dot{Q} , thereby leading to shunting and hypoxemia. Pulmonary infarction of the area distal to the occlusion is rare because of the redundancy of the pulmonary circulation and because of oxygenation of lung parenchyma by bronchial arteries and by alveolar oxygen.

CLINICAL PRESENTATION

The classic presentation of acute pulmonary embolism includes acute shortness of breath accompanied by chest pain, hemoptysis, severe hypoxemia, and circulatory collapse as a result of shock. However, more often than not, the presentation is subtle, and the diagnosis might be difficult to make without a high level of suspicion, particularly in young individuals with otherwise healthy lungs. Dyspnea on exertion and atypical chest pain might be the only symptoms on initial presentation. Therefore, a careful history is paramount when evaluating patients for thromboembolic disease, especially those at high risk for this disorder as a result of stasis, malignancy, and previous history of venous thrombosis as well as other risk factors. The physical examination might reveal abnormalities in lung auscultation ranging from isolated crackles to diffuse wheezing. Pleural effusions might be underlying areas of dullness to percussion during the physical examination. Edema of the extremities, especially if the edema is asymmetrical, might point to venous thrombosis. In deep vein thrombosis, dorsiflexion of

Table 19-1 World Health Organization Classification of Pulmonary Hypertension

Group I. Pulmonary Arterial Hypertension

- Idiopathic (primary)
- Familial
- Related conditions, e.g., collagen vascular disease, portal hypertension, systemic-to-pulmonary shunts, HIV infection
- Associated with significant venous or capillary involvement: pulmonary veno-occlusive disease and pulmonary-capillary hemangiomatosis
- Persistent pulmonary hypertension of the newborn

Group II. Pulmonary Venous Hypertension

- Left-sided atrial or ventricular heart disease
- Left-sided valvular heart disease

Group III. Pulmonary Hypertension associated with Hypoxemia

- Chronic obstructive pulmonary disease
- Interstitial lung disease
- Sleep-disordered breathing
- Alveolar hypoventilation disorders
- Chronic exposure to high altitude
- Developmental abnormalities

Group IV. Pulmonary Hypertension Due to Chronic Thrombotic Disease, Embolic Disease, or Both

- Thromboembolic obstruction of proximal pulmonary arteries
- Thromboembolic obstruction of distal pulmonary arteries
- Pulmonary embolism (tumor, parasites, foreign material)

Group V. Miscellaneous

- Sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangiomatosis, compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

the foot may cause calf pain as a result of stretching the calf muscles and deep veins (Homan sign). Signs of pulmonary hypertension and right ventricular strain, such as increased pulmonary component of the second heart sound or right ventricular heave, are not usually appreciated unless there is a massive pulmonary embolus or preexisting heart or lung disease.

EVALUATION

In severe cases, arterial blood gas measurement may show acidemia, hypoxemia, and hypercapnia, but subtle changes such as mild alkalosis might be the only abnormalities. A normal Paco_2 in a patient with tachypnea and presumably hyperventilation suggests increased dead space and, in the appropriate setting, might point to the diagnosis. However, a normal alveolar-arterial oxygen-tension gradient ($A-a\text{DO}_2$) does not exclude acute pulmonary embolism. An elevated level of lactic dehydrogenase (LDH) might be the result of tissue infarction, but this test is also insensitive and nonspecific. Some have advocated the use of plasma D-dimer levels in patients who might have pulmonary thromboembolism, but these are not specific either because they are elevated in patients with several unrelated medical conditions such as congestive heart failure, chronic illness, and connective tissue disorders. The main usefulness of plasma D-dimer levels is its negative predictive value.

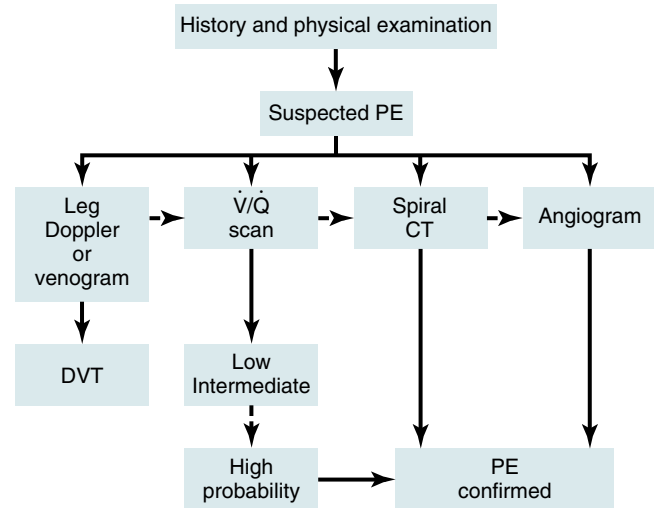

Figure 19-1 Tests commonly used in the evaluation of patients who may have pulmonary embolism (PE). Doppler ultrasound or venogram of the leg is useful to evaluate deep vein thrombosis (DVT). Ventilation-perfusion (V/Q) scans are most useful when they are normal or show lesions highly suggestive of intravascular clot. Unfortunately, these findings are not the case in many patients, requiring further investigation. Spiral computed tomography (CT) has high sensitivity and specificity and allows for the evaluation of thoracic structures in addition to assessing the vasculature. Angiography is considered the gold standard, but it is often not needed if other noninvasive tests are used alone or in combination.

The electrocardiogram may show atrial tachyarrhythmias or evidence of right heart strain as evidenced by a new right bundle branch block, right ventricular strain pattern, and the $S_1Q_{III}T_{III}$ pattern that mimics inferior myocardial infarction. The chest radiograph is often normal but may show atelectasis, isolated infiltrates, or a small pleural effusion. Oligemia (Westermark sign), an abrupt cutoff of pulmonary vessels or enlarged central pulmonary arteries (Fleischer sign), and pleural-based area of increased opacity (Hampton hump) might also be noted. Independent of these findings, chest radiographs are not sensitive enough to diagnose pulmonary embolism. Three diagnostic methods are used for the diagnosis of pulmonary embolism: the \dot{V}/\dot{Q} scan, chest computed tomography (CT), and pulmonary arteriography (Fig. 19-1). The \dot{V}/\dot{Q} scan compares lung ventilation by radiolabeled tracer gas with lung perfusion by radiolabeled micro-occlusive particles. The usefulness of the \dot{V}/\dot{Q} scan depends greatly on the pre-test probability of the disease, which, in turn, is dependent on the expertise of the clinician and his or her level of certainty. A *high-probability* \dot{V}/\dot{Q} scan is characterized by lobar or multilobar perfusion defects that coincide with areas of normal or relatively normal ventilation and is more than 90% accurate in diagnosing pulmonary embolism. A *normal* \dot{V}/\dot{Q} scan shows no perfusion or ventilation defects and can exclude pulmonary embolism in essentially all cases. However, the test is less reliable when interpreted as *low*, *intermediate*, or *indeterminate* probability. Under such circumstances, pulmonary embolism is likely in between 4% and 66% of patients (Table 19-2), and further testing is necessary for an accurate diagnosis of pulmonary embolism.

Table 19-2 Pulmonary Embolism Likelihood Using Clinical Suggestion and Ventilation-Perfusion Scan

Scan Result	Clinical Probability			All
	80%-100%	20%-79%	0%-19%	
High	96	88	56	87
Intermediate	66	28	16	30
Low	40	16	4	14
Normal	0	6	2	4
All scans	68	30	9	28

Data from The PIOPED Investigators: Value of ventilation/perfusion scan in acute pulmonary embolism: Results of the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED). *JAMA*;263:2753-2759, 1990.

Spiral CT angiography provides a noninvasive and sensitive way to evaluate for pulmonary emboli (**Web Fig. 19-1**). Pulmonary arteriography is the gold standard and should be considered in patients without contraindications to the procedure when other tests are inconclusive and a high likelihood of pulmonary embolism exists. Although complication rates related to this procedure are low, the complications are significant if developed, ranging from pulmonary hypertension and sudden death to idiosyncratic hypersensitivity reactions to dye. For this reason, many clinicians rely on a combination of interventions to arrive at the diagnosis, particularly when pulmonary tests are combined with tests that evaluate the deep veins of the lower extremities such as venography and Doppler ultrasound.

MANAGEMENT

Pulmonary embolism is treated with supportive measures directed at sustaining organ function (e.g., fluid replacement for hypotension, mechanical ventilation for respiratory failure). To date, the only mechanical way to dislodge reliably a pulmonary artery clot is with surgical thromboembolectomy, a procedure with high mortality that requires a high level of expertise. Thromboembolectomy is only used for proximal clots that are long-standing (*chronic thromboembolism syndrome*). Consequently, medical treatments are preferred, and these are directed to prevent further clotting or to dissolve an existing clot. Anticoagulation with regular or low-molecular-weight heparin is recommended in patients without major contraindications to anticoagulation (e.g., upper gastrointestinal bleeding, hemorrhagic stroke). Their administration through subcutaneous injection appears to be as efficient as intravascular administration. The use of thrombolytic medications (e.g., tissue plasminogen activator) is usually reserved for patients with increased risk for mortality as a result of circulatory collapse caused by obstruction to the flow in large or multiple pulmonary vessels.

Idiopathic Pulmonary Arterial Hypertension

IPAH is an uncommon disorder that is progressive and usually fatal without treatment. The median survival after

the diagnosis of the disease is about 3 years without treatment. Variables associated with poor survival include heart failure, Raynaud phenomenon, elevated right atrial pressure, significantly elevated mean pulmonary arterial pressure, and decreased cardiac index. The peak incidence of IPAH is between the ages of 20 and 45 years, and it affects women more frequently than men. The cause of IPAH is unknown. However, some cases occur in families, termed *familial pulmonary arterial hypertension* (FPAH). The genetic cause of FPAH has been determined and is due to mutations in bone morphogenetic protein receptor type 2 and related receptors in the transforming growth factor- β family. Some cases of pulmonary arterial hypertension are associated with other disorders, such as HIV infection, scleroderma, hepatic cirrhosis, and anorectic drug use (see Table 19-1).

The histologic characteristics of IPAH are changes in both the arterial and venous systems. The arteries are more commonly affected, with changes in intima, media, and adventitia. There is medial vascular smooth muscle hypertrophy, adventitial thickening, and in situ thromboses of small pulmonary arteries. Plexogenic pulmonary arteriopathy is the classic pathologic finding in pulmonary arterial hypertension, consisting of medial hypertrophy, intimal proliferation and fibroelastosis, and necrotizing arteritis. The plexiform lesion is an abnormal proliferation of pulmonary endothelial cells with slitlike channels (**Web Fig. 19-2**).

Like pulmonary thromboembolism, the clinical presentation of IPAH can be subtle. The usual symptoms are dyspnea on exertion or chest pains, not typical of angina pectoris. In more severe cases, patients may present with syncope on exertion caused by inability of the restricted pulmonary circulation to accommodate increased cardiac output with exercise. Chest radiographs may reveal prominent pulmonary arteries or right ventricular enlargement (**Web Fig. 19-3**). Pulmonary function tests are usually normal, with the exception of decreased diffusing capacity, reflecting the restricted circulation and decreased surface area available for gas exchange. Indeed, the diagnosis of IPAH is dependent on exclusion of other underlying heart or lung diseases that might result in pulmonary hypertension. Echocardiogram is useful to exclude heart diseases that increase pulmonary venous pressures (e.g., mitral valve stenosis). In addition, echocardiogram may reveal enlarged right atrial and right ventricular cavity size and encroachment of the interventricular septum on the left ventricle (**Web Fig. 19-4**). Furthermore, echocardiogram may be used to estimate the level of pulmonary artery systolic pressure. The definitive diagnosis of IPAH requires right heart catheterization with measurement of pulmonary artery pressures and resistance.

Modern treatment of IPAH improves survival and includes drugs with vasodilator activity such as calcium channel blockers and prostacyclin. Because of the potential adverse effects of calcium channel blockers (decreased preload leading to acute hypotension), continuous intravenous prostacyclin is considered the most effective medical treatment. Other vasodilator drugs now available include endothelin receptor antagonists (e.g., bosentan) and drugs increasing cyclic guanosine monophosphate because of phosphodiesterase inhibition (e.g. sildenafil). These oral agents, plus inhaled or subcutaneous prostacyclin preparations, have dramatically enhanced treatment options for

patients with IPAH. In addition to effects on relaxing vascular smooth muscle constriction, vasodilator drugs also appear to stabilize or reverse vascular remodeling in IPAH. Other interventions include supplemental oxygen, anticoagulation, and judicious use of diuretic medications. Heart-lung, double-lung, or single-lung transplantations have been performed in these patients with some success, but the overall 5-year survival rate in all patients undergoing lung transplantation is only 50%.

Secondary Pulmonary Hypertension

As shown in Table 19-1, pulmonary hypertension is also associated with other disorders that increase pulmonary venous pressure (e.g., mitral valve stenosis) and diseases of the lungs associated with hypoxemia (e.g., sleep apnea and chronic obstructive pulmonary disease). These conditions are frequently termed *secondary pulmonary hypertension*. Both vasoconstriction and vascular remodeling contribute to increased pulmonary vascular resistance in secondary pul-

monary hypertension. For example, alveolar hypoxia causes intense pulmonary vasoconstriction. Long-standing hypoxia causes vascular remodeling that is similar to plexogenic pulmonary arteriopathy, but does not include in situ thromboses or formation of plexiform lesions (**Web Fig. 19-5**). Treatment of secondary pulmonary hypertension is directed at the underlying heart or lung disease. If hypoxia is present, home oxygen therapy should be used.

Cor Pulmonale

It is now recognized that the most frequent cause of death in patients with IPAH is right ventricular failure, also termed *cor pulmonale*. Prolonged increased afterload causes the right ventricle to hypertrophy and then dilate. The interventricular septum shifts to the left, and filling of the left ventricle is decreased, with subsequent decreased cardiac output. Dilation of the right atrium causes atrial tachyarrhythmias and further decreased cardiac output. Treatment of cor pulmonale is directed at treatment of the underlying cause of pulmonary hypertension.

Prospectus for the Future

Translational research has markedly enhanced understanding of the pathogenesis of pulmonary hypertensive disorders, and this has resulted in development of therapies that increase quality of life and improve mortality. There is increased appreciation of the role of increased vascular cell proliferation in the development of pulmonary vascular remodeling. In particular, abnormal proliferation of pulmonary endothelial cells and development of plexiform lesions have raised the suggestion that IPAH might be a disease of hyperproliferative pulmonary endothelium. In addition, little is understood regarding the

adaptive changes of the right ventricle to chronically increased afterload. Future investigations are needed to understand and better treat cor pulmonale. In contrast, less new information is available about pulmonary thromboembolic disease. Although new inhibitors of the coagulation cascade are currently under investigation, understanding of the mechanisms that lead to this illness has not dramatically changed during the past decade. Studies are needed in the area of genetic predisposition for thromboembolic disease as well as in vascular dysfunction leading to thrombus formation.

Disorders of Respiratory Control

Sharon Rounds and Matthew D. Jankowich

During the transition between wakefulness and sleep, input from the behavioral control system decreases, the hypoxic drive to breathing is reduced, and the ventilatory response to partial pressure of carbon dioxide in arterial blood (P_{aCO_2}) is diminished. These changes are most dramatic during rapid eye movement (REM) sleep. *Sleep-disordered breathing* refers to a diverse group of conditions in which these physiologic variations are heightened, resulting in abnormal respiratory function and fragmented sleep.

Of the sleep-related disorders, sleep apnea has received the most attention. *Apnea* is defined as the complete cessation of airflow for 10 seconds or longer. *Hypopnea* is a significant decrease in airflow. Occasional episodes of apnea and hypopnea are expected during normal sleep, and their frequency increases with age. However, in patients with sleep apnea, the frequency and duration of the episodes are increased, leading to sleep fragmentation and to hypoxemia and hypercapnia. Upper airway obstruction (i.e., obstructive sleep apnea [OSA]) or decreased central respiratory drive (i.e., central sleep apnea) may be the cause of sleep apnea. In some patients, both disorders are present.

Some studies suggest that the prevalence of sleep-disordered breathing may be as high as 9% in women and 24% in men, but prevalence levels depend on the definition used. Sleep-disordered breathing is usually defined as a respiratory disturbance index or frequency of abnormal respiratory events that number at least five episodes per hour of sleep. Higher prevalence estimates occur in the older adult population, with some studies showing more than 80% prevalence in older patients. Children are also affected, although less frequently (about 2%).

Obstructive Sleep Apnea

OSA is the most common of the sleep apnea syndromes and is considered to affect close to 6% of middle-aged and older men; it is less common in women. In these patients, the upper airway relaxation that occurs during sleep is such that complete occlusion of the airway results, and, consequently,

cessation of airflow occurs. After variable periods of airway occlusion, the patient arouses, re-establishes muscle tone, and opens the airway. This vicious cycle is repeated many times during the night, resulting in recurring episodes of hypoxemia. During airway occlusion, sympathetic tone is increased, resulting in vasoconstriction and hypertension, which persists during the waking hours. Indeed, OSA is the most common identifiable cause of systemic hypertension. With airway occlusion, intrathoracic pressure becomes more negative with inspiration. Episodes of hypoxemia can be associated with bradycardia and cardiac arrhythmias. These events are believed to be linked mechanistically to the increased incidence of stroke and coronary artery disease in patients with OSA. An important physiologic consequence of airway occlusion is arousal from sleep, resulting in fragmented sleep. Because apneas are more frequent during REM sleep, patients complain of lack of refreshing sleep. Patients with OSA have an increased incidence of motor vehicle crashes, presumably related to somnolence while driving. Interestingly, patients with OSA display an increased incidence of diabetes mellitus and other manifestations of the metabolic syndrome. The cardiovascular complications of OSA appear to be at least partially reversible with treatment of OSA.

CLINICAL MANIFESTATIONS

The diagnosis of OSA is suggested when patients complain of morning headaches, recurrent awakenings, and daytime somnolence that affects daytime activities, including driving. Complaints of snoring and gasping episodes may be elicited from sleeping partners. Difficulties in maintaining sleep as a result of frequent awakenings may lead to mood effects and decreased quality of life. Recent weight gain, sedatives and sleeping pills, or alcohol intake may heighten these symptoms.

The primary risk factors for OSA are obesity (although variable) and abnormal upper airway anatomy caused by macroglossia, long soft palate and uvula, enlarged tonsils, or micrognathia. Increased neck diameter (>17 cm in men and

>16 cm in women) may also be noted. A narrow oropharynx as a result of a small pharyngeal opening or redundant soft tissue is often observed. Patients may be hypertensive and, in extreme cases, may show right-sided heart failure, which results as a consequence of prolonged episodes of hypoxemia and pulmonary vasoconstriction leading to pulmonary hypertension.

EVALUATION

Chest radiographic images and pulmonary function testing are usually not helpful in the evaluation of patients with sleep apnea. In some cases, OSA is associated with the obesity-hypoventilation syndrome, which is characterized by significant obesity associated with chronic hypoventilation and hypoxemia (*pickwickian syndrome*). In such cases, arterial blood gases show hypoxemia and hypercapnia, and blood cell counts might suggest polycythemia. Although rare, hypothyroidism, acromegaly, and amyloidosis can cause or enhance OSA, and these conditions should be considered.

A formal diagnosis requires overnight polysomnography during which continuous recordings of electrocardiographic and electroencephalographic tracings are made while the patient sleeps. In addition, airflow, oxygen saturation, and respiratory, eye, chin, and limb muscle movements are monitored and recorded. OSA is diagnosed in sleeping patients (confirmed by the electroencephalographic tracings) who develop cessation of airflow despite repeated muscular efforts to breathe (**Web Fig. 20-1**). These episodes may be accompanied by transient hypoxemia and cardiac arrhythmias. A score is derived from these data that defines clinically significant sleep apnea.

Polysomnography will distinguish OSA from central sleep apnea, during which cessation of airflow is associated with halted respiratory movements. Polysomnography is also important to rule out other sleep disturbances, such as insomnia, narcolepsy, and parasomnias, as well as restless leg syndrome.

Treatment of sleep apnea includes behavioral and medical approaches. When associated with obesity, weight loss should be enthusiastically encouraged. Avoidance of sedatives and alcohol is also important. Airway obstruction can be prevented with the use of continuous positive airway pressure (CPAP) provided through a tightly fitted mask. CPAP maintains positive airway pressure throughout expiration, thereby preventing collapse of the upper airway. The amount of pressure needed can be titrated, and oxygen can be added to further prevent hypoxemic episodes. CPAP is effective in most patients, but compliance with this technique is variable. Surgical removal of obstructing tonsils, adenoids, and polyps or uvulopalatopharyngoplasty may be useful in patients with specific anatomic abnormalities. A permanent tracheostomy may be necessary in severe cases when other approaches fail. However, in general, the surgical

approach to this disorder is limited to select patients only after CPAP has failed.

Other Disorders Related to Respiratory Control

Central sleep apnea is a rare disorder. It predominates in men and is generally associated with normal body habitus. Patients may complain of daytime sleepiness and insomnia with frequent awakenings. This disorder is due to apnea or hypopnea, resulting from decreased central respiratory drive, and may be a consequence of central nervous system injury (i.e., central apnea may be the result of a structural abnormality of the brainstem) or idiopathic. Affected individuals may hypoventilate even while awake, although they are capable of normal voluntary breaths. During sleep, frequent apnea is common.

In patients with obstructive lung disease, increased work of breathing eventually makes it difficult to maintain sufficient ventilation to maintain normal levels of Paco_2 . When ventilatory capacity declines, hypoventilation causes Paco_2 to increase; the kidneys respond by retaining bicarbonate to keep arterial blood pH at normal levels. These patients appear to have normal ventilatory drive, but they lack the ability to increase minute ventilation to meet increased metabolic demand. This characteristic is observed in certain patients with chronic bronchitis who exhibit the classic description of the “blue bloater.”

Lower brainstem and upper pontine lesions may cause *central hyperventilation*. However, this disorder rarely occurs in the absence of other physiologic or chemical abnormalities. Hepatic cirrhosis and extreme anxiety are all causes of central hyperventilation. Pregnancy can also cause hyperventilation and is thought to be caused by elevated levels of progesterone and other hormones that increase central actions. *Apneustic breathing* consists of sustained inspiratory pauses, resulting from damage to the mid-pons, most commonly caused by basilar artery infarction. *Biot respiration* or *ataxic breathing* is a haphazardly random pattern of sleep and is characterized by shallow breaths; a disruption of the respiratory rhythm generator in the medulla causes this sign.

The regular cycling of crescendo-decrescendo tidal volumes, separated by apneic or hypopneic pauses, characterizes *Cheyne-Stokes respiration*. Patients with this disorder usually have generalized central nervous system disease or congestive heart failure. Heart failure prolongs circulatory times, causing a delay between changes in blood gases at the tissue level and the arrival of those changes at the brainstem chemoreceptors. This delay sets up a cycle of gradual increase to hyperventilation, followed by gradually decreasing ventilation to apnea, and then a repetition of the cycle. Recent studies suggest that OSA and Cheyne-Stokes respiration not only are consequences of congestive heart failure but also contribute to progression of CHF.

Prospectus for the Future

With more than 5% of the population in the United States suffering from sleep-disordered breathing, and with the recognition that these disorders may contribute to systemic illnesses such as hypertension and cardiovascular disorders, interest in early diagnosis and treatment of disorders of respiratory control is growing. In view of the high incidence and potential health consequences of sleep-disordered breathing, physicians must be on the lookout for this condition. The increased inci-

dence of OSA parallels that of obesity in the United States, a public health problem that has been associated with asthma and increased risk for death. It is highly likely that genetic predisposition to OSA accounts for increased incidence in some families. Sleep medicine is an emerging clinical and research area that will continue to receive great attention in the coming decade.

Disorders of the Pleura, Mediastinum, and Chest Wall

F. Dennis McCool

Pleural Disease

The pleura is a thin membrane that covers the entire surface of the lung as well as the inner surface of the rib cage, diaphragm, and mediastinum. There are two pleural membranes: the visceral pleura, which covers the lung; and the parietal pleura, which lines the rib cage, diaphragm, and mediastinum. A layer of mesothelial cells lines both pleural surfaces. The closed space in between the surface of the lung and the chest cavity is referred to as the *pleural space*. A small amount of fluid normally resides in this space and forms a thin layer between the pleural surfaces. Pleural fluid serves as a lubricant for the visceral and parietal pleura as they move against each other during inspiration and expiration.

The blood vessels in the visceral pleura are supplied from the pulmonary circulation and have greater hydrostatic pressure than the blood vessels in the parietal pleura, which are supplied by the systemic circulation. The pressure within the pleural space is subatmospheric during quiet breathing. Fluid is filtered from the higher-pressure vascular structures into the pleural space. The normal fluid turnover is about 10 to 20 mL per day with 0.2 to 1 mL remaining in the pleural space. Pleural fluid usually contains a small amount of protein and a small number of cells that are mostly mononuclear cells. Although both the parietal and visceral pleura contribute to pleural fluid formation, most of the fluid results from filtration of the higher-pressure vessels supplying the parietal pleura. After the fluid enters the pleural space, it is drained from the pleural space by a network of pleural lymphatics located beneath the mesothelial monolayer. The lymphatics originate in stomas on the parietal pleural surface. Under abnormal circumstances, fluid can accumulate in the pleural space. Factors that promote the entry of fluid into the pleural space include an increase in systemic venous pressure, an increase in pulmonary venous pressure, an increase in permeability of pleural vessels, or a

reduction in pleural pressure. Conditions that increase hydrostatic pressure can be seen with congestive heart failure; changes in pleural membrane permeability can be seen in varied inflammatory states; and a reduction in pleural pressure can be seen with atelectasis. Occasionally, microvascular oncotic pressure may be sufficiently reduced to promote fluid entry into the pleural space in patients with hypoalbuminemia. Factors that block lymphatic drainage and interfere with the egress of fluid from the pleural space include central lymphatic obstruction or obstruction of lymphatic channels at the pleural surface by tumor.

PLEURAL EFFUSION

Pleural effusion is the accumulation of fluid in the pleural space. Pleural effusions are generally detected by chest radiography; however, the volume of fluid in the pleural space needs to exceed 250 mL to be visualized on a chest radiograph. When an effusion is present, there is blunting of the costophrenic angle on a posteroanterior chest film; this is a fluid meniscus that can be detected posteriorly also on the lateral chest radiograph, and occasionally fluid can be demonstrated in either the minor or major fissures (**Web Figs. 21-1 and 21-2**). Changes in the contour of the diaphragm may signify a subpulmonic effusion. A decubitus chest radiograph can be obtained to determine whether the fluid is free-flowing or loculated. A computed tomography (CT) scan of the chest provides better definition of the pleural space than plain radiography. Chest CT is particularly useful in differentiating pulmonary parenchymal abnormalities from pleural abnormalities, defining loculated effusions, distinguishing between atelectasis and effusion, and distinguishing loculated effusion from lung abscess (**Web Fig. 21-3**). The edge of a lung abscess usually touches the chest wall and forms an acute angle whereas that of an empyema is usually an obtuse angle.

Table 21-1 Pleural Effusions

Transudates	Exudates		
Congestive heart failure	Infection	Systemic lupus erythematosus	Trauma
Hypoalbuminemia	Empyema	Rheumatoid arthritis	Hemothorax
Nephrotic syndrome	Parapneumonic	Intra-abdominal pathologic abnormalities	Chylothorax
Malnutrition	Malignancy	Pancreatitis	Ruptured esophagus
Cirrhosis	Primary lung cancer	Subphrenic abscess	Miscellaneous
Intra-abdominal fluid	Lymphoma	Complications of abdominal surgery	Myxedema
Ascites	Metastatic cancer	Meigs syndrome	Uremia
Peritoneal dialysis	Pulmonary embolism and infarction	Urinothorax	Asbestosis
	Collagen vascular disease		Lymphedema
			Drug-induced lupus
			Dressler syndrome

From Light RW, Macgregor MI, Luchsinger PC, et al: Pleural effusions: The diagnostic separation of transudates and exudates. *Ann Intern Med* 77:507-513, 1972.

Thoracentesis is a procedure in which fluid is aspirated from the pleural space. Ultrasound or a CT scan can be used to help direct the thoracentesis catheter into collections of fluid that are otherwise difficult to drain. Analysis of pleural fluid may provide a definitive diagnosis; however, even without a definitive diagnosis, pleural fluid analysis can be useful in excluding other possible causes of disease such as infection. Classifying pleural effusions as transudates or exudates greatly assists with the differential diagnosis. The general approach to pleural effusions is outlined in **Web Figure 21-4**.

TRANSUDATES

Effusions that accumulate due to changes in osmotic and hydrostatic forces usually have low protein states and are considered transudates (Table 21-1). Congestive heart failure is the most common cause of a transudate. With heart failure, the effusions are typically bilateral. If the effusion is unilateral, it involves the right hemithorax in most instances. Effusions due to heart failure are related to dysfunction of the left side of the heart, not the right side of the heart. Transudative effusions also may be seen in cirrhosis, nephrotic syndrome, myxedema, pulmonary embolism, superior vena cava obstruction, and peritoneal dialysis. In patients with cirrhosis, the effusions are often right sided, and the mechanism may be related to flow from the peritoneal space across diaphragmatic defects into the pleural space. Transudative effusions are typically small and rarely require drainage to improve symptoms.

EXUDATES

Exudative effusions occur when there is an alteration in vascular permeability and can be observed in inflammatory states, with infection, or with neoplasm. To distinguish an exudate from a transudate, one of three criteria must be fulfilled: (1) pleural fluid-to-serum protein ratio is greater than 0.5; (2) pleural fluid-to-serum lactate dehydrogenase (LDH) ratio is greater than 0.6; and (3) pleural fluid LDH is greater than two thirds the upper limit of normal (Table 21-2). When all three criteria are met, the sensitivity, specificity, and predicted value exceed 98% for an exudative effusion. Measuring pleural fluid cholesterol may also help

Table 21-2 Differentiation of Exudative and Transudative Pleural Effusions

	Exudate	Transudate
Protein	>3 g/dL	<3 g/dL
Pleural and serum protein	>0.5	<0.5
LDH	Two thirds the upper limit of normal	Two thirds the upper limit of normal
Pleural and serum LDH	>0.6	<0.6

LDH, lactate dehydrogenase.

Adapted from Light RW, Macgregor MI, Luchsinger PC, et al: Pleural effusions: The diagnostic separation of transudates and exudates. *Ann Intern Med* 77:507-513, 1972.

distinguish an exudate from a transudate. Pleural fluid cholesterol is derived from degenerating cells within the pleural space and from vascular leakage due to increased permeability. A cholesterol level greater than 45 mg/dL is consistent with an exudative effusion.

Exudative effusions are commonly due to infection. Parapneumonic effusion occurs in patients with bacterial pneumonia and can be further classified as uncomplicated or complicated effusions. Uncomplicated parapneumonic effusions are those that do not require drainage and will respond to antibiotic therapy alone for the underlying pneumonia. By contrast, complicated parapneumonic effusions are those that will not respond to antibiotic therapy alone and will require drainage to prevent the formation of empyema. The transition from uncomplicated to complicated can occur extremely rapidly and in some cases within a 24-hour period. Typically, an uncomplicated parapneumonic effusion will have a pH greater than 7.3, a glucose greater than 60 mg/dL, and an LDH less than 1000 IU/L. A pH level of less than 7.2 usually identifies a complicated effusion. However, this finding is not specific for infection and may be due to malignancy, rheumatoid arthritis, or trauma with esophageal disruption causing an associated reduction in pH level. Complicated exudative effusions due to infections need drainage to avoid sepsis and prevent development of loculation, cutaneous fistulas, lung abscess, bronchopleural fistulas, or fibrothorax. The injection of fibrolytic agents into

the pleural space may prevent the occurrence of fibrothorax; however, treatment of complicated pleural effusions may require thoracotomy and decortication. If pus is aspirated from the pleural space, this defines an empyema, which requires immediate drainage.

Pleural effusions secondary to primary tuberculosis may be seen in up to 30% of patients in endemic areas. The effusion is secondary to increased vascular permeability of the pleural membrane because of a hypersensitivity reaction and not due to direct infection. Typically, the pleural fluid is lymphocyte predominant and culture negative for acid-fast bacilli. Adenosine deaminase levels greater than 50 U/L may be helpful in identifying tuberculous pleural effusions. Tuberculous empyema is distinct from tuberculous pleural effusions and can occur when there is an extension of infection from the thoracic lymph nodes into the pleural space or hematogenous spread of tuberculosis to the pleural space.

Malignant effusions are the second most common cause of exudative pleural effusions and imply a poor prognosis. Seeding of the parietal or visceral pleura with malignant cells can change vascular permeability, resulting in effusion formation. However, the finding of a pleural effusion in an individual with malignancy does not necessarily imply that there is a malignant process in the pleural space. Effusions in these individuals may be due to atelectasis, postobstructive pneumonia, hypoalbuminemia, pulmonary emboli, or complications from radiation or chemotherapy. The most common cause of malignant effusion is lung cancer, followed by breast cancer and lymphoma. An effusion that is bloody suggests a malignant process; however, other causes of bloody pleural effusions include trauma, tuberculosis, collagen vascular disease, or thromboembolic disease. To confirm the diagnosis of malignancy, cytologic examination of the fluid is needed. Malignant cells can be seen in 60% of malignant effusions on the first thoracentesis. Sensitivity rises to 80% if three separate samples are obtained. If needed, a biopsy of the pleura may be useful in identifying the presence of malignancy. Biopsies may be obtained with video-assisted thoracoscopy or, less optimally, in a blinded fashion (through a Cope or Abrams needle). A low pleural fluid pH has prognostic and therapeutic implications for patients with malignant effusions. Patients with low pleural fluid pH due to malignancy tend to have shorter survival and poorer response to chemical pleurodesis. Recurrent malignant pleural effusions may improve with chemical pleurodesis with talc or tetracycline derivatives, but effectiveness is variable, achieving a complete response in little more than 50% of patients.

Systemic inflammatory disorders such as rheumatoid arthritis and lupus erythematosus can be associated with exudative effusions. Rheumatoid pleural effusions are a common intrathoracic manifestation of rheumatoid disease and may be seen in as many as 5% of patients. Pleural fluid rheumatoid factor is often greater than 1:320, and pleural fluid glucose is less than 60 mg/dL, or the pleural fluid-to-serum glucose ratio is less than 0.5. However, a low glucose may be present in complicated parapneumonic effusions or empyema, malignant effusion, tuberculosis pleurisy, lupus pleuritis, and esophageal rupture. In systemic lupus erythematosus, 15% to 50% of patients will have pleural effusions. The pleural fluid antinuclear antibody titer is greater than 1:160.

Measuring pleural fluid amylase may further refine the differential diagnosis of an exudative effusion. Finding amylase greater than the upper limits of normal for serum amylase is consistent with acute pancreatitis, chronic pancreatic pleural effusion, esophageal rupture, or malignancy. Pancreatic disease is associated with pancreatic isoenzymes amylase, whereas malignancy and esophageal rupture are characterized by a predominance of salivary isoenzymes.

PNEUMOTHORAX

Pneumothorax is the accumulation of air in the pleural space. In this instance, pleural pressure becomes positive, and there is compression of underlying lung. Patients with pneumothorax typically present with acute onset of dyspnea. Findings include tachycardia, decreased breath sounds, decreased tactile fremitus, a pleural friction rub, subcutaneous emphysema, hyperresonance, and a tracheal shift to the opposite side. Diagnosis can be made by obtaining an upright chest radiograph. Typically, the visceral pleura separates from the parietal pleura, and air can be seen between the visceral pleural lining and the rib cage. An end-expiratory radiograph will increase the density of lung while reducing its volume, thus highlighting the difference between the lung parenchyma and the pleural gas. Management usually requires insertion of a thoracostomy tube and suction followed by water-seal drainage. However, if the pneumothorax is small and the patient is not in distress, observation alone may be indicated. If there is not a continuing air leak, as from a bronchopleural fistula, the pleural air is reabsorbed into the blood with resolution of the pneumothorax. A tension pneumothorax is a medical emergency that requires immediate decompression by placement of a chest catheter. A tension pneumothorax occurs when pleural pressure reaches levels sufficient to cause mediastinal shift, compression of the vena cava and heart, and hemodynamic compromise. Such physiology implies an ongoing leak of air into the pleural space.

Pneumothorax is often associated with blunt or penetrating trauma. With penetrating trauma, air may leak into the pleural space through the chest wall or the lung. Mechanical ventilation has also been associated with pneumothorax. Patients with underlying lung disease receiving mechanical ventilation may acutely develop a pneumothorax. A sudden rise in peak airway pressures with a reduction in breath sounds can alert the clinician to this complication. Pneumothorax also may occur spontaneously or be secondary to underlying lung disease. Typically, spontaneous pneumothorax occurs in tall, young, thin men, presumably a result of rupture of apical blebs. Underlying lung diseases that can be complicated by pneumothorax include emphysema, cystic fibrosis, granulomatous inflammation, necrotizing pneumonia, pulmonary fibrosis, and lung abscess. Catamenial pneumothorax occurs in patients who have subpleural and diaphragmatic endometriosis; rupture of the endometrial nodules at the time of menstruation causes pneumothorax.

MESOTHELIOMA

Malignant mesotheliomas are neoplasms arising from the serosal membranes of the body cavities. Eighty percent of

mesotheliomas originate in the pleural space. Generally, individuals are older than 55 years, and there is an association with asbestos exposure in the distant past. Symptoms include shortness of breath, chest pain, and weight loss. The most common radiologic presentation is a large unilateral pleural effusion that may completely opacify the hemithorax. There may be circumferential pleural thickening, usually associated with various amounts of calcified pleural plaque and effusions. CT of the chest is the most accurate noninvasive method for assessing stage and progression of mesothelioma. The diagnosis requires a biopsy; the most efficient way of obtaining tissue is by thoracoscopy. The overall prognosis for patients with malignant mesothelioma is poor. No particular therapy has emerged as superior to supportive therapy alone in terms of survival.

Mediastinal Disease

The mediastinum is the central part of the thoracic cavity between the lungs that contains the heart and aorta, esophagus, trachea, lymph nodes, and thymus. The mediastinum is bordered by the two pleural cavities laterally, the diaphragm inferiorly, and the thoracic inlet superiorly. The mediastinal space can be divided into three compartments: anterior, middle, and posterior. The localization of mediastinal masses into one of these compartments assists in the differential diagnosis (Fig. 21-1).

The anterior mediastinal compartment is anterior to the pericardium and includes lymphatic tissue, thymus, and the great veins. Lesions most commonly found in the anterior mediastinum are thymomas, germ cell tumors, lymphomas, intrathoracic thyroid tissue, and parathyroid lesions. Thymomas consist of 20% of mediastinal neoplasms in adults, and they are the most common anterior mediastinal primary neoplasm in adults. Symptoms due to myasthenia gravis may be present in one third of patients with thymoma. Patients with systemic lymphoma often have involvement of the mediastinum. However, 5% to 10% of patients with lymphoma present with primary mediastinal lesions. Posterior mediastinal masses include neurogenic tumors and cysts, meningocele, lymphoma, aneurysm of the aorta, and esophageal disorders such as diverticula and neoplasm. Cysts found in the mediastinum include pericardial cysts, bronchogenic cysts, enteric cysts, thymic cysts, and thoracic duct cysts. All these are benign but can produce compressive symptoms. Lung cancer can present with mediastinal adenopathy, a sign of unresectable disease (**Web Fig. 21-3**). The treatment of a mediastinal mass depends on the underlying pathology. For example, some require surgical resection, others radiation or chemotherapy, and some can be monitored over time.

MEDIASTINITIS

Inflammation of the mediastinal structures can be acute or chronic. Acute mediastinitis is a rapidly progressive condition secondary to infection and can be iatrogenic secondary to invasive procedures resulting in esophageal or tracheobronchial rupture or occur as a result of trauma and tissue necrosis. Chest imaging studies may show a widening of the mediastinum, pneumothorax, or hydrothorax. Treat-

Figure 21-1 Masses of the mediastinum and their anatomic location.

ment requires antibiotics, pleural drainage, and mediastinal evacuation. Chronic mediastinitis (fibrosing mediastinitis) is a progressive illness that is due to granulomatous infections, neoplasm, radiotherapy, or occasionally drugs such as methysergide, or is idiopathic. Patients usually remain asymptomatic until vascular or neurologic structures are affected. Superior vena cava syndrome may be a consequence of chronic mediastinitis. Diagnosis and treatment often require surgical exploration.

Chest Wall Disease

The chest wall is composed of the bony structures of the rib cage, the articulations between the ribs and the vertebrae, the diaphragm, and other respiratory muscles. Normal function of this “ventilatory pump” is needed to bring oxygen from the atmosphere into the body. A wide variety of chest wall and neuromuscular disorders can result in dysfunction of the ventilatory pump. These disorders typically result in a restrictive dysfunction characterized by a reduction in total lung capacity and vital capacity with a normal residual volume. Hypoventilation may ensue resulting in hypercapnia, atelectasis, and hypoxemia.

SKELETAL DISEASE

Kyphoscoliosis and ankylosing spondylitis are disorders that involve the spine and its articulations; pectus excavatum involves the sternum, flail chest affects the ribs, and obesity

Figure 21-2 Schematic depicting the lines constructed to measure the Cobb angle of scoliosis (A) and kyphosis (B).

adds to the soft tissue mass of the ribcage and abdomen. These disorders primarily affect the respiratory system by stiffening the chest wall. Of these disorders, kyphoscoliosis produces the most severe restrictive impairment. Kyphoscoliosis refers to a group of disorders characterized by excessive spinal curvature in the lateral plane (scoliosis) and sagittal plane (kyphosis). The degree of curvature can be assessed by measuring the Cobb angle (Fig. 21-2). Greater degrees of spinal curvature are associated with greater restriction and an increased risk for respiratory failure. Kyphoscoliosis may be due to neuromuscular disease, associated with congenital vertebral malformations, or idiopathic. Idiopathic kyphoscoliosis is the most common form, usually manifesting in late childhood or early adolescence and affecting females more than males (ratio of 4:1). It is thought to be a multi-gene condition with autosomal or sex-linked inheritance and variable phenotypic expression. A defect in the chromatin-remodeling gene family (*CHD-7*) has been associated with idiopathic kyphoscoliosis.

Factors that contribute to respiratory failure in these patients are inspiratory muscle weakness, underlying neuromuscular disease, sleep disordered breathing, and airway compression due to distortion of lung parenchyma and twisting of airways. Treatment consists of general supportive measures such as immunizations against influenza and pneumococci, smoking cessation, maintenance of a normal body weight, supplemental oxygen, and treatment of respiratory infections. Nocturnal hypoventilation can be treated with noninvasive positive-pressure ventilation, which is typically delivered through a nasal or full facemask. Indications for instituting noninvasive ventilation include symptoms suggestive of nocturnal hypoventilations, signs of cor pulmonale, nocturnal oxymoglobin desaturation, or an elevated daytime Paco_2 .

OBESITY

Obesity is a major health problem throughout the world affecting both children and adults. Body fat usually constitutes 15% to 20% of body mass in healthy men and 25% to 30% of body mass in healthy women. In obesity, the body fat content may increase by as much as 500% in women and 800% in men. The degree of obesity can be assessed by the body mass index, which is the ratio of body weight (BW) in kilograms to the square of the height (Ht) in meters ($\text{BW}/$

Ht^2). Individuals with a BMI between 18.5 and 24.9 kg/m^2 are normal, and those with a BMI greater than 30 kg/m^2 are considered severely or morbidly obese. Reductions in functional residual capacity and expiratory reserve volume are the most common pulmonary function abnormalities in obesity. When obesity is associated with hypoventilation, it is termed the *obesity-hypoventilation syndrome* (pickwickian syndrome). The most important consequence of this is chronic hypoventilation and pulmonary hypertension. Nocturnal noninvasive positive-pressure ventilation can be helpful in reversing these abnormalities. Weight loss is the optimal therapy but is not always attainable, and long-term weight loss maintenance is even more difficult. Pharmacotherapy or bariatric surgery should be considered in obese individuals who do not achieve weight control with conventional therapy (diet, enhanced physical activity, and behavioral therapy).

DIAPHRAGM PARALYSIS

The diaphragm separates the thorax from the abdomen and is the major muscle of inspiration. Diaphragm weakness or paralysis can involve either one or both hemidiaphragms. Unilateral diaphragm paralysis is more common than bilateral diaphragm paralysis. The most frequent causes of unilateral paralysis include traumatic phrenic nerve injury, herpes zoster, cervical spinal disease, and compressive tumors. Patients may be asymptomatic, or the abnormality may be discovered as an incidental finding of an elevated hemidiaphragm on chest radiograph. Diagnosis is confirmed by noting paradoxical upward motion of the affected diaphragm during a vigorous sniff maneuver with fluoroscopy. There is no specific treatment for this disorder, but recovery following the initial injury is occasionally seen. When disabling symptoms are present and there is significant elevation on chest radiograph, surgical plication of the diaphragm has been attempted with some success.

Bilateral diaphragm paralysis is most often seen in the setting of a disease producing generalized muscle weakness or motor neuron disease such as amyotrophic lateral sclerosis. Orthopnea is an especially prominent symptom, and patients often have difficulty sleeping in the supine position. Pulmonary function tests are associated with severe restrictive impairments. When assuming the supine position, there may be a further reduction in vital capacity by as much as 50%. Bilateral diaphragm paralysis can be difficult to diagnose. Finding low lung volumes is often attributed to a poor inspiratory effort, and fluoroscopic sniff testing can yield false-negative results as well as false-positive results. Measurement of transdiaphragmatic pressure is reliable; however, this is somewhat invasive requiring placement of catheters in the esophagus and stomach. Alternatively, B-mode ultrasound of the diaphragm in the zone of apposition is a noninvasive means of diagnosing diaphragm paralysis. Bilateral diaphragm paralysis may not be reversible unless the underlying disease is treatable; however, recovery has been noted in more than 50% of individuals with idiopathic diaphragm paralysis or paralysis due to neuralgic amyotrophy (brachial plexus neuritis) in small series. Nocturnal hypoventilation can be treated with noninvasive positive pressure ventilation.

Prospectus for the Future

Numerous advances can be expected in treating individuals with pleural, mediastinal, and chest wall diseases. Recent progress in pleural fluid analysis using novel biomarkers and nucleic acid amplification tests may lead to more rapid and accurate diagnosis of tuberculous pleural effusions. Assays of pleural fluid tumor markers and chromosome analysis are promising developments in attempts to differentiate malignant and nonmalignant effusions. Mesothelioma remains resistant to traditional therapeutic approaches; however, evolving technology centered on gene therapy may constitute a new treatment modality. Better visualization of mediastinal structures will be achieved as magnetic resonance imaging (MRI) evolves and becomes more routinely applied to examine the chest. Molecular tracers targeting tumor receptors or proteins may be

used with MRI and positron-emission tomography imaging techniques to better differentiate between malignant and benign mediastinal masses. Noninvasive nocturnal ventilation remains a cornerstone of therapy in patients with chest wall and neuromuscular diseases, but compliance can be problematic. Continued evolution of techniques to deliver nocturnal noninvasive ventilation may improve compliance with treatment, and application of this technique to patients with obesity-hypoventilation syndrome may reduce morbidity and mortality in these individuals. Patients with diaphragm paralysis due to high cervical spinal cord lesions may benefit from recent advances in intramuscular diaphragm pacing. This technique may provide an alternate means of treating respiratory failure in these individuals and others with diaphragm paralysis.

Infectious Diseases of the Lung

Brian Casserly and Sharon Rounds

Pneumonia is defined as infection of the lower respiratory tract parenchyma by agents such as bacteria, viruses, fungi, or even parasites. It should be distinguished from pneumonitis, which is an inflammation of the lungs from a variety of noninfectious causes, including chemicals, blood, radiation, and autoimmune processes. Pneumonia, the sixth leading cause of death in the United States, is responsible for 4 to 10 million respiratory infections each year.

Microbial agents can be introduced to the lungs through several routes. The most common route is by aspiration of oropharyngeal secretions. *Legionella* species, mycobacteria, endemic fungi, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and most viral infections are examples of pneumonia caused by direct inhalation of organisms, resulting in geographic and seasonal clustering of cases. Much less commonly, pneumonia can arise from hematogenous or embolic spread of infection from infected heart valves or venous clot. The small vessels of the pulmonary circulation act as filters for venous blood carrying small clusters of bacteria from the source. Hematogenous pneumonias, therefore, are often multifocal with peripheral lesions susceptible to rapid cavitation.

Diagnosis and therapy are dependent on clinical, imaging, and laboratory data. Patients usually exhibit respiratory symptoms, including productive cough, dyspnea, chest pain, and occasionally hemoptysis. Other, less specific symptoms include fever, general malaise, myalgias, and weight loss. The presentation may be acute (days to weeks), as observed in bacterial pneumonia, or subacute or chronic (weeks to years), as observed with tuberculosis (TB). Immunocompromised patients (e.g., those with human immunodeficiency virus [HIV] infection), may be predisposed to specific illnesses, and knowledge of the specific impairment in host defense mechanisms may help determine the cause of the infection.

The chest radiograph plays an important role. A parenchymal opacity is observed in the patient with pneumonia (Web Fig. 22-1); however, noninfectious disorders that

mimic pneumonia exist, and no radiographic finding is entirely specific for infection.

The initial antibiotic choice may be guided by Gram stain of respiratory secretions. This requires the demonstration of a satisfactory sputum sample (defined as >25 polymorphonuclear leukocytes and <10 epithelial cells in each low-power field) and the presence of a predominant organism (>8 to 10 organisms per high-power field), particularly if the same bacteria are found within white blood cells. However, despite extensive laboratory testing, a causative organism can be identified in only about 50% of all pneumonia cases. See Table 22-1 for the most common causative agents of pulmonary infections.

Clinical guidelines have been developed to provide a systematic approach to the diagnosis and management of pneumonia. A key question that should be asked in the initial evaluation of pneumonia is whether the pneumonia is community acquired or health care associated.

Community-Acquired Pneumonia

Community-acquired pneumonia occurs twice as frequently during winter, and those at the extremes of age (<5 years and >65 years) are at increased risk. *Streptococcus pneumoniae* is the most common causative agent. *S. pneumoniae* is a gram-positive, diplococcal bacterium whose encapsulated structure protects it from host defense. Patients may have an antecedent upper respiratory tract infection, followed by the sudden onset of fever, shaking chills, dyspnea, and pleurisy. Cough productive of purulent, rust-colored sputum is common. Imaging studies show alveolar consolidation. Sputum Gram stain is positive in only 45% of bacteremic cases. Therefore, the diagnosis is confirmed by culture of the organism from a usually sterile site, such as blood, pleural fluid, or cerebrospinal fluid. In many cases, the diagnosis is presumptive, and recommended antibiotic coverage for

Table 22-1 Organisms Causing Pulmonary Infections

Pathogen	Community Acquired	Nosocomial
Bacterial	70%-80%	90%
<i>Streptococcus pneumoniae</i>	60%-75%	3%-9%
<i>Haemophilus influenzae</i>	4%-5%	
<i>Legionella</i> sp.	2%-5%	Up to 25%
<i>Staphylococcus aureus</i>	1%-5%	10%-20%
Gram-negative bacilli	Rare	50%
Atypical	10%-20%	Rare
<i>Mycoplasma pneumoniae</i>	5%-18%	—
<i>Chlamydia psittaci</i>	2%-3%	—
<i>Coxiella burnetii</i>	1%	—
Virus	10%-20%	Rare
Influenza virus	—	8%
Hantavirus	—	Rare

Adapted from Modai J: Empiric therapy of severe infections in adults. Am J Med 88:125-175, 1990.

community-acquired pneumonia is designed to cover this organism (see later).

M. pneumoniae is a slow-growing, facultative anaerobic organism that accounts for 25% to 60% of all atypical pneumonias. *M. pneumoniae* is a common cause of pneumonia in patients between the ages of 5 and 35 years who may initially exhibit upper respiratory tract symptoms, pharyngitis, and bullous myringitis. Dry cough, fever, gastrointestinal symptoms, headache, and myalgias are common. Uncommon complications include cold agglutinin–induced hemolysis, hepatitis, erythema multiforme, the syndrome of inappropriate antidiuretic hormone, pericarditis, myocarditis, and neurologic abnormalities. The chest radiograph may show fine interstitial reticulonodular infiltrates in patients, which are often relatively asymptomatic. The diagnosis is based on clinical and epidemiologic features. Acute and convalescent serologic findings are required to confirm the diagnosis, but are not helpful during the acute illness.

Other common causes of community-acquired pneumonia are *C. pneumoniae* and *Haemophilus influenzae*. Patients with co-morbid conditions and those older than 65 years are also at risk for pneumonia from *Legionella* species, *Staphylococcus aureus*, and gram-negative organisms. Anaerobic infection should be considered when large amounts of oropharyngeal secretions are aspirated and in patients with chronic infections in the gingivodental crevice.

Diagnostic tests for community-acquired pneumonia should include a chest radiograph and complete blood count. The role of routine sputum and blood cultures in this setting is controversial. The recommended treatment for community-acquired pneumonia is a course (7 to 10 days) of a macrolide antibiotic (erythromycin, clarithromycin, or azithromycin). If there are co-morbidities such as chronic heart or lung disease, an extended spectrum fluoroquinolone (e.g., levofloxacin, moxifloxacin, or gemifloxacin) or a β lactam (amoxicillin) plus a macrolide should be used. The choice of treatment should also be influenced by local antibiotic resistance patterns.

An important decision in the care of community-acquired pneumonia is whether the patient requires hospital admission. This decision should take into consideration the known risk factors for increased mortality from pneumonia. These include age 65 years or older; the presence of co-morbidities such as diabetes mellitus, renal, or congestive heart failure; altered mental status; tachycardia (>125 beats per minute); tachypnea (>30 breaths per minute); high fever (>38.3° to 40° C); hypotension (systolic blood pressure < 90 mm Hg); hypoxia (SaO_2 < 90% or Pao_2 < 60 mm Hg); multilobar involvement on chest radiograph; and identification of high-risk pathogens such as gram-negative organisms and *S. aureus*. For hospitalized patients, initial therapy for community-acquired pneumonia usually includes a cephalosporin such as ceftriaxone or cefuroxime, with or without a macrolide. Antibiotic treatment should be given as soon as possible because mortality can increase even after a short delay (>8 hours) in receiving appropriate antibiotics. Sputum and blood cultures should be obtained before instituting antibiotic therapy.

Nosocomial Pneumonia

Nosocomial pneumonia is pneumonia that occurs after hospitalization. Nosocomial pneumonia is subdivided into three categories: hospital-acquired pneumonia (HAP); ventilator-associated pneumonia (VAP); and health care–associated pneumonia (HCAP). HAP is defined as pneumonia that occurs 48 hours or more after admission and that did not appear to be incubating at the time of admission. VAP is a type of HAP that develops more than 48 to 72 hours after endotracheal intubation. HCAP is defined as pneumonia that occurs in a nonhospitalized patient with extensive health care contact. This includes recent hospitalization, residence in a nursing home or other long-term care facility, and recent intravenous therapy. These patients should be considered at high risk for resistant organisms and therefore inappropriate for routine, empirical therapy for community-acquired pneumonia.

Nosocomial pneumonia is the second most common infection in hospitalized patients and the most common infection in the intensive care unit. The pathogenesis of nosocomial pneumonia is based on colonization of the oropharynx and stomach with virulent pathogens and the subsequent aspiration of these organisms into the lower respiratory tract. Gastric colonization by gram-negative organisms is enhanced by neutralization of gastric acidity. In the first 5 days of hospitalization, *H. influenzae*, *S. pneumoniae*, and *S. aureus* are often isolated. After this time, pneumonia is often caused by *Pseudomonas aeruginosa*, *S. aureus*, anaerobic microbes, *Acinetobacter* species, and various gram-negative enteric bacilli. This finding has important therapeutic implications because these organisms are more commonly associated with multidrug antibiotic resistance. Treatment is dependent on combined chemotherapy with β lactam antipseudomonal penicillin or cephalosporin, together with an aminoglycoside or a quinolone. Vancomycin is added if methicillin-resistant *S. aureus* is suspected. A more definitive identification of organisms and their sensitivity to antibiotics is often sought in these patients using more invasive measures, including endotracheal

aspirate in intubated patients or flexible fiberoptic bronchoscopy. However, the best predictor of patient outcome with nosocomial pneumonia appears to be adequacy of the initial empirical antibiotic regimen.

Complications of Pneumonia

Parapneumonic effusion is a neutrophilic exudative effusion adjacent to a lung with pneumonia (**Web Fig. 22-2**). It can resolve with antibiotics alone or can require drainage in addition to antibiotics. As a pneumonia progresses, inflammatory pulmonary liquid leaks into the pleural space, first appearing as an uncomplicated effusion. At this point, the effusion will resolve with antibiotic therapy alone. As bacteria and inflammatory cells follow, the inflammatory process is marked by anaerobic metabolism, cytokine production, fibrin deposition in the pleural space, and thickening of the pleura. There is no universally accepted definition of *empyema*. However, most clinicians include in the term *empyema* all pleural effusions that are grossly purulent or contain microorganisms identified by a positive Gram stain or culture. *Empyema* must always be treated with pleural drainage, usually by a chest thoracostomy tube. Highly inflammatory parapneumonic effusions may behave as if they are infected, although microorganisms are never identified. There have been effusions described as “complicated” parapneumonic effusions, and these are identified clinically by a pH of less than 7.1 and a glucose level of less than 40 mg/dL. It is important to recognize that complicated effusions generally require drainage in addition to antibiotic therapy.

The major risk factor for the development of *lung abscess* is aspiration resulting in a more indolent, polymicrobial infection, usually involving both aerobes and anaerobes. Conditions predisposing patients to aspiration, such as alcoholism, seizures, or stroke, are associated with an increased incidence of lung abscess. The presence of poor dentition increases the anaerobic bacterial load in the mouth and thus the likelihood of infection after an aspiration event. For aspiration-related infection, the antibiotic chosen should reflect the predominance of anaerobes. In trials of empirical therapy for lung abscess, clindamycin showed superiority over penicillin, probably because the incidence of penicillin-resistant anaerobes in lung abscesses is 15% to 20%. Antibiotics should be continued for 6 weeks, and drainage should be reserved for very large abscesses or failure to resolve with antibiotics.

Mycobacterium Tuberculosis Infection

Infection with *Mycobacterium tuberculosis*, an aerobic, non-motile, acid-fast rod with niacin production, causes TB. In 1997, the World Health Organization Global Surveillance and Monitoring Project estimated 8 million new cases per year of TB, including 3.5 million cases of infectious pulmonary disease. In addition, 16.2 million cases of the disease

existed. An estimated 1.87 million individuals die from TB each year, and the global case-fatality rate was 23%, with 50% in some African countries with high HIV rates. In the United States, TB increased at an alarming rate in the early 1990s as a result of the surge of HIV infection, drug abuse, inner-city poverty, and homelessness.

TB infection occurs when aerosolized, contaminated droplets (expectorated by a diseased person) are inhaled by another individual and the droplet or droplet nuclei reaches an alveolus. This is almost always a latent infection, called *latent tuberculosis infection* (LTBI). If the innate immune system of the host fails to eliminate the latent infection, the bacilli proliferate inside alveolar macrophages and kill the cells. The infected macrophages produce cytokines and chemokines that attract other phagocytic cells, including monocytes, other alveolar macrophages, and neutrophils, which eventually form a nodular granulomatous structure called the *tubercle*. If the bacterial replication is not controlled, the tubercle enlarges, and the bacilli enter the local draining lymph nodes. This leads to lymphadenopathy, a characteristic manifestation of primary TB. The lesion produced by the expansion of the tubercle into the lung parenchyma and lymph node involvement is called the *Ghon complex*. The bacilli continue to proliferate until an effective cell-mediated immune (CMI) response develops, usually 2 to 6 weeks after infection. Failure by the host to mount an effective CMI response and tissue repair leads to progressive destruction of the lung. Bacterial products, tumor necrosis factor- α , macrophage antimicrobial effector molecules such as reactive oxygen intermediates (ROI) and reactive nitrogen intermediates (RNI), and the contents of cytotoxic cells (granzymes, perforin) all can contribute to the development of caseating necrosis that characterizes a tuberculous granuloma (**Fig. 22-1**).

If mycobacterial growth is unchecked, the bacilli may spread hematogenously to produce disseminated TB. Miliary

Figure 22-1 Necrotizing granuloma in lung infected with *Mycobacterium tuberculosis*.

TB is a disseminated form with lesions resembling millet seeds. Bacilli can also spread mechanically by erosion of the caseating lesions into the lung airways. It is at this point that the host becomes infectious to others. If untreated, 80% of patients will die. Others will develop chronic disease or recover spontaneously. The chronic disease is characterized by repeated episodes of spontaneous healing with fibrotic changes around the lesions and tissue breakdown. Healing by complete spontaneous eradication of the bacilli is rare.

Reactivation TB results when the persistent bacteria in a host suddenly proliferate. Only 5% to 10% of patients with no underlying medical problems who become infected develop reactivation disease in their lifetime. Although immunosuppression is clearly associated with reactivation TB, it is not clear what host factors specifically maintain the infection in a latent state for many years and what triggers the latent infection to become overt.

The diagnosis of latent TB infection is dependent on a positive tuberculin test, which does not necessarily indicate active disease, but only previous infection. The standard Mantoux test is an intradermal injection of 0.1 mL (5 tuberculin units) of purified protein derivative (PPD) tuberculin in the skin of the forearm. The injection site is evaluated 48 to 72 hours later. The reading is based on the diameter of the indurated or swollen area. Patients are at high risk for developing active TB early after tuberculin conversion, and thus treatment is recommended for LTBI. The risk for active disease is 5% within 2 years of exposure and another 5% per year thereafter. HIV patients are an exception and have a 40% risk for active disease within several months of conversion. The current recommendations as to what constitutes a positive PPD test take into account the degree of clinical suspicion of LTBI (Table 22-2).

Treatment of patients suspected of having active disease includes at least four drugs—isoniazid, 5 mg/kg per day; rifampin, 10 mg/kg per day; ethambutol, 5 to 25 mg/kg per day; pyrazinamide, 15 to 30 mg/kg per day—and should

be considered before a formal diagnosis is made. Factors suggesting active disease include exposure to active TB, pulmonary symptoms, and cavitary disease on imaging studies. If the diagnosis of TB is confirmed, the drugs are continued for 2 months, barring adverse reactions to drug therapy. After 2 months, the regimen can be tailored, depending on drug-sensitivity studies, and continued for another 4 months with at least two active drugs. Rates of drug-resistant TB are increased in certain populations (e.g., recent immigrants from high TB areas, homeless people).

Resistance is detected in 9% of patients who have not received previous therapy and in 22.8% of those with prior treatment. In patients with drug-resistant TB, treatment should include at least three drugs that have not been administered before and to which the organism is susceptible in vitro. Treatment should continue for at least 18 to 24 months. Direct observation of therapy is recommended to ensure compliance.

Pneumocystis Pneumonia

Pneumocystis jiroveci, formerly called *pneumocystis carinii* (PCP), is an opportunistic fungus that occurred mainly in malnourished premature infants and in adults with hematologic malignancy undergoing chemotherapy in the pre-acquired immunodeficiency syndrome (AIDS) era. However, its incidence rose significantly in the late 1980s and 1990s in patients with AIDS with low CD4⁺ lymphocyte counts (<250 cells/m³). Patients may complain of nonproductive cough, fever, dyspnea, and weight loss. The symptoms are slowly progressive over weeks in the patient infected with HIV. Oral candidiasis, increased serum lactic dehydrogenase (LDH), increased Aa-oxygen gradient, and a decreased CD4⁺ count are independent predictors of HIV-related pneumocystis pneumonia.

Chest radiographic images may show diffuse, bilateral interstitial infiltrates, but they may be clear in up to 15% of patients (Web Fig. 22-3). Other findings include isolated infiltrates, cavitary lesions, nodular masses, pneumothorax, and a military pattern. Hilar and mediastinal adenopathy are rare. Identifying the organism in sputum, which is effective in 60% to 85% of patients, will help with diagnosis. Bronchoscopy with bronchoalveolar lavage can increase the yield (86%), especially if a transbronchial biopsy is included (98% to 100%).

Prophylaxis can be provided by oral trimethoprim-sulfamethoxazole or aerosolized pentamidine. When pneumonia is present, the therapy of choice is trimethoprim-sulfamethoxazole. However, significant adverse effects, including leukopenia, nausea, vomiting, and elevation of liver transaminases, are associated with this therapy. Intravenous pentamidine is a reasonable alternative to trimethoprim-sulfamethoxazole, but this therapy could be complicated by hypoglycemia. Less toxic drug regimens are available (e.g., trimethoprim and dapsone, clindamycin and primaquine), but these are recommended only after failure of other medications. Corticosteroids should be considered in patients with severe disease as demonstrated by significant hypoxemia (e.g., PaO₂ < 70 mm Hg). Corticosteroids decrease the likelihood of progression to respiratory failure.

Table 22-2 Prophylaxis against Tuberculosis in Adults

PPD	Prophylaxis Indicated Regardless of Age	Prophylaxis Indicated if <35 Years Old
5 mm	Close contacts recently diagnosed with TB HIV positive or HIV risk factors Fibrotic changes on chest radiograph	
10 mm	Diabetes mellitus Immunosuppression Hematologic malignancy Injection drug use Renal failure Malnutrition	PPD increased >10 mm within 2 yr Native of high-prevalence country High-risk ethnic minorities Residents and staff of long-term care facilities
15 mm	PPD increased >15 mm within 2 yr	No risk factors

HIV, human immunodeficiency virus; PPD, purified protein derivative of tuberculin; TB, tuberculosis.

Prospectus for the Future

Lung infection continues to represent a source of high morbidity and mortality rates, both in the community and in health care settings. A significant portion of these infections affect the extremes of age—children and older adults. Although industry continues to search for new antibiotics with higher safety and effectiveness profiles, the judicious use of agents currently available will help prevent or delay drug resistance while newer agents are being developed.

Continued efforts are needed to reinforce vaccination against infectious agents including influenza and *Streptococcus pneumoniae*. HIV infection and tuberculosis continue to be public health problems in the United States, but are particularly a problem in Africa, where effective HIV therapy is less available. This was highlighted by the identification of extensively drug-resistant tuberculosis (XDR-Tb), which is caused by a strain of *M. tuberculosis* that is resistant to many available anti-mycobacterial agents and is difficult to cure. Emerging organisms present new challenges.

On March 15, 2003, worldwide attention was drawn to Severe Acute Respiratory Syndrome (SARS) by the World Health

Organization (WHO), with descriptions of cases of a rapidly progressive respiratory illness in the Guangdong province of China, Hong Kong, Vietnam, Singapore, and Canada.

There have been four influenza pandemics during the past century, and each has been caused by the emergence of a novel influenza virus. In the 1957 and 1968 pandemics, the new viruses contained components of previous human and avian influenza viruses. Sporadic transmission of avian influenza H5N1 to more than 350 humans since 2004 has prompted concerns that conditions are suitable for emergence of the next pandemic. Estimates of potential global mortality related to pandemic avian influenza are as high as 62 million deaths, and presently there is no specific treatment available. In 2009 the H1N1 (“swine”) influenza virus emerged in Mexico, has spread world-wide, and is officially termed a pandemic by the WHO. At least initially, H1N1 has been complicated by relatively low mortality, but it is possible that this influenza virus may mutate to produce more severe disease in humans.

Essentials in Critical Care Medicine

Brian Casserly and Sharon Rounds

Critical care medicine has evolved dramatically during the past decades because of the development of new technologies as well as clinical trials that have established standards for the management of patients in the critical care setting. Since the epidemic of poliomyelitis in the 1950s, intensive care units have clearly proved beneficial in treating acute reversible disorders. However, because of the innovative nature of the technology used and the need for close monitoring and intensive management, the delivery of critical care medicine is expensive, accounting for up to 30% of total hospital costs.

Patients in intensive care units (ICUs) are a heterogeneous population treated for diverse conditions ranging from septic shock and respiratory failure to diabetic ketoacidosis and upper gastrointestinal bleeding. This chapter discusses a few of the most common conditions encountered in the ICU setting that are often managed by pulmonologists. These topics include acute respiratory failure and mechanical ventilation, acute lung injury, and shock.

Acute Respiratory Failure and Mechanical Ventilation

Acute respiratory failure results when the lung can no longer accomplish adequate gas exchange, a condition that is fatal if left untreated. Hypoxemic respiratory failure refers to respiratory failure associated with failure to oxygenate, whereas hypercarbic respiratory failure is the failure to ventilate. These disorders are manifested by alterations in arterial partial pressure of oxygen (P_{aO_2}) and carbon dioxide (P_{aCO_2}), respectively. The values of P_{aO_2} and P_{aCO_2} that define respiratory failure are somewhat arbitrary, but respiratory compromise is evident when the P_{aO_2} is less than 60 mm Hg while the patient breathes room air or the P_{aCO_2} is higher than 45 mm Hg. It is important to recognize that these values are not synonymous with the need for mechani-

cal ventilation, nor do they preclude the need for mechanical ventilation.

The management of respiratory failure depends on the clinical presentation. Patients with respiratory failure who are awake, cooperative, and hemodynamically stable may tolerate aggressive respiratory therapy, without intubation and mechanical ventilation, as long as gas exchange and overall status are continually monitored. This setting often describes patients with chronic obstructive pulmonary disease (COPD) who can sometimes tolerate a P_{aCO_2} level as high as 85 mm Hg, which can occur in the absence of severe respiratory acidosis. In contrast, patients in respiratory failure with evidence of severe respiratory distress (e.g., respiratory rate >30 breaths per minute), mental deterioration (e.g., impaired judgment, confusion, hallucinations, somnolence), or hemodynamic instability (e.g., bradydysrhythmias or tachydysrhythmias, hypotension) usually require intubation and mechanical ventilation. In the latter circumstances, waiting for arterial blood gas determinations is not necessary and could dangerously delay therapy. Although arterial blood gas evaluation is crucial when determining the need for mechanical ventilation in the patient with respiratory failure, the patient's clinical status will ultimately dictate the course of action.

Mechanical Ventilation

Mechanical ventilation primarily uses the principals of positive pressure ventilation. Air is forced into the central airways, increasing central airway pressure. Air follows the pressure gradient from the central airways to the alveoli, which inflates the lungs. As the lungs inflate and the device stops forcing air into the central airways, the intra-alveolar pressure increases and central airway pressure decreases. Exhalation occurs when the air follows the newly reversed pressure gradient from the alveoli to the central airways.

The principal benefits of mechanical ventilation during respiratory failure are improved gas exchange and decreased work of breathing. Mechanical ventilation improves gas

exchange by improving ventilation-perfusion ratio (\dot{V}/\dot{Q}) matching. The improved \dot{V}/\dot{Q} matching is primarily a consequence of decreased physiologic shunting. Altered lung mechanics (e.g., increased airways resistance, decreased compliance) and increased respiratory demand (e.g., metabolic acidosis) increase the work of breathing. The ventilatory muscles and diaphragm can tire while trying to maintain the elevated work of breathing, resulting in respiratory failure. Mechanical ventilation can assume some or all of the increased work of breathing, allowing the ventilatory muscles to recover from their fatigue. Deteriorating gas exchange, unresponsive to conservative measures, and respiratory distress are the most common reasons for mechanical ventilation in patients with acute respiratory failure.

NONINVASIVE MECHANICAL VENTILATION

Although intubation and mechanical ventilation are usually the preferred options in respiratory failure that is considered reversible, noninvasive positive-pressure ventilation (NPPV) has proved useful in selected patients. NPPV refers to positive-pressure ventilation delivered through a noninvasive interface (nasal mask, facemask, or nasal plugs), rather than an invasive interface (endotracheal tube, tracheostomy). Its use has become more common as benefits are increasingly recognized. Selecting patients for NPPV requires careful consideration of its indications and contraindications. Generally speaking, a trial of NPPV is worthwhile in patients with acute cardiogenic pulmonary edema or hypercapnic respiratory failure due to COPD who do not require emergent intubation and do not have contraindications to NPPV. Contraindications to NPPV include cardiac or respiratory arrest; inability to cooperate, protect the airway, or clear secretions; severely impaired consciousness; facial surgery, trauma, or deformity; anticipated prolonged duration of mechanical ventilation; and recent esophageal anastomosis.

INVASIVE MECHANICAL VENTILATION

Once a decision to intubate is made, an experienced operator should expeditiously perform intubation. Complications of intubation are usually related to prolonged hypoxemia as a result of delays in the procedure, but they also include vomiting and aspiration of gastric contents, trauma to the vocal cords, bleeding, pneumothorax, cardiac arrhythmias, and cardiac arrest. Once inserted, the endotracheal tube should be secured and its position assessed by examining for breath sounds, followed by chest radiography for confirmation. Direct visualization through a bronchoscope is occasionally needed for successful intubation. A ventilator should be available before the procedure is begun so that mechanical ventilation can start as soon as the endotracheal tube is secured.

Initial ventilator settings may vary, but typically they include a ventilator mode, fraction of inspired oxygen (F_{iO_2}) of 1 (or 100%), respiratory rate set at 10 to 12 breaths per minute, and tidal volume of 400 to 600 mL. The adequacy of the ventilator settings needs to be determined with repeated arterial blood gas levels and the clinical evaluation of the patient. Persistent cyanosis, pallor, diaphoresis, and restlessness may suggest that the tube is misplaced or that

the ventilator settings are insufficient to ventilate the patient appropriately. Positive end-expiratory pressure (PEEP) might be required in patients with refractory hypoxemia. PEEP prevents the premature collapse of the alveoli during expiration and improves \dot{V}/\dot{Q} matching, leading to improved oxygenation. Once the settings are adjusted to maintain relatively normal levels of arterial blood gases (pH, 7.3 to 7.45; $P_{aO_2} > 60$ mm Hg; P_{CO_2} , 30 to 45 mm Hg), attention should be given to developing a *maintenance* plan that will secure adequate oxygenation and ventilation until the cause of the respiratory failure is treated and the failure is reversed. This plan should include assessment of the need for sedation, appropriate strategy of mechanical ventilation, supportive measures to achieve hemodynamic stability, nutritional assessment, and therapies targeting the initial injurious process that triggered the respiratory failure (e.g., pneumonia, pulmonary embolism, asthma, shock). Most patients require sedation to diminish discomfort and to decrease the work of breathing, but it should be administered carefully because sedation is often accompanied by a decrease in blood pressure.

Commonly used modes of ventilation are determined by the duration of inspiration, which can be limited by volume, pressure, flow, or time. During volume-limited ventilation, inspiration ends after delivery of a preset tidal volume. Airway pressure is variable during volume-limited ventilation and is related to respiratory system compliance, airway resistance, and tubing resistance. *Assist control (AC)*, *continuous mandatory ventilation (CMV)*, and *synchronized intermittent mandatory ventilation (SIMV)* are examples of modes of ventilation that can be volume limited. CMV has a set rate and set tidal volume which does not allow spontaneous breathing by the patient. Patient-ventilator asynchrony is a big problem, and therefore CMV is rarely used. The assist-control mode of ventilation is similar to CMV in that there is a set rate and tidal volume, but this mode allows the patient to initiate additional spontaneous breaths. When the machine senses that the patient is attempting to take a breath, it delivers the selected tidal volume. SIMV is similar to assist-control in that a set rate and tidal volume are selected. The patient is also able to generate a spontaneous breath. However, this spontaneous breath may have a very small tidal volume, yet entail significant work of breathing. Consequently, this mode of mechanical ventilation is seldom used except when weaning patients from mechanical ventilation.

The pressure control mode of ventilation uses machine breaths that are pressure cycled, not volume cycled. With pressure control ventilation, the pressure to be used for each breath is ordered. If the patient attempts a spontaneous breath, a machine breath at the designated pressure is delivered. This may be helpful in limiting airway pressures in patients with bronchospasm or stiff lungs because it limits the risk for pneumothorax (barotrauma). Because tidal volumes may vary, the pressure control mode must be titrated carefully at the bedside to determine the proper pressure settings.

Pressure support ventilation is used only for spontaneously breathing patients. The inspiratory and expiratory pressures are selected, and there are no mandatory machine breaths. Patients find this to be a more comfortable mode of mechanical ventilation. However, pressure support ventilation

should only be used for patients with a stable respiratory drive (not sedated heavily) and stable lung compliance. Pressure support ventilation is typically used for patients who are weaning from mechanical ventilator support.

Pressure-regulated volume control, airway pressure release ventilation, and high-frequency ventilation are newer modalities that are increasingly used in clinical practice.

SETTINGS

Numerous settings need to be considered when mechanical ventilation is initiated. These include tidal volume, respiratory rate, trigger mode and sensitivity, fraction of inspired oxygen, PEEP, flow rate, and flow pattern.

The appropriate initial *tidal volume* depends on numerous factors, most notably the disease for which the patient requires mechanical ventilation. The tidal volume can then be increased or decreased incrementally to achieve the desired pH and arterial carbon dioxide tension (P_{aCO_2}). Generally speaking, large tidal volumes can cause barotrauma or volutrauma, which increases the risk for ventilator-associated lung injury. Therefore, tidal volume should not be increased without considering effects on airway pressure or the likelihood of ventilator-induced lung injury.

An optimal method for setting the *respiratory rate* has not been established. Once the tidal volume has been established, the respiratory rate can be incrementally increased or decreased to achieve the desired pH and P_{aCO_2} , while monitoring auto-PEEP. Patients who are breathing spontaneously will set their own respiratory rates in all modes of ventilation except CMV.

The lowest possible *fraction of inspired oxygen* (F_{iO_2}) necessary to meet oxygenation goals should be used. This will decrease the likelihood that adverse consequences of supplemental oxygen will develop, such as absorption atelectasis, accentuation of hypercapnia, airway injury, and parenchymal lung injury.

PEEP is generally added to prevent end-expiratory alveolar collapse. This generally improves \dot{V}/\dot{Q} matching and arterial oxygenation and allows reduction in F_{iO_2} , thereby reducing the risk for oxygen toxicity. However, elevated levels of applied PEEP can have adverse consequences, such as reduced preload (decreases cardiac output), elevated plateau airway pressure (increases risk for barotrauma), and impaired cerebral venous outflow (increases intracranial pressure). The optimal PEEP is that which enhances oxygenation without lung hyperinflation and decreased blood pressure.

Respiratory therapists typically also adjust the inspiratory flow rate, flow pattern, and amount of negative pressure required to “trigger” a mechanical ventilator breath. If these ventilator settings are not adjusted with due consideration of the patient’s respiratory mechanics, two common problems can occur: *asynchrony* and *auto-PEEP*. Patient-ventilator asynchrony occurs if the phases of breaths delivered by the ventilator do not match the breathing pattern of the patient. Patient-ventilator asynchrony can cause dyspnea, increase the work of breathing, and prolong the duration of mechanical ventilation. It is detected by careful observation of the patient and examination of the ventilator waveforms. Generally, the abnormality that is most readily apparent is

failure of the ventilator to trigger a breath when the patient makes an inspiratory effort. Auto-PEEP is usually seen when patients are not fully emptying their lungs during expiration before the initiation of the next breath. This is known as *stacking breaths* or generating auto-PEEP. This is particularly worrisome in patients who have exacerbations of COPD or status asthmaticus requiring mechanical ventilation. In ventilated patients, auto-PEEP may cause barotrauma or hemodynamic collapse owing to high intrathoracic pressures preventing blood return to the right ventricle.

Weaning from Mechanical Ventilation

The complications of endotracheal intubation and mechanical ventilation are many; trauma to the lung from high ventilator pressures (barotrauma), volutrauma and ventilator-induced lung injury, and pneumonia are the most significant. Therefore, the patient who is mechanically ventilated must be treated aggressively and monitored carefully. Weaning from mechanical ventilation should be considered when the original insult that caused respiratory failure has cleared, especially if the patient is awake and cooperative and shows no signs of respiratory or hemodynamic instability. Weaning is usually not attempted if requirements for oxygen supplementation remain high ($F_{iO_2} > 0.5$). Conventional parameters that determine whether weaning is possible include negative inspiratory force, vital capacity, tidal volume, respiratory rate, and minute ventilation (Table 23-1). Unfortunately, the strength of these parameters lies in the ability to predict failure to wean rather than in the ability to predict successful spontaneous breathing. A better way to assess weaning capability is to engage the patient in a short *weaning trial* during which support from the ventilator is diminished. This trial can be achieved by allowing the patient to breathe oxygen for 1 hour without providing supporting pressure. Another strategy is to decrease the pressure generated by the ventilator during a trial of continuous positive airway pressure (CPAP). The patient is monitored for any signs of distress or hemodynamic instability, and arterial blood gas levels are measured to determine the effectiveness of spontaneous ventilation. If the patient tolerates the trial, extubation may be indicated, depending on the patient’s clinical status and his or her underlying condition. In general,

Table 23-1 Conventional Weaning Parameters

Parameters	Weanable Values	Normal Ranges
NIF (cm of water)	<-20	<-50
VC (mL/kg)	>10	>65-75
V_T (mL/kg)	<5	>5-7
RR (breaths/min)	<32	12-20
V_E (L/min)	>10	>10
Rapid shallow breathing index (RSBI) (RR/V_T)	<105	<40

NIF, negative inspiratory force; RR, respiratory rate; VC, vital capacity; V_E , minute ventilation; V_T , tidal volume.

only 10% to 15% of patients who are extubated on the basis of the results of these trials require reintubation.

If the patient fails the weaning trial, attempts should be made to identify the factors responsible for the failure to wean. In very sick patients, all obvious contributory factors may have been identified and corrected, but the patient still requires a more prolonged weaning trial before extubation. Two weaning strategies are recommended in this setting. The first is to engage the patient in spontaneous ventilation trials without positive pressure for 1 hour once or twice each day with total ventilatory support between trials, usually through assisted-control ventilation. The length of the spontaneous breathing trials can be progressively increased until the patient no longer requires mechanical support. The other strategy uses pressure support ventilation. The inspiratory pressure is progressively decreased until the patient can breathe spontaneously without ventilatory support. Both strategies appear to be equally effective, although weaning through pressure support ventilation might be preferred in patients with chronic lung disease who have been mechanically ventilated for prolonged periods.

Acute Lung Injury

Acute lung injury in its most severe form is called *acute respiratory distress syndrome* (ARDS). Acute lung injury is characterized by increased permeability of the alveolar-capillary membrane leading to flooding of the alveolar spaces with proteinaceous material. ARDS is defined by clinical measures of the severity of lung dysfunction (e.g., Pao_2/FiO_2). This process is triggered by direct injury to the lung, as observed in aspiration pneumonia, smoke inhalation, and a near-drowning event, or systemic injury such as trauma, surgery, sepsis, burns, long-bone fractures, pancreatitis, uremia, transfusion therapy, shock, drug intoxication, or cardiopulmonary bypass. About 150,000 cases of ARDS are reported each year in the United States, and aspiration pneumonia and sepsis are the most common associated conditions. The morbidity rate associated with ARDS is high, and about 30% to 50% of patients die.

ARDS is the pulmonary manifestation of a systemic disorder that appears to trigger a dysregulated inflammatory response to injury. Uncontrolled inflammation causes injury to the pulmonary vascular endothelium and epithelium, which results in increased permeability of both physiologic barriers, allowing the extravasation of proteinaceous edema fluid from the intravascular space and its accumulation into the lung interstitium and alveolar spaces (**Web Fig. 23-1**). Injury to the lung epithelium results in decreased absorption of water from the alveolar space. This condition is often referred to as *noncardiogenic* or *increased permeability pulmonary edema*. In the lung, these processes cause right-to-left intrapulmonary shunting of blood, resulting in refractory hypoxemia, and decreased lung compliance that increases the work of breathing. The chest radiograph reveals diffuse bilateral alveolar infiltrates (**Web Fig. 23-2**). Failure of other organs is frequent; consequently, multiorgan failure is common, especially in the setting of sepsis.

Histologically, ARDS is characterized by diffuse alveolar damage with hyaline membranes (**Web Fig. 23-3**). The damage is further exaggerated by reductions in the quantity

and quality of the synthesized surfactant leading to atelectasis. After a few days, the tissue shows hyperplasia of type II pneumocytes (**Web Fig. 23-4**) and deposition of connective tissue resulting in fibrosis. These events can be worsened by mechanical ventilation through positive pressure, hyperdistention, and hyperoxia.

A diagnosis of ARDS should be considered in patients with a predisposing condition (e.g., sepsis), bilateral pulmonary infiltrates on chest radiograph, and refractory hypoxemia (i.e., usually a Pao_2/FiO_2 of 200 mm Hg or less), in the absence of significant cardiac dysfunction. Currently, the treatment of ARDS relies on supportive measures directed at eradicating the injurious agent, sustaining the cardiovascular system, providing nutrition, and avoiding fluid overload. Recently, a ventilatory management strategy designed to deliver low-tidal volumes (about 6 mL/kg body weight) has proved beneficial, resulting in increased survival. Corticosteroids, surfactant replacement, and extracorporeal oxygenation have not proved beneficial and are not recommended. Oxygenation can be improved by PEEP and prone ventilation, but these interventions do not appear to affect the natural course of the disease. Because there is no available therapy that lessens acute lung injury or hastens repair, the key to care of patients with ARDS is meticulous supportive care and avoidance of complications, such as ventilator-associated pneumonia or catheter-related sepsis.

Shock

Shock is defined as systemic organ hypoperfusion, usually associated with hypotension, which leads to cell injury and death. Four classifications are provided: (1) cardiogenic shock (i.e., decreased cardiac output as a result of dysfunction), (2) hypovolemic shock (i.e., decreased intravascular volume), (3) septic or redistributive shock (i.e., decreased systemic vascular resistance), and (4) obstructive shock (i.e., decreased cardiac output as a result of obstruction to flow). (Anaphylactic shock caused by an allergic reaction to a drug or a related insult is not discussed in this text.)

When encountering a patient in shock, the strategy is to gain vascular access quickly and to replace volume aggressively while making a careful assessment of the situation. This strategy is particularly appropriate when shock is thought to be the result of hypovolemia or sepsis. In the case of cardiogenic shock, strategies designed to improve cardiac function should be implemented, including administration of inotropic drugs or, in severe unresponsive cases, cardiac bypass or cardiac-assist devices. In the case of severe hypovolemia, administration of saline is usually sufficient. With sepsis, fluid replacement, antibiotic therapy, and drainage of any infected space are paramount. In select patients in whom severe sepsis is diagnosed early, intravascular administration of a recombinant version of activated protein C (drotrecogin alfa [activated]) has been shown to improve survival. Obstructive shock is the result of obstruction to blood flow, as observed in massive pulmonary embolism or *saddle embolus* lodged at the bifurcation of the right and left pulmonary arteries. In this setting, relieving the obstruction mechanically or through other methods (e.g., thrombolysis) or supporting the patient's circulation until the obstruction subsides is important.

Table 23-2 Useful Resting Hemodynamic Parameters (Pulmonary Artery Catheter)

Parameters	Normal Ranges
Right atrial pressure or central venous pressure	0-5 mm Hg
Right ventricular pressure (systolic/diastolic)	25/0-5 mm Hg
Pulmonary artery pressure (systolic/diastolic)	25/8-12 mm Hg
Pulmonary capillary wedge pressure	8-12 mm Hg
Cardiac output	3.5-7 L/min
Cardiac index	2.5-4.5 L/min/m ²
Oxygen consumption	200-250 mL/min
Arteriovenous oxygen content	3.5-5.5 mL/100 mL
Mixed venous oxygen content	18 mL/100 mL
Mixed venous oxygen saturation	75%
Stroke volume	70-130 mL/beat
Stroke volume index	40-50 mL/beat/m ²
Left ventricular stroke work index	45-60 g/beat/m ²
Systemic vascular resistance	800-1200 dyne/sec/cm ⁻⁵
Pulmonary vascular resistance	150-250 dyne/sec/cm ⁻⁵

In the management of shock, monitoring blood pressure and organ perfusion is of utmost importance. A central venous line will facilitate the delivery of fluids, and an arterial line will allow for accurate monitoring of blood pressure. In cases in which aggressive fluid replacement is not effective and the exact cause of shock remains unknown, the placement of a pulmonary artery catheter (Swan-Ganz catheter) may be useful. This catheter allows for the direct assessment of pressures in the right atrium, right ventricle, and pulmonary artery, as well as measurement of the pulmonary capillary wedge pressure, and it allows for the assessment of the cardiac output. These values can then be used in equations that allow for calculating derived parameters such as cardiac index, systemic and pulmonary vascular resistance, and oxygen content. Information generated by the use of this catheter and the equations needed to calculate derived parameters are described in Tables 23-2 and 23-3. These values are useful in distinguishing the different types of shock (Table 23-4). Concerns have been raised about the true usefulness and benefit-risk ratio associated with this procedure. Significant expertise is required for the insertion of these catheters and for the adequate interpretation of the data generated.

Systemic Inflammatory Response Syndrome

The systemic inflammatory response syndrome (SIRS) is a constellation of clinical signs and symptoms triggered by the host response to diverse insults. The most common cause of SIRS is infection, which is called *sepsis*. However, not infrequently, SIRS can be triggered by noninfectious disorders such as pancreatitis and drug intoxication. The diagnosis of

Table 23-3 Equations to Calculate Derived Parameters

$$CO = \frac{VA}{(CaO_2 - CvO_2)}$$

$$CI = \frac{CO}{\text{Body surface area (BSA)}(m^2)}$$

Oxygen content (CxO₂) = % saturation × Hgb (g/dL) × 1.39 + (PxO₂ × 0.003)

Oxygen delivery (DO₂) (mL/min/m²) = CI × CaO₂

$$SV = \frac{CO}{\text{Heart rate (beats/min)}}$$

$$SVI = \frac{SV}{BSA}$$

$$LVSWI = \frac{1.36X (MAP - PCWP) \times SI}{100}$$

$$\text{Mean arterial pressure (MAP)} = \frac{(2 \times \text{diastolic}) + \text{systolic}}{3}$$

$$= \frac{\text{diastolic} + \text{systolic} - \text{diastolic}}{3}$$

$$= \frac{\text{diastolic} + \text{pulse pressure}}{3}$$

$$SVR = \frac{MAP - CVP}{CO} \times 80$$

$$PVR = \frac{\text{Mean PA pressure} - PCWP}{CO} \times 80$$

Table 23-4 Hemodynamic Variables in the Four Types of Shock

Type of Shock	Pulmonary Capillary Wedge Pressure	Cardiac Index	Systemic Vascular Resistance Index
Hypovolemic	Low	Low	High
Cardiogenic	High	Low	High
Extracardiac obstructive	Normal or low (high in tamponade)	Low	High
Distributive	Normal or low	High (rarely low)	Low

Adapted from Parrillo JE, Ayres SM (eds): Major Issues in Critical Care Medicine. Baltimore, Williams & Wilkins, 1984.

SIRS requires at least two of the following criteria: (1) temperature higher than 38° C or less than 36° C; (2) tachycardia greater than 90 beats per minute; (3) tachypnea greater than 20 breaths per minute; or (4) P_aCO₂ less than 32 mm Hg; and (5) white blood cell count greater than 12,000/μL or less than 4000/μL. This systemic response may result in dysfunction of many organs, including the lung, liver, kidneys, heart, and central nervous system, which is referred to as multiple-organ dysfunction syndrome or multiple-organ system failure. The prognosis worsens as more organs become involved with mortality ranging from 30% in less severe cases to more than 90% with five or more failing organs.

Noxious Gases, Fumes, and Smoke Inhalation

The inhalation of certain gases and fumes may cause asphyxia or cellular and metabolic injury (Table 23-5). Carbon monoxide poisoning is a common and frequently unsuspected

Table 23-5 Toxic Gases and Fumes

Injuries	Agents	Occupational Exposures
Simple asphyxia	Carbon dioxide Nitrogen Methane	Mining, foundries Mining, diving Mining
Cellular hypoxia and oxygen transport	Carbon monoxide Cyanide Hydrogen sulfide	Mining, combustion in closed spaces Smoke inhalation Petroleum refining
Direct tissue injury	Ammonia Chlorine Nitrogen dioxide Phosgene Cadmium, mercury	Fertilizer, cleaning agents Bleaches, swimming pools Farming, fertilizer, combustion in closed spaces Welding, paint removal Welding

cause of inhalational injury and results in tissue hypoxia by competitively displacing oxygen from hemoglobin. Affinity of carbon monoxide for hemoglobin is about 250 times greater than that of oxygen. The correlation between carbon monoxide levels and symptoms is weak, but generally patients with levels greater than 30% are symptomatic. Symptoms may range from confusion or fatigue to nausea, headache, and profound coma. The diagnosis is based on clinical grounds and supported by laboratory data. Carbon monoxide intoxication might occur in closed automobiles and by exposure to kerosene heaters or charcoal fires in closed spaces. In suggested cases, arterial blood gas levels should be obtained with measured (not calculated) hemoglobin-oxygen saturation. A carbon monoxide level should be measured in patients with a measured systemic arterial oxygen saturation (SaO_2) lower than the calculated SaO_2 obtained from the arterial oxygen tension. Treatment includes 100% inspired oxygen. Hyperbaric oxygen might be useful, but the clinical use of this therapy is unclear.

Inhalation of caustic substances such as ammonia, chlorine, and hydrogen fluoride causes acute symptoms of eye and upper airway inflammation. Pain, lacrimation, rhinorrhea, and upper airway symptoms usually prompt the individual to flee the environment. Inhalation of nitrogen dioxide (silo filler's disease) occurs in farmers who work in silos where fermentation of grain produces large quantities of the gas. Most patients recover without sequelae, but a small minority of patients may develop bronchiolitis obliterans.

Table 23-6 Common Drug Overdoses

Drug Overdose	Clinical Syndrome	Basic Treatment
Acetaminophen (paracetamol)	0.5-24 hr: nausea, vomiting 24-72 hr: nausea, vomiting, right upper quadrant pain, abnormal liver function tests and prothrombin time 72-96 hr: liver necrosis, coagulation, defects, jaundice, renal failure, hepatic encephalopathy 4 days-2 wk: resolution of liver dysfunction	Elimination: gastric lavage (if <1 hr after ingestion) Activated charcoal (if <4 hr after ingestion) (both longer if sustained-release product) Treatment: <i>N</i> -acetylcysteine for toxic ingestion
Amphetamines	Hypertension, tachycardia, arrhythmias, myocardial infarction, vasospasm, seizures, paranoid psychosis, diaphoresis, tachypnea	Elimination: Activated charcoal for oral ingestion Agitation/seizures: benzodiazepines Hypertension: control agitation, α -antagonists (phentolamine), vasodilators (nitroglycerin, nitroprusside, nifedipine) Hyperthermia: control agitation, external cooling
Iron	0.5-6 hr: nausea, vomiting, gastrointestinal discomfort, gastrointestinal bleed, drowsiness, hypoglycemia, hypotension 6-24 hr: latency, quiescence (may not occur in severe ingestions) 6-48 hr: shock, coma, seizures, coagulopathy, acidosis, cardiac failure 2-7 days: hepatotoxicity, coagulopathy, metabolic acidosis, renal insufficiency 1-8 wk: gastrointestinal disorders, achlorhydria	Elimination: gastric lavage and/or whole-bowel irrigation with polyethylene glycol electrolyte solution, especially when radio-opaque tablets on kidney-ureter-bladder radiograph Shock: intravenous fluids and blood (if hemorrhage present); vasopressors if needed Antidote: deferoxamine to chelate iron, when iron levels >500 mcg/dL or severe ingestion suspected
Tricyclic antidepressants	Wide-complex tachyarrhythmias, hypotension, seizures	Tachyarrhythmias: alkalinizing blood (pH 7.5-7.55) with intravenous bicarbonate Seizures: benzodiazepines Hypotension: fluid resuscitation, vasopressors
Salicylate	Respiratory alkalosis (initially), metabolic acidosis (after substantial absorption), pulmonary edema, platelet dysfunction, nausea, vomiting, hearing loss, agitation, delirium	Elimination: activated charcoal, hemodialysis (for severe poisoning), alkalinization of urine Agitation/delirium: alkalinize blood with intravenous bicarbonate

Metal fume fever causes influenza-like symptoms as a result of the inhalation of metal oxides generated by welding. Inhalation of platinum, formalin, and isocyanates may precipitate asthma. Pneumonitis can be induced by high-intensity inhalation of cadmium and mercury vapors.

Smoke inhalation may cause direct thermal injury that is usually confined to the upper airways, but it may also produce injury to the lower airways if exposure to sufficient steam occurs as a result of the high thermal content of water. Laryngeal edema, airway inflammation, and mucus can lead to airway obstruction, which requires intubation. Anoxia occurs from consumption of oxygen by fire, as well as from cytotoxic injury from gases such as carbon monoxide, cyanide, and oxidants liberated during combustion. Cyanide poisoning uncouples oxygen from energy production and requires prompt treatment with 100% oxygen and sodium

thiosulfate. The combustion of natural and synthetic polymers often produces aldehydes, acetaldehyde, and acrolein, which have a high irritant potential. The treatment of patients with inhalation injuries is supportive with close attention to the airway. Oxygen should be provided, and continuous monitoring of cardiac and hemodynamic status is necessary. Sometimes intubation and mechanical ventilation are needed to overcome airway obstruction and the development of respiratory failure.

Drug Overdoses

Drug overdoses are common causes of admission to the ICU. The presenting complaints and management of the more common overdoses that result in medical emergencies are summarized in Table 23-6.

Prospectus for the Future

It is anticipated that in the very near future there will be an explosion of demand for intensive care hospital resources. First, an aging society with multiple co-morbidities is poised to require intensive care when hospitalized. The oldest baby boomers are 62 years old, and they are quickly coming to an age at which their need for critical care services markedly rises. This will have significant implications for allocation of health care resources. The administration of critical care medicine units and the delivery of care in those units are changing at a rapid pace with the standardization of care through the development of critical care pathways. Over the past few years, studies have assessed the value of early assessment and aggressive treatment of shock through *goal-directed therapy*, the use of low-volume ventilation in patients with ARDS, the development of new strategies designed to accelerate weaning from

mechanical ventilation, and the development of biomarkers for the early detection of ventilator-associated pneumonia. Although more information about critical illnesses is generated each year, the main obstacle to improving the outcomes in the critical care setting is the limited use of these relatively new strategies in critical care units inside and outside academic institutions. Of note, compliance with proved new therapies is being fostered, among other mechanisms, through 24-hour coverage of critical care units by trained experts, the use of electronic records, and assessment of compliance with treatment protocols. Randomized, controlled studies designed to test new drugs and other strategies in the critical care setting are underway and are likely to improve care of the critically ill patient. Research into mechanisms of acute lung injury and repair will hopefully result in more specific therapies for ARDS.

Neoplastic Disorders of the Lung

Matthew D. Jankowich and Jason M. Aliotta

Lung Cancer

Lung cancer is the leading cause of cancer death in both men and women in the United States, and an estimated 1 million people die worldwide of lung cancer each year. Despite recent advances in the understanding of the biology of lung cancer and the introduction of new chemotherapeutic agents for its treatment, the 5-year survival rate for patients with lung cancer is 15%. A major reason for this poor rate of survival relates to the fact that most patients with lung cancer are diagnosed during the advanced stages of the disease when surgical resection is less likely to be curative. Most bronchogenic carcinomas are classified as two major types: (1) *small cell* carcinoma (SCLC) (**Web Fig. 24-1**) and (2) *non-small cell* carcinoma (NSCLC). NSCLCs are the most common and include squamous cell carcinoma (30%) (**Web Fig. 24-2**), adenocarcinoma (32%) (**Web Fig. 24-3**), and large cell carcinoma (10%) (**Web Fig. 24-4**), whereas SCLCs account for less than 20% of all bronchogenic carcinomas.

Smoking is the leading cause of lung cancer, a cause-and-effect relationship that was recognized as early as the 1940s. The risk for lung cancer is proportionate to cigarette pack-years smoked (packs per day \times years smoked) with a peak incidence in the sixth and seventh decades. Exsmokers show a persistent risk for lung cancer throughout life. Passive smoking is thought to be the cause of lung cancer in a significant percentage of nonsmokers who develop the disease. Nonsmokers who live with smokers have more than a 30% increased risk for developing lung cancer. However, nonsmokers do develop lung cancer that is thought to be unrelated to environmental tobacco exposure; the cause of this phenomenon is poorly understood. Other risk factors for lung cancer include environmental hazards such as asbestos exposure. Tobacco smoking is an important cofactor of lung cancer in the setting of asbestos exposure. Radon increases the risk for lung cancer; this risk is most common in miners. Radon exposure in the home is less significant, but in view of the increased risk, home radon testing is recommended.

The exact mechanisms by which these factors promote lung cancer remain unclear, but they are likely to cause genetic abnormalities that, when unopposed, promote the oncogenic transformation of lung epithelial cells. Because of the redundant repair mechanisms available to the lung, many individual genetic *hits* appear necessary. These *hits* affect the expression of proto-oncogenes, suppressor genes, and growth factors. Proto-oncogenes, similar to members of the *ras* family (e.g., *k-ras*), control cell cycling, growth, and differentiation. Mutations in *ras* genes have been detected in more than 50% of squamous cell cancers and in 68% of adenocarcinoma cells. Other proto-oncogenes implicated in the pathogenesis of lung cancer are *c-erb*, *rb*, *p53*, *c-myc*, and *c-src*. Mutations in tumor suppressor genes (e.g., *p21*) might also promote the development of lung cancer. Growth factors, such as gastrin-releasing peptide, insulin-like growth factor, and epidermal growth factor, promote tumor cell proliferation through the activation of protein kinase pathways (e.g., protein kinase B, mammalian target of rapamycin [mTOR]) that stimulate cellular proliferation. Epidermal growth factor receptor mutations are prominent in nonsmokers who develop lung cancer and may indicate a unique molecular basis for lung cancer in these patients.

There is growing evidence that different lung cancers arise not only as a result of certain permissive oncogenic mutations but also because the cancer cell's local environment, or *niche*, supports its growth. Data generated from animal models support the concept that the lung has specific anatomic regions that contain populations of cells responsible for replacing damaged cells during routine maintenance and injury. These *resident stem cells* are not only capable of self-renewal but also can give rise to specialized and fully differentiated cells of the lung, including tracheal and alveolar epithelium. It has been suggested that resident stem cell signaling and differentiation pathways are maintained within distinct cancer types and that destabilization of this signaling machinery may participate in the pathogenesis of certain lung cancers. Animal models support a direct relationship between tracheal epithelial progenitor cells and tumor cells

in human squamous cell carcinoma. These cells are basal epithelial cells located in submucosal gland duct junctions or intracartilaginous boundaries of the trachea and express cytokeratins 5 and 14. Neuroendocrine body (NEB) microenvironments maintain putative stem cell populations for the bronchiolar epithelium. Cells within this niche include variant Clara cell-specific protein (CCSP)-expressing cells, linked to nonsquamous NSCLC, and pulmonary neuroendocrine cells (PNEC), linked to SCLC. PNEC-derived SCLC tumors are believed to be capable of circumventing existing control mechanisms that regulate normal NEB-associated proliferation, in part by undergoing genetic mutations that result in autonomous sonic hedgehog (Shh) signaling. In addition, alveolar epithelial stem cells located in the bronchoalveolar duct junction (BADJ) have been linked to the pathogenesis of various adenocarcinomas because both cell types co-express CCSP and surfactant protein C (Sp-C).

CLINICAL PRESENTATION

Patients may complain of mild cough, dyspnea, increased sputum production, hemoptysis, chest pain, and weight loss. Localized pleuritic chest pain suggests chest wall invasion (Web Fig. 24-5). Hoarseness is caused by involvement (or compression) of the left recurrent laryngeal nerve and suggests mediastinal or hilar involvement. A pleural effusion is observed in 9% of patients and can be related to direct tumor involvement of the pleura or obstruction of lymph flow from the mediastinal nodes (Web Fig. 24-6). The presence of a malignant pleural effusion precludes resection. The superior vena cava is involved in less than 5% of patients, but obstruction may result in *superior vena cava syndrome*, characterized by edema of the face and upper extremities due to impaired venous return. Despite its implications, its involvement typically does not represent a medical emergency. Dysphagia suggests esophageal involvement.

The physical examination may be normal or may reveal changes in the lung examination, such as crackles (e.g., postobstructive pneumonia (Web Fig. 24-7); inspiratory wheeze, suggestive of airway obstruction; or dullness to percussion as a result of underlying pleural effusion. Lymph node enlargement in the neck (Web Fig. 24-8) or axillary areas is suggestive of metastatic disease. The most common sites of metastases are the lymph nodes, liver (Web Fig. 24-9), brain, adrenal glands, kidneys, and lungs.

Lung cancers that occur in the apex of the chest and invade apical chest wall structures are known as *superior sulcus* or *Pancoast tumors* (Web Fig. 24-10). These tumors often result in symptoms and physical findings caused by direct extension to adjacent structures. The classic description involves a syndrome of pain radiating down the arm due to tumor erosion into the brachial plexus. Tumor erosion into the cervical sympathetic chain can result in *Horner syndrome*, which is characterized by the following triad of physical findings: ptosis, miosis, and anhidrosis over the face and forehead.

NON-SMALL CELL CARCINOMAS

Most cases of lung cancer are due to NSCLCs. Of these, *adenocarcinomas* and *squamous cell carcinomas* are the most common.

Squamous cell carcinomas arise from the epithelial layer of the bronchial wall as normal columnar epithelial cells undergo metaplasia, eventually being replaced by increasingly atypical squamous epithelial cells. A localized carcinoma (*carcinoma in situ*) forms and later extends beyond the bronchial mucosa as it becomes invasive. Because most squamous cell carcinomas (60% to 80%) tend to be located within central airways (Web Fig. 24-11), the airway lumen may become obstructed, leading to collapse of the lung (atelectasis) or postobstructive pneumonia. Although necrosis and cavity formation may occur in any lung tumor, this feature is more common with squamous cell carcinomas (see Web Fig. 24-5). Because of their slow rate of growth, these tumors have the lowest propensity for metastasis of all types of lung cancer. Pathologically, squamous cell carcinomas can be distinguished from other NSCLCs by the presence of keratinization, pearl formation, and intercellular bridging.

Adenocarcinomas represent the most common type of lung cancer as well the most common type in nonsmokers (nearly 20% of all cases). In contrast to squamous cell carcinomas, adenocarcinomas are most often found in the periphery of the lung (75%) (Web Fig. 24-12). This tumor is frequently associated with malignant pleural effusions (60%) and has a high propensity for distant metastasis. Pathologically, adenocarcinomas can form glandlike structures and produce mucus. The tumor cells stain positive for carcinoembryonic antigen (CEA), mucin, and surfactant apoprotein. Adenocarcinomas respond poorly to therapy and carry a very poor prognosis. Alveolar or *bronchoalveolar cell carcinomas* represent a subset of adenocarcinomas and are the most common form of lung cancer found in nonsmokers and young patients. They can develop as a lung infiltrate or as a solitary nodule and can be accompanied by bronchorrhhea. Pathologically, malignant cells can appear to grow and spread along preexisting alveolar walls.

Large cell carcinomas also frequently develop as a peripheral lesion and may be associated with pneumonitis and hilar adenopathy. Two subtypes can exist: *giant cell*, an anaplastic tumor that has a median survival for patients younger than 1 year; and *clear cell*, a tumor that resembles renal cell carcinoma and has fewer malignant features. Pathologically, large cell carcinomas lack the glandular and squamous features typical of other NSCLCs and cytologic features typical of SCLCs. In this respect, it is considered a diagnosis by exclusion.

SMALL CELL LUNG CARCINOMA

Small cell carcinoma is strongly associated with cigarette smoking. Tumor cells are of pulmonary neuroendocrine cell origin and are often associated with paraneoplastic syndromes (Table 24-1). SCLCs typically are perihilar in location, not infrequently originating in the main bronchi, and often have associated lymphadenopathy (Web Fig. 24-13). These tumors metastasize rapidly, most commonly to the thoracic lymph nodes, bones, liver, adrenal glands, and brain. Most patients have metastatic disease at the time of presentation. SCLC has traditionally been staged as *limited disease* (confined to one hemithorax) or *extensive disease* (distant metastases), although a TNM staging system has recently been suggested. SCLC is an aggressive lung tumor,

Table 24-1 Paraneoplastic Syndromes Associated with Bronchogenic Carcinoma

Syndrome	Cell Type	Mechanism
Hypertrophic pulmonary osteoarthropathy and clubbing	All except small cell	Unknown
Hyponatremia	Small cell most common; may be any type	SIADH, ectopic antidiuretic hormone production by tumor
Hypercalcemia	Usually squamous cell	Bone metastases, osteoclast-activating factor, parathyroid hormone–like hormone, prostaglandins
Cushing syndrome	Usually small cell	Ectopic ACTH production
Eaton-Lambert myasthenic syndrome	Usually small cell	Voltage-sensitive calcium channel antibodies in >75%; affects presynaptic neuronal calcium channel activity
Other neuromyopathic disorders	Small cell most common; may be any type	Antineuronal nuclear antibodies, also known as anti-Hu; others unknown
Thrombophlebitis	All types	Unknown

ACTH, adrenocorticotropic hormone; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

and, without treatment, the median survival of patients with this cancer is less than 5 months. The overall survival at 5 years is 5% and has not improved significantly over the past several decades.

MANAGEMENT

The management of lung cancer includes strategies targeting prevention, early detection, and treatment. Of these, the most effective approach is prevention. Because tobacco abuse is the main causal agent known to promote the development of lung cancer, strategies designed to prevent people from smoking or to promote smoking cessation should be encouraged. Individuals who are successful at quitting smoking have a lower long-term rate of lung cancer death than individuals who continue to smoke. A diet rich in fruits and vegetables may protect against the development of lung cancer in smokers. However, high-dose supplemental β carotene has been shown to increase the relative risk for lung cancer in two randomized controlled trials, and should not be recommended. There is no evidence that other supplemental vitamins reduce lung cancer risk.

Because lung cancer typically presents at an advanced stage, when cure is not possible, an effective strategy for early detection of lung cancer at a curative stage would be desirable. Therefore, there has long been interest in lung cancer screening. Unfortunately, randomized trials of screening with chest radiographic studies or sputum cytologic testing did not demonstrate a decrease in lung cancer mortality. Current trials focus on the use of low dose computed tomography (CT). The National Lung Screening Trial, sponsored by the National Cancer Institute, is a randomized trial of whether CT or chest radiography can reduce lung cancer mortality in smokers and has recently completed enrollment. Until results from this trial are available, there is no current recommended screening modality for the early detection of lung cancer in at risk patients.

When a suspected lung cancer is identified, either incidentally or because of clinical symptoms, a tissue diagnosis is essential in most patients, unless they are too debilitated to undergo treatment. If imaging reveals sites of suspected metastasis, the site of biopsy should be chosen to determine the greatest extent of spread, or highest stage, of the tumor if this is feasible. If the apparent tumor is confined to the

chest, bronchoscopy is appropriate for central masses, whereas transthoracic needle aspiration of more peripheral lesions can be performed. If present, pleural effusion should be sampled to assess for malignant cells. In some cases, if the pretest probability is very high that the lung lesion is a primary lung cancer, and there is no imaging evidence of disease spread, direct referral for surgical resection may be appropriate.

Once a lung cancer is diagnosed, staging is necessary to determine the treatment and prognosis. For NSCLC, staging is critical to determine whether the patient would benefit from surgical resection for curative intent, or from other treatment modalities such as chemotherapy. Chest CT, including images of the upper abdomen, is useful to delineate the location and size of the primary tumor and to examine for mediastinal lymph nodes, pleural disease, and adrenal or liver metastases. However, CT has limited ability to distinguish benign versus malignant lymphadenopathy in the mediastinum. Positron-emission tomography (PET) using 18-fluorodeoxyglucose (FDG) is more sensitive and specific than CT in the detection of mediastinal lymph node metastases and may also detect unexpected metastases elsewhere in the body. In general, suspected mediastinal or extrathoracic metastases demonstrated by imaging should be confirmed with tissue sampling before determining that a patient is not an operative candidate. Techniques for invasive staging of the mediastinal lymph nodes include endoscopic transbronchial needle aspiration, endoscopic ultrasound-guided needle aspiration, and mediastinoscopy. Mediastinoscopy is also frequently performed to rule out mediastinal spread of disease in patients without definite imaging evidence of lymph node involvement before definitive resection of the lung cancer. PET scanning is limited in its ability to detect brain lesions, and head CT with intravenous contrast or magnetic resonance imaging (MRI) should be performed if the clinical history or examination suggests brain metastasis. Bone scans are useful for the investigation of suspected bony metastases if there are corresponding symptoms.

The treatment of lung carcinoma depends on the stage. See Table 24-2 for the International Staging System for Lung Cancer. Occasionally, SCLCs can be resected if no evidence of metastasis is found, but most SCLCs are treated with chemotherapy, with thoracic external-beam radiation if

Table 24-2 TNM Staging System for Lung Cancer**Primary Tumor (T)**

- T1—Tumor \leq 3 cm diameter without invasion more proximal than lobar bronchus
- T2—Tumor $>$ 3 cm diameter or tumor of any size with any of the following characteristics:
 Invasion of visceral pleura
 Atelectasis of less than entire lung
 Proximal extent at least 2 cm from carina
- T3—Tumor of any size with any of the following characteristics:
 Invasion of chest wall
 Involvement of diaphragm, mediastinal pleura, or pericardium
 Atelectasis involving entire lung
 Proximal extent within 2 cm of carina
- T4—Tumor of any size with any of the following:
 Invasion of mediastinum
 Invasion of heart or great vessels
 Invasion of trachea or esophagus
 Invasion of vertebral body or carina
 Presence of malignant pleural or pericardial effusion
 Satellite tumor nodule(s) within same lobe as primary tumor

Nodal Involvement (N)

- N0—No regional node involvement
- N1—Metastasis to ipsilateral hilar and/or ipsilateral peribronchial nodes
- N2—Metastasis to ipsilateral mediastinal and/or subcarinal nodes
- N3—Metastasis to contralateral mediastinal or hilar nodes or ipsilateral or contralateral scalene or supraclavicular nodes

Metastasis (M)

- M0—Distant metastasis absent
- M1—Distant metastasis present (includes metastatic tumor nodules in a different lobe from the primary tumor)

Stage Groupings of TNM Subsets

Stage IA	T1 N0 M0	Stage IIIA	T3 N1 M0
Stage IB	T2 N0 M0		T1-3 N2 M0
Stage IIA	T1 N1 M0	Stage IIIB	Any T N3 M0
Stage IIB	T2 N1 M0		T4 Any N M0
	T3 N0 M0	Stage IV	Any T Any N M1

disease is limited. Combinations of cisplatin and etoposide are the standard chemotherapeutic regimen. Although chemotherapy and radiation often produce a dramatic response and sometimes are curative for limited disease, relapse is typical, and subsequent treatments are less effective. Prophylactic cranial radiation may be performed. Surgery is the only curative therapy for NSCLC and is indicated for patients with stage I or II NSCLC who are operative candidates. Lobectomy (or greater) extent of resection is considered superior to more limited resection such as a wedge resection. Adjuvant chemotherapy is appropriate for patients with stage II disease. For patients with stage IIIA lung cancer, the optimal treatment strategy remains unclear, in part because of the heterogeneity of patients in this group. In general, these patients are not candidates for surgery alone, if at all, and a treatment plan should be developed for each patient in a multidisciplinary setting. In stage IIIB,

surgery may rarely be indicated for some T4 N0-1 M0 tumors. However, most patients with stage IIIB NSCLC are not surgical candidates, and 5-year survival is poor for this group. Combined, ideally concurrent, chemotherapy and radiotherapy are preferable to radiotherapy alone in patients with stage IIIB NSCLC. In stage IV, chemotherapy is recommended because it improves survival and provides palliation for symptoms.

Targeted molecular therapies are an area of active interest in lung cancer treatment. Highlighting the challenges of these new targeted therapies, bevacizumab, a humanized monoclonal antibody against vascular endothelial growth factor, was associated with hemoptysis, which was sometimes fatal, in patients with squamous cell carcinoma in an early-stage trial. However, bevacizumab improved survival when added to a standard platinum-based chemotherapeutic regimen in patients with nonsquamous NSCLC. Erlotinib, a tyrosine kinase inhibitor targeting the activity of the epidermal growth factor receptor, is approved for the second-line treatment of metastatic NSCLC. Targeting the epidermal growth factor receptor appears to have benefit in particular patient groups, such as women, never-smokers, and Asians, harboring particular receptor mutations.

Special Circumstances

SOLITARY PULMONARY NODULE

A *solitary pulmonary nodule* (SPN) is a single, rounded lesion in the lung that is 3 cm or less in diameter. Although these lesions are commonly lung cancers in certain patient populations, the differential diagnosis of this radiographic finding is broad and includes many malignant and benign etiologies. In addition to primary lung cancer (with adenocarcinoma the most common type to present as an SPN (see **Web Fig. 24-12**), other malignant etiologies include bronchial carcinoma tumors and metastatic foci from extrapulmonary malignancies (most common sources include malignant melanoma, sarcoma, colon, kidney, breast, and testicle). Benign etiologies include benign tumors of the lung (hamartomas (**Web Fig. 24-14**), infectious granulomas (from fungal diseases including histoplasmosis and coccidioidomycosis as well as mycobacterial disease), lung abscess, vascular abnormalities (arteriovenous malformation), rounded atelectasis, and pseudotumor (pleural fluid trapped within a fissure).

When confronted with a patient with a solitary pulmonary nodule, determining the likelihood of malignancy is critically important because early resection of malignant nodules is usually curative, whereas resection of benign nodules exposes the patient to an unnecessary risk for surgery. Diagnostic evaluation includes consideration of certain *clinical features*, including patient **age** and **risk factors**. The probability of an SPN being malignant increases with patient age. However, even in younger individuals ($<$ 35 years), SPNs may still be malignant, so a benign etiology should not be assumed. The probability of lung cancer is greater when an SPN is detected in an individual with a heavy smoking history. Certain *radiographic features* can also be helpful in predicting whether an SPN is benign or malignant. **Size** of the SPN is important because larger lesions are more likely to be malignant. Lesions 4 to 7 mm in size in

individuals without a history of cancer have been described to have a 0.9% chance of being malignant, whereas this likelihood increases to 18% for lesions 8 mm to 2 cm and 50% for those above 2 cm. SPNs with smooth and discrete **borders** are more likely to be benign, whereas those with irregular and spiculated borders are more likely to be malignant. Patterns of **calcification** suggestive of a benign SPN include diffuse, central, laminated (or onion-skin), and popcorn patterns. Lesions with peripheral or eccentric (asymmetrical) calcifications are more likely to be malignant. Imaging studies should be compared with previous studies if available because the presence of an SPN without a **change in size** for more than 2 years dramatically reduces the likelihood of it being malignant.

Further characterization of SPNs typically includes the use of imaging modalities including **chest CT** because it is able to provide more specific information about the location, pattern of calcification, and edge characteristics of nodules as well as identifying unsuspected lymphadenopathy, synchronous parenchymal lesions, or invasion of the chest wall or mediastinum. More recently, metabolic imaging with **PET** has been used by clinicians to distinguish benign and malignant SPNs as those that are malignant typically take up FDG avidly. A negative PET will exclude malignancy in most cases because the negative predictive value for the test is quite high (90% to 95%). However, false-negative results can occur with certain tumors, including bronchioloalveolar cell carcinomas and carcinoids. In addition, PET is less sensitive for small lesions and should not be used routinely to evaluate SPNs smaller than 8 to 10 mm. A positive PET can be less helpful because the positive predictive value of the test is lower (80%) as certain benign lesions (infectious, inflammatory, granulomatous) take up FDG.

The initial management of an SPN uses *clinical* and *radiographic features* to help the clinician to estimate a *pretest probability* of malignancy. Several validated prediction models exist and may aid in this process, but these are generally as accurate as estimates made based on the clinical judgment of experienced clinicians. Although many reasonable approaches exist, guidelines published by the American College of Chest Physicians in 2007 describe a diagnostic algorithm for SPNs 8 mm to 3 cm in size. These guidelines recommend that SPNs with a **low** pretest probability of malignancy can be followed with serial CT scans at 3, 6, 12, and 24 months. SPNs with a **high** pretest probability of malignancy should be removed surgically (provided that the patient is a candidate for surgery), either by thoracotomy or by a less invasive thoracoscopic approach for more peripherally located lesions (video-assisted thoracic surgery [VATS]). A more definitive resection (lobectomy) would then be offered if the SPN is found to be malignant. Management of the most common type of SPN, those with an **intermediate** pretest probability, may include the use of **FDG-PET** to further characterize the lesion, or nonsurgical biopsies, either CT-guided (for peripheral lesions) or bronchoscopic (for central lesions). Those with a negative work-up may be followed by serial CT scans with the low probability group. For those with positive tests or for patients who desire a more aggressive diagnostic approach, surgical options may be pursued. Management recommendations for SPNs smaller than 8 mm were published by the Fleischner Society in 2005. Serial CT scans at various intervals, as determined

by SPN size and whether the patient is considered to be high risk (history of smoking or of other risk factors) or low risk (minimal or absent history of smoking and of other risk factors) have been suggested.

PARANEOPLASTIC SYNDROMES

Paraneoplastic syndromes are usually neurologic syndromes that are rare and are elicited by a patient's immune response to tumors of the lung, ovaries, breast, and lymphatic system (see Table 24-2). Neurologic symptoms develop over weeks and may include difficulties in walking or swallowing, loss of muscle tone, loss of fine-motor coordination, slurred speech, memory loss, vision problems, dementia, sleep disturbances, seizures, and vertigo. Neurologic paraneoplastic syndromes include stiff person syndrome, encephalomyelitis, cerebellar degeneration, neuromyotonia, and sensory neuropathy. Neuromuscular junction disorders can occur, as observed in the Lambert-Eaton myasthenic syndrome and in myasthenia gravis. Myopathies are observed and can exhibit symptoms reminiscent of polymyositis. Retinopathies, certain visual loss syndromes, hyponatremia, hypercalcemia, and Cushing syndrome can also be manifestations of a paraneoplastic syndrome.

Evaluation of Surgery for the Patient with Lung Cancer

A multidisciplinary approach, using the expertise of a thoracic surgeon specializing in lung cancer, a medical oncologist, a radiation oncologist, and a pulmonologist, is often used to evaluate patients with lung cancer for surgical resection. The presurgical evaluation of patients with lung cancer involves staging of the tumor (see Table 24-2), the determination of surgical resectability, and the evaluation of lung function to determine whether the patient is a good candidate for surgery. Staging of a tumor begins with a careful history and physical examination, followed by a CT scan of the chest. Mediastinoscopy is often needed to evaluate mediastinal nodes. Other tests (e.g., PET scans, CT scans of the head) are necessary if specific symptoms or findings from the physical examination or laboratory results are suggestive of extrapulmonary involvement. Once it is determined that surgery is the most appropriate approach based on staging, evaluation of the patient's general status and ability to tolerate the procedure is necessary. Because many patients with lung cancer have co-morbid conditions that increase the likelihood of an adverse perioperative cardiovascular event, a preoperative cardiologic evaluation may be warranted.

A comprehensive preoperative physiologic assessment is important to estimate the preoperative risk from underlying pulmonary disease. Because lung cancer is more common in smokers, many patients have chronic lung disease (e.g., chronic obstructive pulmonary disease [COPD]), and lung function testing is necessary as an initial step in the presurgical evaluation. Forced expiratory volume in 1 second (FEV₁) measured by spirometry is commonly used to assess the suitability of patients with lung cancer for surgery. Patients

with an FEV₁ higher than 2 L (for pneumonectomy), higher than 1.5 L (for lobectomy), or more than 80% of predicted are considered to have an average preoperative risk. For patients with an acceptable FEV₁ but with unexplained dyspnea on exertion or evidence of interstitial lung disease on chest imaging, further work-up, including the measurement of carbon monoxide diffusion capacity (DLCO), is necessary. In this situation, if the measured DLCO is more than 80% of predicted, the patient is still considered to have an average preoperative risk. For patients with a low DLCO or FEV₁, a radionuclide perfusion scan may be performed

to estimate the predicted postoperative values for both of these tests. If the predicted postoperative DLCO or FEV₁ is more than 40%, it is thought that these patients also have an average preoperative risk. For all others, cardiopulmonary exercise testing (CPET) may be done to determine the maximum capacity of an individual's body to transport and utilize oxygen during *incremental exercise*, or Vo₂max. If the measured Vo₂max is less than 10 to 15 mL O₂/kg body weight per minute (roughly equivalent to being unable to climb one flight of stairs), the patient would be considered to have increased preoperative risk.

Prospectus for the Future

Lung cancer is the number one cause of cancer death in both women and men in the United States, with tobacco exposure representing the main predisposing factor. Despite the widespread use of aggressive treatment, including chemotherapy, the 5-year survival rate for lung cancer was 15% in the United States for the period from 1996 to 2004. The focus of efforts should remain prevention through smoking cessation programs, continued public education on the hazards of smoking, and discouraging young individuals from using cigarettes. Screening for lung cancer in at-risk individuals may ultimately become a part of the routine assessment, although whether imaging strategies or novel techniques for identifying signature DNA modifications in the respiratory epithelium or blood of a smoker will ultimately be the modality of choice remains to be seen. Chemoprevention remains elusive, with trials of vitamin and antioxidant strategies proving disappointing or

even hazardous. The focus in chemopreventive strategies has shifted to anti-inflammatory drugs, and the outcomes of trials of these agents will be of interest. Improvements in the care of patients with a diagnosis of lung cancer are needed. Novel approaches to SCLC are emerging from the research on this tumor's molecular pathogenesis, and targeting of specific pathways, like the sonic hedgehog signaling pathway, may provide the breakthrough needed to improve survival in this condition after a decades-long plateau. Defining the best adjuvant strategies to decrease recurrence rates after surgery; individualizing care by identifying optimal candidates for targeted molecular therapies to maximize treatment effects; identifying and targeting cancer stem cells and overcoming cancer stem cell drug resistance; and examination of nonsurgical tumor ablative strategies for the marginal surgical candidate are among the many areas of necessary and ongoing research in NSCLC.

Preoperative and Postoperative Care

25 Preoperative and Postoperative Care – LAU * EAGLE

Preoperative and Postoperative Care

Wei C. Lau and Kim A. Eagle

More than 40 million people undergo noncardiac surgical procedures in the United States annually. It is estimated that the incidence of cardiac complications after noncardiac surgical procedures is between 0.5% and 1%. Consequently, about 200,000 to 400,000 people will suffer from perioperative cardiac complications. Moreover, one out of four or more of these patients will die. Patients who survive a postoperative myocardial infarction (MI) are twice as likely to die in the following 2 years as patients with uneventful surgical procedures. Emerging evidence-based practices dictate that the practicing physician should thoughtfully perform an individualized evaluation of the surgical patient to provide an accurate preoperative risk assessment, risk stratification, and modification of risk parameters that can then guide the framework for optimal perioperative risk reduction strategies. This chapter reviews preoperative and postoperative cardiovascular risk assessment, targeting intermediate-risk to high-risk patients to strategically guide perioperative preventive therapies that may favor optimal outcome.

Evaluation of Intermediate-Risk to High-Risk Patients

Mortality is extremely low with safe delivery of modern-day anesthesia in low-risk patients undergoing low-risk surgery (Table 25-1). Simple standardized preoperative screening questionnaires have been developed for the purpose of identifying patients at intermediate to high risk that may benefit from a more detailed clinical evaluation (Table 25-2). Evaluation of such surgical patients should always begin with a thorough history and physical examination with 12-lead resting echocardiogram (ECG) in accordance with the American College of Cardiology/American Heart Association (ACC/AHA) guideline recommendations. Determining the urgency of the surgery should be included in the history

because true emergent procedures are associated with an unavoidably higher morbidity and mortality. Preoperative testing should only be done for specific clinical conditions based on the history. Thus, healthy patients of any age undergoing elective surgical procedures without coexisting medical conditions should not require any testing unless the degree of surgical stress may result in unusual changes from the baseline state. The history should focus on symptoms of occult cardiac disease.

Preoperative Cardiac Risk Assessment

Assessment of exercise tolerance in preoperative risk stratification and precise prediction of in-hospital perioperative risk is most applicable in patients who self-report worsening exercise-induced cardiopulmonary symptoms, patients who may benefit from noninvasive or invasive cardiac testing regardless of scheduled surgical procedure, and patients with known coronary artery disease (CAD) or with multiple risk factors and the ability to exercise. For predicting perioperative events, “poor” exercise tolerance has been defined as the inability to walk four blocks and climb two flights of stairs or as the inability to meet a metabolic equivalent (MET) level of 4 (Table 25-3). Further clinical risk assessment often uses risk indices derived from empirical multivariable predictive models based on available clinical information that identified risk factors to identify patients at elevated perioperative cardiac risk. Previous studies have prospectively compared several cardiac risk indices with one another, and the revised cardiac risk index (RCRI) is favored by many given its accuracy and simplicity (Table 25-4). The RCRI relies on the presence or absence of six identifiable predictive factors, which include high-risk surgery, ischemic heart disease, congestive heart failure, cerebrovascular disease, diabetes mellitus, and renal failure. Each of the RCRI predictors is assigned one point, when present. The risk for cardiac events (including MI, pulmonary edema, ventricular

Table 25-1 Surgery-Specific Risk

Higher Risk

- Emergent major operations, especially in elderly patients
- Aortic and other major vascular (endovascular and nonendovascular) surgery
- Noncarotid peripheral vascular surgery
- Prolonged surgery associated with large fluid shift and/or blood loss

Intermediate Risk

- Major thoracic surgery
- Major abdominal surgery
- Carotid endarterectomy
- Head/neck surgery
- Orthopedic surgery
- Prostate surgery

Lower Risk

- Eye, skin, and superficial surgery
- Endoscopic procedures

Table 25-3 Functional Status

Excellent (activities requiring >7 METs)

- Carry 24 lb up eight steps
- Carry objects that weigh 80 lb
- Outdoor work (shovel snow, spade soil)
- Recreation (ski, basketball, squash, handball, jog or walk 5 mph)

Moderate (activities requiring >4 but <7 METs)

- Have sexual intercourse without stopping
- Walk at 4 mph on level ground
- Outdoor work (garden, rake, weed)
- Recreation (roller-skate, dance, foxtrot)

Poor (activities requiring <4 METs)

- Shower/dress without stopping, strip and make bed, dust, wash dishes
- Walk at 2.5 mph on level ground
- Outdoor work (clean windows)
- Recreation (golf, bowl)

MET, metabolic equivalent.

Table 25-2 Standardized Preoperative Questionnaires*

1. Age, Weight, Height
2. Are you:
 - a. Female and 55 years of age or older or male and 45 years of age or older?
 - b. If yes, are you also 70 years of age or older?
3. Do you take anticoagulant medications ("blood thinners")?
4. Do you have or have you had any of the following heart related conditions?
 - a. Heart disease
 - b. Heart attack within the last 6 months
 - c. Angina (chest pain)
 - d. Irregular heartbeat
 - e. Heart failure
5. Do you have or have you ever had any of the following?
 - a. Rheumatoid arthritis
 - b. Kidney disease
 - c. Liver disease
 - d. Diabetes
6. Do you get short of breath when you lie flat?
7. Are you currently on oxygen treatment?
8. Do you have a chronic cough that produces any discharge or fluid?
9. Do you have lung problems or diseases?
10. Have you or any blood member of your family ever had a problem with any anesthesia other than nausea?
 - a. If yes, describe
11. If female, is it possible that you could be pregnant?
 - a. Pregnancy test
 - b. Please list date of last menstrual period

*University of Michigan Health System patient information report. Patients who answer yes to any of questions 2 through 9 should receive a more detailed clinical evaluation.

fibrillation or primary cardiac arrest, and complete heart block) (see Table 25-4) can then be predicted. Based on the presence of 0, 1, 2, 3, or more of these clinical predictors, the rates of major cardiac complications are estimated to be 0.4% to 0.5%, 0.9% to 1.3%, 4% to 6.6%, and 9% to 11%, respectively (Fig. 25-1). Cardiac risk particularly increases with two or more predictors, and is greatest with three predictors or more. The clinical utility of the RCRI is to identify patients at higher risk for cardiac complications and to determine whether they may benefit from further risk stratification with noninvasive cardiac testing or initiation of preoperative preventive medical management.

PREOPERATIVE NONINVASIVE CARDIAC TESTING FOR RISK STRATIFICATION

Evidence discourages widespread application of preoperative noninvasive cardiac testing for all patients. Rather, a selective approach based on clinical risk categorization appears to be both effective and cost-effective. The selection of noninvasive cardiac stress tests for the occasional patient should anticipate that the patient will meet guidelines for coronary revascularization after coronary angiography or an adjustment in medical therapy, and no testing is recommended when it might delay surgical intervention for urgent or emergent conditions. There is potential benefit of coronary revascularization through identification of asymptomatic but high-risk patients (patients with left main disease, left main equivalent disease, or triple coronary vessel disease with poor left ventricular function). However, evidence does not support aggressive attempts to identifying intermediate-risk patients with asymptomatic but advanced CAD when coronary revascularization appears to offer little advantage over excellent medical therapy. An RCRI score of ≥ 3 in patients with severe myocardial ischemia suggestive of left main or three-vessel disease should lead to consideration of coronary revascularization before noncardiac surgery for appropriate patients. Noninvasive cardiac testing is most appropriate if it is anticipated that a patient will meet guidelines for initiation of additional medical therapy or coronary angiography and coronary revascularization in the event of a positive test. Pharmacologic stress tests, instead of exercise tests, are typically reserved for patients with functional limitations. Dobutamine echocardiography and nuclear perfusion testing for purposes of identifying patients at risk for perioperative MI or death have excellent negative predictive

values (near 100%) but poor positive predictive values ($<20\%$). Thus, a negative study is reassuring, but a positive study is still only a weak predictor of a “hard” perioperative cardiac event. Which higher risk patients are most likely to benefit from preoperative noninvasive cardiac testing and treatment strategies to improve outcomes is not well defined.

CHOICES OF NONINVASIVE CARDIAC TESTING

The choices among noninvasive tests should be based on the need to assess valvular or ventricular function and on which test is most reliable and available locally. Dobutamine stress echocardiography is often used because it has excellent overall predictive performance, as well as providing additional information about valvular and left ventricular dysfunction. A rapidly developing diagnostic modality is dobutamine stress magnetic resonance imaging (MRI), although sensitivity and specificity data are still pending at this time.

Exercise Testing

In general, poor functional capacity associated with exercise-induced ischemia indicates a higher risk for perioperative cardiac events, and achieving an excellent workload indicates a lower risk. The ability to attain 75% to 85% of maximal age-predicted heart rate is predictive of a lower rate of perioperative cardiac events. In patients with baseline ECG abnormalities and an inability to exercise secondary to comorbid conditions, pharmacologic stress echocardiography or nuclear imaging is preferred.

Dipyridamole-Thallium Imaging Stress Test

Preoperative dipyridamole-thallium imaging has excellent negative predictive value (between 90% and 100%), and low positive predictive value (6% and 67%), making it more useful for reducing risk estimates when negative than for identifying very-high-risk patients when positive. The presence of thallium redistribution, especially in increasing numbers of myocardial segments, identifies patients at greater risk for perioperative cardiac complications, whereas the presence of fixed defects identifies patients at intermediate risk, particularly for late cardiac events.

Dobutamine Stress Echocardiography

The number of myocardial segments demonstrating wall motion abnormalities or wall motion changes at low infusion rates of dobutamine identifies patients at higher risk for perioperative cardiac events. The predictive value of dobutamine and dipyridamole stress echocardiography and of dipyridamole-thallium myocardial perfusion scintigraphy in patients undergoing major vascular surgery demonstrated a trend favoring dobutamine stress echocardiography.

Ambulatory Electrocardiographic Monitoring

Studies using preoperative ambulatory ECG monitoring have demonstrated a predictive value similar to that of dipyridamole thallium. However, current evidence does not support its sole use for identifying patients to be referred for coronary angiography.

PREOPERATIVE INVASIVE CARDIAC TESTING FOR RISK STRATIFICATION

Recommendations for perioperative coronary angiography are similar to those for patients with suspected or known CAD in general and should conform to the ACC/AHA guidelines for coronary angiography. This procedure should be considered for patients who have evidence of being at high risk for adverse outcome based on noninvasive test results, unstable angina, angina refractory to medical treatment, high-risk results on noninvasive testing, or a nondiagnostic test in patients at high risk undergoing high-risk noncardiac surgery. It should be considered on an individual basis for limited to extensive ischemia during noninvasive testing, for patients at intermediate risk undergoing high-risk surgery with nondiagnostic test results, for patients convalescing from MI who need urgent noncardiac surgery, and for patients with perioperative MI. In patients who have a high clinical risk (RCRI > 3) and who have high-risk features on noninvasive cardiac testing should be considered for diagnostic cardiac catheterization (see Fig. 25-1).

PREOPERATIVE RISK MODIFICATION TO REDUCE PERIOPERATIVE CARDIAC RISK

Coronary Revascularization

Retrospective analyses of the Coronary Artery Surgery Study (CASS) registry and Bypass Angioplasty Revascularization Investigation (BARI) and prospective study of patients enrolled in the Coronary Artery Revascularization Prophylaxis (CARP) trial have shown that prophylactic coronary revascularization with either coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI) provides no short-term or mid-term benefit for patients without left main disease or multivessel CAD in the presence of poor left ventricular systolic function. High-risk patients who have successfully undergone PCI or CABG before elective noncardiac surgeries experience fewer adverse perioperative cardiovascular events compared with similar patients treated with medications alone. However, the mortality and morbidity associated with PCI or CABG appears to offset the potential benefit of coronary revascularization before any high-risk cardiac surgery like major vascular surgery. Thus, evidence is lacking in support for elective coronary revascularization as a primary strategy in perioperative risk reduction in intermediate-risk patients undergoing major noncardiac surgery. Recommendations for PCI are similar to those for patients with suspected or known CAD in general and should conform to the ACC/AHA guidelines. Although catheter-based PCI in the perioperative setting is associated with lower procedural risk than CABG, studies have shown that the placement of a stent in a coronary artery shortly before plastic surgery may increase perioperative risk for MI and cardiac death due to in-stent thrombosis. Recommendations by the AHA/ACC Society for Cardiovascular Angiography and Intervention, American College of Surgeons, and American Dental Association Science Advisory Committee are for a 30- to 45-day delay of surgery in patients taking administration of thienopyridine dual-antiplatelet therapy after bare-metal coronary stent placement, and a 365-day wait for a drug-eluting stent. For

patients who need to undergo noncardiac surgery imminently (2 to 6 weeks), drug-eluted stents should not be implanted, and balloon angioplasty appears to be a reasonable alternative. If noncardiac surgery is urgent or emergent, CABG combined with the noncardiac surgery could be considered; however, cardiac risks, the risk for bleeding, and the long-term benefit of coronary revascularization must be weighed.

Currently, studies suggest that optimal medical therapy is the preferred strategy for the intermediate- to high-risk patient population with RCRI score greater than or equal to 2 and without documented severe myocardial ischemia. As noted previously, the CARP trial demonstrated that preoperative coronary revascularization strategies to reduce perioperative cardiovascular risk did not offer significant benefit above and beyond excellent medical treatment in intermediate- to high-risk patients undergoing vascular surgery. However, high-risk patients with left main coronary stenosis, severe aortic stenosis, left ventricular ejection fraction less than or equal to 20%, or unstable coronary symptoms were excluded from the trial. In many of these patients, coronary or valve surgery is indicated on its own merit, without factoring in the noncardiac surgery. Thus, coronary revascularization may be appropriate if diagnostic catheterization reveals left main disease or multivessel disease with depressed ejection fraction. Using the information obtained from the composite algorithm (Fig. 25-2), a key decision is whether the risk for perioperative cardiac events is sufficiently low to proceed with surgery. For patients identified at high cardiac risk who are not candidates for coronary revascularization, this may result in a decision to perform a less extensive or limiting major plastic reconstruction, consider laparoscopic versus open procedures or alternative palliative procedures, or attempt to modify cardiac risk by additional intraoperative and perioperative therapies.

β -adrenergic Antagonists

Two previous clinical trials and a recent retrospective analysis of a large national database supported the use of β blockers for perioperative cardiac risk reduction in intermediate- to high-risk patients undergoing major noncardiac surgery, and particularly for major vascular surgery. However, prescribing perioperative β blockers should be based on a thorough assessment of a patient's perioperative cardiac risk (RCRI = 2) and not broad inclusion criteria, to yield a favorable risk-to-benefit ratio in patients who are at increased cardiac risk. For patients with or without mild to moderate reactive airway disease, it is advised to use the cardioselective β blocker of choice, and titrate to a target resting heart rate of 60 to 65 beats per minute. In intermediate- to high-risk patients without a long-term indication for β blockers, the medications can be administered intravenously as a preoperative medication on the day of surgery, with a targeted heart rate of 60 to 65 beats per minute, and continued for more than 7 days, preferably 30 days, after surgery. This targeted heart rate of 60 to 65 beats per minute should be titrated to avoid intraoperative and postoperative heart rate of less than 50 beats per minute and systolic blood pressure of less than 100 mm Hg. Intravenous preparations should be substituted for oral medication if patients are unable to take or absorb pills in the perioperative period.

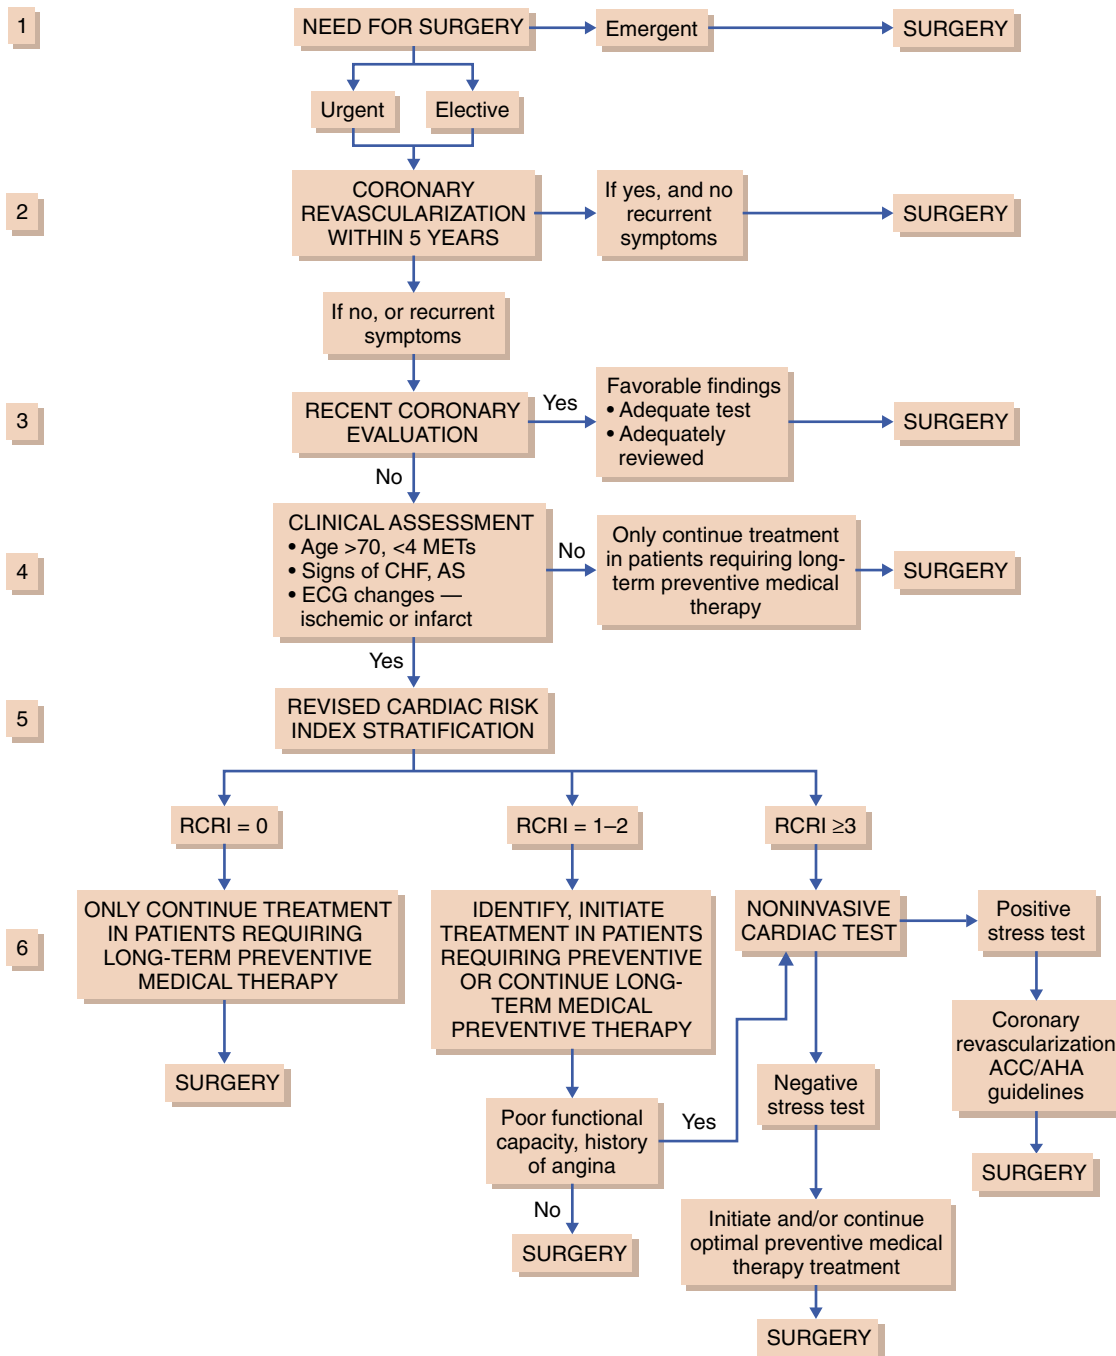

Figure 25-2 Stepwise clinical evaluation for diagnostic cardiac catheterization: (1) emergency surgery; (2) prior coronary revascularization; (3) prior coronary evaluation; (4) clinical assessment; (5) revised cardiac risk index; (6) risk modification strategies. Preventive medical therapy included β -blocker and statin therapy. ACC, American College of Cardiology; AHA, American Heart Association; CHF, congestive heart failure; ECG, electrocardiogram; MET, metabolic equivalent; RCRI, reverse cardiac risk index.

The ACC/AHA guideline focusing on recommendations for perioperative β -blocker therapy suggested using β blockers for the following situations: (1) β blockers should be continued in all high-risk patients previously receiving β -blocker therapy undergoing vascular surgery; (2) β blockers should be administered to all high-risk patients identified by myocardial ischemia on preoperative assessment undergoing vascular surgery; (3) β blockers are probably recommended for high-risk patients defined by multiple clinical

predictors undergoing intermediate- or high-risk procedures; (4) β blockers may also be considered for intermediate-risk patients defined by a single clinical predictor undergoing intermediate- or high-risk procedures; (5) β blockers may be considered in low-risk patients defined by clinical predictors not receiving β -blocker therapy undergoing vascular surgery; and (6) β blockers should not be administered in preoperative patients with absolute contraindications to β blockers. As noted, the data favoring a

benefit of β blockers for perioperative risk reduction are most robust in patients undergoing vascular surgery, in whom concomitant CAD is particularly common.

The recent results from the Perioperative Ischemic Evaluation (POISE) trial have addressed the limitation of the ACC/AHA recommendations for perioperative β blockers due to few randomized control trials, in regard to the beneficial effects, the method of titration, the optimal dosing regimen, the route of administration, and the risks of perioperative β blockers. The POISE trial randomized 8351 intermediate- to high-risk patients older than 45 years to either a long-acting oral metoprolol succinate (metoprolol CR) or placebo. A high starting dose of metoprolol CR was administered: 100 mg was started orally 2 to 4 hours before surgery and was continued 0 to 6 hours after surgery (or slow intravenous infusion of 15 mg every 6 hours was administered until patients were able to receive the drug orally), and was continued daily for 30 days. The medication was withheld if systolic blood pressure fell below 100 mm Hg or heart rate was below 50 beats per minute. The results showed that cardiac death, nonfatal MI, or cardiac arrest was reduced in the metoprolol group compared with placebo (5.8% versus 6.9%; hazard ratio, 0.84; 95% confidence interval [CI], 0.70 to 0.99; $P = .04$). However, there was an increased incidence of mortality and stroke in the metoprolol group compared with the placebo group (3.1% versus 2.3%, $P = .03$; and 1% versus 0.5%, $P = .005$, respectively). Thus, for every 1000 patients treated, metoprolol CR would prevent 11 MIs in intermediate- to high-risk patients undergoing major noncardiac surgery, at a cost, however, of eight deaths and five disabling strokes. Stroke was associated with perioperative hypotension, bleeding, atrial fibrillation, and a history of stroke or transient ischemic attack. The POISE trialists highlighted the importance of a clear risk and benefit assessment for the initiation of preoperative β blockers (see Fig. 25-2). β blockers should also be carefully titrated and not abruptly initiated on a high-dose regimen to achieve the desired heart rate in the intermediate- and high-risk patients undergoing noncardiac surgery.

α_2 -adrenergic Agonists

For intermediate- to high-risk patients undergoing major noncardiac surgery who do not tolerate β blockers, evidence supports alternative prophylactic use of α_2 -adrenergic agonists for perioperative cardiac risk reduction. These should only be initiated in stable patients and titrated carefully to prevent significant hypotension and bradycardia.

HMG-CoA Reductase Inhibitors (Statins)

Prospective and retrospective evidence support the perioperative prophylactic use of statins for reduction of perioperative cardiac complications in patients with established atherosclerosis. Although the future role of statin prophylaxis in the reduction of perioperative cardiac risk reduction awaits definitive clarification by the ongoing European (DECREASE IV) trial, perioperative statin therapy should currently be considered in intermediate- to high-risk patients with known atherosclerosis undergoing major noncardiac surgery to reduce perioperative and long-term cardiac risk.

Calcium Channel Blockers

Evidence is lacking to support the use of calcium channel blockers as a prophylaxis strategy to decrease perioperative risk for major noncardiac surgery.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor antagonists are frequently prescribed for the management of hypertension, congestive heart failure, chronic renal failure, and ischemic heart disease. Evidence supports the discontinuation of ACE inhibitors and angiotensin receptor antagonists for 24 hours before noncardiac surgery because of adverse circulatory effects after induction of anesthesia in patients on a chronic ACE inhibitor regimen, and use of vasopressin agonists for refractory hypotension after induction of anesthesia.

Oral Antithrombotic Agents

Evidence-based recommendations regarding perioperative use of aspirin, clopidogrel, or both to reduce cardiac risk currently lacks clarity. A substantial increase in perioperative bleeding and transfusion requirement in patients receiving dual antiplatelet therapy has been observed. The discontinuation of clopidogrel 5 days before and the decision to hold aspirin 5 to 7 days before major surgery to minimize the risk for perioperative bleeding and transfusion must be balanced with the potential increased risk for an acute coronary syndrome, especially in high-risk patients with recent coronary stent implantation. If clinicians elect to withhold aspirin before surgery, it should be restarted as soon as possible postoperatively, especially after vascular graft procedures.

Intraoperative Strategies for Reducing Perioperative Risk

ANESTHETIC MANAGEMENT

Epidural anesthesia and analgesia may improve the outcome of major noncardiac surgery by better suppression of surgical stress, a positive effect on postoperative nitrogen balance, more stable cardiovascular hemodynamic response, reduced blood loss, better peripheral vascular circulation, and better postoperative pain control. Conflicting results from several meta-analyses have been published that examined the safety of general and neuraxial (epidural or spinal) anesthesia on cardiac complications. Rodgers and colleagues reviewed 141 trials, including 9559 patients, and found that overall mortality was reduced by about one third (odds ratio, 0.70; 95% CI, 0.54 to 0.90) in patients randomized to receive neuraxial anesthesia compared with patients who received general anesthesia. Lower rates of venous thrombosis, pulmonary embolism, pneumonia, and respiratory depression were also observed in patients who were provided neuraxial anesthesia. However, there are no existing data to support significant differences in cardiovascular events between the two techniques. A combined neuraxial blockade and general

anesthesia technique has its merits when indicated to reduce the intraoperative general anesthesia requirements. Evidence from a meta-analysis of randomized controlled trials supported postoperative epidural analgesia for the purposes of pain relief for more than 24 hours to help reduce the rate of postoperative MI (rate difference, -3.8% ; 95% CI, -7.4% , -0.2% ; $P = .049$), with subgroup analysis favoring thoracic epidural analgesia compared with systemic analgesia. Neuraxial anesthesia, especially when used for postoperative analgesia, confers reduced postoperative cardiopulmonary complications better or equal to general anesthesia; however, conflicting evidence limits the support for its broad recommendation as the technique of choice for major surgery. Studies have demonstrated that pain management in the perioperative period is crucial for reducing cardiac risk. Adequate pain control reduces catecholamine surges, which are probably responsible for increasing myocardial oxygen demand, induction of coronary vasospasm, increasing the tendency for plaque rupture, and development of a hypercoagulable state. A hematocrit of more than 10 mg/dL and an oxygen tension higher than 60 facilitate tissue oxygenation and help decrease myocardial necrosis.

INTRAOPERATIVE PULMONARY ARTERY CATHETER

The current evidence on whether the use of pulmonary artery catheters (PACs) or a central venous catheter is beneficial for high-risk patients undergoing major noncardiac surgery is controversial. Recommendations from the practice guidelines for PAC in an updated report by the American Society of Anesthesiologist Task Force on PAC does not support the routine use of PAC when there is a low risk for hemodynamic complications in low- or intermediate-risk patients. In a large multicenter randomized trial, Sandham and associates found no benefit to therapy directed by a PAC over standard care in elderly, high-risk surgical patients. PAC may be considered for patients with signs and symptoms of heart failure preoperatively who have a very high postoperative incidence of heart failure, or for high-risk patients with limited ventricular reserve who are undergoing procedures that are likely to cause major hemodynamic shifts.

INTRAOPERATIVE TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Because ischemia-induced myocardial wall motion abnormalities appear earlier than ischemia-induced electric abnormalities, intraoperative transesophageal echocardiography (TEE) was proposed to be a more sensitive monitor of ischemia than conventional intraoperative 2-lead ECG. Similarly, 12-lead ECG monitoring was also proposed to have greater sensitivity than conventional intraoperative ECG. However, when compared with intraoperative monitoring using 2-lead ECG, routine monitoring for myocardial ischemia with TEE or 12-lead ECG during noncardiac surgery lacked robust evidence for incremental value in identifying patients at high risk for perioperative ischemic outcomes. Thus, the routine use of intraoperative TEE is not recommended for monitoring and guiding therapy during noncardiac surgery, except in emergent scenarios in which

the etiology of an acute persistent and life-threatening hemodynamic instability needs to be determined.

MAINTENANCE OF BODY TEMPERATURE DURING NONCARDIAC SURGERY

Current ACC/AHA guidelines recommend the maintenance of body temperature in a normothermic range for procedures other than using hypothermia to provide organ protection. A retrospective analysis of a prospective randomized controlled trial demonstrated that hypothermia (core temperature $< 35^{\circ}\text{C}$) was associated with an increased risk for myocardial ischemia compared with a core temperature greater than or equal to 35°C . A randomized controlled trial in 300 high-risk patients undergoing noncardiac surgery in which patients were randomized to active warming or routine care demonstrated that adverse cardiac events (unstable angina, myocardial ischemia, cardiac arrest, and MI) occurred less frequently in the normothermic group than in the hypothermic group (1.4% versus 6.3%; $P = .02$). Furthermore, hypothermia was an independent predictor of adverse cardiac events by multivariable analysis (relative risk, 2.2; 95% CI, 1.1 to 4.7; $P = .04$), indicating a 55% reduction in risk when normothermia was maintained.

Postoperative Cardiac Risk Assessment

MONITORING FOR MYOCARDIAL INFARCTION

A protocol involving an ECG immediately after surgery and on the first and second postoperative days has the highest sensitivity for detection of postoperative MI, whereas routine measurements of serial creatine kinase and CK-MB had high false-positive rates and do not increase the sensitivity. The myocardium-specific biomarkers such as troponin I and troponin T have emerged as the most sensitive and specific biochemical markers of myocardial injury and infarction and have been associated with an increased risk for cardiac events if their levels are found elevated in the postoperative period. Current recommendations favor monitoring for signs of cardiac dysfunction in patients with evidence of CAD. In such patients undergoing surgical procedures associated with high cardiac risk, ECG at baseline, immediately after surgery, and on the first 2 days postoperatively is recommended. Measurement of cardiac biomarkers should be reserved for patients at high risk and for those who demonstrate ECG changes, angina typical of acute coronary syndrome, or hemodynamic evidence of cardiovascular dysfunction.

POSTOPERATIVE RISK STRATIFICATION AND MANAGEMENT STRATEGIES

Postoperative patient care involves assessment and treatment of modifiable cardiac risk factors, including hypertension, hyperlipidemia, smoking, obesity, hyperglycemia, and physical inactivity. Patients who sustain a perioperative MI or develop evidence of myocardial ischemia should be carefully investigated because they are at substantial cardiac risk

over the subsequent 5 to 10 years. Noninvasive testing to assess left ventricular function and inducible ischemia should be undertaken to identify patients who may benefit from revascularization or optimization of medical therapy. Postoperative heart failure and pulmonary edema should be treated similar to pulmonary edema in the nonoperative setting. An emergency ECG and serial troponin assays are helpful in the event of acute myocardial ischemia.

Noncardiac Surgery in Patients with Specific Cardiovascular Conditions

VALVULAR HEART DISEASE

Special consideration has to be given in preoperative risk assessment for patients with valvular heart disease. All patients undergoing noncardiac surgery should be assessed especially for aortic stenosis by physical examination and two-dimensional echocardiography for any suspicious murmur. One recent study has demonstrated that patients with aortic stenosis have a fivefold increased risk for perioperative mortality and nonfatal MI compared with patients without aortic stenosis. The adjusted relative risks for adverse events is 5.2 for asymptomatic aortic valve gradients between 25 and 50 mm Hg (moderate aortic stenosis) and 6.8 for gradients above 50 mm Hg (severe aortic stenosis). Patients with severe symptomatic aortic stenosis should undergo aortic valve replacement before plastic surgery, if they are thought to be acceptable surgical candidates. In rare instances, balloon aortic valvuloplasty may be justified before elective plastic surgery. A retrospective study suggested that selected patients with asymptomatic severe aortic stenosis could safely undergo noncardiac surgery with careful hemodynamic monitoring. Thus, all patients undergoing noncardiac surgery should be assessed diligently for systolic murmurs accompanied by chest radiography with or without ECG and echocardiographic confirmation as a stepwise diagnostic approach.

There is less known about the perioperative risks associated with mitral stenosis and mitral regurgitation in patients undergoing noncardiac surgery. Clearly, a preoperative history and physical examination, chest radiograph, or ECG will usually provide clues to the diagnosis, which can be confirmed by echocardiography. Accurate diagnosis may help optimize intraoperative anesthetic strategies, choice of pharmacologic intervention and invasive monitoring, and postoperative medical management. Heart rate should be controlled to ensure a sufficient diastolic filling period and avoid pulmonary congestion in patients with mild to moderate mitral stenosis. Patients with severe mitral stenosis are likely to benefit from balloon mitral valvuloplasty or surgical repair before high-risk surgery.

Patients with aortic or mitral valvular regurgitation benefit from volume control and afterload reduction. In aortic insufficiency, it is thought that faster heart rates are better tolerated in this particular condition than slow heart rates because slow heart rates lead to increased diastolic filling and can exacerbate left ventricular volume overload.

Except for perioperative antibiotic prophylaxis to prevent bacterial endocarditis and the need for effective anticoagulation strategies, perioperative complications in patients with prosthetic heart valves are probably similar to those in patients with comparable degrees of native valvular heart disease. In patients with a mechanical valve prosthesis, recommendation for anticoagulation are as follows: in patients requiring minimally invasive procedures (dental, superficial plastic surgery, and biopsies), the international normalized ratio should be reduced briefly to the low or subtherapeutic range, the normal dose of oral anticoagulation resumed promptly after the procedure; and perioperative unfractionated heparin is recommended for patients in whom the risk for bleeding with oral anticoagulation is high and the risk for thromboembolic without anticoagulation is also high (e.g., mechanical mitral valve). Patients between these two extremes should undergo individual assessment for the risk and benefit of reduced anticoagulation with warfarin versus perioperative heparin initiation and brief interruption surrounding surgery.

ARRHYTHMIAS AND CONDUCTION DEFECT

Ventricular and atrial arrhythmias historically are identified as predictors of perioperative cardiac complications. As such, identification of a preoperative arrhythmia warrants a careful evaluation for the presence and severity of underlying ischemic heart disease, cardiomyopathy, or other conditions that may contribute to perioperative complications. Generally, asymptomatic arrhythmias or conduction defects warrant observation only and maintenance of an optimal metabolic state. However, third-degree atrioventricular block can increase operative risk and may necessitate pacing.

CONGESTIVE HEART FAILURE AND LEFT VENTRICULAR DYSFUNCTION

Congestive heart failure (CHF) has been identified as a significant marker of cardiac risk for noncardiac surgery. Every effort should be made to identify the etiology of CHF and optimally control it preoperatively because it is a known risk factor for postoperative cardiac complications. However, there are no evidence-based recommendations for optimal perioperative strategy in patients with heart failure undergoing intermediate- to high-risk noncardiac surgery other than making sure that such patients are taking medications known to improve patients with heart failure in the long-term. Because proper treatment of heart failure depends greatly on its underlying etiology (especially systolic dysfunction versus diastolic dysfunction), characterizing this before elective noncardiac surgery can help in tailoring therapy to each patient. Close monitoring of the volume status is needed to avoid perioperative decompensation. Use of intravenous inotropic agents, vasodilators, or both for a short duration in the perioperative period may be useful to prevent or treat CHF depending on the situation.

HYPERTROPHIC CARDIOMYOPATHY

Patients with echocardiographically documented hypertrophic cardiomyopathy (HCM) are at risk for exacerbation

of dynamic left ventricular outflow tract (LVOT) obstruction during periods of tachycardia, hypotension, or increased inotropy. General anesthesia or neuraxial block can lead to peripheral vasodilation and sympathetic autonomic blockade that may decrease venous return and further exacerbate LVOT obstruction. Observational studies of patients with HCM undergoing noncardiac surgery suggest that for most operations, patients with compensated HCM tolerate the perioperative period well. Perioperative cardiac risk reduction strategies should include avoidance of hypovolemia, vasodilators, phosphodiesterase inhibitors, β -adrenergic agonists, and diligent attention to volume repletion and selected use of α -adrenergic agonists. Patients with hypertrophic cardiomyopathy are at significant risk for developing perioperative hypotension, CHF, and arrhythmias and should be monitored closely.

CONGENITAL HEART DISEASE

Studies have demonstrated that patients with left-to-right cardiac shunts with residual hemodynamic abnormalities after surgical repair experience decreased cardiac output in response to stress. Vigorous treatment of ongoing CHF is required for such patients before noncardiac surgery. Patients with a large left-to-right shunt but only a slight increase in pulmonary artery resistance should undergo cardiac repair before noncardiac surgery. Patients with irreversible pulmonary artery hypertension have an extremely high risk associated with nonsurgical procedures and should not undergo elective procedures unless there is absolutely no alternative. Patients with prior repair of coarctation of the aorta have a significant risk for sudden death during

follow-up, caused by residual cardiac defects with CHF, rupture of a major vessel, dissecting aneurysm, or complications arising from severe atherosclerosis. Such patients also have a high incidence of residual hypertension. Therefore, these patients require careful preoperative assessment and close hemodynamic monitoring during the intraoperative and postoperative periods. Patients with tetralogy of Fallot are also prone to sudden cardiac death. Monitoring and aggressive prevention and treatment of life-threatening arrhythmias such as ventricular tachycardia, or atrioventricular block, are needed for such patients in the perioperative period.

Surgery in patients with cyanotic congenital heart disease with right-to-left shunts poses several unique problems. Most cyanotic patients are polycythemic and therefore are prone to thrombotic complications. Use of diuretics should generally be avoided in such patients because dehydration may increase the blood viscosity and, in turn, increase the tendency for thrombosis, particularly cerebral thrombosis. Patients with a hematocrit greater than 70% should be considered for plasmapheresis before noncardiac surgery. Phlebotomy is not advisable in this circumstance because this can decrease intravascular blood volume and thus increase cyanosis. Patients with a hematocrit between 55% and 65% should receive intravenous fluids starting the night before the surgery. Patients with congenital heart disease should also receive appropriate prophylaxis for bacterial endocarditis. One retrospective report suggested that, with careful monitoring and precautions as outlined previously, patients with right-to-left shunts could undergo noncardiac surgery with relatively few complications, with careful attention not to introduce air into the vascular system.

Prospectus for the Future

CAD accounts for most deaths in patients undergoing noncardiac surgery, in whom perioperative MI is associated with high mortality rates. The success of standardized evidence-based preoperative and postoperative cardiac risk reduction strategies in patients undergoing noncardiac surgery pivots around collaborative teamwork and sound communication among surgeons, anesthesiologist, the patient's primary care physician, and the consultant. The risk for a perioperative cardiac complication varies with the severity of the surgical procedure and with RCRI stratification. A systematic stepwise approach for preoperative cardiac risk assessment for noncardiac surgery facilitates a decision as to whether the risk for perioperative cardiac events is sufficiently low to proceed with surgery. Preoperative noninvasive cardiac testing should be based on a discrete clinical risk categorization, and the choices among

noninvasive tests should be based on the need for coronary, valvular, or ventricular function assessment, and which test is most reliable and available locally. In patients with strong suspicion of having or being at risk for CAD, β blockers should be given in the perioperative period, starting at least 24 hours and preferably days before the procedure and titrated to a heart rate of 60 beats per minute and continued postoperatively. Optimal postoperative patient care involves assessment and treatment of modifiable cardiac risk factors, including pain management, hypertension, hyperlipidemia, smoking, obesity, hyperglycemia, and physical inactivity. Finally, patients who sustain a nonfatal perioperative MI or develop evidence of ischemia should be carefully investigated because they are at substantial cardiac risk over the subsequent months and years.

Elements of Renal Structure and Function

Robert L. Safirstein

Elements of Renal Structure

GROSS ANATOMY

The human kidneys are a pair of bean-shaped organs situated in the retroperitoneal space, positioned on either side of the vertebral column at the level of the lower thoracic and upper lumbar vertebrae. The right kidney is slightly lower than the left kidney because of the location of the liver. Each adult kidney weighs about 120 to 170 g and measures about $12 \times 6 \times 3$ cm. A coronal section of the kidney shows two distinct regions (Fig. 26-1A). The pale outer region, or *cortex*, is about 1 cm thick. The dark inner region is the medulla and contains 6 to 15 (average, 8) conical structures called *pyramids*. The base of each pyramid is situated at the corticomedullary junction, and the apex extends into the hilum of the kidney as the papilla. The medulla is subdivided further into an outer zone containing the outer and inner stripe of the outer medulla, and an inner zone containing the papilla. This distinction, which is apparent grossly, is important because of the specific tubular and vascular components distinct to each region, all of which are important in the function of the kidney, to be described in subsequent sections.

The concave medial aspect of the kidney is the site of the renal hilum through which pass the branches of the renal artery and vein, lymphatics, nerves, and the expanding upper region of the ureter called the *renal pelvis*. The renal pelvis communicates with a flattened space within the kidney called the *renal sinus*, in which the renal pelvis branches into major and minor calyces to collect the urine emerging through the merged collecting ducts within the renal pyramids.

RENAL BLOOD SUPPLY

Blood is delivered to each kidney from a main renal artery branching from the aorta at the level of the first lumbar vertebra (see Fig. 26-1B). The renal artery enters the hilum

and usually divides into two main segmental branches, which are further subdivided into several lobar arteries supplying the upper, middle, and lower regions of the kidney. These vessels branch further as they enter the renal parenchyma and create interlobar arteries that course toward the renal cortex along the lateral margin of the medullary pyramids. At the corticomedullary junction, these smaller arteries provide perpendicular branches that continue in an archlike manner, appropriately named the *arcuate arteries*. Interlobular arteries arise from the arcuate arteries and branch radially within the cortex. The glomerular capillaries receive blood through afferent arterioles that originate from these terminal interlobular arteries. The efferent arteriole leaves the glomerular capillary bed and supplies a network of vessels that surround the tubular structures. The efferent arterioles of the juxtamedullary glomeruli form hairpin loops called *vasa recta* that extend deep into the medulla.

INNERVATION OF THE KIDNEY

Kidneys are richly innervated by the autonomic nervous system. Sympathetic nerve endings are present in all segments of renal vasculature, tubules, and the juxtaglomerular apparatus. Stimulation of the renal sympathetic nerves enhances the release of renin from the juxtaglomerular cells, thereby increasing angiotensin and aldosterone production.

NEPHRON

The basic structural and functional unit of the kidney is the nephron (Fig. 26-2). Each human kidney contains about 1 million nephrons, and each nephron is composed of two major components: a filtering element that consists of an enclosed capillary network (the renal corpuscle) and its attached tubule. Most of the components of the renal corpuscle are contained within the glomerulus, which consists of Bowman capsule, which in turn encloses the glomerular tuft. The tubule components that emerge from Bowman capsule include in succession the proximal tubule, a

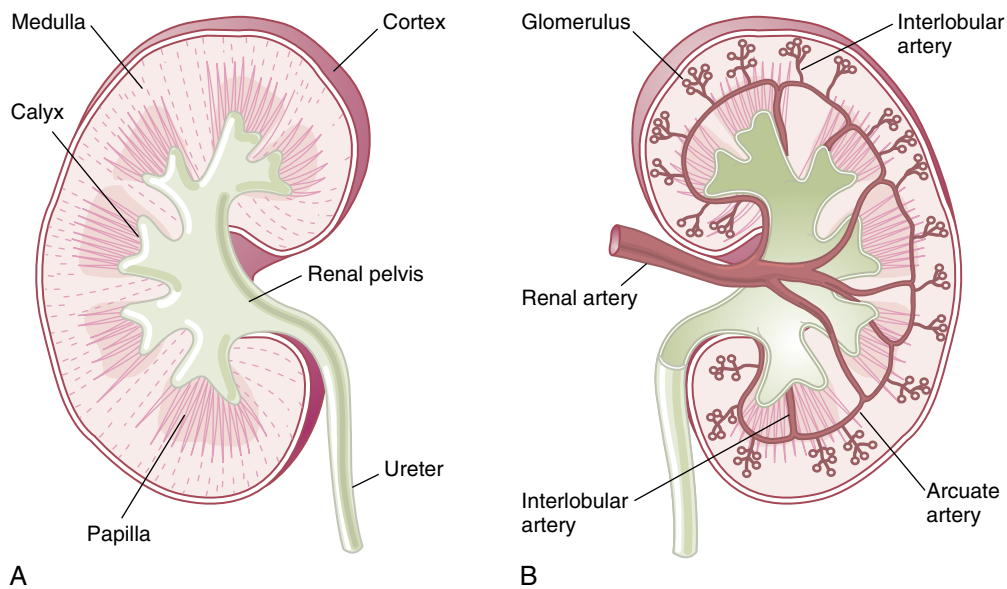

Figure 26-1 Basic renal structure. **A**, Urinary collecting structures. **B**, The arterial supply.

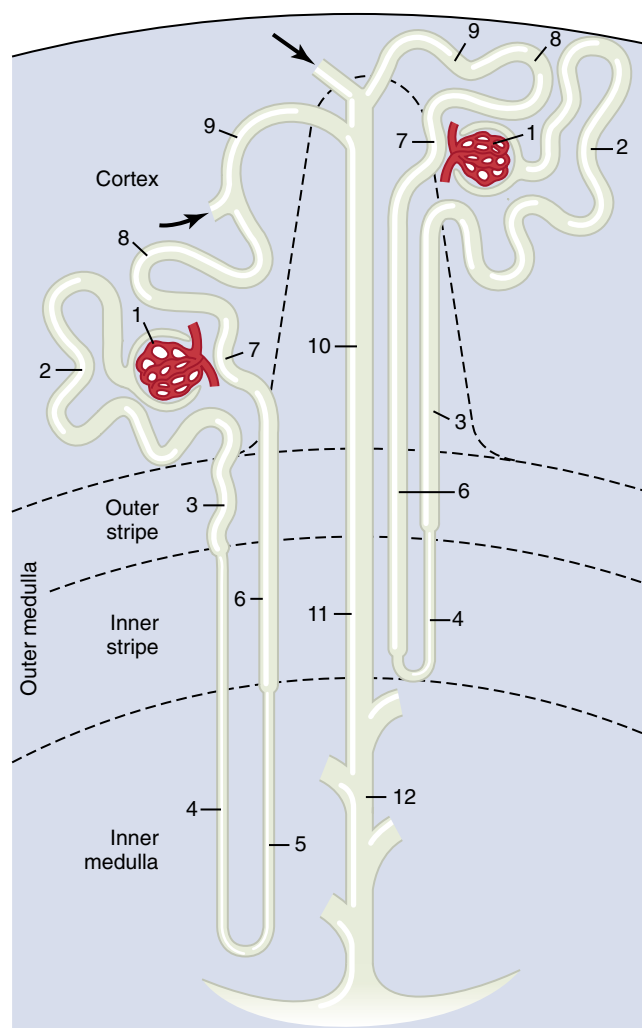

Figure 26-2 Organization of two nephrons. Each nephron consists of a glomerulus (1), proximal convoluted tubule (2), proximal straight tubule (3), thin descending limb of the loop of Henle (4), thin ascending limb (5), thick ascending limb (6), macula densa (7), distal convoluted tubule (8), and connecting tubule (9). Several nephrons coalesce to empty into a collecting duct (10), the outer medullary collecting duct (11), and the inner medullary collecting duct (12). The deeper glomerulus gives rise to nephron along with loop of Henle, which descend to the papillary tip, whereas the more superficial glomerulus has a loop of Henle that bends at the junction between the inner and outer medulla. (Modified from Briggs JP, Kriz W, Schnermann JB: Overview of kidney function and structure. In: Primer on Kidney Diseases, 4th ed. Philadelphia, Saunders, 2005).

convoluted and straight portion; the loop of Henle (composed of the straight portion of the proximal tubule, the thin descending limb, thin ascending limbs of long-looped nephrons, and the medullary thick ascending limb); and the distal tubule, which includes the cortical segment of the thick ascending limb that courses close to its glomerular pole and includes the macula densa, the post macula densa segment, and the convoluted portion of the distal tubule. The collecting duct system follows and is composed first of the connecting segment followed by the collecting ducts, which have both cortical as well as outer and inner medullary segments.

Nephrons are mainly classified on the basis of whether they possess a short or a long loop of Henle. The short-looped nephrons usually originate from the superficial and mid-cortical regions, and their loops of Henle bend within the outer medulla. By contrast, the long-looped nephrons originate from the juxtamedullary (corticomedullary) region, and their loops of Henle extend into the inner medulla. A minority of these juxtamedullary nephrons have loops that penetrate deeply in the inner medulla to reach the papilla before turning upward.

RENAL CORPUSCLE (GLOMERULUS)

The glomerulus (Fig. 26-3) is a unique network of capillaries suspended between the afferent and efferent arterioles enclosed within an epithelial structure (Bowman capsule). The capillaries are arranged into lobular structures called *glomerular tufts* and are lined by a thin layer of endothelial cells. The core of the glomerulus consists of the mesangium,

which consists of mesangial cells and a surrounding mesangial matrix. Other components of the glomerulus include the glomerular basement membrane and visceral and parietal epithelial cells. The afferent and efferent arterioles enter and leave the glomerulus at the vascular pole, and Bowman capsule continues as the proximal tubule at the urinary pole. The efferent arteriole splits up into another capillary network that surrounds the adjacent tubules to form the peritubular capillary network. The renal corpuscle thus consists of the parietal epithelium of Bowman capsule, a visceral epithelium surrounding the glomerular tuft, endothelial cells lining the capillaries, the glomerular basement membrane, and the intraglomerular mesangial cells within a mesangial matrix. These elements work in synchrony to maintain high hydraulic permeability and establish the charge and size permselectivity of the ultrafiltration process.

Epithelial Cells

The visceral epithelial cells, or podocytes, are highly specialized pericytes with a complex cytoarchitecture and prominent surface features best exemplified by interdigitating projections onto the surface of the glomerular endothelium called *foot processes*. Between these projections is the slit diaphragm, which is the most important barrier to transglomerular passage of macromolecules into the glomerular ultrafiltrate (Fig. 26-4). Hereditary forms of nephrotic syndrome are associated with mutations in genes whose products establish the slit diaphragm structure, and which are derived from the podocyte. Included in this group are mutations in nephrin, podocin, α -actinin 4, and CD2-associated

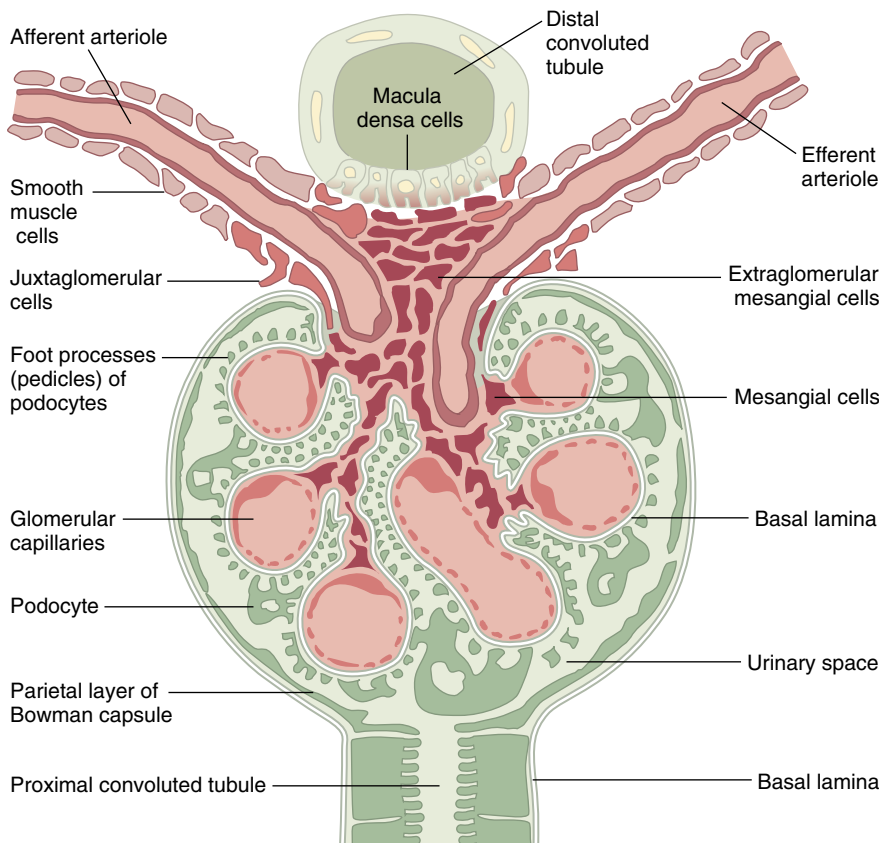

Figure 26-3 Schematic diagram of a renal glomerulus and the structures associated at the vascular pole (*top*) and urinary pole (*bottom*) (not drawn to scale). Mesangial cells are associated with the capillary endothelium and the glomerular basement membrane. The macula densa cells of the distal tubule are shown intimately associated with the juxtaglomerular cells of the afferent arteriole and the extraglomerular mesangial cells. (Modified from Kriz W, Sakai T: Morphological aspects of glomerular function. In Davison AM [ed]: *Nephrology: Proceedings of the Tenth International Congress of Nephrology*. London, Baillière-Tindall, 1987.)

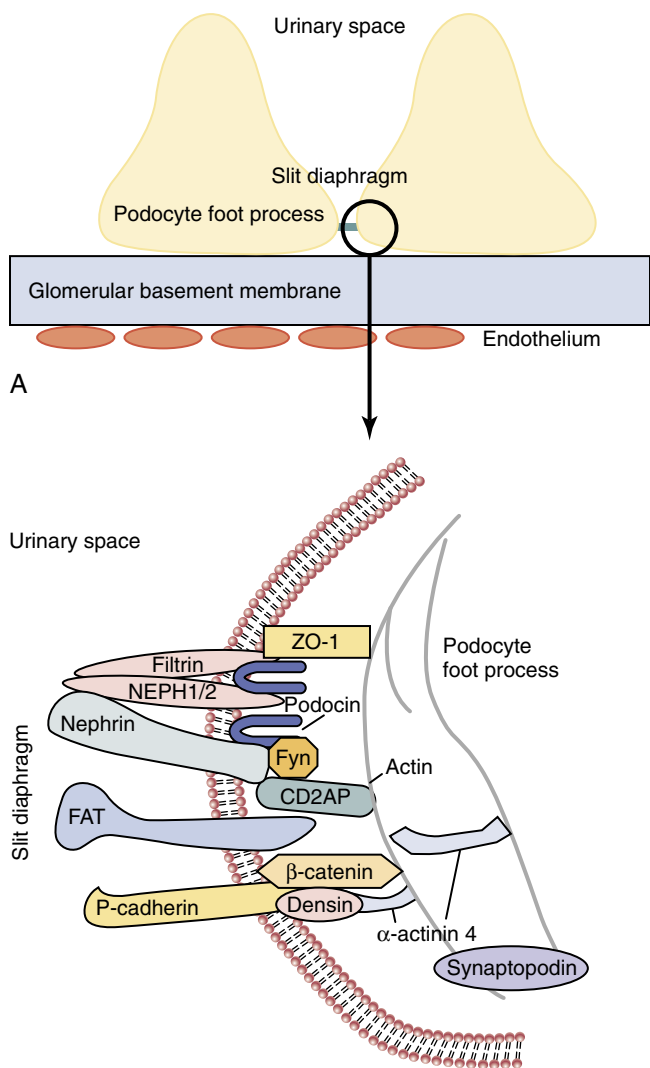

Figure 26-4 **A**, Schematic picture of podocyte architecture. **B**, Key slit area molecules and their interlinkages. (From Holthofer, H. Molecular architecture of the glomerular slit diaphragm. *Nephrol Dial Transplant* 2007;22:2124-2128.)

protein. An activating mutation in the transient receptor potential cation channel 6, another podocyte protein, causes a congenital form of focal glomerular sclerosis with onset of disease during the third and fourth decade of life. Injury to the podocytes leads to proteinuria and disturbances of podocyte architecture and results in the retraction, or effacement, of these foot processes and proteinuria. These changes are characteristic of all progressive renal disease syndromes.

Endothelial Cells

A thin layer of fenestrated endothelial cells lines the glomerular capillary lumen. These fenestrae are larger than most in the body and are in part responsible for the high ultrafiltration coefficient of the human glomerulus. A cell coat that is rich in polyanionic glycoproteins covers the endothelial surface and accounts for the lower permeability of negatively charged proteins, like albumen, of the glomerular filtration barrier. As elsewhere in the body, these endothelial cells regulate coagulation, inflammation, and vasomotor tone. They express surface antigens of the class 2 histocompatibility complex, express adhesion molecules for leukocytes, bind

factors IXa and Xa, release and bind von Willebrand factor, and synthesize and release endothelin-1 and nitric oxide. Diminished vascular epidermal growth factor action at the glomerular endothelial cell is responsible for the syndrome of preeclampsia.

Glomerular Basement Membrane

The glomerular basement membrane is a layer of hydrated gel composed of glycoproteins containing interwoven collagen fibers (type IV and V collagen). Heparinases that digest heparin-rich glycoproteins lead to dramatic increases in the permeability of the basement membrane to anionic proteins, indicating that the basement membrane is an important determinant of the glomerular protein filtration barrier. These components are made by both podocytes and endothelial cells. The lack of type IV collagen as a result of mutation of the collagen type IV α_5 subunit gene on the X chromosome leads to Alport syndrome.

Mesangium

Glomerular capillaries course along a structure called the *mesangium*, which is composed of mesangial cells embedded in a mesangial matrix (see Fig. 26-3). Mesangial cells have structural characteristics of smooth muscle cells and contain actin, myosin, and α -actinin. The cells are attached through cytoplasmic projections that tether them to the basement membrane through microfibrils, which associate with fibronectin, the most abundant protein of the mesangial matrix. This arrangement affects the contractile force of the mesangial cells. A minority of the mesangial cells also participate in the phagocytosis of macromolecules, including immune complexes. These cells possess receptors for growth factors, such as platelet-derived growth factor; constrictor peptides, such as endothelin and arginine vasopressin; and cytokines. They can produce extracellular matrix when stimulated by these factors and may participate in the abnormal matrix production in many forms of glomerular disease.

Juxtaglomerular Apparatus

Tightly adherent to every glomerulus at a site between the entry and the exit of the arterioles is a plaque of distal tubule cells called the *macula densa*. These specialized cells, together with the intervening matrix of the mesangium and the specialized granular cells of the contacting arterioles, form the juxtaglomerular apparatus. Under conditions of varying salt delivery, this region has been shown to regulate glomerular filtration, whereby the flow of NaCl past this region is kept constant by a process termed *tubuloglomerular feedback*. Modulation of tubuloglomerular feedback by the renin-angiotensin system, nitric oxide, and adenosine can be demonstrated in genetic ablation of these systems. Ablation of the juxtaglomerular apparatus renin-producing cells causes severe developmental abnormalities of the kidney demonstrating that these cells play a role in normal kidney development. The structure is also the site of renin formation, which is sensitive to salt concentration. These cells are richly innervated by sympathetic neurons.

TUBULE

The glomerular corpuscle funnels ultrafiltrate into the renal tubules. The proximal tubule begins at the urinary pole of

the glomerulus and consists of two segments. The initial segment, the proximal convoluted tubule, is located in the cortex. The second segment, the straight portion of the proximal tubule, is located in the medullary ray and enters the medulla to form part of the loop of Henle. The thin descending limb of the loop of Henle forms a hairpin turn in the medulla and returns toward the cortex, forming the distal tubule. The distal tubule consists of two segments: the thick ascending limb of the loop of Henle and the distal convoluted tubule. The distal tubule leads to the connecting segment, which marks the transition between distal tubule and the collecting segment. The collecting segment comprises the cortical collecting duct and the outer and inner medullary collecting ducts. These segments of the collecting duct differ not only in regional distribution but also in the mix of cells found within each segment, the distribution of transporters specific to each segment, and responsiveness to hormones that regulate transport. The collecting ducts terminate as the papillary collecting ducts, or the ducts of Bellini, which empty into the renal pelvis at the tips of the renal papillae.

Elements of Renal Physiology

The main functions of the kidney are to maintain and regulate body fluid composition, including its red blood cell mass, excrete waste products of metabolism and xenobiotics, and regulate calcium and phosphate balance (Table 26-1). Although filtration, reabsorption, and secretion are fundamental to the regulation of body fluid composition, less obvious is how the kidney's capacity to synthesize, metabolize, and secrete hormones and lipids contributes to its regulation of electrolyte metabolism and blood pressure. The first step in this complex process is the formation of an ultrafiltrate of plasma at the glomerulus. This fluid, which is free of cellular elements and most of the plasma proteins, flows through the various tubular segments, where it is modified by the processes of reabsorption and secretion to restore the fluid and ionic composition of the body perturbed by

metabolism and diet. How each of the structures of the nephron contributes to the achievement of this balance in which intake matches output is outlined in the following sections.

RENAL BLOOD FLOW

About one fifth of the cardiac output perfuses the kidneys and represents the highest blood flow rate by weight of any organ in the body. About one fourth of the blood reaching the kidney per minute is filtered by the glomerulus. Blood cells and protein are excluded from the filtration barrier, and this blood passes to the peritubular capillary network, where its high oncotic pressure helps return the fluid reabsorbed from the filtrate to the blood. The medulla, which receives its blood from the postglomerular blood through the specialized capillaries of the vasa recta, receives only 15% of the renal blood flow (RBF). The normal kidney possesses the ability to autoregulate RBF, during which it is held constant over a wide range of arterial pressures. When arterial pressure increases, the operation of the system increases resistance in the afferent arteriole and reduces resistance in the efferent arteriole, whereas a fall in arterial pressure results in the opposite changes in afferent and efferent resistance. Both the inherent reaction of the arterioles to changes in perfusion pressure and the operation of the tubuloglomerular feedback system participate in these autoregulatory adjustments under normal physiologic conditions. In the diseased kidney, however, this process is severely restricted.

GLOMERULAR FILTRATION RATE

An ultrafiltrate of the blood is formed in the glomerulus driven by Starling forces as in other capillary beds. The glomerular circulation is ideally suited for high rates of filtration because the high ultrafiltration pressure generated by the afferent and efferent arterioles, the unusually high hydraulic permeability of the filtration barrier, and the tortuous course of the capillaries in the glomerular stalk, which increases the surface area available for filtration, all contribute to the large volume of fluids entering the tubule com-

Table 26-1 Renal Homeostatic Functions

Function	Mechanism	Affected Elements

Glucose homeostasis	Gluconeogenesis	Glucose supply (maintained) in prolonged starvation

partment. Normal glomerular filtration rate (GFR), which depends on body size, age, diet, and physiologic state, is typically given as 100 mL per minute for women and 120 mL per minute for men. Normal pregnancy raises GFR. Although the most accurate means by which GFR is measured is the clearance of inulin, its measurement is labor intensive and thus not clinically useful for screening purposes. Instead, serum creatinine and endogenous creatinine clearance are used most frequently to estimate changes in GFR. Reductions in GFR, the hallmark of renal disease, can be caused by multiple changes in glomerular function. They include reductions in numbers of nephrons, as occurs in chronic renal disease, reduced glomerular perfusion, from circulatory collapse or specific elevation in the resistance in the afferent arteriole, or obstruction to the flow of urine by urinary bladder outflow obstruction. Reductions in blood flow, without reduced hydrostatic pressure, as occurs in severe heart failure, also reduce GFR by reducing effective net ultrafiltration pressure. Renal disease, whether primary or secondary, impairs the generation of filtrate by different combinations of these mechanisms and will be highlighted in subsequent chapters.

TUBULAR FUNCTION

The glomerular filtrate is modified as it courses down the nephron to become the urine. Net absorption of the filtrate and its constituents best characterize Na^+ , Cl^- , H_2O , HCO_3^- , glucose, amino acids, phosphates, Ca^{2+} , Mg^{2+} , uric acid, and others, whereas H^+ , NH_4^+ , and a number of organic acids and bases are added to the filtrate. Urea and K^+ undergo both processes, and the net result depends primarily on the underlying physiologic state and diet. One of the most striking characteristics of the renal tubule is its cellular heterogeneity, and these differences underlie its unique transport characteristics. This heterogeneity is best exemplified by the transport proteins that are unique to each segment and the responsiveness to drugs that inhibit transport. Each segment's role in modifying the final urine will be discussed separately.

PROXIMAL TUBULE

The proximal tubule reclaims at least 60% of the filtered load of Na^+ , Cl^- , H_2O , urea, and K^+ and fully 90% of the filtered HCO_3^- (Fig. 26-5). It achieves these high rates of absorption without detectable differences in osmotic gradients between blood and filtrate. Almost all the filtered glucose and amino acids are reclaimed from the filtrate during passage along the proximal tubule. Phosphates are reabsorbed at this site, and the activity of this transport route is significantly affected by parathyroid hormone (PTH). The primary mechanisms of transport of these solutes across the proximal tubule are linked to sodium by coupling primary active transport through the Na^+, K^+ -ATPase at the basolateral membrane, with secondary active transport mechanisms primarily distributed in the luminal brush border membranes of the proximal tubule (see Fig. 26-5). The structural feature of the proximal tubule that enables large transepithelial mass flow is the large brush border of the luminal membrane, which enlarges membrane area greatly. This polarity of the renal epithelium is basic to achieving vectorial transport throughout the nephron.

The other structural attribute that defines a transporting epithelium is the presence of highly specialized regions where cells are joined, called *junctional complexes*. These complexes are found at the apical surface and not only bind the cells together and maintain polarity but also establish a potential space by which solute and water may pass through a paracellular transport route. The electrical classification of the proximal tubule as a “leaky epithelium” is determined by the specific characteristics of the constituents of the junctional complex. Water movement through these channels and the differing selectivity for solutes establish the solvent drag effect, in which significant movement of salt and water may be accomplished. Protein constituents of the junctional complex may be defective and lead to transport defects such as the congenital hypercalciuria noted in the syndrome of hypomagnesemic hypercalciuria, in which a mutation of paracellin appears to be responsible for the urinary calcium and magnesium loss.

Figure 26-5 The major transport processes of the proximal tubular cells. See text for explanation.

The reabsorption of bicarbonate in the proximal tubule perhaps best illustrates the exquisite efficiency of the structural-functional relationships illustrated in Figure 26-5. Protons are secreted into the lumen through the operation of the $\text{Na}^+\text{-H}^+$ exchanger (NHE) located in the brush border. The transporter is regulated by cAMP, whose action depends on specific structural associations with the NHE-related factor (NHERF) and the cytoskeleton (Web Fig. 26-1). The potential energy stored in the Na^+ gradient established by the operation of the $\text{Na}^+\text{,K}^+\text{-ATPase}$ drives this exchange. The HCO_3^- thus generated is extruded across the basolateral membrane accompanied by Na through the $\text{Na}^+\text{-HCO}_3^-$ co-transporter. The efficient operation of the system is facilitated by two isozymes of carbonic anhydrase: one at the luminal membrane to dehydrate the carbonic acid formed by H excretion into the lumen, and another intracellularly to form HCO_3^- from the hydroxyl ions formed by H exit from the cell. When the operation of the NHE is coupled to a formate/chloride exchanger present on the apical membrane of the proximal tubule, the net result is NaCl reabsorption. Thus, the polarity of these transport processes and their coupling achieves efficient proton secretion and NaCl and $\text{Na}^+\text{HCO}_3^-$ reabsorption at low expenditure of energy.

Phosphate transport is achieved by sodium-dependent phosphate co-transporters in the proximal tubule and is regulated by hormones. PTH, secreted by the parathyroid glands, is phosphaturic and inhibits phosphate transport through a G-protein-coupled receptor that reduces cyclic adenosine monophosphate (cAMP) generation in the proximal tubule cell. Genetic studies of a familial disorder of phosphate metabolism have revealed mutations in genes that regulate phosphate reabsorption. Fibroblast growth factor 23 (*FGF-23*) is perhaps most important in this regard and the most important regulator of renal phosphate reabsorption as well as the synthesis of 1,25-dihydroxyvitamin D. Activating mutations in *FGF-23* is responsible for autosomal dominant hypophosphatemic rickets and for tumor-associated osteomalacia. *FGF-23* inhibits phosphate reabsorption by reducing expression of Na^+ -dependent phosphate transporters. The predominant source of *FGF-23* is bone osteocytes and osteoblasts. Extremely high levels of *FGF-23* characterize chronic renal failure and may be responsible for the defective 1,25-dihydroxyvitamin D synthesis in this disease.

In the straight portion of the proximal tubule, organic acids such as uric acid and drugs such as penicillin are secreted. Most diuretics are also secreted in this nephron segment and inhibit luminal solute transport at sites downstream in the nephron. Furthermore, ammonia synthesis, an important step in renal acid excretion, also occurs in the proximal tubule.

The physical forces surrounding the tubule also govern solute and water reabsorption in proximal tubules. For example, a high peritubular capillary hydrostatic pressure, as occurs in volume infusion, impairs water and sodium reabsorption from the proximal tubule. By contrast, a high colloid oncotic pressure in the peritubular capillary favors the absorption of water and electrolytes from the proximal tubule. The primary determinant of these physical forces is the filtration fraction, or that portion of the glomerular plasma that is filtered. It is low during volume expansion and high during heart failure.

Figure 26-6 The loop of Henle is responsible for additional absorption of filtrate. Water is absorbed in the solute-impermeable descending limb. The concentrated medullary interstitium, established by solute transport at the water-impermeable ascending limb, drives water absorption from the descending limb. The hyperosmolar interstitium also provides the driving force for urinary concentration at the collecting duct. The relative osmolarity of the tubular fluid and interstitium is demonstrated by the numerals.

LOOP OF HENLE

The loop of Henle begins at the corticomedullary junction as the thin descending limb and then makes a hairpin turn and continues as the thin ascending limb (Fig. 26-6). It becomes the medullary thick ascending limb (MTAL) at the level of the outer medulla and ends in the macula densa at the level of the glomerulus from which it originated. Each segment of the loop has a different permeability for sodium chloride and water, so that about 15% of the volume of the isotonic ultrafiltrate is absorbed and about 25% of the sodium chloride is absorbed. Passive water absorption in the thin descending limb and salt absorption in the thin ascending limb of the loop occur as a result of the selective permeability of these segments. This differential absorption converts the isotonic fluid entering from the proximal tubule into a dilute fluid delivered to the distal tubule.

A major participant in both diluting the tubule fluid and generating high medullary interstitial solute concentration is the MTAL (Fig. 26-7). The MTAL limb absorbs sodium chloride by an active, energy-dependent process. Specifically, luminal transport involves a $\text{Na}^+\text{/K}^+\text{/}2\text{Cl}^-$ co-transporter (NKCC2). Chloride exit from the cell is through a chloride channel whose activity is augmented by raising intracellular chloride concentration. K^+ entering the cell through the co-transporter is recycled at the luminal membrane through a K^+ channel and supports several functions. It maintains co-transporter activity, enables K^+ secretion, and generates a positive transcellular potential that drives Na^+ , Ca^{2+} , and Mg^{2+} absorption through the cation selective paracellular pathway. This cation selectivity is determined by the specific paracellular protein paracellin. Genetic defects

Figure 26-7 Major transport process of the medullary thick ascending limb (MTAL). See text.

in each of these proteins have been found in patients with phenotypes typical of Bartter syndrome (see Chapter 28). Because this segment is impermeable to water, the luminal fluid leaving the thick ascending limb is made hypotonic with regard to plasma by active salt absorption, a critical step in urinary dilution. The addition of sodium chloride to the medullary interstitium is the primary step that allows a multiplicative process to build and maintain the interstitial hypertonicity necessary to absorb water from thin descending limbs and from collecting ducts during antidiuresis. Furosemide is a potent inhibitor of the co-transporter. Antidiuretic hormone (ADH) increases thick ascending limb NaCl transport by raising cAMP within the cell, whereas prostaglandin inhibits ADH-induced increased intracellular cAMP content and NaCl transport. A newly recognized regulatory role occurs through the activation of the calcium-sensing receptor (CaSR) (**Web Fig. 26-2**), which inhibits NaCl transport by reducing K⁺ recycling and reduces the concentration of urine. This latter function is important to prevent urinary stone formation in periods of high calcium intake.

The hairpin arrangement and countercurrent flow of the loop helps maintain high interstitial osmolality compared with the isotonic nature of the cortex. A similar organization of the vasa recta allows the sodium chloride absorbed from the loop of Henle and urea absorbed from the papillary collecting duct to be trapped within the interstitium and increases interstitial osmolality further. The integrity of these anatomic relationships is essential to the concentrating ability of the kidney.

A significant portion of calcium reabsorption occurs within the loop of Henle. Calcium absorption in the medullary portion of the thick ascending limb varies with the magnitude of the positive luminal transepithelial voltage generated by active salt absorption and occurs through the Ca²⁺-selective paracellular pathway. The thick ascending

limb of the loop of Henle is also the major site of magnesium reabsorption and most probably occurs by a similar mechanism.

DISTAL NEPHRON

The distal nephron may be divided into three segments: the distal convoluted tubule (DCT), the connecting tubule (CNT), which is a transitional epithelial, and the collecting duct. The collecting duct in the cortex consists of both intercalated cells and principal cells, whereas the collecting ducts in the medulla are exclusively composed of principal cells.

The DCT (Fig. 26-8) is a water-impermeable segment of the nephron that continues the dilution of luminal fluid initiated by the thick ascending limb. Sodium absorption in the distal convoluted tubule occurs primarily by a thiazide diuretic-sensitive (TSC), chloride-coupled co-transporter similar to the one found in the thick ascending limb but that does not depend on K⁺. Genetic defects in the NaCl co-transporter are responsible for Gitelman syndrome (discussed in Chapter 28). A series of newly described kinases, the WNKs (*with no lysine*), regulate this co-transporter, and mutations in this group of genes cause a syndrome that is the mirror image of Gitelman syndrome by activating TSC function. This segment is also important in the regulation of calcium balance because PTH and vitamin D increase calcium transport here. Luminal calcium uptake proceeds through channels in the luminal membrane driven by the large electrochemical gradient for calcium entry and is regulated by the *KLOTHO* gene, originally identified as an anti-aging gene, but later shown to increase calcium reabsorption at this site as well. Calcium exit, which is active, proceeds predominantly through an Na-Ca exchanger and to a minor degree through a calcium adenosine triphosphatase (ATPase). The exit step is the major site by which PTH regulation occurs. Sodium transport in this segment is

Figure 26-8 Major transport processes of the distal convoluted tubule (DCT) See text.

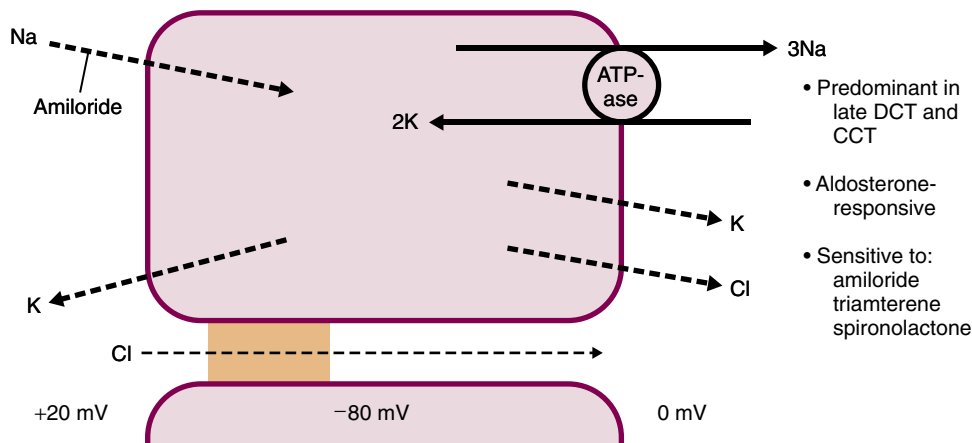

Figure 26-9 Major transport processes of the cortical collecting duct (CCD). See text. CCT, cortical collecting duct; DCT, distal convoluted tubule.

not affected by ADH or aldosterone. Inhibition of the NaCl co-transporter, by thiazides for example, augments calcium reabsorption by increasing calcium entry and promoting calcium exit as a consequence of reduced NaCl entry.

The collecting duct begins with the connecting tubule, which possesses a mixture of distal tubule and cortical collecting duct transport characteristics. The functional aspects of the collecting duct epithelium are crucial to achieving salt and water homeostasis (Fig. 26-9). In states of volume depletion and maximal aldosterone production, the urine can be rendered virtually free of sodium. The first or cortical regions of the collecting duct are lined by a mixture of principal cells and intercalated cells (Fig. 26-10). The number of the intercalated cells decreases as the collecting duct descends into the medulla, so they are absent in collecting ducts below the first portion of the inner medulla. Transepithelial sodium reabsorption is accomplished by the operation of the epithelial sodium channel (ENaC) (**Web Fig. 26-3**) at the luminal

membrane and the basolateral Na⁺,K⁺-ATPase. The principal mode of regulation of ENaC is by regulating its expression at the luminal surface of the cell. Aldosterone increases the rate of Na⁺ transport in this segment, as does ADH, whereas prostaglandins and the natriuretic peptides reduce it. Aldosterone also hyperpolarizes the basolateral membrane, provoking net K⁺ secretion through K⁺ channels in each membrane.

The intercalated cells do not participate in Na⁺ reabsorption or K⁺ secretion but instead participate in acid-base homeostasis and K⁺ secretion. Two types of intercalated cells exist; the first secrete acid, while the second secrete base, depending on the polarity of the transport proteins. The type A cell (see Fig. 26-10) reclaims the last amount of filtered bicarbonate and achieves final titration of urinary buffers, including ammonia, by proton secretion. There is evidence for the existence of both an H⁺ and an H⁺,K⁺-ATPase. Basolateral HCO₃⁻ exit is accomplished in exchange for Cl⁻

Figure 26-10 Major transport processes of the type A intercalated cell of the outer medullary collecting duct. See text for information.

Figure 26-11 The inner medullary collecting duct (IMCD) cell and the effect of intracellular cGMP elevation in its inhibition. The failure of this inhibitory system to repress salt transport during congestive heart failure suggests that it is an important therapeutic site for its treatment. Cl, chloride; PDIE, phosphodiesterase.

through an anion exchanger (pendrin), and the Cl^- that enters the cell is extruded through a Cl^- channel. Reversal of this polarity of the proton pumps and anion exchanger leads to HCO_3^- secretion in the type B intercalated cell, but these cells disappear at the inner stripe of the outer medulla. Aldosterone stimulates urinary acidification principally by promoting Na^+ reabsorption and increasing luminal electronegativity. Increased sodium delivery to these sites, as occurs during volume expansion and diuretic use, stimulates proton excretion by stimulation of sodium transport at this site as well. The role of the intercalated cell in K^+ secretion is discussed in the next section.

The epithelial cells of the inner medullary collecting duct (IMCD) (Fig. 26-11) are taller and have less mitochondria than those of the outer medullary collecting duct

(OMCD). There is also a richly featured lateral intercellular space that probably facilitates the transfer of fluid and urea that is provoked by ADH here. This site demonstrates the presence of inhibitory cyclic guanosine monophosphate (cGMP)-responsive ENaC proteins that are activated by natriuretic peptides, like atrial natriuretic peptide (ANP). This is the site for the operation of the “escape phenomenon,” in which atrial stretch due to volume expansion leads to the release of ANP and suppression of collecting duct sodium transport and natriuresis. Another key regulator is nitric oxide (NO), which also inhibits ENaC through a cGMP pathway. Failure of these systems to operate during congestive heart failure (CHF) is an important determinant of edema production and suggests that it would be a fruitful therapeutic target.

POTASSIUM SECRETION ALONG THE DISTAL NEPHRON

Potassium secretion, which may begin in the thin descending limb of the loop of Henle, is significant along the collecting ducts because the potassium that appears in the urine is mostly a result of secretion by these segments. The SK channel, which has a low conductance, is found in the principal cells, whereas the maxi-K⁺ channel is found in both principal and intercalated cells. Many factors influence potassium secretion, and these can be classified as apical and peritubular factors. The principal apical factor determining K⁺ secretion is tubule flow rate. In addition to reducing the luminal K⁺ concentration and stimulating the diffusion of intracellular K⁺ down its concentration gradient into the tubular lumen, tubule flow rate increases K⁺ secretion itself by activating the maxi-K⁺ channel. Volume expansion with NaCl also raises sodium delivery to the collecting ducts, which stimulates sodium reabsorption and increases luminal electronegativity. Increased luminal weak acids and decreased Cl concentration increase K⁺ secretion, whereas intraluminal acidity inhibits K⁺ secretion. The latter effect has been shown to be due to a decrease in luminal membrane K⁺ conductance. Inhibitors of K⁺ secretion are either inhibitors of Na⁺ channels, like triamterene and amiloride, which depolarize the luminal membrane potential, or inhibitors of the K⁺ channel itself like barium. The peritubular factors that affect K⁺ transport are potassium, hydrogen, bicarbonate, and hormones. Increased K⁺ concentration in the plasma increases K⁺ secretion directly and by provoking aldosterone secretion. This stimulation by aldosterone is inhibited by spironolactone. Distal K⁺ secretion is decreased by metabolic acidosis and increased by metabolic alkalosis.

WATER REABSORPTION ALONG THE DISTAL NEPHRON

The ability of the distal nephron to alter its ability to reabsorb water and urea in response to reduced water intake is in striking contrast to the relative invariability of water reabsorption in the proximal nephron, it does so by changing its permeability characteristics for water and urea along the nephron in response to ADH. The cells of the distal nephron are minimally permeable to water and urea in the absence of ADH and, in that circumstance, can deliver the hypotonic (50 to 100 mOsm/kg of H₂O) fluid issuing from the distal convoluted tubule unchanged into the urine. When ADH is present, water passes across the collecting duct tubule wall readily, and the luminal fluid tonicity approaches that of the interstitium. It does so by inserting preformed water channels in the luminal membrane of principal cells. Maximal urinary concentrating ability thus depends on the availability of ADH and its receptor, plus the hypertonicity of the medullary interstitium generated from thick ascending limb sodium chloride absorption and trapping of salt and urea through the countercurrent system. Urea plays a special role because its permeability is increased only in the most terminal portions of the collecting duct. The movement of urea is mediated by specific urea transporters responsive to ADH along a steep gradient for urea diffusion established by the continued water reabsorption that takes place at sites proximal to these terminal collecting

ducts. The urea moving into the interstitium deep in the medulla is trapped by the countercurrent system and exerts an additional osmotic force to draw water out of the collecting ducts and thin descending limbs that extend to these regions. Prostaglandins impair distal water reabsorption through several mechanisms, including blockade of ADH action in the collecting duct as well as increasing medullary blood flow. Thus, nonsteroidal anti-inflammatory drugs, by blocking prostaglandins, may impair renal free water excretion. Endothelin also inhibits water reabsorption at this site.

Other Renal Homeostatic Functions

WASTE EXCRETION

The kidney is responsible for elimination of nitrogenous products of protein catabolism. This is accomplished primarily by filtration at the glomerulus. Because homeostatic requirements necessitate the maintenance of low concentrations of these compounds, large volumes of ultrafiltrate formation are necessary for excretion of the absolute quantity of material. The normal daily GFR of 180 L makes such mass elimination possible.

Tubule secretion, especially at the straight portion of the proximal tubule is another route by which xenobiotics and toxins are cleared from the blood. Organic acids (e.g., hippurate, urate, and lactate), organic bases (e.g., morphine), and many xenobiotics are excreted by carrier-mediated processes served by two families of proteins; the adenosine triphosphate (ATP)-binding cassette proteins and the solute carrier proteins. The secretory process is the major route of elimination for substances that are protein bound. A large number of drugs, including antibiotics and diuretics, are excreted through this mechanism. Mutations and polymorphisms in these proteins have been shown to be responsible for potentially nephrotoxic retention of drugs, and changes in the levels of these proteins correlate with response to chemotherapy. These carrier proteins have ushered in the era of pharmacogenomic research, by which specific targeting of therapy will be individualized to the particular genomic structure of these carriers.

REGULATION OF BLOOD PRESSURE

The kidney plays a major role in the genesis of hypertension, as confirmed by genetic disorders of salt transport. Regulation of the abundance of each of the major salt transport proteins has been documented to regulate blood pressure. Activating mutations in the TSC transporter causes a syndrome of hypertension and hyperkalemia, or familial hyperkalemic hypertension. Perhaps most important among them is the gain-in-function mutation discovered in patients with Liddle syndrome in which the ENaC is activated. These patients have severe hypertension and die from early-onset cardiovascular and cerebrovascular disease. Inactivating mutations in ENaC cause pseudohypoaldosteronism type I, a disorder of severe sodium wasting and hypotension. It appears likely that genomic variations in transport proteins and their regulatory pathways may underlie the syndrome of essential hypertension.

RENAL HORMONAL REGULATION

The kidney contributes to the metabolic degradation of a number of peptide hormones, including most pituitary hormones, glucagon, and insulin, by tubular cells. Decreased renal catabolism of insulin in diabetic patients with renal insufficiency may cause hypoglycemic episodes.

The kidney is also the major site of *erythropoietin* production. This hormone is a highly glycosylated, 39,000-Da protein. It is produced in the renal cortex, but the cell has not been identified with certainty. Erythropoietin stimulates red blood cell production by its effect on the bone marrow. Erythropoietin production increases in states of decreased tissue oxygen delivery. This may occur as a result of chronic hypoxemia, as seen in persons living at high altitudes or in patients with lung disease, or as a result of decreased oxygen-carrying capacity of blood, as seen in anemic individuals.

The kidney contributes to calcium homeostasis not only by directly regulating the excretion of Ca^+ , phosphate, and acid but also by affecting hormonal production. *Vitamin D* requires two enzymatic hydroxylations to become a potent hormone that regulates intestinal calcium absorption. After

hydroxylation in the liver at the 25 position of the molecule, renal proximal tubular cells add a second hydroxyl ion at the 1 or 26 position. This hydroxylation step is controlled and stimulated by several hormones, including PTH and *KLOTHO*, as well as by low serum phosphate. As noted previously, the juxtaglomerular cells produce and secrete *renin*. Renin promotes the formation of angiotensin II, a potent vasoconstrictor that is a stimulus to aldosterone secretion. Aldosterone stimulates renal sodium absorption and excretion of potassium and hydrogen ions. Overproduction of elements of the renin-angiotensin system, including aldosterone, cause clinical syndromes of hypertension.

GLUCOSE HOMEOSTASIS

The kidney participates in the regulation of plasma glucose by its ability to synthesize glucose by the gluconeogenic pathway. Lactate, pyruvate, and amino acids are used by the kidney for gluconeogenesis. This function becomes important in prolonged starvation states, in which up to 40% of plasma glucose is contributed by the kidney. Absence of this gluconeogenic pathway in patients with severe renal dysfunction may contribute to hypoglycemia in diabetics.

Prospectus for the Future

- The role of podocyte injury in renal disease progression will be elucidated further.
- The detailed three-dimensional molecular structure of the major salt and water transporters not only will reveal the mechanism by which they accomplish transfer of molecules across biologic membranes but also will reveal how they interact with regulatory proteins, how disease causing mutations work. Such detailed information may help in the design of newer therapeutic agents for such disorders.
- More detailed understanding of the operation of the tubuloglomerular feedback system will have important therapeutic implications for the treatment of acute and chronic renal disease.
- Molecular biology and molecular genetics will continue to inform the pathophysiology of human renal disease.

Approach to the Patient with Renal Disease

Michelle W. Krause, Thomas A. Golper, Raymond C. Harris, and Sudhir V. Shah

Assessment of the Patient with Kidney Disease

HISTORY AND PHYSICAL EXAMINATION

It is estimated that kidney disease affects about 10% of the adult population in the United States and worldwide. Given these numbers, it is disturbing that there is still inadequate physician awareness of how to identify these patients with chronic kidney disease. The recognition that both acute and chronic forms of kidney disease are common should prompt physicians to pay particular attention to the detection of kidney disease. Individuals with insidious chronic kidney disease may exhibit either few or vague symptoms, such as fatigue, malaise, or anorexia, or more easily detected signs and symptoms in acute renal failure with hypertension, edema, changes in urine production, hematuria, or dark-colored (*cola-colored*) urine. A history of diabetes and hypertension, along with duration and other concomitant organ complications such as retinopathy or neuropathy, are important in determining the association to the cause of kidney disease. Similarly, a history of recurrent urinary tract infections with reflux nephropathy, chronic obstruction with recurrent renal calculi, or a family history of kidney disease in Alport syndrome is helpful in determining the cause of kidney disease. With an aging population, it is important to inquire about the quality of the urinary stream in males, including hesitancy and frequent nocturia, and these symptoms must not be dismissed as merely a sign of aging. Incomplete bladder emptying can occur with neuropathy as well as prostatism and can contribute to subclinical obstruction with significant long-term consequences to kidney function. Other pertinent historical information required when assessing kidney disease includes inquiry into other systemic disorders that affect kidney function such as arthralgias and skin rash in autoimmune diseases, fever and pharyngitis in postinfectious glomeru-

lonephritis, and medications—including prescription drugs, over-the-counter medications, illicit drugs, and herbs—in acute and chronic interstitial nephritis. One of the most important factors in determining whether kidney disease is acute or chronic in nature is to review previous medical records to obtain a baseline assessment of kidney function.

The physical examination may show signs of a systemic illness that is responsible for the patient's kidney disease. A careful examination of the retina may suggest the presence of diabetes, hypertension, bacterial endocarditis, and cholesterol emboli (**Web Fig. 27-1**). In addition, examination of skin for the presence of edema, rash, and purpura and joint examination for signs of arthritis are important (**Web Fig. 27-2**). A rectal examination in men or a pelvic examination in women is crucial to exclude a process that might cause urinary obstruction.

RENAL FUNCTION TESTS

An approximate assessment of glomerular filtration rate (GFR) is most easily obtained by measuring the concentration of creatinine and urea nitrogen in the serum. Creatinine is a metabolite of creatine, a major muscle constituent. In a specific individual, the daily rate of production of creatinine is constant and is determined by the mass of skeletal muscle. Glomerular filtration eliminates nearly all creatinine, and the concentration of creatinine in the serum has been used as a marker of renal function. The normal range for serum creatinine concentration is 0.8 to 1.3 mg/dL in men and 0.6 to 1.1 mg/dL in women. The serum creatinine value is lower in women and elderly people because of less muscle mass, which leads to a lower rate of creatinine production. However, a value in this range does not necessarily imply normal renal function. For example, in a patient whose creatinine increases from 0.6 to 1.2 mg/dL, a 50% decrease in GFR has occurred, despite creatinine remaining in the normal range. Certain drugs such as cimetidine, trimethoprim, triamterene, and amiloride may interfere with creati-

nine excretion and cause a false elevation in the serum creatinine value.

The blood urea nitrogen (BUN) concentration is often used in conjunction with the serum creatinine concentration as a measure of renal function. Urea is the major end product of protein metabolism, and its production reflects both the dietary intake of protein and the protein catabolic rate. Glomerular filtration excretes urea, but a significant amount of urea is reabsorbed along the tubule, particularly in sodium-avid states such as volume depletion. Consequently, the BUN value may vary in relation to the extracellular fluid volume, whereas the serum creatinine concentration is less dependent on volume status, although serum creatinine will also increase somewhat in sodium-avid states (so-called prerenal azotemia). The usual ratio of urea nitrogen to creatinine concentration in the serum is 10:1. This ratio is increased in a large number of clinical settings (Table 27-1).

Based on the limitations of creatinine and BUN alone in estimating kidney function, the National Kidney Foundation (NKF) and the Kidney Disease Outcomes Quality Initiative (K/DOQI) developed clinical practice guidelines that recommend measuring the creatinine clearance (C_{cr}) to estimate the GFR (see <http://www.kdoqi.org>). The C_{cr} may be measured by 24-hour urine collection or mathematically by the Cockcroft-Gault formula or Modification of Diet in Renal Disease (MDRD) formula (Table 27-2). Two major errors limit the accuracy of C_{cr} in 24-hour urine collections: (1) increasing creatinine secretion and (2) incomplete urine collection. About 10% of creatinine is secreted by proximal tubular cells into the urine in individuals with normal kidney function, and this percentage may be increased in individuals with kidney disease, thus leading to an overestimation of the true GFR. Therefore, the NKF K/DOQI clinical practice guidelines recommend using mathematical equations rather than 24-hour urine collections for C_{cr} to estimate the GFR.

Recently, cystatin C has been described as another valid marker in estimating kidney function. Cystatin C is a cysteine protease that is produced by all nucleated cells, released into the bloodstream, and then completely filtered by the glomerulus. Cystatin C is not affected by conditions that alter muscle mass such as sex, age, and chronic diseases (e.g., cancer, liver disease), and it may be more reliable than cre-

Table 27-2 Calculation of the Creatinine Clearance**24-Hour Urine Collection**

$$C_{cr} = U_{cr} \times V/P_{cr}$$

where C_{cr} = clearance of creatinine (mL/min)

U_{cr} = urine creatinine (mg/dL)

V = volume of urine (mL/min) (for 24-hr volume: divide by 1440)

P_{cr} = plasma creatinine (mg/dL)

Cockcroft-Gault Formula

$$C_{cr} = (140 - \text{age in years}) \times (\text{lean body weight in kg})$$

Scr = serum creatinine in mg/dL $\times 72$

For women, multiply final value by 0.85

Modification of Diet in Renal Disease Formula

$$GFR = 186 \times (Cr)^{-1.154} \times \text{age} - 0.203 \times 1.212 \text{ (if African American)} \times 0.742 \text{ (if woman)}$$

Normal range: 95-105 mL/1.75 m² per minute

atinine is in estimating the GFR. The widespread use of cystatin C, however, has not been uniformly adopted, and its future use in assessing kidney function is not clear.

Tests that examine the ability of the kidney to maintain salt and water balance, as well as acid-base homeostasis, are used to evaluate renal tubular function. The water deprivation test can assess the maximal urinary concentrating ability. In the patient with polyuria who may have a defect in urinary concentrating ability, the administration of 5 units of aqueous vasopressin, once the urinary osmolality reaches a steady state, distinguishes between patients with central and those with nephrogenic diabetes insipidus. Patients with central diabetes insipidus develop a doubling of the urinary osmolality with aqueous vasopressin. In contrast, individuals with nephrogenic diabetes insipidus do not respond with further increase in urinary concentration.

The fractional excretion of various solutes in the urine provides useful information about the tubular handling of a solute relative to its GFR. The fractional excretion of sodium (Fe_{Na}) or chloride (Fe_{Cl}) is the fraction of sodium (or chloride) filtered at the glomerulus that is ultimately excreted in the urine (Table 27-3). Determinations of the Fe_{Na} and Fe_{Cl} are most useful in the differential diagnosis of acute oliguric renal failure. Notably, they can be calculated on a spot specimen because the volume terms in the numerator and denominator cancel each other. A value for Fe_{Na} less than 1% suggests a prerenal condition, such as volume depletion, whereas a value greater than 3% is consistent with parenchymal renal disease, such as acute tubular necrosis or interstitial nephritis. The Fe_{Na} may, however, be less than 1% in patients with acute glomerular disease or radiocontrast-induced acute renal failure. In patients with persistent vomiting, the urinary chloride concentration is typically low and is an accurate index of volume depletion.

Acidification of the urine is an important tubular function that can be assessed by the measurement of the urine pH. In the presence of systemic acidosis (arterial pH < 7.3), the urine pH should be less than 5.3. Failure to acidify urine in the presence of systemic acidosis suggests distal renal tubular acidosis. In patients with a hyperchloremic metabolic acidosis, the urinary anion gap ($U_{Na} + U_{K} - U_{Cl}$) can be used to

Table 27-3 Calculation of the Fractional Excretion of Sodium

Fractional Excretion of Sodium (Fe_{Na}) = Fraction of Sodium Filtered at the Glomerulus that Is Ultimately Excreted in the Urine

Fe_{Na} = clearance of sodium/clearance of creatinine

$$Fe_{Na} = (U_{Na}/P_{Na})/(U_{Cr}/P_{Cr})$$

where P_{Na} = plasma sodium (mEq/L)

P_{Cr} = plasma creatinine (mg/dL)

U_{Na} = urine sodium (mEq/L)

U_{Cr} = urine creatinine (mg/dL)

distinguish extrarenal versus renal causes of the acidosis. A negative urinary anion gap is seen with extrarenal causes, such as loss of bicarbonate with diarrhea.

A normal individual excretes less than 150 mg per day of protein. The glomerular basement membrane serves as an effective barrier to the passage of high-molecular-weight proteins such as albumin, and the renal tubules have the capacity to reabsorb the small amount of protein that is filtered. An increase in proteinuria may occur as a transient phenomenon in individuals with febrile illnesses or after vigorous exercise. Postural or orthostatic proteinuria is a benign condition that is confirmed by the absence of proteinuria in overnight urine collection while the patient is supine. Persistent proteinuria almost always indicates renal disease. There are settings with markedly elevated central venous pressures in which some proteinuria is frequently seen in the absence of significant glomerular pathology, such as severe heart failure and possibly morbid obesity; however, in patients with underlying renal disease, such conditions will frequently exacerbate the amount of proteinuria. Proteinuria may be quantified with either a 24-hour urine collection or a random urine protein-to-urine creatinine (U pro/Cr) ratio. For example, a random U pro/Cr ratio of 1 correlates to 1 g per day of proteinuria. Because of the limitations of 24-hour urine collections previously discussed, the NKF K/DOQI clinical practice guidelines recommend that a U pro/Cr ratio assessment be performed to quantify proteinuria. Individuals who excrete more than 3.5 g per day of protein have, with rare exceptions, glomerular disease. Less than 3.5 g per day of urinary protein can be found in patients with both glomerular and tubular diseases. For individuals without overt proteinuria on urinalysis but with conditions that are associated with kidney disease such as diabetes mellitus, early identification of underlying kidney damage can be assessed by measuring microalbuminuria. Microalbuminuria is defined as the excretion of 30 to 300 mg per day of albumin and is associated with progression of renal disease and with higher cardiovascular morbidity and mortality in patients with diabetes mellitus and hypertension.

URINALYSIS

Urinalysis is a simple, noninvasive, and inexpensive means of detecting renal disease. A clean-catch voided urine specimen should be examined promptly using both chemical and

microscopic means. Normal urine ranges from almost colorless to deep yellow, depending on the concentration of the urochrome pigment. Abnormal urine colors may be a sign of disease or may indicate the presence of an infection, pigment, drug, or dye. The presence of red blood cells or myoglobin often results in red or smoke-colored urine. Cloudiness of the urine may occur when a high concentration of white blood cells is present (pyuria) or when amorphous phosphates precipitate in alkaline urine.

A chemical assessment of the urine is performed with the *dipstick*, a plastic strip impregnated with various reagents that detect the pH, protein, hemoglobin, glucose, ketones, leukocyte esterase, and nitrite in the urine. These assays are semiquantitative and are graded on the basis of color changes in the various reagent strips. The dipstick method for detecting urinary protein is more sensitive for albumin, although it does not detect albumin in the microalbuminuria range (discussed earlier) and does not detect immunoglobulins or tubular proteins (Tamm-Horsfall mucoprotein). The major disadvantage of the dipstick method is its failure to detect immunoglobulin light chains or Bence Jones proteins secreted in multiple myeloma. The urine sulfosalicylic acid test is an alternate test that detects all urinary proteins by a process of precipitation. Highly concentrated urine may show trace to 1+ protein (10 to 30 mg/dL) in a normal individual. The finding of blood in the urine is abnormal and generally indicates the presence of intact red blood cells. Blood detected by a dipstick that cannot be accounted for by red blood cells in the urine sediment is the result of either hemoglobin or myoglobin, often in association with rhabdomyolysis. Leukocyte esterase and nitrites are usually positive in the presence of infection. A negative test, however, does not rule out infection.

Microscopic examination of the urine sediment is used to detect cellular elements, casts, crystals, and micro-organisms (Table 27-4) (**Web Fig. 27-3**). *Microscopic hematuria* is defined as more than two red blood cells per high-power field on a centrifuged urine specimen. Red cells of glomerular origin tend to be dysmorphic, whereas nonglomerular red cells are uniform in size and shape. *Pyuria* is defined as the presence of more than four white blood cells per high-power field. The presence of pyuria suggests urinary tract infection or inflammation. Sterile pyuria (negative culture in the presence of pyuria) suggests the diagnosis of prostatitis, chronic urethritis, renal tuberculosis, renal stones, papillary necrosis, or interstitial nephritis. A more specific test for interstitial nephritis involves documenting eosinophiluria by Wright stain or Hansel stain. However, certain infections can also cause eosinophiluria. Furthermore, the absence of urinary eosinophils does not rule out a diagnosis of interstitial nephritis. Renal tubular epithelial cells are large, with prominent nuclei, and are often seen in acute tubular necrosis, glomerulonephritis, or pyelonephritis. Epithelial cells in the urinary sediment may derive from any site along the urinary tract from the renal pelvis to the urethra. Renal tubular cells that contain absorbed lipids are termed *oval fat bodies*. Free fat droplets in the urine are usually observed in association with heavy proteinuria.

Urinary casts are cylindrical structures derived from the intratubular precipitation of Tamm-Horsfall protein. The presence of red or white blood cells in the casts provides

presumptive evidence of inflammatory parenchymal renal disease. *Red blood cell casts* most frequently indicate the presence of a proliferative glomerular lesion but may also be seen in patients with acute interstitial nephritis. *Renal tubular cell casts* in a patient with acute renal failure help

confirm the diagnosis of acute tubular necrosis. The presence of *leukocyte casts* in a patient with urinary tract infection indicates a diagnosis of pyelonephritis rather than a lower urinary tract infection. Leukocyte casts may also be observed in patients with interstitial nephritis and, less commonly, in those with glomerulonephritis. Mixed cellular casts are noted when casts contain both red and white blood cells and are more frequently seen with acute interstitial nephritis.

In the absence of specific symptoms, crystals of calcium oxalate (envelope shaped) and uric acid (rhomboid shaped) identified in acidic urine are of little clinical significance. The presence of cystine crystals (benzene-ring shaped) in the urine indicates the rare disease cystinuria. Triple phosphate crystals (coffin-lid shaped) may be identified in alkaline urine. The presence of bacteria in an unspun urine specimen is significant and provides presumptive evidence for a urinary tract infection.

Table 27-4 Microscopic Examination of the Urine

Finding	Associations
Casts	
Red blood cells	Glomerulonephritis, vasculitis, interstitial nephritis
White blood cells	Interstitial nephritis, pyelonephritis
Epithelial cells	Acute tubular necrosis, interstitial nephritis, glomerulonephritis
Granular	Renal parenchymal disease (nonspecific)
Waxy, broad	Advanced renal failure
Hyaline	Normal finding in concentrated urine
Fatty	Heavy proteinuria
Cells	
Red blood cells	Urinary tract infection, urinary tract inflammation
White blood cells	Urinary tract infection, urinary tract inflammation
Eosinophils	Acute interstitial nephritis, atheroembolic disease, some infections
(Squamous) epithelial cells	Contaminants
Crystals	
Uric acid	Acid urine, acute uric acid nephropathy, hyperuricosuria
Calcium phosphate	Alkaline urine
Calcium oxalate	Acid urine, hyperoxaluria, ethylene glycol poisoning
Cystine	Cystinuria
Sulfur	Sulfa-containing antibiotics

Major Renal Syndromes

A patient with renal disease may be classified into separate clinical syndromes based on type and manifestation of renal injury as described in Table 27-5.

Acute nephritic syndrome is a clinical syndrome characterized by the relatively abrupt onset of kidney dysfunction accompanied by the presence of red blood cell casts and dysmorphic erythrocytes in the urine sediment, as well as varying degrees of proteinuria, which are highly suggestive of glomerular origin. Sodium avidity in the acute nephritic syndrome is considerably greater than what would be expected from decreased GFR. Plasma albumin is generally normal; consequently, a significant fraction of the retained sodium remains intravascularly and may explain the presence of hypertension, plasma volume dilution, circulatory overload, and congestive heart failure. Although acute post-streptococcal glomerulonephritis is the prototype for the acute nephritic syndrome, other infections may also lead to

Table 27-5 Major Renal Syndromes

Syndrome	Definition	Example
Acute nephritic syndrome	Abrupt onset of renal insufficiency accompanied by edema and hematuria that is glomerular or tubular in origin	Poststreptococcal glomerulonephritis
Nephrotic syndrome	Increased glomerular permeability manifested by massive proteinuria (>3.5 g/1.73 m ² per day), edema, and hypoalbuminuria	
With <i>bland</i> urine sediment (pure nephrotic)	Oval fat bodies, coarse granular casts	Minimal change disease
Asymptomatic urinary abnormalities	Isolated proteinuria (<2.0 g/1.73 m ² per day) or hematuria (with or without proteinuria)	Immunoglobulin A nephropathy
Tubulointerstitial nephropathy	Renal insufficiency associated with non-nephrotic-range proteinuria and functional tubular defects	Sarcoidosis
Acute renal failure	An abrupt decline in renal function sufficient to result in retention of nitrogenous waste (e.g., blood urea nitrogen and creatinine)	Acute tubular necrosis
Rapidly progressive renal failure	Rapid deterioration of renal function over a period of weeks to months	Rapidly progressive glomerulonephritis
Tubular defects	Isolated or multiple tubular transport defects	Renal tubular acidosis

this syndrome. Acute nephritic syndrome may also be caused by primary glomerular diseases, such as mesangioproliferative glomerulonephritis, and multisystem diseases that include systemic lupus erythematosus, Henoch-Schönlein purpura, vasculitis, and essential mixed cryoglobulinemia (Web Fig. 27-4).

Nephrotic syndrome is characterized by increased glomerular permeability exhibited by proteinuria in excess of 3.5 g/1.73 m² body surface area per day. A variable tendency exists toward edema, hypoalbuminemia, and hyperlipidemia. Patients with the nephrotic syndrome, in addition to proteinuria, may demonstrate oval fat bodies, coarse granular casts, and occasional cellular elements, but the lack of active sediment with dysmorphic red blood cells, and red blood cell casts is characteristic. The differential diagnosis includes glomerular diseases such as minimal change disease, membranous nephropathy, focal segmental glomerulosclerosis (FSGS), diabetic nephropathy, and amyloidosis. In patients with a mixed clinical picture (nephrotic-nephritic syndrome), membrane proliferative nephritis, systemic lupus erythematosus, postinfectious glomerulonephritis, and mixed essential cryoglobulinemia are the most likely diagnostic considerations.

The term *rapidly progressive renal failure* is applied to patients who have more than a 50% loss in kidney function over weeks to months. This condition is in contrast to patients with *acute renal failure*, who have an abrupt decline in renal function over several days, and to patients with *chronic renal failure*, who have a decline in renal function over months to years. The differential diagnosis of a patient who presents with rapidly progressive renal failure is shown in Table 27-6. One of the important but uncommon causes of rapidly progressive renal failure is rapidly progressive glomerulonephritis. This condition is a clinical syndrome that is typically associated with extensive glomerular crescent formation (Web Fig. 27-5) as the principal histologic finding on renal biopsy. Dysmorphic erythrocytes, red blood cell casts, and moderate proteinuria are characteristic in rapidly progressive glomerulonephritis.

Acute renal failure is a syndrome that can be broadly defined as an abrupt decline in renal function sufficient to result in kidney impairment over days to a few weeks. Acute renal failure can result from a decrease in renal blood flow (prerenal azotemia), intrinsic parenchymal disease (intrare-

nal azotemia), or obstruction to urine flow (postrenal azotemia). The general approach for evaluating acute renal failure is detailed in Chapter 33.

Tubulointerstitial nephropathy represents a group of clinical disorders that principally affect the renal tubules and interstitium, with relative sparing of the glomeruli and renal vasculature. In most patients, the disease can possibly be classified into acute interstitial nephritis or chronic interstitial nephropathy based on the rate of progression of renal dysfunction. Chronic tubulointerstitial nephropathy is characterized by renal insufficiency, non-nephrotic-range proteinuria, and tubular damage disproportionately severe relative to the degree of kidney impairment. Thus, patients with chronic tubulointerstitial disease often have modest degrees of sodium wasting, hyperkalemia, and a normal anion gap metabolic acidosis even when renal dysfunction is modest. Acute interstitial nephritis, often caused by a medication, is characterized by the sudden onset of clinical signs of renal dysfunction associated with a prominent inflammatory cell infiltrate within the renal interstitium and is often important in the differential diagnosis of patients with acute renal failure.

Imaging of the Urinary Tract

One of the most common imaging studies of the urinary tract is the renal ultrasound. Renal ultrasonography is a noninvasive method of obtaining an anatomic image of the kidney and the collecting system. This technique is particularly useful for determining kidney size; for detecting renal masses, cysts, and dilation of the collecting system; and for identifying hydronephrosis. At the time of the sonogram, the bladder should be imaged, especially in the immediate postvoiding state, because an accurate determination of bladder emptying is easy to obtain. The absence of hydronephrosis on a sonogram does not rule out obstructive uropathy, particularly in the presence of acute obstruction, volume depletion, or retroperitoneal fibrosis. In a patient with advanced renal failure, the presence of bilateral kidneys typically smaller than 8 cm implies a chronic, irreversible process, whereas the presence of normal-sized kidneys of 11 to 13 cm indicates acute renal failure or chronic renal failure caused by diseases such as diabetes, amyloidosis, or multiple myeloma. In addition to size, the echogenicity of the parenchyma is assessed. Scarred kidneys are far more echogenic. Duplex ultrasonography, in which B-mode ultrasonography has been combined with pulsed Doppler imaging, may be useful in detecting disease of the major renal arteries or veins. Ultrasound can easily identify simple cysts. However, complex cysts or solid lesions require further investigation by computed tomography (CT) or magnetic resonance imaging (MRI). Discrepancy in kidney size by more than 1.5 cm may suggest ischemic damage to the kidney such as renovascular disease, reflux nephropathy with scarring of the kidney, or congenital abnormalities. Ultrasonography is routinely used to guide kidney biopsy, to introduce nephrostomy tubes, or to drain fluid collection around the kidney.

Table 27-6 Causes of Rapidly Progressive Renal Failure

Obstructive uropathy
Malignant hypertension
Rapidly progressive glomerulonephritis
Thrombotic thrombocytopenic purpura, hemolytic uremic syndrome
Atheromatous embolic disease
Bilateral renal artery stenosis
Scleroderma crisis
Multiple myeloma
Systemic lupus erythematosus

Intravenous pyelography (IVP) involves the intravenous administration of iodinated radiographic contrast medium that is excreted through the kidney by glomerular filtration. The contrast medium concentrates in the renal tubules and produces a nephrogram image within the first few minutes after injection. As the medium passes into the collecting system, the calyces, renal pelvis, ureters, and bladder are visualized. The use of IVP over ultrasonography is required when a more detailed imaging study of anatomic structures is required or when evaluating obstruction and acute nephrolithiasis. The disadvantage of IVP is the requirement for radiocontrast, which can induce nephrotoxicity, particularly in patients with renal insufficiency as defined by an estimated GFR of less than 60 mL/1.73 m² per minute, volume depletion, diabetes, or congestive heart failure. For most institutions, contrast CT has taken the place of classic IVP.

Retrograde pyelography is performed by injecting radiocontrast material directly into the ureters at the time of cystoscopy. This technique is useful in defining obstructing lesions within the ureter or renal pelvis, particularly in the setting of a nonvisualizing kidney on IVP. Ureteric stones can be removed during this procedure using a special basket.

CT of the kidney is usually done by instilling a contrast medium, except when investigating renal calculi or hemorrhage. CT is most helpful in evaluating renal masses, complex cysts, and perinephric and vascular pathologic conditions such as renal vein thrombosis. In select cases, CT is used to guide kidney biopsy or fluid collection, such as that from a perinephric abscess. As in other imaging studies of the urinary tract, CT often uses radiocontrast agents and is contraindicated in individuals with impaired kidney function.

MRI uses high magnetic fields and radiofrequencies to construct images. MRI is most helpful in delineating complex renal masses, staging renal tumors, detecting invasion of renal veins, and diagnosing renovascular disease; it is also used as an alternative to CT in patients with kidney failure to avoid using radiocontrast agents because gadolinium is non-nephrotoxic, although gadolinium should be avoided if possible when the GFR is less than 40 mL per minute because of its possible role in inducing nephrogenic systemic fibrosis. Technical improvement in magnetic resonance angiography has enhanced the detection of renal artery stenosis and may grade the severity of the disease. MRI should be avoided in patients with implanted ferromagnetic devices such as pacemakers.

Radionuclide imaging provides important noninvasive information about kidneys. The test involves the intravenous administration of radiolabeled compounds, after which images are taken with a gamma camera. Pregnancy is the only contraindication for renal radionuclide imaging. The uses of renal radionuclide imaging are listed in Table 27-7.

Renal arteriography involves the direct injection of radiographic contrast medium into the aorta and renal arteries and is used to assess renal vasculature. It is particularly useful in evaluating patients with suggested renal artery stenosis or thrombosis and those with a renal mass. Patients with unexplained hematuria or with a suggested vascular malforma-

tion should have a renal arteriogram. Individuals with polyarteritis nodosa may require selective renal arteriography to detect microaneurysms. Renal vein catheterization is used to confirm the diagnosis of renal vein thrombosis or to obtain blood samples from the renal vein. Although CT or MRI is used to confirm the diagnosis of renal vein thrombosis, renal venography may be required when the diagnosis is in doubt or when the initial diagnostic suspicion is high. CT angiogram and magnetic resonance angiography have been used in screening, but these involve venous injections without direct access to the renal arteries, so that interventions require a separate procedure.

Renal Biopsy

Most renal biopsies are performed when a glomerular lesion is suggested and less commonly in patients with unexplained acute or chronic renal failure. Table 27-8 lists the indications for kidney biopsy. The percutaneous biopsy is the most commonly used technique and is a relatively safe procedure. Potential complications of a closed renal biopsy include hematuria, renal hematoma, vascular laceration with the development of arteriovenous fistula, and the inadvertent biopsy of liver, spleen, or bowel. Percutaneous kidney biopsy is contraindicated in solitary or ectopic kidneys (except kidney transplants), horseshoe kidney, uncontrolled bleeding disorders, uncontrolled hypertension, renal infection, renal neoplasm, and uncooperative patients.

Prospectus for the Future

The early identification of kidney disease needs to be determined well before changes in serum parameters that are elevated after significant kidney impairment has occurred. Novel urinary biomarkers are emerging as diagnostic tools that will help identify individuals at risk for kidney disease and will allow for the development of novel therapeutic interventions that prevent the development of kidney failure or limit progressive loss of kidney function.

Additionally, genetic analysis of individuals with kidney disease may allow for directed therapeutic regimens that decrease the risk for progressive kidney disease and the ultimate need for dialysis therapies or renal transplantation in the future.

Fluid and Electrolyte Disorders

Thomas E. Andreoli* and Robert L. Safirstein

The content of fluid and electrolytes in the cells and fluid compartments of the body are remarkably constant under normal conditions despite a widely varying intake. This constancy is maintained by fluid and solute shifts across the cells of the body and by the capacity of the kidney to adjust the urinary excretion of water, electrolytes, and solutes to match intake and the needs of the body. In health, the solute content of body water is maintained between 285 and 295 mOsm/kg of water. Tight regulation of body water and solute concentrations is made possible by the remarkable ability of the kidney to regulate urine volume from 500 mL to 24 L per 24-hour period. The ability of the kidney to carry out its functions is intrinsically tied to the thirst-neurohypophyseal-renal axis.

Volume Disorders

Water constitutes about 60% of total-body weight in humans (Fig. 28-1). Total-body water is inversely proportional to the amount of body fat, which varies with age, gender, and nutritional status. About two thirds of the total-body water is in the intracellular compartment. Three fourths of the extracellular water is in the interstitial space, and one fourth is in the plasma. Potassium and magnesium constitute the major cations of the intracellular space, whereas sodium is the major cation of the extracellular space. Phosphate and protein are the major anions of the intracellular space, whereas chloride and bicarbonate are the major anions of extracellular space. The cell membrane represents the barrier between the intracellular and extracellular fluid compartments. Because membranes are relatively permeable to water, the osmotic gradient determines the movement of fluid across the cell membrane. Thus, except for transient changes, the intracellular and extracellular fluid compartments are in *osmotic equilibrium*. The transfer of fluid between the vascular and interstitial compartments occurs across the capillary wall and is governed by the balance between hydrostatic pressure gradients and plasma oncotic pressure gradients, as related in the *Starling equation*:

$$J_V = (K_f \times [\Delta P - \sigma \Delta \Pi])$$

where J_V is the rate of fluid transfer between vascular and interstitial compartments, K_f is the water permeability, ΔP is the difference between capillary and interstitial hydrostatic pressure, $\Delta \Pi$ equals the difference between capillary and interstitial oncotic pressure, and σ is the reflection coefficient (albumin = 1).

Thus, an increase in the driving force for fluid movement into the interstitial compartment may result from a decrease in the colloid oncotic pressure of plasma, as may occur in hypoalbuminemia, or an increase in the capillary hydrostatic pressure, as occurs in congestive heart failure.

NORMAL VOLUME HOMEOSTASIS

The kidney plays a crucial role in regulating the constancy of extracellular fluid (ECF) volume. The response to a reduction in ECF volume consists of hemodynamic responses that adjust cardiac output and peripheral vascular resistance to maintain blood pressure, as well as primary renal responses that adjust external sodium and water balance. Together, this response has been termed the *integrated volume response* (Fig. 28-2). Hemodynamic alterations occur within minutes of a perceived volume reduction and are characterized by tachycardia, increased peripheral resistance from arterial vasoconstriction, and decreased venous capacitance from venoconstriction. Renal conservation of salt and water lags behind by 12 to 24 hours and involves the release of various hormones (see Fig. 28-2). Stimulation of the extra-renal baroreceptors also results in the release of antidiuretic hormone (ADH), which promotes water retention in the kidney. Vasoconstrictive factors, such as endothelins produced and released by vascular endothelial cells, also play a role in modulating systemic hemodynamics. Elevation of the efferent arteriolar resistance increases the filtration fraction, increases peritubular protein concentration, and increases sodium and water reabsorption in proximal tubules. Vasodilator prostaglandins, such as prostaglandin E_2 , modulate these vasoconstrictive influences and maintain

*Deceased.

the glomerular filtration rate (GFR) by enhancing the renal blood flow in states associated with ECF volume depletion. This action is the reason that nonsteroidal anti-inflammatory drugs are so deleterious during volume depletion.

In response to volume expansion, the renal excretion of salt and water is increased because of the suppression of the

forementioned pathways. The release of atrial natriuretic peptide is a major factor promoting natriuresis in volume-expanded states. Atrial natriuretic peptide is released from the atrial myocytes in response to atrial stretch associated with volume expansion. This peptide release promotes natriuresis by increasing GFR and inhibiting collecting duct sodium reabsorption.

2/3 of body weight =

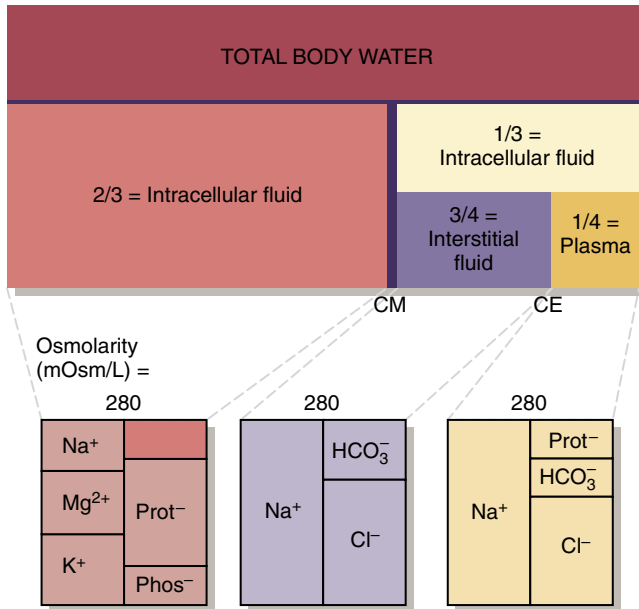

Figure 28-1 Composition of body fluid compartments. The compartments are anatomically defined by the cell membrane (CM) and capillary endothelium (CE). The osmolar concentration among compartments is equivalent despite wide variation in cation and anion composition.

ABNORMAL VOLUME REGULATION

The integrated volume response depends on afferent mechanisms that sense changes in the *effective circulating volume* (ECV). ECV is difficult to define because it is not a measurable and distinct body fluid compartment. ECV relates to the *fullness* and tension within the arterial tree. Because only 15% of total blood volume is in the arterial compartment, arterial blood volume can be decreased in relation to the holding capacity of the arterial tree. In most circumstances, ECV correlates with the total ECF volume, except in certain disorders in which ECV is decreased in the presence of an increased total ECF volume (Table 28-1). In these disorders, the ECV is decreased as a result of either decreased cardiac output or arterial vasodilation, which decreases fullness and tension in the arterial circulation.

Because the afferent sensors respond to ECV rather than to the total ECF volume, in disease states such as congestive heart failure and hepatic cirrhosis, during which ECV is low, continued activation of the *integrated volume response* occurs and thus promotes further salt and water retention.

VOLUME DEPLETION

Disorders of extracellular volume result from alterations in sodium balance. The causes of true volume depletion (e.g.,

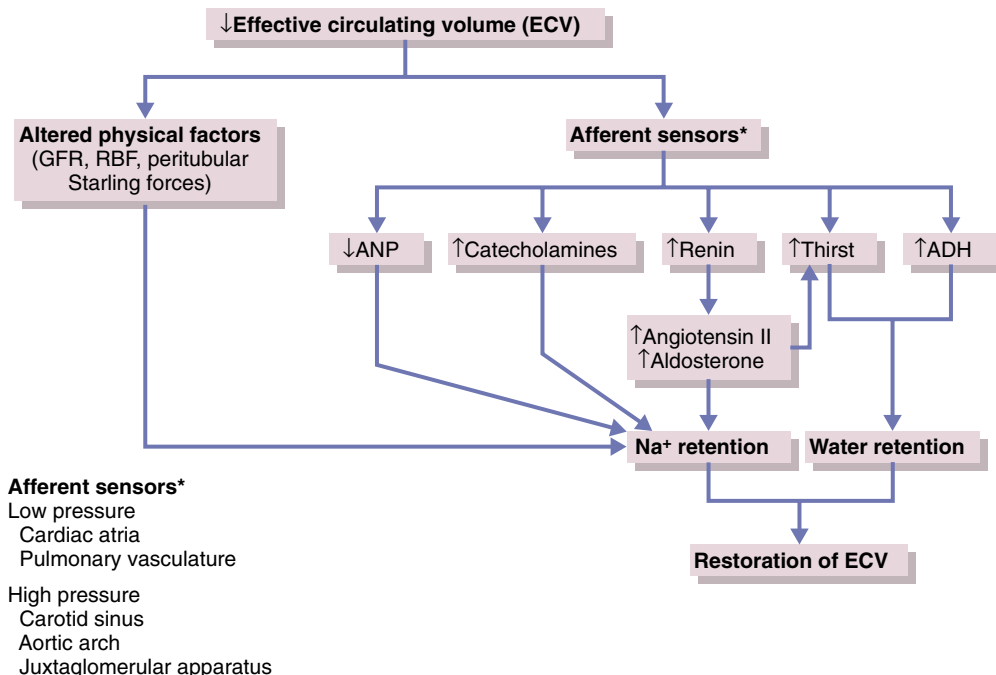

Figure 28-2 Volume repletion reaction. ADH, antidiuretic hormone; ANP, atriopeptin; GFR, glomerular filtration rate; RBF, renal blood flow.

Anaphylaxis

decreased ECV and total ECF volume) are listed in Table 28-2. Extrarenal losses are the most common clinical causes of volume depletion, and when they occur with normal renal function, the urine is highly concentrated, salt poor, and acidic. When volume depletion occurs from renal losses, the urine is inappropriately dilute and sometimes rich in salt. The syndrome of nephrogenic diabetes insipidus is one such cause, and in congenital forms of the syndrome, loss-of-function mutations occur in the V2 vasopressin receptor (X-linked), as well as autosomal dominant and recessive forms caused by inactivating mutations of the collecting duct water channel aquaporin-2. The clinical findings in states of true volume depletion are secondary to an underfilling of the arterial tree and to the renal and hemodynamic responses to this underfilling. Mild volume depletion may be associated with orthostatic dizziness and tachycardia. As the intracellular compartment becomes further depleted, recumbent tachycardia becomes evident, and urine output diminishes. Patients with severe volume depletion may exhibit vasoconstriction, hypotension, mental obtundation, cool extremities, and negligible urine output. Many of these clinical features can be explained based on effects of vasoconstrictor hormones, such as catecholamine and angiotensin II, that are released in response to hypovolemia.

Significant volume depletion can occur in the absence of classic clinical findings. States of volume depletion in patients receiving cardiovascular drugs and excess renal sodium loss from intrinsic renal disease or diuretics are examples of clinical circumstances in which an assessment of the state of hydration may be difficult. An appropriate clinical history is always mandatory, particularly prior knowledge of the patient's body weight. If doubt exists about the state of hydration, particularly in critically ill patients, measurement of the central venous pressure by means of catheterization permits assessment of the intravascular volume status.

The absolute quantity and the rate of fluid replacement depend on the severity of volume depletion, which is estimated by the clinical presentation. If fluid repletion is to involve parenteral infusions, the distribution of the infused fluid should be considered. Nearly all the volume of solutions containing 0.9% sodium chloride and colloid is retained in the extracellular space, and these are the preferred parenteral solutions for the treatment of hypovolemia. By contrast, only one third of infused 5% glucose in water (D₅W) remains in the extracellular compartment.

VOLUME EXCESS

Volume expansion occurs when salt and water intake exceeds renal and extrarenal losses. The causes are listed in Table

Table 28-2 Causes of Volume Depletion

Gastrointestinal Losses

Upper: bleeding, nasogastric suction, vomiting

Lower: bleeding, diarrhea, enteric or pancreatic fistula, tube drainage

Renal Losses

Salt and water: diuretics, osmotic diuresis, postobstructive diuresis, acute tubular necrosis (recovery phase), salt-losing nephropathy, adrenal insufficiency, renal tubular acidosis

Water: diabetes insipidus

Skin and Respiratory Losses

Sweat, burns, insensible losses

Sequestration Without External Fluid Loss

28-3. The underlying disturbance common to these disorders is sodium and water retention by the kidney. The sodium and water retention may be primary, resulting in increased ECV, or secondary, in response to a decreased ECV. The net result of renal sodium and water retention is an alteration of Starling forces that leads to increased capillary hydrostatic pressure and favors fluid shifts from the intravascular to interstitial space. Most patients with nephrotic syndrome have an increased ECV resulting from primary renal sodium retention. In advanced liver disease, the ECV is decreased because of arterial underfilling from vasodilation that results in secondary renal sodium retention. However, in early liver disease, the volume excess may result from primary renal sodium retention. Severe hypoalbuminemia associated with liver disease, nephrotic syndrome, or severe malnutrition may overwhelm the local capillary homeostatic mechanisms and may lead to edema formation.

The mainstay in treating volume excess is dietary sodium restriction in combination with diuretics (Table 28-4). Diuretics enhance natriuresis by inhibiting the reabsorption of sodium at various sites along the nephron. The cardinal example of a proximal tubular diuretic is acetazolamide, a *carbonic anhydrase inhibitor*, which blocks proximal

Table 28-4 Characteristics of Commonly Used Diuretics

Agent	Site	Primary Effect	Secondary Effect
Carbonic anhydrase inhibitors (acetazolamide)	Proximal tubule	Blocking of \downarrow Na^+ - H^+ exchange	K^+ , HCO_3^- loss
Loop diuretics (furosemide, bumetanide, ethacrynic acid)	Thick ascending limb of loop of Henle	\downarrow $\text{Na}^+/\text{K}^+/2 \text{Cl}^-$ transport	K^+ loss \uparrow H^+ secretion \uparrow Ca^{2+} excretion
Thiazide Diuretics			
Thiazides	Distal convoluted tubule	\downarrow NaCl co-transport	\downarrow K^+ loss \downarrow H^+ secretion \downarrow Ca^{2+} excretion
Metolazone	Distal tubule, proximal tubule	\downarrow NaCl reabsorption	—
Aldosterone antagonists (spironolactone)	Cortical collecting duct	\downarrow Na^+ reabsorption	\downarrow K^+ loss \downarrow H^+ secretion
Primary sodium channel blockers (triamterene, amiloride)	Cortical collecting duct	\downarrow Na^+ reabsorption	\downarrow K^+ loss \downarrow H^+ secretion

Ca^{2+} , calcium; Cl^- , chloride; H^+ , hydrogen; HCO_3^- , bicarbonate; K^+ , potassium; Na^+ , sodium; NaCl , sodium chloride.

reabsorption of sodium bicarbonate. Consequently, prolonged use of acetazolamide may lead to hyperchloremic acidosis. Metolazone, a member of the thiazide class of diuretics, in addition to blocking sodium reabsorption in the distal tubule, exerts its natriuretic effect in the proximal tubule. Because the proximal tubule is the major site for phosphate reabsorption, profound phosphaturia may accompany the use of metolazone. *Loop diuretics* such as furosemide and bumetanide inhibit the sodium, chloride, and potassium co-transporter of the thick ascending limb of the loop of Henle. *Thiazide diuretics* inhibit the sodium and chloride co-transporter of the distal tubule. The loop diuretics promote calcium excretion, and the thiazide diuretics decrease calcium excretion. Thus, the former are useful in managing hypercalcemia, whereas the latter are useful in preventing calcium stone formation. Spironolactone, an *aldosterone antagonist*, decreases sodium reabsorption in the cortical collecting duct. Primary *sodium channel blockers* such as amiloride also block sodium reabsorption in the cortical collecting duct by an aldosterone-independent mechanism. The last two groups of diuretics do not cause hypokalemia, which is a common complication associated with the use of other diuretics. In states of severe sodium retention and edema formation, such as severe congestive heart failure and nephrotic syndrome, a combination of diuretics working at different sites in the nephron may be more effective than the use of a single class of diuretics. Moreover, using potassium-sparing diuretics in combination with a potassium-wasting diuretic can minimize potassium and magnesium deficits. In patients with cirrhosis and ascites, abdominal paracentesis with concomitant intravenous infusion of some colloid has been used as a good therapeutic alternative to diuretics.

Osmolality Disorders

Body fluid osmolality, the ratio of solute to water in all fluid compartments, is maintained within an extremely narrow

range. Because water moves freely across most cell membranes, changes in the ECF osmolality cause reciprocal changes in the intracellular volume. The ECF osmolality can be approximated by calculating the serum osmolality based on the major solutes in that compartment:

$$\text{Calculated osmolality} = (2 \times \text{sodium}) + (\text{glucose} \div 18) + (\text{BUN} \div 2.8)$$

where the glucose and blood urea nitrogen (BUN) concentrations are expressed as milligrams per deciliter and the serum sodium concentration is expressed as milliequivalents per liter.

Measured osmolality usually equals the calculated osmolality. However, in the presence of osmotically active substances, such as ethanol, methanol, or ethylene glycol, the measured osmolality is higher than the calculated osmolality. Under these circumstances, the *osmolar gap* (measured minus calculated osmolality) provides a clue to the presence of toxins and gives an estimated concentration of these solutes. Alterations in the plasma sodium concentration almost always reflect changes in water balance. Because sodium is the major cation in the ECF, disorders of osmolality are generally reflected by an abnormal sodium concentration in the ECF.

Regulation of osmolality involves changes in renal water excretion, and the sodium excretion is not affected by osmoregulatory factors unless concomitant ECV depletion exists. ECF osmolality is regulated by dual pathways in the *water repletion reaction* (Fig. 28-3). Osmoreceptor cells in the central nervous system that are located in the wall of the third ventricle sense minor changes in the osmolality of blood in the internal carotid circulation. Neuronal signals from osmoreceptors stimulate the release of ADH from the posterior pituitary gland and simultaneously stimulate the sensation of thirst. ADH causes renal water conservation by increasing water permeability and water reabsorption in the collecting ducts. Thirst leads to an increase in water intake. When the ECF volume is reduced by about 10%, water

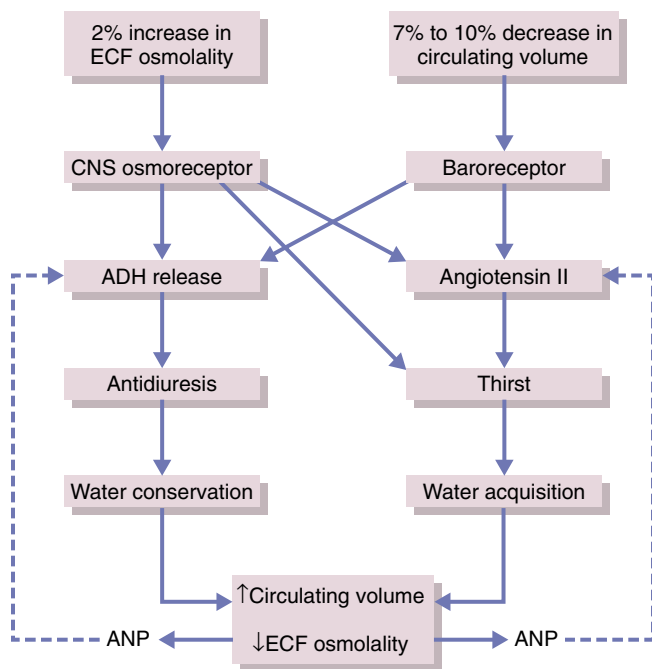

Figure 28-3 Water regulatory mechanisms. Alterations in extracellular fluid (ECF) osmolality or volume stimulate (solid lines) thirst and release of antidiuretic hormone (ADH). The net result is a positive water balance. Counter-regulation is provided by the inhibitory effects (dashed lines) of atriopeptin (ANP). CNS, central nervous system.

retention is activated as a means of replenishing ECF volume irrespective of osmolality. In this case, baroreceptors in the venous and arterial circulation stimulate ADH release through neuronal pathways. This *nonosmotic* stimulation of ADH release occurs independently of osmoreceptor function. Water repletion activates mechanisms that counter-regulate water conservation. Suppression of thirst and inhibition of ADH release lead to decreased water intake and increased renal water excretion.

Hyponatremia

PATHOPHYSIOLOGIC FACTORS

A diagnostic approach to hyponatremia, the most common electrolyte disorder in hospitalized patients, is outlined in Figure 28-4. The causes of hyponatremia show an association with normal, high, or low total-body sodium content. In some hyponatremic disorders, the serum osmolality is elevated; thus, the intracellular water content is not increased, and no risk for brain edema exists. Hyperglycemia and the use of hypertonic mannitol may result in hyponatremia because of water shift from the intracellular to extracellular space. Hyponatremia associated with normal serum osmolality may be seen in patients with extreme hyperlipidemia and hyperproteinemia, resulting from methodologic errors in techniques to measure serum electrolyte concentration. The increasing use of ion-selective electrodes for these measurements is making these causes of *pseudohyponatremia* uncommon. Hyponatremia may also be seen in patients who undergo transurethral resection of the prostate or hysteroscopic examination because of the absorption of large

amounts of hypo-osmolar glycine or sorbitol irrigating solutions.

Most hyponatremic disorders are associated with hypo-osmolality. In principle, hypo-osmolality can result from an increase in water intake or a decrease in renal water excretion, or both. Under normal circumstances, the kidneys can excrete 16 to 20 L of water free of solutes, or *free water*, per day. Water excretion may be impaired secondary to a reduced GFR, reduced ECV, impaired sodium-chloride reabsorption in the renal diluting segments of the distal nephron, which can be caused by severely reduced solute intake, and failure to suppress ADH secretion in response to hypotonicity (syndrome of inappropriate secretion of ADH [SIADH]). Finally, there is a rare congenital syndrome, the nephrogenic syndrome of inappropriate antidiuresis (NSIAD), which is caused by a gain in function mutation of the V2 vasopressin receptor, such that the latter is activated even in the absence of vasopressin. Marathon runners develop hyponatremia, which can be fatal, as a result of the inability to excrete ingested water during the race.

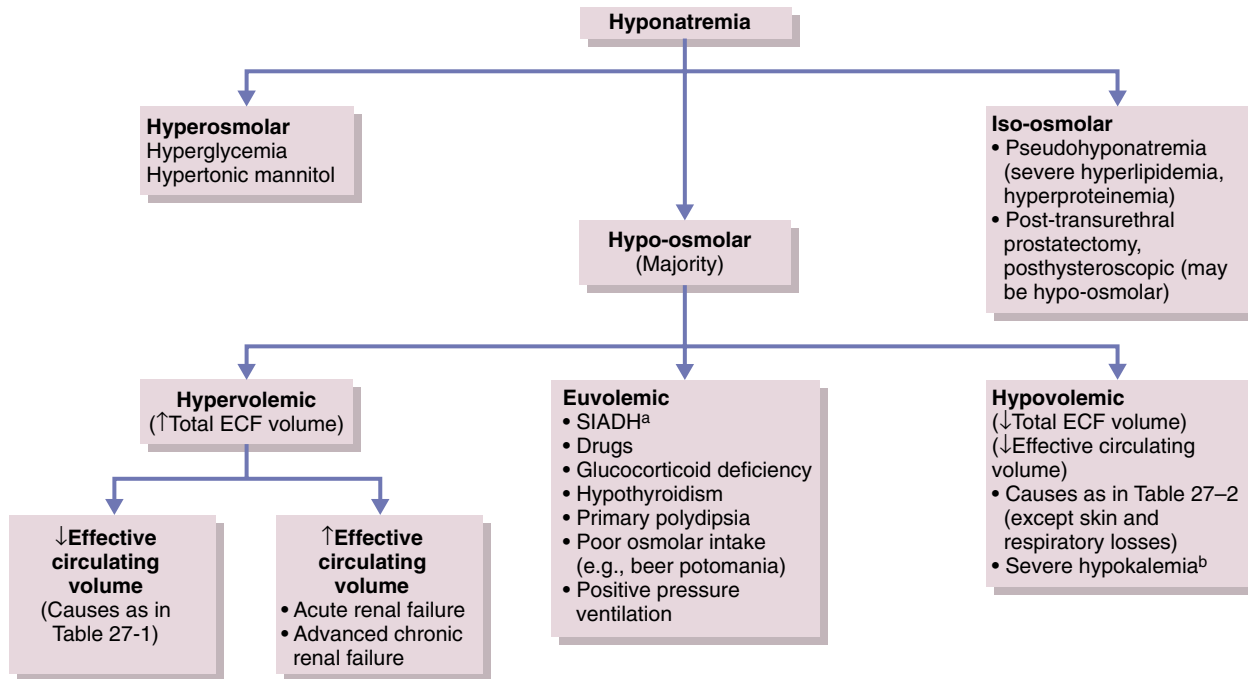

Because of the large capacity of normal kidneys to excrete free water, even in patients with *primary polydipsia*, the hyponatremia is caused by both large water intake and impaired water excretion. Hyponatremia may also occur with modestly increased water intake in the presence of impaired GFR or decreased solute intake. In patients with decreased GFR, renal water excretion is impaired because of decreased delivery of filtrate to the distal nephron. Patients with chronic starvation or beer potomania have deficient oral intake of solutes. Because renal water excretion depends on osmolar intake, these patients may develop hyponatremia at a modestly increased level of water intake.

More commonly, hyponatremia occurs as a result of the inability to dilute urine maximally because of reduction in the rate of salt absorption by the diluting segment, sustained nonosmotic release of ADH, or a combination of these two factors. In the disorders associated with decreased ECV, nonosmotic ADH release occurs and promotes water retention by the kidney. In addition, these patients have enhanced proximal sodium-chloride reabsorption with diminished distal delivery. These disorders may be associated with signs of either volume expansion or volume depletion.

SIADH is the prototype of the primary release of ADH or ADH-like substances. It occurs most often in association with pathologic processes of the central nervous system or pulmonary system. Many medications can enhance the release of ADH or can potentiate its effect (Table 28-5). The circulating ADH allows excessive water absorption in the collecting duct with a modest expansion of the ECF volume. With the increase in volume, renal perfusion is increased, and the kidney subsequently decreases sodium reabsorption in an attempt to reestablish euvolemia. Two infants have recently been described with apparent SIADH in which the serum vasopressin levels are suppressed. Evaluation revealed gain of function mutations of the V2 vasopressin receptor in these patients.

DIAGNOSIS AND TREATMENT

The signs and symptoms of hyponatremia are related to brain cell swelling caused by an increase in the brain water content resulting from water shift from a hypo-osmolar

^aSIADH patients may have modest volume expansion.

^bSeen in patients with hypokalemia due to diuretic use and may be due to Na⁺ entry into the cells to replace K⁺ loss.

extracellular environment. Hence, hyponatremic disorders should be considered in any patient who has acute mental status changes. An assessment of the volume status by physical examination is the most important initial step in the diagnostic approach to patients with hyponatremia. The most difficult differential diagnosis among hyponatremic disorders involves the distinction between patients who have reduced ECV and those who have SIADH. In both instances, the urine osmolality may be inappropriately concentrated relative to the serum osmolality. In reduced ECV, the urine sodium concentration is negligible, whereas it is usually higher than 30 mEq/L in patients with SIADH. High BUN and serum uric acid levels also suggest reduced ECV. When hyponatremia is associated with a low BUN and uric acid level, SIADH is the most likely diagnosis.

Baseline data should include body weight, serum electrolytes, serum osmolality, urine electrolytes, and urine osmolality; frequent measurement of serum and urine electrolytes, intake, and urine output should be performed during the treatment of hyponatremia. As a general rule, the administration of sodium solutions with a tonicity greater than that of urine raises serum sodium concentrations. The treatment should depend on the underlying clinical disease and volume status of the patient. Sodium and water intake should be restricted in the volume-expanded patient. In patients with decreased ECV and true hypovolemia, secondary to extrarenal losses, treatment should include isotonic sodium chloride.

In patients with SIADH, restriction of water intake is the mainstay of therapy. However, this is difficult to achieve

^aMay be hypovolemic.

^bUnder “sequestration,” only rhabdomyolysis may cause hypernatremia owing to shift of water from extracellular to intracellular space.

Figure 28-5 Diagnostic approach to hypernatremia.

because patients are invariably thirsty, particularly in the southern regions of the United States. Demethylchlor-tetracycline and lithium, while proposed, are not generally acceptable. Hypertonic saline, particularly in patients with SIADH, will produce a profound natriuresis, and hyponatremia will develop rapidly. The most rational approach to therapy is the use of furosemide in combination with normal saline. Furosemide forces the excretion of a urine which is half-normal saline, whereas the administration of normal saline helps correct the hyponatremia. The vasopressin receptor antagonist conivaptan has been shown to be effective in treating hyponatremia as well.

When hyponatremia occurs acutely (<48 hours), cerebral edema can ensue. The typical signs and symptoms include headache, nausea, vomiting, weakness, incoordination with falls, delirium, and seizures. Patients in whom hyponatremia develops over days to weeks may exhibit more subtle neurologic signs and symptoms.

The rate of correction of serum sodium depends on the symptoms and duration of hyponatremia. The correction of serum sodium with acute hyponatremia may be achieved rapidly (up to 2.5 mEq/L per hour) until central nervous system symptoms and seizures subside. Even under these circumstances, an absolute change of serum sodium of more than 20 mEq/L/day should be avoided. In patients with chronic hyponatremia (>48 hours), the serum sodium concentration should be corrected at a rate of 0.5 mEq/L per hour until it reaches 120 mEq/L. Patients with asymptomatic hyponatremia (acute or chronic) do not need aggressive therapy. This caution is necessary because of the occurrence of central pontine myelinolysis with too rapid correction.

Hypervolemic hypotonic hyponatremia secondary to cirrhosis, congestive heart failure, or renal failure should be treated not only by measures directed at the underlying disease but also with loop diuretics to help promote the excretion of hypotonic urine. Water restriction should be maintained at less than 1 L per 24-hour period. For patients with chronic SIADH that is not responsive to treatment of the underlying cause, free-water restriction alone is often sufficient. In resistant cases and in patients with neurologic symptoms, a combination of furosemide and normal or high dietary sodium intake is necessary. V₂-receptor antagonists are increasingly used in these cases as well.

Hypernatremia

PATHOPHYSIOLOGIC FACTORS

In most instances, hypernatremia is caused by excess water loss, rather than by sodium gain. Hypertonicity of the plasma is a powerful stimulus for thirst. Patients who are unable to sense thirst owing to diseases of the brain and patients who are physically unable to obtain water may develop hypernatremia. Most patients with hypernatremia, however, exhibit a primary defect in urinary concentrating ability along with insufficient administration of free water (Fig. 28-5).

Water can be lost in the urine, in excess of electrolytes, and in conditions characterized by the presence of large quantities of osmotically active solutes in the filtrate. This type of *osmotic diuresis* can occur in patients with hyperglycemia, after the infusion of mannitol, or in patients who are excreting excessive amounts of amino acids or urea. The last situation occurs in patients receiving high-protein tube feedings or total parenteral nutrition.

Diabetes insipidus is a disorder in which the collecting tubule is impermeable to water. Patients may have a central defect in the release of ADH or a defect in renal responsiveness to the hormone (nephrogenic).

In hypernatremia caused by osmotic diuresis, urine osmolality may be higher than serum osmolality because of the presence of solutes such as glucose, mannitol, or urea in the urine.

TREATMENT

Hypernatremia that is associated with hypovolemia implies a sodium deficit in addition to the water deficit and requires isotonic saline infusion. In other patients, hypotonic intravenous solutions (D₅W, half-normal saline, or quarter-normal saline) should be administered to correct hypernatremia. The water content of these fluids varies according to the electrolyte concentration. For example, 1 L of D₅W essentially equals 1 L of free water because glucose is eventually metabolized. However, 1 L of half-normal saline or quarter-normal saline contains 500 or 750 mL, respectively, of free water. In addition, if other solutes, such

as potassium or magnesium, are added to the intravenous fluids, their contribution to the tonicity of the administered fluid should be taken into account. Administration of solutions that are hypotonic relative to the urine corrects hypernatremia.

The serum sodium concentration can be used as a guide to the replacement of free water by the following formula:

$$\text{Water deficit} = 0.6 \times \text{body weight (kg)} \times (1 - [140/\text{Na}^+])$$

where Na^+ = plasma sodium, and body weight (kg) = estimated body weight when hydrated.

The treatment of patients with central diabetes insipidus is discussed in Chapter 65.

As is the case in patients with hyponatremia, the rate of correction of hypernatremia is important. In chronic hypernatremia (>36 to 48 hours), the brain generates compounds that raise the intracellular osmolality and thereby minimize cell shrinkage. This process is metabolically driven and is slow to return to normal. Thus, rapid correction of plasma osmolality may lead to a shift of water to the relatively hypertonic intracellular compartment and may result in brain edema. As a general rule, hypernatremia should be corrected over 48 hours at a rate not exceeding 0.5 mEq/L per hour, or 12 mEq/L per day.

Disturbances in Potassium Balance

The human body contains about 3500 mEq of potassium. With a normal concentration of 3.5 to 5 mEq/L, the ECF contains about 70 mEq of potassium, or only 2% of total-body stores. In response to a dietary potassium load, rapid removal of potassium from the extracellular space is necessary to prevent life-threatening hyperkalemia. For example, in the absence of a homeostatic mechanism, if a person ingests 50 mEq of dietary potassium in a single meal (the average daily American diet contains 100 to 120 mEq of potassium per day), the serum potassium might rise to 7 mEq/L (assuming an extracellular volume of 14 L with a baseline serum potassium of 4 mEq/L). Thus, the initial adaptation to a potassium load is the rapid redistribution of potassium from the extracellular space to the intracellular space. Various hormones, including insulin, aldosterone, and catecholamines, cause movement of potassium into cells. The acid-base status of the patient is another determinant of the serum potassium concentration because potassium moves across cell membranes driven by pH gradients between the cell and the ECF compartments. The greatest effect on the serum potassium concentration is associated with metabolic acidosis involving mineral acids. The cellular permeability to the anions of the mineral acids is low; consequently, the basolateral membrane is hyperpolarized, provoking potassium movement into the blood. By contrast, metabolic acidosis caused by organic acids, such as lactic acid and keto acids, does not cause hyperkalemia. The anions of these acids are relatively permeable and accompany hydrogen into the cell. This situation diminishes the electrochemical gradient favoring potassium efflux.

Although these mechanisms affect the distribution of potassium between the fluid compartments, other mechanisms are necessary to maintain overall potassium balance. People ingest about 100 mEq of potassium daily, the bulk of which is eliminated by the kidneys. Increased potassium excretion results from enhanced distal nephron potassium secretion by the principal cells of the connecting tubule and collecting duct into the tubular lumen down an electrochemical gradient. Factors that enhance this gradient promote potassium secretion. These factors include the rate of distal tubular flow, the distal delivery of sodium, the presence of poorly reabsorbable anions in the tubular fluid, and stimulation by aldosterone.

The ratio of extracellular to intracellular potassium establishes the resting membrane potential of the cell. Hence hyperkalemia or hypokalemia is associated with alteration of the resting membrane potential, which accounts for most of the symptoms and findings in these disorders.

DIAGNOSTIC APPROACH

A careful history with emphasis on the patient's diet and use of medications and laxatives should be obtained. Spurious hyperkalemia and hypokalemia must be excluded. In addition to serum electrolytes and magnesium, urine electrolytes and urine osmolality should be obtained. The next step should be to determine whether abnormal renal potassium handling is involved in the genesis of the disorder. This state may be determined by measuring the 24-hour urine potassium excretion. In extrarenal hyperkalemia, renal potassium excretion should be more than 200 mEq/day, and if hypokalemia is caused by extrarenal losses, the renal potassium excretion should be less than 20 mEq/day.

HYPERKALEMIA

The ratio of intracellular to extracellular potassium concentration is the major determinant of the resting potential of the cell membrane. As the extracellular potassium concentration increases, the cell membrane is partially depolarized, the sodium permeability is diminished, and the ability to generate action potentials is decreased. In muscle tissue, this change accounts for muscle weakness and paralysis. In the heart, hyperkalemia exhibits as changes in the electrocardiogram. These changes include peaked T waves, decreased amplitude or the absence of P waves, wide QRS complexes, sinus bradycardia, and conduction defects.

A pathophysiologic approach to the causes of hyperkalemia is outlined in Figure 28-6. Vigorous phlebotomy techniques can result in lysis of red blood cells, a process that releases intracellular potassium into the serum sample. Thrombocytosis ($>1 \times 10^6/\mu\text{L}$) and leukocytosis ($>60,000/\mu\text{L}$) may also be associated with *spurious hyperkalemia*. These disorders can be diagnosed rapidly by determining the plasma and serum concentrations of potassium. True hyperkalemia is present if these values differ by less than or equal to 0.2 mEq/L.

Chronic renal insufficiency does not cause hyperkalemia unless it is advanced, with a GFR ranging from less than 10 to 15 mL per minute. Thus, hyperkalemia in chronic renal insufficiency is usually caused by a distal nephron defect in potassium secretion rather than by the impaired GFR, as

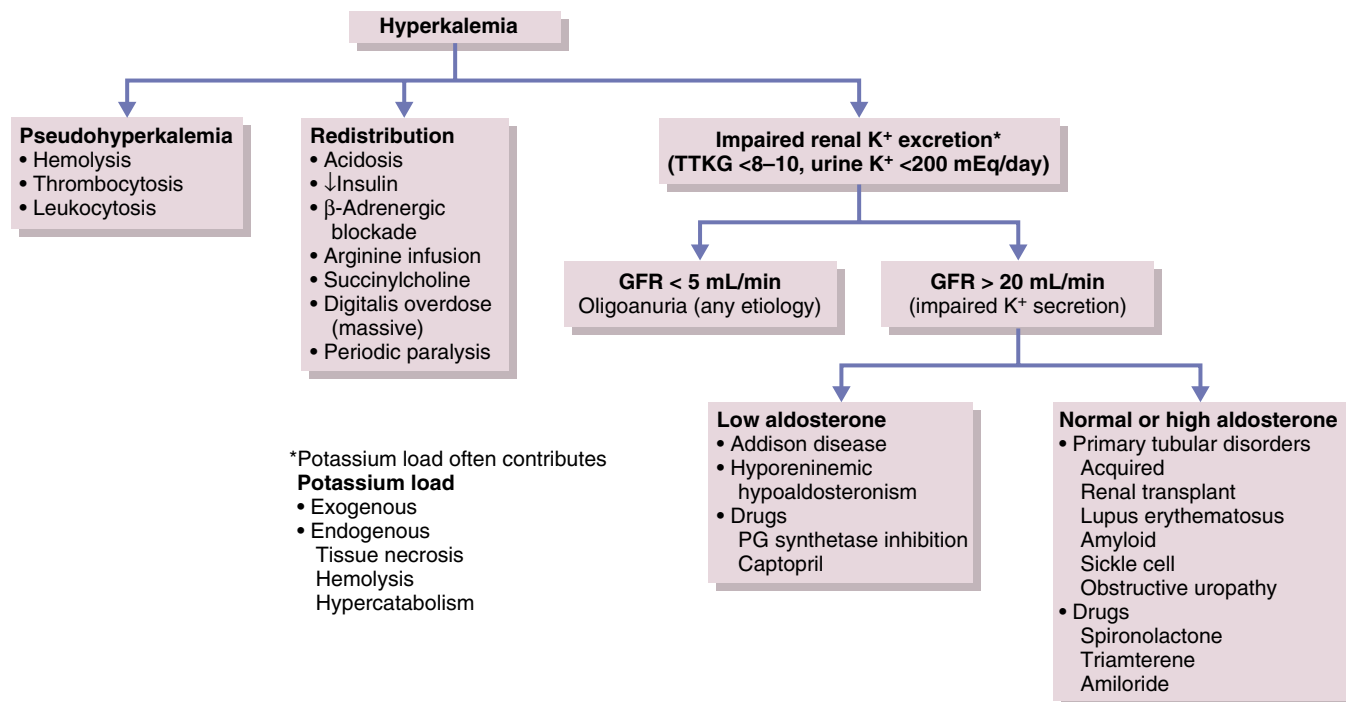

Figure 28-6 Diagnostic approach to hyperkalemia. GFR, glomerular filtration rate; PG, prostaglandin; TTKG, transtubular potassium gradient.

shown in Figure 28-6. Failure to increase plasma aldosterone by the administration of corticotropin or furosemide confirms the diagnosis of *hyporeninemic hypoaldosteronism*. Prostaglandin deficiency may play a role in the pathogenesis of this disorder. Determination of the urine potassium in response to a single dose of an oral mineralocorticoid (such as 9 α -fludrocortisone) may help differentiate hypoaldosteronism from aldosterone resistance. In aldosterone resistance, no increase in urine potassium excretion occurs in response to the mineralocorticoid.

Treatment of hyperkalemia depends on the urgency of clinical findings. When electrocardiogram changes consistent with hyperkalemia are present, the most rapid method of reversing the effects of hyperkalemia is to reestablish the normal membrane potential. Calcium antagonizes the membrane effects of hyperkalemia and can provide rapid protection of the cardiac conduction system. This protection, however, is short lived and must be accompanied by other therapies to decrease the extracellular potassium concentration. The distribution of potassium into the intracellular compartment by administration of sodium bicarbonate, β_2 -adrenergic agonists, or insulin rapidly decreases the serum concentration of potassium. The ultimate goal of the treatment is the net removal of potassium from the body. Exchange resins, such as sodium polystyrene sulfonate, can enhance potassium excretion from the gastrointestinal tract. Attempts can be made to enhance renal excretion by improving the distal delivery of sodium with sodium bicarbonate and administration of loop diuretics. Finally, dialysis can be used to remove excess extracellular potassium. For long-term management of patients with an aldosterone deficiency, an oral preparation of a mineralocorticoid can be used. Discontinuing any offending drug that may contribute to the patient's hyperkalemia is mandatory.

HYPOKALEMIA

Because potassium is the most abundant intracellular cation, its deficiency results in a wide variety of defects. For example, rhabdomyolysis and adynamic ileus have been associated with hypokalemia. Chronic hypokalemia stimulates thirst and may cause nephrogenic diabetes insipidus. However, the most prominent abnormalities relate to the cardiovascular system. Typically, hypokalemia is associated with flattening of the T waves and development of U waves. The most urgent abnormality is an association with arrhythmias, particularly in patients receiving digitalis. Hypokalemia, through stimulation of renal ammonia synthesis, may worsen hepatic encephalopathy in patients with hepatic cirrhosis.

A diagnostic approach to hypokalemia is outlined in Figure 28-7. As in hyperkalemia, spurious hypokalemia can also occur with leukocytosis ($>60,000$ cells/ μ L), resulting from active uptake of potassium by white blood cells from the serum. True hypokalemia is caused by redistribution, extrarenal potassium loss, poor intake, or renal potassium losses. Because only 2% of total-body potassium is distributed in the extracellular compartment, serum potassium measurements may not accurately reflect the total-body stores. In fact, hypokalemia can occur in the presence of normal total-body potassium stores. This state occurs when potassium shifts from the extracellular space to the intracellular space. Excess circulating catecholamines, insulin administration, and alkalosis are the major causes of redistribution of potassium from the extracellular space to the intracellular space. Redistribution hypokalemia is particularly important in the clinical setting of myocardial infarction and exacerbation of chronic obstructive pulmonary disease. These patients are especially prone to arrhythmias because excess catecholamines (in response to stress or

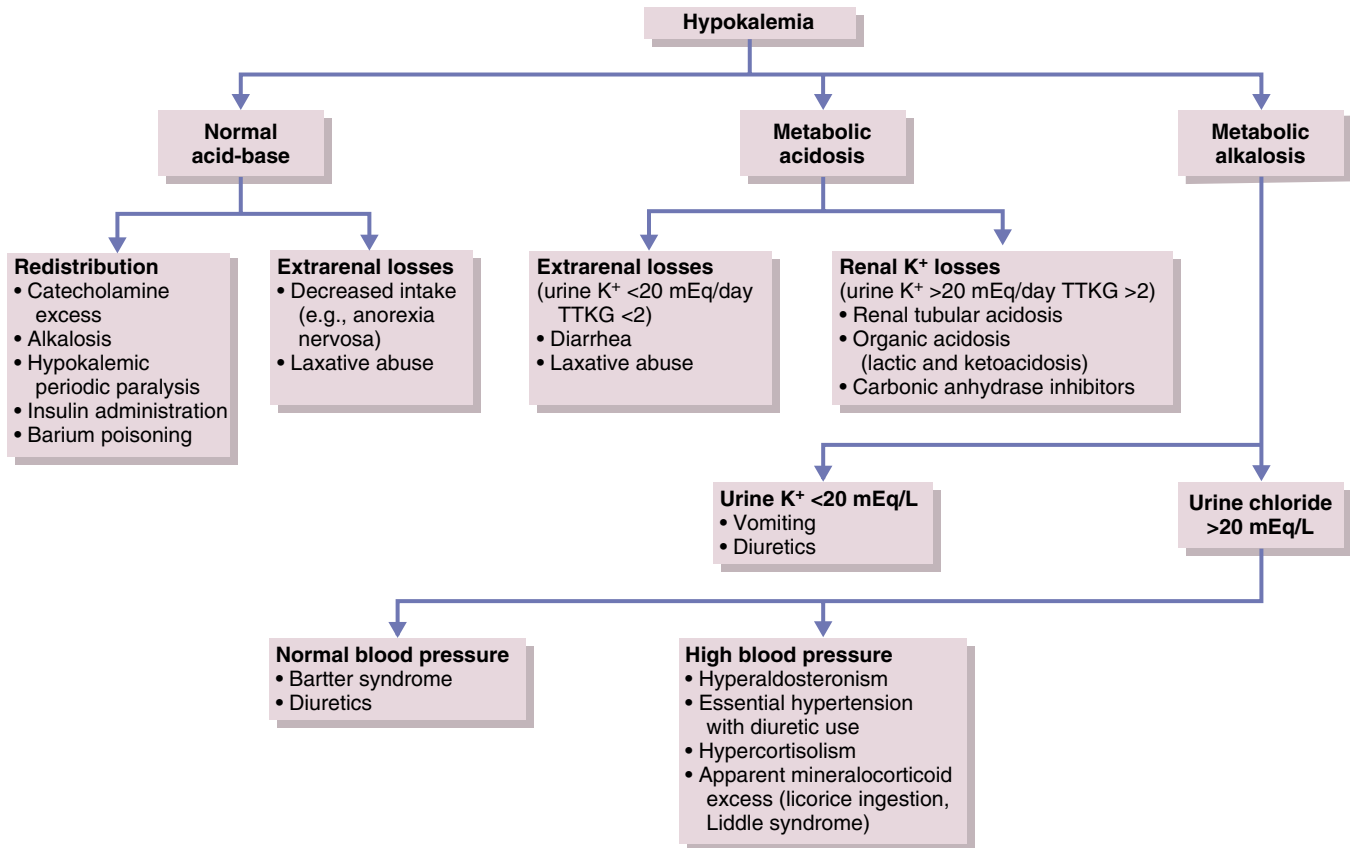

Figure 28-7 Diagnostic approach to hypokalemia. TTKG, transtubular potassium gradient.

inhaled β_2 agonists) cause potassium shifts in the setting of total-body potassium depletion from frequent diuretic usage.

In patients with hypokalemia, the acid-base status, the presence or absence of hypertension, and measurement of urinary chloride and potassium are helpful in narrowing the diagnostic possibilities. In patients with diuretic abuse (usually patients with eating disorders), the urine sodium and chloride concentrations are high in the presence of metabolic alkalosis, a profile similar to that of *Barter syndrome*, which is a rare genetic defect usually seen in adolescents with other neurologic abnormalities and caused by reduced activity of the sodium, potassium, and chloride (NKCC2) co-transporters in the thick ascending limb (see later). In this setting, a urine screen for diuretics may be necessary to make the diagnosis. In comparison, patients with surreptitious vomiting have a low urinary chloride concentration. Patients who abuse laxatives have low urine sodium and chloride concentrations, with metabolic acidosis or normal acid-base status. Glycyrrhizic acid, the active ingredient in licorice, blocks 11β -dehydrogenase, an enzyme that inactivates glucocorticoids, and its inhibition results in unregulated activation of the mineralocorticoid receptors in the distal nephron.

Determination of serum magnesium should always be performed in a patient with hypokalemia. Hypokalemia that is associated with hypomagnesemia is resistant to therapy unless concomitant magnesium deficiency is corrected.

Given the factors that determine transmembrane potassium shifts, the net potassium deficit may be difficult to

calculate. An estimate for a 70-kg man based on the serum concentration is a 100- to 200-mEq deficit in total-body potassium when the serum concentration decreases from 4 to 3 mEq/L. At less than 3 mEq/L, every 1-mEq/L decrease in the serum concentration of potassium reflects an additional 200- to 400-mEq deficit in total-body potassium. Hypokalemia should be treated with oral potassium supplementation. Intravenous potassium administration should only be used in urgent situations, such as in patients with arrhythmias or digitalis toxicity, and intolerance to oral formulations in patients with adynamic ileus. The rate of intravenous potassium administration generally should not exceed 10 mEq per hour; only under electrocardiographic monitoring, the potassium administration rate can be increased up to 20 mEq per hour. Hypokalemia associated with long-term diuretic therapy may be treated with the addition of a potassium-sparing diuretic.

Bartter and Gitelman Syndromes

A major advance in the study of inherited disorders of salt-wasting syndromes has been the demonstration that Bartter and Gitelman syndromes result from mutation of specific ion transport proteins expressed by cells of the distal nephron. The dysfunction of the thiazide-sensitive sodium-chloride co-transporter (NCCT) in Gitelman syndrome, and the bumetanide-sensitive sodium-potassium-chloride

Table 28-6 Various Bartter Syndromes

	Type 1	Type 2	Type 3	Type 4	Type 5

Table 28-7 Known Pathophysiology of Gitelman Syndrome

Loss of functional mutation: NCCT
<i>NaCl</i> wasting
Secondary hyperaldosteronism: K wasting
Cellular hyperpolarization secondary decreased Cl ⁻ entry
↑ Apical ECaC entry
↑ Basolateral Na/Ca exchange
Net effect: hypocalciuria
Mg wasting: uncertain mechanism

(NKCC2) co-transporter in Bartter syndrome cause salt wasting, extracellular volume depletion, secondary hyperaldosteronism, and hypokalemia.

The various characteristics of the five different Bartter syndromes and the Gitelman syndromes are shown in Tables 28-6 and 28-7. Stated briefly, Bartter syndrome is a genetically heterogeneous disease. Based on molecular genetic studies, five different subtypes of Bartter syndromes can be distinguished. Type I, or neonatal Bartter syndrome, is caused by loss of function mutations in the sodium-potassium-chloride co-transporter NKCC2. NKCC2 is encoded by the *SCL12A1* gene on chromosome 15. This sodium-potassium-chloride co-transporter is expressed in the apical cell membranes of the thick ascending limb of the loop of Henle (TAL), and normally accounts for about 30% of total reabsorption of sodium filtered by the glomerulus. Patients with this syndrome present early in life with a severe systemic disorder characterized by marked sodium and potassium wasting, polyhydramnios, and significant hypercalciuria and nephrocalcinosis. Prostaglandin synthesis and excretion are significantly increased and may account for much of the systemic symptoms.

Bartter syndrome type II is due to loss of function mutation of the *KCNJ1* gene on chromosome 11, encoding the inward rectifier voltage-dependent potassium channel ROMK. The potassium channel ROMK is localized in the apical membrane of TAL but is also expressed in the cortical collecting duct. In the TAL, the potassium flow through this channel into the renal tubule is necessary for NKCC2 activity, which needs adequate luminal potassium supply. In the cortical collecting duct, this channel is also involved in the excretion of dietary potassium. In this syndrome, an aberrant ROMK channel leads to malfunction of the NKCC2 co-transporter and results in salt wasting, high tubular flow, and distal potassium wasting. Bartter syndrome type III is

caused by loss of function mutations of the *CLCNKB* gene on chromosome 1 encoding a chloride channel protein CLC-Kb. This protein is expressed in the basolateral cell membranes of the TAL and is responsible for the reabsorption of sodium chloride in the TAL.

The renal salt wasting in Bartter type III syndrome is less severe than types I and II. Recently, Bartter syndrome type IV was found to be caused by loss of function mutation of the *BSND* gene (Bartter syndrome and sensorineural deafness) on chromosome 1p31. The *BSND* gene encodes barttin, a protein expressed in the basolateral membrane of the TAL. Barttin is the β subunit of the CLC-Kb chloride channel; it is necessary for CLC-Kb delivery to the plasma membrane; and in the cochlea, it co-localizes with chloride channels CLC α and CLC β . These patients present also with sodium, potassium wasting, and impaired cochlear function and deafness. Recently, the presence of hypokalemic alkalosis due to Bartter syndrome type V was found in patients with autosomal dominant hypocalcemia. In this disease, hypocalcemia was related to gain of function mutation of the calcium-sensing receptor (CaSR). The CaSR is heavily expressed at the basolateral membrane of the TAL, where it is thought to play an important inhibitory role in regulating the transcellular transport of sodium, chloride, and calcium. Activation of the basolateral CaSR in the TAL reduces apical K⁺ channel activity, which induces a Bartter-like syndrome. Genetic activation of the CaSR by these mutations is also expected to increase urinary calcium excretion by inhibiting the generation of the lumen positive potential difference that drives paracellular calcium transport in the TAL.

To date, Gitelman syndrome appears to be molecularly homogeneous. Although a loss of function mutation of the *SLC12A3* gene in chromosome 16q13 has been identified as one of the causes, recent genetic characterization of Gordon syndrome, a disease with clinical features opposite to Gitelman syndrome, suggests the possibility that similar mirror-image mutations and possibly more than one, might account for Gitelman syndrome. The *SLC12A3* gene encodes the renal thiazide-sensitive sodium-chloride co-transporter NCCT. NCCT is responsible for the sodium reabsorption in the distal tubule, which accounts for about 7% of the total filtered sodium. Although Gitelman syndrome is a milder disorder than Bartter syndrome, patients do report significant morbidity related to muscular symptoms, fatigue, and increased risk for cardiac arrhythmias in patients having a prolonged QT interval. Although plasma renin activity is increased, renal prostaglandin excretion is not elevated, another feature that distinguishes Gitelman syndrome from Bartter syndrome.

A major phenotypic difference between Bartter and Gitelman syndromes involves urinary calcium excretion. The hypercalciuria of Bartter syndrome is believed to result largely from dysfunction of thick ascending limb cells. Calcium absorption, which is passive and paracellular, is driven by lumen-positive transepithelial voltage that is generated by NKCC2 co-transport and luminal K⁺ recycling. When NKCC2 co-transport is reduced or blocked by loop diuretics or genetic abnormality, the lumen positivity declines, and calcium reabsorption declines. What is not entirely clear is why the loss of luminal positivity does not lead to increased magnesium excretion. In addition to this mechanism, increased distal delivery of NaCl, as a result of dysfunction of the TAL raises intracellular chloride concentration, which in turn inhibits apical calcium channel of distal convoluted tubule (DCT) cells, further contributing to calcium retention and nephrolithiasis. In contrast to patients with Bartter syndrome, patients with Gitelman syndrome invariably demonstrate hypocalciuria.

The hypocalciuria of Gitelman syndrome resembles the clinical beneficial effects of DCT diuretics (thiazides and others) to reduce urinary calcium excretion. The mechanisms of hypocalciuria in Gitelman syndrome are well established. First, mild contraction of the ECF volume increases calcium reabsorption along the proximal tubule. Second, reduction in NaCl entry to DCT cells stimulates transepithelial calcium transport. When apical Na and Cl entry into DCT cells is inhibited, because of either diuretic treatment or genetic disease, the intracellular chloride concentration declines. Lower intracellular Cl activity hyperpolarizes the cell and activates calcium entry through the distinctive apical calcium channels ECaC and CaT2, expressed in the DCT cells. Because calcium movement from lumen to cell must be balanced, the increased calcium entry to DCT cells stimulates calcium efflux through the basolateral Na⁺/Ca⁺ exchanger and the Ca-ATPase. Therefore, the resultant effect is the development of hypocalciuria.

Although the pathogenesis of calcium disorders in Bartter and Gitelman syndromes is relatively clear, only recently has the pathogenesis of magnesium disorders associated with these syndromes been clarified. Gitelman syndrome is associated with severe hypomagnesemia, whereas Bartter syndrome is not. Recent observations in genetic disorders of hypomagnesemia, as well as clinical observations in patients undergoing chemotherapy with anti-epidermal growth factor (EGF) antibodies have helped to clarify the molecular mechanisms involved in magnesium transport. Magnesium is absorbed along the entire nephron, but the predominant site for reabsorption is along the distal tubule. In the medullary and cortical TAL, magnesium, along with calcium, is reabsorbed through a charge-selective paracellular path. Mutations in claudin-16 (also called paracellin) and claudin-19 cause severe hypomagnesemia and nephrocalcinosis. In the DCT, a specific channel, the transient receptor potential melastatin, subfamily 6 channel, TRPM6, mediates magnesium reabsorption. Mutations in the *EGF* gene, which is expressed in the distal tubule, cause hypomagnesemia, and anti-EGF antibodies induce hypomagnesemia. The latter observations suggest a regulatory role of EGF in the reabsorption of magnesium. Knockout of the thiazide-sensitive sodium chloride co-transporter and inhibition of this transporter with thiazides cause hypomagnesemia and reduce

TRPM6 expression. Thus, reduced expression of the TRPM6 channel is the most likely explanation of the hypomagnesemia seen in Gitelman syndrome.

Disturbances in Acid-Base Balance

Most metabolic processes occurring in the body result in the production of acid. The largest source of endogenous acid production is from the complete catabolism and oxidation of glucose and fatty acids ultimately to carbon dioxide and water. Pulmonary ventilation excretes the volatile acid produced by such cellular respiration, about 22,000 mEq of hydrogen daily, as carbon dioxide. Cellular metabolism of sulfur-containing amino acids, the oxidation of phosphoproteins and phospholipids, nucleoprotein degradation, and the incomplete combustion of carbohydrates and fatty acids result in the formation of nonvolatile acids. These processes produce about 1 mEq/kg body weight of hydrogen daily. Nonvolatile acid excretion is effected through the kidney. The primary factors regulating alteration in the rate of minute ventilation are changes in cerebrospinal fluid and arterial blood pH.

The normal concentration of hydrogen in arterial blood is 40 mEq/L, equal to a pH of 7.40. This concentration is maintained relatively constant despite variations in the endogenous and exogenous acid inputs. Circulating and intracellular buffers acutely neutralize an acid load. The capacity of these buffering systems is limited, however, and would be quickly depleted by normal endogenous acid production. Mechanisms for excreting acid must therefore be effective to regenerate these buffers to maintain acid-base homeostasis.

RENAL HYDROGEN ION EXCRETION

The kidney contributes to acid-base homeostasis by the reclamation of 4500mEq of bicarbonate filtered at the glomerulus daily and by the generation of new bicarbonate. This renal bicarbonate generation is given by the equation for net acid excretion (NAE):

$$E_{\text{NAE}} = E_{\text{NH}_4^+} + E_{\text{TA}} - E_{\text{HCO}_3^-}$$

where $E_{\text{NH}_4^+} + E_{\text{TA}}$ is the rate of ammonium and titratable acid excretion, respectively, and $E_{\text{HCO}_3^-}$ is the rate of bicarbonate excretion. Although not difficult, measurement of NAE is not routinely done, and thus analysis of acid-base disorders has relied on indirect but more readily available measurements.

The principal process of renal bicarbonate generation is accomplished by urinary acidification and ammonia generation. Ammonia is generated from glutamine and secreted into the tubule fluid by the proximal tubule epithelium. Acidification is accomplished by proton secretion by distinct transporters uniquely distributed along the nephron. These transporters were highlighted in Chapter 26, and this chapter discusses how they modify the tubular fluid pH. The acidification profile of tubular fluid is shown in Figure 28-8. Tubule fluid pH falls slightly along the proximal tubule by

Figure 28-8 pH changes along the rat nephron.

the operation of the sodium-hydrogen exchanger type 3 (NHE3) located at the luminal membrane. This proton secretion is linked to bicarbonate reabsorption, and nearly 90% of the filtered load of bicarbonate is reabsorbed from the tubule fluid during its course along the proximal tubule. The proximal tubule is a high-capacity bicarbonate reabsorption system whose rate results from the presence of carbonic anhydrase in the luminal membrane. Carbonic anhydrase in the luminal membrane rapidly catalyzes the dehydration of carbonic acid to carbon dioxide and water and thus restricts the fall in tubule fluid pH along the proximal tubule and prevents the development of too steep a pH gradient into which sodium-hydrogen exchange takes place. The distal tubule, on the other hand, lacks a luminal carbonic anhydrase and has a limited capacity to reabsorb bicarbonate. However, given that the bicarbonate concentration reaching these sites is low and the principal buffers in the tubule fluid along these sites are ammonia and phosphate ions, the continued operation of the distal proton pumps lowers the prevailing urinary pH to sometimes 1000-fold below the pH of the initial filtrate. Along these sites, however, the full operation of the kidney in acid-base homeostasis is observed as the urinary buffers are titrated by secreted protons from pumps distributed along the distal nephron and excreted into the urine.

The rate of bicarbonate generation is not fixed and responds to changes in volume and electrolyte status, hormones, and acid-base parameters. Proximal bicarbonate reabsorption is increased during volume depletion, by elevation in the partial pressure of carbon dioxide (P_{CO_2}), as seen in chronic respiratory acidosis, and by hypokalemia. Conversely, volume expansion or the reduction of the P_{CO_2} lowers the proximal tubular reabsorptive rate for bicarbonate. Aldosterone and ambient P_{CO_2} affect the rate of distal nephron hydrogen ion secretion.

ASSESSMENT OF ACID-BASE STATUS

A systematic approach to assessing acid-base status consists of several steps, as summarized in Table 28-8. The initial step

Table 28-8 Systemic Approach to the Analysis of Acid-Base Disorders

Assess the accuracy of the acid-base parameters using the Henderson equation ($H^+ = 24 \times [P_{CO_2}/HCO_3^-]$) or the Henderson-Hasselbalch equation ($pH = 6.1 + \log[HCO_3^-/0.03] \times P_{CO_2}$).

Obtain a good history and perform a complete physical examination, looking for clues to a particular acid-base disturbance.

Calculate the serum anion gap: $Na^+ - (HCO_3^- + Cl^-)$.

Identify the primary acid-base disturbance and assess whether a simple or mixed acid-base disturbance is present.

Examine serum electrolytes and ancillary laboratory data.

Measure urine pH and urine electrolytes, urine urea nitrogen, and glucose to calculate the urine anion gap ($Na^+ + K^+ - Cl^-$) or urine osmolal gap (measured osmolality $- [2(Na^+ + K^+) + [urea\ nitrogen/2.8] + [glucose/18]]$).

*Measurement of urine Na^+ and Cl^- and urine pH should be obtained when metabolic alkalosis is present. Measurement of urine electrolytes, urine glucose, and urine pH should be obtained when an element of normal anion gap metabolic acidosis is present.

is to obtain arterial and venous blood samples to measure blood pH and P_{CO_2} , as well as serum electrolytes to determine the nature of the acid-base disturbance. Validation of the internal consistency of the calculated and measured bicarbonate should be carried out. Based on the pH, P_{CO_2} , and serum bicarbonate, a minimum diagnosis should be established. Next, a measurement of the compensatory response and the anion gap should be performed. If the compensation of a primary acid-base defect is inappropriate, then a mixed acid-base disorder is considered (Table 28-9). The anion gap is useful in the diagnostic approach to metabolic acidosis. When an organic acid, such as lactic acid, is added to the ECF compartment, the bicarbonate concentration falls as the acid is buffered. The anion gap increases as the organic base is accumulated. Quantitatively, the increase in anion gap should be equivalent to the decrease in bicarbonate concentration. Thus, by adding the difference between the calculated and normal anion gap to the prevailing bicarbonate concentration, an estimate of the *starting* bicarbonate concentration can be made. An abnormally elevated initial bicarbonate concentration indicates concomitant metabolic alkalosis. After establishing the nature of the acid-base disorder and whether it is complex or simple, examination of the urine pH and urine anion or osmolal gap can also provide useful information.

METABOLIC ACIDOSIS

Metabolic acidosis is characterized by a decrease in the serum bicarbonate concentration. This decrease occurs either by excretion of bicarbonate-containing fluids or by utilization of bicarbonate as a buffer of acids. In the latter instance, the nature of the base may affect the electrolyte composition. Thus, considering metabolic acidosis by means of the anion gap is convenient (Table 28-10).

Metabolic acidoses with a normal anion gap is most commonly caused by extrarenal losses of bicarbonate, as occurs in diarrheal diseases, but may also be caused by abnormally high renal excretion of bicarbonate and by the addition of

Table 28-9 Nature of Adaptive Response to Primary Acid-Base Disorders

Primary Acid-Base Disturbance	Initiating Mechanism	Secondary Physiologic Response
Metabolic acidosis	↓ plasma HCO_3^-	↓ Paco_2 of 1.0-1.3 mm Hg for each 1 mEq/L fall in plasma HCO_3^- $\text{Paco}_2 = (1.5 \times \text{HCO}_3^-) + 8 + 2$
Metabolic alkalosis	↑ Plasma HCO_3^-	↑ Paco_2 of 0.4 to 0.7 mm Hg for each 1 mEq/L rise in plasma HCO_3^-
Respiratory acidosis	↑ Paco_2	<i>Acute:</i> ↑ plasma HCO_3^- of 1 mEq/L for every 10-mm Hg rise in Paco_2 <i>Chronic:</i> ↑ plasma HCO_3^- of 3.5 mEq/L for every 100-mm Hg fall in Paco_2
Respiratory alkalosis	↓ Paco_2	<i>Acute:</i> ↓ plasma HCO_3^- of 2 mEq/L for every 10-mm Hg fall in Paco_2 <i>Chronic:</i> ↓ plasma HCO_3^- of 4-5 mEq/L for every 10-mm Hg fall in Paco_2

Note: Rare cases with Paco_2 values greater than 55 mm Hg have been reported.

Table 28-10 Causes of Metabolic Acidosis

Normal Anion Gap

Bicarbonate losses
 Extrarenal
 Small bowel drainage
 Diarrhea
 Renal
 Proximal renal tubular acidosis
 Carbonic anhydrase inhibitors
 Primary hyperparathyroidism
 Failure of bicarbonate regeneration
 Distal renal tubular acidosis
 Aldosterone deficiency
 Addison disease
 Hyporeninemic hypoaldosteronism
 Aldosterone insensitivity
 Interstitial renal disease
 Aldosterone antagonists
 Ureteroileostomy (ileal bladder)
 Acidifying salts
 Ammonium chloride
 Lysine or arginine hydrochloride
 Diabetes mellitus (recovery phase)

Wide Anion Gap

Reduced excretion of acids
 Renal failure
 Overproduction of acids
 Ketoacidosis
 Diabetic
 Alcoholic
 Starvation
 Lactic acidosis
 Toxin ingestion
 Methanol
 Ethylene glycol
 Salicylates

Modified from Andreoli TE: Disorders of fluid volume, electrolyte, and acid-base balance. In Wyngaarden JB, Smith LH Jr, Bennett JC (eds): Cecil Textbook of Medicine, 19th ed. Philadelphia: WB Saunders, 1992, p 523.

substances yielding hydrochloric acid, as when arginine hydrochloride is administered.

The urinary anion gap is defined as follows:

$$\text{Urinary anion gap} = (\text{sodium} + \text{potassium}) - \text{chloride}$$

The equation provides an approximate index of urinary ammonium excretion, as measured by a negative urinary anion gap. Thus, a normal renal response would be a negative urinary anion gap, generally in the range of 30 to

50 mEq/L. In such an instance, the acidosis is probably caused by gastrointestinal losses rather than by a renal lesion.

The causes of acidosis characterized by a wide anion gap are listed in Table 28-10. In severe *renal failure*, inorganic compounds such as phosphates and sulfates are the major contributors to the increased anion gap. Organic compounds also accumulate in patients with severe renal failure. *Ketoacidosis* results from accelerated lipolysis and ketogenesis caused by relative or absolute insulin deficiency. Alcoholic ketoacidosis and starvation ketoacidosis result from the suppression of endogenous insulin secretion caused by inadequate carbohydrate ingestion. In addition, in alcoholic ketoacidosis, insulin resistance contributes to ketone formation. The syndrome of *lactic acidosis* results from impaired cellular respiration. Lactate is produced from the reduction of pyruvate in muscle, red blood cells, and other tissues as a consequence of anaerobic glycolysis. In situations of diminished oxidative metabolism, excess lactic acid is produced. This anaerobic state also favors a shift of keto acids to the reduced form, β -hydroxybutyrate. The nitroprusside reaction, which is catalyzed by the keto acids acetoacetate and acetone, is thus nonreactive in the setting of lactic acidosis. Lactic acidosis occurs most commonly in disorders characterized by inadequate oxygen delivery to tissues, such as shock, septicemia, and profound hypoxemia. Certain toxins may also sufficiently alter mitochondrial function and establish an effective anaerobic state. Some of these toxins may undergo metabolism into organic acids that can contribute to the generation of acidosis characterized by a large anion gap. Methanol is metabolized by alcohol dehydrogenase to formic acid. Ethylene glycol is metabolized to glycolic and oxalic acids. Salicylates are themselves acidic compounds and can cause acidosis characterized by a wide anion gap.

The treatment of metabolic acidosis depends on the underlying cause and the severity of the manifestations. The rapid administration of parenteral sodium bicarbonate is generally indicated when the pH is less than 7.1 and hemodynamic instability is evident. Oral bicarbonate supplementation may be sufficient if the acidosis is caused by gastrointestinal bicarbonate loss or renal tubular acidosis (RTA). Treatment of organic acidosis should be directed at the underlying disorder. If the generation of the organic acid can be interrupted, the organic base pair may be metabolized, effectively regenerating bicarbonate. The acidemia of diabetic ketoacidosis, for example, can be effectively treated by administration of insulin, thereby inhibiting further ketogenesis. In lactic acidosis, therapy should be directed

toward improving tissue perfusion. In alcoholic and starvation ketoacidosis, administration of dextrose-containing intravenous fluids corrects the acidosis.

RENAL TUBULAR ACIDOSIS SYNDROMES

Currently, three major RTA syndromes have been identified. These syndromes are discussed later, and their principal characteristics are described in Table 28-11.

Proximal Renal Tubular Acidosis Syndromes

Proximal RTA occurs either alone or as the full Fanconi syndrome, with glycosuria, aminoaciduria, and phosphaturia. In proximal RTA, the threshold is reduced from 25 mmol/L to about 18 to 20 mmol/L (Fig. 28-9). Thus, a single-pulse loss of bicarbonate of about 850 to 900 mEq takes place.

Table 28-11 Renal Tubular Acidosis Syndromes

Type	Locus	Defect
Proximal	S ₁ -S ₃	↓ HCO ₃ ⁻ threshold
Hyperkalemic	CCD principal cell	↓ V _M (-) leading to ↓ H ⁺ secretion
Gradient limited	OMCD intercalated cells	Three specific defects in H ⁺ secretion

CCD, cortical collecting duct; OMCD, outer medullary collecting duct; S, segment; V_M (-), negative transepithelial voltage in the OMCD.

Proximal RTA occurs in a significant number of systemic diseases, most notably Wilson disease, cystinosis, and the gammopathies, especially light-chain disease; it is also seen in renal transplantation. Several molecular defects have been identified that also cause proximal RTA:

- Mutations in the carbonic anhydrase II gene, which reduce its expression. It is transmitted as an autosomal-recessive syndrome characterized by osteopetrosis, cerebral calcification, and mental retardation.
- Mutations in the *SCLC4A4b* gene that codes for the basolateral membrane sodium-bicarbonate transporter. This lesion is also an autosomal-recessive disease characterized by glaucoma, cataracts, band keratopathy, and psychomotor retardation.
- Mutations in the *SLC9A3* gene, which encodes the luminal NHE3 transport protein.

Generalized Fanconi syndrome, which appears to be the consequence of a deficit in adenosine triphosphate (ATP) production in the proximal tubule, which reduces the activity of the basolateral sodium-potassium adenosine triphosphatase (Na⁺,K⁺-ATPase). This reduction is seen in severe phosphate depletion as well as in hereditary fructose intolerance.

The focus of treatment is to enhance proximal bicarbonate reabsorption by reducing ECF volume. This reduction is achieved most commonly by salt restriction. An attempt to raise serum bicarbonate by oral bicarbonate therapy is counterproductive because it raises extracellular volume, enhances bicarbonaturia, provokes kaliuresis and phosphaturia, and produces hypokalemia and hypophosphatemia. Supplemental potassium to correct the hypokalemia is often necessary.

Figure 28-9 Bicarbonate titration curve in proximal renal tubular acidosis (RTA). Normal bicarbonate titration is shown by the solid line. Note that in patients with proximal RTA, bicarbonate excretion begins to appear in the urine when serum bicarbonate concentration exceeds 16 to 18 mmol/L, whereas in normal individuals, bicarbonate does not appear until serum bicarbonate is above 22 to 24 mmol/L. Below the threshold, patients with proximal RTA can reabsorb filtered bicarbonate nearly completely.

Figure 28-10 Bicarbonate titration curve in gradient-limit renal tubular acidosis. Note the fixed bicarbonate excretion at any level serum bicarbonate (compare with Fig. 28-9).

Hyperkalemic Renal Tubular Acidosis Syndromes

This second major group of RTA is theoretically caused by defects in principal cell function and takes three clinical forms. Pseudohypoaldosteronism I is inherited as an autosomal-recessive disease characterized by hyperkalemia, sodium wasting, and failure to thrive. Serum aldosterone is elevated, and the defect is unresponsive to administration of mineralocorticoids. A truncated form of epithelial sodium channel (ENaC) is found with low activity and massive sodium loss and is treated by large amounts of oral sodium. A second form, termed *familial hyperkalemic hypertension*, or *Gordon syndrome*, is characterized by hyperkalemia and sodium avidity, often accompanied by low renin and mild hypertension. The defect is responsive to loop diuretics and sodium restriction.

Gordon syndrome is also responsive to thiazide diuretics, which inhibit the sodium-chloride co-transporter (NCC) in the distal tubule. This form of hyperkalemic RTA is caused by a loss of function mutation in *WNK-4* (with no lysine), which inhibits NCC function (discussed in Chapter 26). Thus, the activity of the NCC is increased, reducing delivery to the collecting duct and consequent reduction in flow and voltage mediated potassium excretion. Because sodium reabsorption is increased in the distal tubule, hypercalciuria is prominent, and nephrocalcinosis occurs.

The third form of hyperkalemic RTA is an acquired disease usually associated with interstitial fibrosis. In this form, serum aldosterone and renin are reduced even in the presence of hyperkalemia. The reason for this defect in aldosterone secretion and responsiveness to administered mineralocorticoids is unknown but suggests defects in principal cell function. The disease responds partially to furo-

semide and cautious liberalization of salt intake without provoking hypertension.

The third major category of RTA is the so-called gradient-limited form and appears to be caused by a defect in outer medullary collecting duct function. Both principal and intercalated cell transports are defective. This disease is characterized by a fixed defect in bicarbonate excretion without apparent threshold (Fig. 28-10) and a fixed excretion of alkaline urine. Most commonly, the disease is the consequence of an inherited defect in the activity of the hydrogen-ATPase or potassium-hydrogen-ATPase. Acquired damage to the latter can also occur in autoimmune diseases, most notably Sjögren syndrome. This damage also occurs in sickle cell disease and primary hyperparathyroidism when these are associated with interstitial kidney damage. Drugs such as amphotericin and lithium may also cause damage. Impaired function of the basolateral band III chloride-bicarbonate exchanger is also thought to explain isolated cases because mutations have been found in the *AE1* gene that codes for it. Multiple mutations in the *AE1* gene may also occur, and in such cases, RTA is associated with ovalocytosis.

In all cases of distal, gradient-limited RTA, hyperchloremic acidosis occurs and is accompanied, because of sodium loss, by secondary hyperaldosteronism, leading to potassium depletion. In children, the syndrome impairs growth, and it may be associated with hypokalemic muscle paralysis, hypercalciuria, and nephrocalcinosis. Therapy consists of bicarbonate replacement as well as potassium replacement. Particularly in children, large amounts of bicarbonate may be required to ensure normal growth. Distal RTA is also complicated by a low urinary excretion of citrate, which leads to severe nephrocalcinosis.

METABOLIC ALKALOSIS

A gain in base or loss of acid increases the bicarbonate concentration of the ECF. Normally, an elevation of the serum

bicarbonate concentration is corrected by excretion of the excess bicarbonate. The maintenance of *metabolic alkalosis*, therefore, implies a defect in the renal mechanism regulating bicarbonate excretion. This failure to excrete excess bicarbonate occurs by both physiologic responses to volume depletion, especially if hypercapnia and hypokalemia accompany the alkalosis, or by pathophysiologic responses, as occur in autonomous mineralocorticoid excess.

The most common cause of metabolic alkalosis is gastric loss of hydrochloric acid by vomiting or mechanical drainage. Diuretic (thiazide and loop) use is commonly associated with metabolic alkalosis. Volume depletion associated with vomiting and diuretic use enhances proximal bicarbonate reabsorption. Enhanced activity of sodium-hydrogen exchange at this site, and consequent enhanced volume reabsorption, results in enhanced bicarbonate reabsorption (see Chapter 26). Volume depletion also leads to aldosterone secretion, which stimulates distal nephron hydrogen secretion and augments potassium secretion. Repair of the alkalosis under these circumstances requires administration of sodium chloride and potassium. Endogenous or exogenous mineralocorticoid excess (see Fig. 28-7) is unresponsive to volume administration as extracellular volume is expanded. The stimulation of distal hydrogen secretion by aldosterone is sufficient to limit bicarbonate excretion and stimulate potassium secretion. Repair of this disorder requires removal of the excess mineralocorticoid. In all these disorders, concomitant hypokalemia promotes the maintenance of metabolic alkalosis.

Excessive alkali ingestion (e.g., milk-alkali syndrome) is an uncommon cause of metabolic alkalosis and results from impaired renal bicarbonate excretion caused by renal failure in the setting of excess alkali intake. In this instance, both hypercalcemia and vitamin D excess are thought to play roles in damaging the kidney. Removal of alkali often corrects the alkalosis, but renal function remains reduced if nephrocalcinosis is prominent.

The determination of urinary chloride concentrations is helpful in formulating a rational approach to the diagnosis and treatment of metabolic alkalosis. In patients with hypertension since childhood, alkalosis, hypokalemia, and low urinary chloride, consideration should be given to Liddle syndrome. These features resemble mineralocorticoid excess, but renin and aldosterone levels are suppressed (pseudohypoaldosteronism). The disorder is inherited as an autosomal recessive disorder with mutations in the *ENaC* gene that result in deletion of the C-terminal region of the protein. This condition results in reduced degradation and increased density of sodium channels in the luminal membrane of the principal cells of the collecting duct (see Chapter 26). The clinical features are a consequence of the enhanced salt reabsorption, resultant volume expansion, and increased distal nephron potassium and proton secretion.

Patients with high urinary chloride and alkalosis and who are hypertensive require work-up for hypercorticism, which may be autonomous, as in primary aldosteronism and Cushing disease or secondary to renal artery stenosis. Rarer still are the 11- β -hydroxylase deficiencies, or *apparent mineralocorticoid excess* (AME), in which reduced conversion of glucocorticoids reaching the collecting duct leads to overstimulation of ENaC. Another such syndrome of congenital hypertension and alkalosis is glucocorticoid-remediable

aldosteronism (GRA), which is caused by a gene duplication in which the promoter for the 11- β -hydroxylase gene drives the aldosterone synthase gene and leads to adrenocorticotropic hormone-responsive aldosterone synthesis. In each of these instances, hyperactivity of ENaC leads to all clinical features of the syndrome.

Normotensive or hypotensive conditions with alkalosis, hypokalemia, and high urinary chloride consist of two distinct forms: Bartter syndrome and Gitelman syndrome. Each syndrome involves distinct abnormalities in segment-specific sodium chloride reabsorption, as well as differences in calcium and magnesium excretion. In Bartter syndrome (see Table 28-6), several disabling mutations in genes affecting the reabsorption of sodium chloride across the TAL have been characterized, including loss-of-function mutations in the NKCC2 co-transporter, the ROMK channel protein, and the basolateral chloride channel, and a gain in function mutation of the calcium-sensing receptor. Each of these mutations causes salt wasting, including enhanced calcium excretion, volume depletion, and, in many instances, reduced blood pressure. The reduction in ECF volume causes a secondary hyperaldosteronism, which, when coupled with enhanced sodium delivery to the collecting duct, causes potassium wasting and enhanced proton excretion. In Gitelman syndrome, disabling mutations in the DCT thiazide-sensitive sodium-chloride co-transporter have been described. The phenotypic characteristics of Gitelman syndrome in contradistinction to Bartter syndrome are the reduced calcium excretion and hypercalcemia observed, as might be expected from inhibition of the sodium-chloride co-transporter (see Chapter 26). The cause of hypermagnesuria in Gitelman syndrome is reduced expression of TRPM6 channel in the DCT.

RESPIRATORY ACIDOSIS

Respiratory acidosis occurs with any impairment in the rate of alveolar ventilation. Acute respiratory acidosis occurs with a sudden depression of the medullary respiratory center (narcotic overdose), with paralysis of the respiratory muscles, and with airway obstruction. Chronic respiratory acidosis generally occurs in patients with chronic airway disease (emphysema), with extreme kyphoscoliosis, and with extreme obesity (pickwickian syndrome).

The serum bicarbonate concentration is increased, the magnitude of which depends on the acuity and the severity of the respiratory disorder. The compensatory increase in serum bicarbonate in prolonged hypercapnia (>1 week) is primarily a function of bone buffering as the kidney plays a relatively minor role in the increase. Acute increases in the P_{CO_2} result in somnolence, confusion, and, ultimately, carbon dioxide narcosis. Asterixis may be present. Because carbon dioxide is a cerebral vasodilator, the blood vessels in the optic fundi are often dilated, engorged, and tortuous. Frank papilledema may be present in patients with severe hypercapnic states.

The only practical therapy of acute respiratory acidosis involves treatment of the underlying disorder and ventilatory support. In patients with chronic hypercapnia who develop an acute increase in the P_{CO_2} , attention should be directed toward identifying the factors that may have aggravated the chronic disorder. Diuretics often exacerbate the

increase in serum bicarbonate and result in a mixed disorder of metabolic alkalosis and respiratory acidosis. Under these circumstances, acidification of the serum may be necessary to improve ventilation.

RESPIRATORY ALKALOSIS

Respiratory alkalosis occurs when hyperventilation reduces the arterial P_{CO_2} and consequently increases the arterial pH. Acute respiratory alkalosis is most commonly a result of pregnancy; it may also occur in damage to the respiratory centers, in acute salicylism, in fever and septic states,

in advanced liver disease, and when respiratory rate is increased in pneumonia, pulmonary embolism, and congestive heart failure. The disorder may be produced iatrogenically by injudicious mechanical ventilatory support. Chronic hyperventilation occurs in the acclimatization response to high altitudes caused by reduced ambient partial pressure of oxygen.

Acute hyperventilation is characterized by lightheadedness, paresthesias, circumoral numbness, and tingling of the extremities. Tetany occurs in severe cases. When anxiety provokes hyperventilation, air rebreathing with a paper bag generally terminates the acute attack.

Prospectus for the Future

- Identification of additional gene mutations informative about the renal regulation of water and solute transport
- Design of small molecules to inhibit salt and water transport in specific nephron segments for the treatment of hypertension and edema

Glomerular Diseases

Jamie P. Dwyer and Julia B. Lewis

Each human kidney contains nearly 1 million glomerular capillary tufts, which derive from an afferent arteriole and are held together by the mesangial matrix. The glomerular capillary tufts drain into an efferent arteriole forming an arteriolar portal system. Fenestrated endothelial cells, the glomerular basement membrane (GBM), and delicate foot processes extending from epithelial podocytes, which are interconnected to each other by slit diaphragms (Web Fig 29-1), form a selective filtration barrier between the capillary blood and urinary space (Web Fig 29-2A). Each glomerular tuft has an associated renal tubule that drains into the urologic system. Nearly one fourth of the blood of each heartbeat is filtered by the kidney (about 120 to 180 L per 24 hours). Remarkably, despite the 12,000 to 18,000 g of protein filtered by the capillaries each day, less than 150 mg appears in urine. This is accomplished in part by the negatively charged GBM and the 4-nm slit-pore membranes restricting the movement of large or negatively charged proteins. Therefore, the glomerulus serves as a size- and charge-selective barrier to the movement of proteins and cells from the capillary blood into the urinary space.

The glomerulus can be injured by a variety of means, including genetic mutations producing familial diseases, immune-mediated inflammation, vascular injury, deposition of abnormal proteins, and infection. These injuries result in diverse glomerular diseases manifesting clinically as proteinuria, hematuria, pyuria, and vascular changes.

Clinical Syndromes

Glomerular diseases can have diverse clinical manifestations, including hematuria (Web Fig. 29-3), proteinuria, pyuria (Web Fig. 29-4), hypertension, fluid retention, edema, and a reduction in glomerular filtration rate (GFR). Glomerular diseases can be acute, developing over days; subacute, developing over weeks; or chronic, developing over months or years. Distinct clinical syndromes have been described; however, these syndromes are not always mutually exclusive (Table 29-1) The acute nephritic syndrome is characterized by hypertension, hematuria, edema, red blood cell (RBC) casts (Fig. 29-1) or dysmorphic RBCs (Web Fig. 29-5), modest proteinuria (1 to 2 g per 24 hours), and decreased

GFR. If the loss of GFR (seen as a rise in serum creatinine) occurs over days, acute nephritis is called rapidly progressive glomerulonephritis (RPGN) and is associated with crescentic glomerulonephritis on renal biopsy. Patients with the clinical syndrome of RPGN in whom the disease extends to the lungs are classified as having a pulmonary-renal syndrome (Table 29-2). In nephrotic syndrome, the patient excretes more than 3.5 g of protein in a 24-hour urine collection and has edema, hypoalbuminemia, and hypercholesterolemia. In long-standing nephrotic syndrome, decreased GFR and hypertension often develop (e.g., in diabetic nephropathy). Many glomerular diseases present with microscopic or gross hematuria and either no or mild proteinuria. Hematuria may be the only manifestation of some glomerular diseases throughout their course, as in thin basement membrane disease, or may be an early manifestation that progresses over time to involve other clinical signs such as decreased GFR, as in antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis. When abnormal proteins, such as paraproteins, are deposited in or accumulate in the glomerulus in glomerular deposition diseases, the clinical manifestations can range from asymptomatic mild proteinuria to severe nephrotic syndrome. Glomerular vascular syndromes occur in patients in whom the injury is primarily

Figure 29-1 Immunofluorescence demonstrating a linear pattern of immunoglobulin G.

Table 29-1 Clinical Syndromes

Acute Nephritic Syndromes

Poststreptococcal glomerulonephritis
 Subacute bacterial endocarditis
 Lupus nephritis* (WHO class III or IV)
 Anti-GBM disease, Goodpasture syndrome
 ANCA-associated vasculitis (Wegener granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome)*
 Cryoglobulinemia*
 IgA nephropathy
 Henoch-Schönlein purpura
 Membranoproliferative glomerulonephritis

Nephrotic Syndromes

Minimal change disease
 FSGS
 MGN
 Diabetic nephropathy
 Lupus nephritis (WHO class V)
 ANCA-associated vasculitis
 Deposition diseases
 Nail-patella syndrome
 Fabry disease
 Syphilis (MGN)
 Schistosomiasis (MPGN, FSGS, amyloid)

Primarily Hematuria Manifested Glomerular Diseases

IgA nephropathy
 Thin basement membrane disease
 Alport syndrome
 MGPN
 Lupus nephritis (WHO class II or III)
 ANCA-associated vasculitis (early)*
 Sickle cell disease

Glomerular Deposition Diseases

Light-chain deposition disease
 Amyloidosis
 Fibrillary glomerulonephritis, immunotactoid glomerulonephritis
 Fabry disease

Glomerular Vascular Syndromes

Hypertensive nephrosclerosis
 Cholesterol emboli
 Sickle cell disease
 Thrombotic thrombocytopenia purpura, hemolytic uremic syndrome
 Antiphospholipid antibody syndrome
 ANCA-associated vasculitis
 Henoch-Schönlein purpura
 Cryoglobulinemia*
 Amyloidosis
 Ischemic nephropathy

Infection-Associated Syndromes

Poststreptococcal glomerulonephritis
 Subacute bacterial endocarditis
 HIV (FSGS)
 Hepatitis B and C (MGN and MPGN, respectively)
 Syphilis
 Leprosy
 Malaria
 Schistosomiasis

*May present as a pulmonary-renal syndrome.

ANCA, antineutrophil cytoplasmic antibody; FSGS, focal segmental glomerulosclerosis; GBM, glomerular basement membrane; IgA, immunoglobulin A; MGN, membranous glomerulonephritis; MPGN, membranoproliferative glomerulonephritis; WHO, World Health Organization.

Table 29-2 Differential Diagnosis of Rapidly Progressive Glomerulonephritis

Linear Immune Staining

Anti-GBM disease
 Goodpasture syndrome
 Rarely membranous glomerulonephritis

Granular Immune Staining

Subacute bacterial endocarditis (past infectious)
 Lupus nephritis
 Cryoglobulinemia
 Membranoproliferative glomerulonephritis (type II more than type I)
 Immunoglobulin A nephropathy, Henoch-Schönlein purpura
 Idiopathic

No Immune Staining (Pauci-immune)

Antineutrophil cytoplasmic antibody-associated vasculitis (Wegener granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome)
 Idiopathic

localized to the renal vasculature and is usually associated with hematuria and mild proteinuria. Lastly, a wide variety of infections can produce inflammatory reactions in the glomerulus, ranging from nephritic syndrome with RPGN to mild proteinuria or nephrotic syndrome.

The classification of glomerular diseases is hampered by the fact that an individual glomerular disease can present with more than one constellation of clinical signs or symptoms. For example, lupus nephritis can present as nephrotic syndrome, rapidly progressive glomerulonephritis, or asymptomatic hematuria. Hence, all classifications of glomerular diseases are complex and somewhat arbitrary. Each of the major glomerular diseases is discussed next, and potential alternate manifestations are noted (see Table 29-1).

Evaluation of Glomerular Diseases

A detailed history and physical examination can help clarify the differential diagnosis of glomerular lesions. Onset and timing may be important (e.g., nephrotic syndrome in a child suggests minimal change nephropathy). Associated physical examination findings may add to the diagnosis (e.g., Raynaud phenomenon in lupus nephritis, livedo reticularis in cholesterol emboli). Assessment for anemia, thrombocytopenia, eosinophilia, microangiopathic hemolysis, serologies for antinuclear antibody (ANA), ANCA, anti-GBM antibody, antibodies to hepatitis B and C, HIV, rheumatoid factor, anti-DNAse B, antistreptolysin O (ASO) titer, cryoglobulin, and monoclonal proteins may help in narrowing the diagnostic possibilities. Urine microscopy is a critical element in the evaluation of a patient with glomerular diseases and may reveal hematuria, RBC casts, oval fat bodies or fatty casts (**Web Fig. 29-6**), or proteinuria. Measurement of 24-hour creatinine clearance and proteinuria helps distinguish the presence or absence of nephrotic syndrome and assesses GFR. Ultimately, a specific diagnosis may rely on a renal biopsy. Indications for renal biopsy vary from patient to patient and between countries. Renal biopsy allows one

Figure 29-2 Glomerulus demonstrating crescent formation.

to make a diagnosis and can be determined by light microscopy if the disease is focal (involving <50% of glomeruli) or diffuse (involving >50% of glomeruli), segmental (involving a portion of a glomerulus) or global (involving the entire glomerulus). It can also demonstrate so-called crescent formation (Fig. 29-2), which is the pathologic hallmark of rapidly progressive glomerulonephritis. Immunofluorescence microscopy can identify types of immunoglobulin deposition and location (e.g., linear immunoglobulin G [IgG] staining in Goodpasture syndrome (Fig. 29-1)). There may be minimal or no immune deposition (pauci-immune glomerulonephritis). Electron microscopy can show the location of electron-dense deposits (e.g., subepithelial deposits in poststreptococcal glomerulonephritis (**Web Fig. 29-7**) or subendothelial deposits in proliferative lupus nephritis (**Web Fig. 29-8**)).

General Treatment Guidelines for Glomerular Disease

Specific therapies for the different glomerular disease are noted next. In all forms of glomerular disease, treatment of hypertension, if present, is indicated with a target blood pressure of 130/80 mm Hg. For many glomerular diseases, including all those associated with proteinuria, treatment with drugs that inhibit the renin-angiotensin system is recommended. It has also been suggested that accelerating therapy to maximally reduce proteinuria should be a goal. Volume overload, manifested by edema, should be treated by reduction in salt and water intake and judicious use of diuretics. Hypercholesterolemia should be controlled with dietary modification and pharmacologic therapy. If a hypercoagulable state exists, anticoagulation may be necessary. Every effort should be made to avoid exposure to nephrotoxins because patients with glomerular disease may be at increased risk for acute kidney injury. Lastly, close monitoring of renal function by a specialist is indicated in most cases.

Shunt nephritis

Acute Nephritic Syndromes

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Poststreptococcal glomerulonephritis (PSGN) can occur as a postinfectious complication of skin and throat infections with particular M types (nephritogenic strains) of streptococci. PSGN due to streptococcal pharyngitis occurs in fewer than 5% of people infected, typically 1 to 3 weeks after the pharyngitis. Streptococcal impetigo is a less common cause of PSGN than pharyngitis but leads to PSGN in as many as 50% of infected people 2 to 6 weeks after the impetigo. In undeveloped countries, PSGN can occur in an epidemic form, but in Western countries, it typically occurs sporadically in the summer and autumn. PSGN can occur in adults but usually occurs in children between the ages of 2 and 14 years.

Patients present classically with acute nephritis, characterized by hematuria, pyuria, RBC casts, edema, hypertension, systemic symptoms of headache and malaise, flank pain due to renal capsular swelling, and oliguric renal failure. Because the hematuria occurs after the pharyngitis, it is called *metapharyngitic* or *postpharyngitic* hematuria. Five percent of children and 20% of adults have nephrotic range proteinuria. A subclinical disease has also been reported, characterized by asymptomatic microscopic hematuria. Early in the course, 90% of patients will have decreased levels of C₃ and CH₅₀ with normal levels of C₄. Patients with PSGN must be distinguished from other glomerular diseases associated with hypocomplementemia (Table 29-3). Rheumatoid factor, cryoglobulins, and ANCA may all be positive. Increased titers of ASO antibodies (30%), anti-DNAase (70%) or antihyaluronidase antibodies (40%) can help confirm the diagnosis. Histologically, the kidney demonstrates a diffuse proliferative glomerulonephritis with hypercellularity of mesangial and endothelial cells (**Web Figs. 29-9 and 29-10**), glomerular infiltrates of polymorphonuclear leukocytes, and granular, “lumpy-bumpy” subendothelial and subepithelial deposits of IgG, IgM, and complement. Treatment is supportive and may require renal replacement therapy. Antibiotic therapy does not alter the course of PSGN. Immunosuppressive therapy is also ineffective. Complete recovery occurs in 90% to 95% of patients; in children, recovery is usually seen within 3 to 6 weeks of the onset of nephritis, whereas in adults, proteinuria and hematuria may continue for 1 to 2 years. End-stage renal disease (ESRD) is uncommon, occurring in 1% to 3% of adults and rarely in children.

SUBACUTE BACTERIAL ENDOCARDITIS

Endocarditis-associated glomerulonephritis is a complication of subacute bacterial endocarditis. Patients present with hematuria, pyuria, and mild proteinuria, or less commonly with RPGN. Laboratory examination reveals an elevated erythrocyte sedimentation rate, hypocomplementemia, a positive rheumatoid factor, cryoglobulinemia (type III), and anemia. Renal biopsy reveals a focal proliferative glomerulonephritis with abundant mesangial, subendothelial, and subepithelial deposits of IgG, IgM, and complement. Patients who present with RPGN have crescents on renal biopsy. Embolic infarcts or abscesses may also be present. Treatment is antibiotics for 4 to 6 weeks, and the prognosis is good.

Glomerulonephritis can also occur in patients with infected ventriculoatrial and ventriculoperitoneal shunts (shunt nephritis); pulmonary, intra-abdominal, pelvic, or cutaneous infections; and infected vascular prostheses. Treatment is eradication of the infection.

LUPUS NEPHRITIS

Sixty percent of adults and 80% of children with systemic lupus erythematosus (SLE) develop renal abnormalities. The clinical manifestations and treatment of lupus nephritis are closely linked to the renal pathology (Table 29-4). Clinical signs and laboratory data can include hematuria, proteinuria, RBC casts, hypertension, hypocomplementemia, and anti-double-stranded DNA (anti-dsDNA) antibodies. Renal biopsy is critical to distinguish the variants of lupus nephritis (Web Fig. 29-11), and patients with lupus often undergo multiple biopsies as their lupus-related renal lesions may vary over time. The World Health Organization (WHO) has outlined distinct patterns of lupus-related glomerular injury (see Table 29-4). WHO class I lesions have minimal clinical manifestations and either normal histology or minimal mesangial deposits. Prognosis is excellent, and no treatment is required. WHO class II nephritis demonstrates mesangial immune complex deposition with mesangial proliferation, but few clinical renal manifestations, normal renal function, and a good prognosis. Specific treatment is generally not necessary. WHO class III lesions demonstrate focal lesions

with proliferation and scarring (focal proliferative lupus nephritis), and patients with class III lesions have diverse clinical courses. Patients can present with hypertension, hematuria, proteinuria, nephrotic syndrome (25% to 33%), or elevated serum creatinine (25%). Some patients with only mild focal proliferation involving a small percentage of glomeruli respond to steroid therapy alone with an excellent prognosis. Others with more severe proliferation involving a greater percentage of glomeruli have a worse prognosis, and therapy with steroids and other immunosuppressive drugs (cyclophosphamide, mycophenolate) is required. WHO class IV nephritis demonstrates global, diffuse proliferative lesions involving most of the glomeruli (diffuse proliferative lupus nephritis). Clinically, patients present with the most severe manifestations, including RPGN, hematuria, RBC casts, hypertension, proteinuria (50% nephrotic range), and declining renal function. Without treatment, WHO class IV lesions have the worst prognosis, and therapy with steroids and immunosuppressive drugs is recommended. If remission is achieved (defined as a return to near-normal renal function and proteinuria <330 mg per 24 hours), long-term renal outcomes are good. The WHO class V lesion has a membranous pattern with subepithelial immune deposits. Class V lesions may also have associated proliferative lesions and are subcategorized. Patients typically present with nephrotic syndrome (60%) and may also have hypertension, renal dysfunction, and renal vein thrombosis as manifestations. Unlike WHO class IV lesions, data on treatment of class V lesions are conflicting. This may reflect heterogeneity of the lesions in the WHO class V category. In patients with severe nephrotic syndrome or elevated serum creatinine, a course of steroids in combination with immunosuppressive agents will improve the disease course. The WHO class VI lesions have 90% scarred or sclerotic glomeruli, which implies ESRD. Importantly, if this lesion is found in biopsy, no further immunosuppressive therapy is indicated. Overall, about 20% of patients with lupus nephritis reach ESRD. Renal transplantation is an option but is usually performed only after 6 months of inactive lupus. Systemic lupus typically becomes quiescent with complete kidney failure, perhaps as a result of the immunosuppression associated with uremia.

Table 29-4 Lupus Nephritis

World Health Organization Class	Histology	Clinical Manifestations	Treatment
1	Normal	Hematuria	None
2	Mesangial immune complexes with proliferation	Hematuria, mild proteinuria	With or without prednisone only
3	Focal endocapillary with or without extracapillary proliferation with subendothelial deposits	Hypertension, hematuria, proteinuria, variable decline in renal function	Mild: prednisone only Severe: prednisone plus cytotoxics or mycophenolate
4	Diffuse endocapillary and extracapillary proliferation with diffuse subendothelial deposits	Hematuria, red blood cell casts, proteinuria, declining renal function, possibly RPGN	Prednisone plus cytotoxics or mycophenolate
5	Membranous with diffuse subepithelial deposits	Nephrotic syndrome	Prednisone plus cytotoxics or mycophenolate
6	Global sclerosis	Near end-stage renal disease	Dialysis, transplantation

ANTIGLOMERULAR BASEMENT MEMBRANE DISEASE

Patients with anti-GBM disease have autoantibodies directed against epitopes in the quaternary structure of the α_3 NC1 domain of type IV collagen found in the GBM. This can present as an isolated glomerulonephritis (anti-GBM disease) or involve collagen IV in the lung, presenting as a pulmonary-renal syndrome called Goodpasture syndrome. It occurs in two age peaks, in young men in their 20s and in men and women in their 60s and 70s, and can be triggered by exposure to infection, smoking, or solvents. Patients can present with hemoptysis, anemia, fever, dyspnea, hematuria, and RPGN (see Table 29-2). About 10% of patients with RPGN have anti-GBM disease. Alternately, usually in older patients, it can present more indolently with isolated hematuria, anemia, and a more gradual loss of renal function. Urgent renal biopsy is diagnostic and reveals a characteristic linear pattern of staining of the capillary loops with IgG (Fig. 29-1) and C₃. Serum can also be tested for anti-GBM antibodies. Treatment consists of high-dose steroids, cyclophosphamide, and plasmapheresis.

ANTINUCLEAR CYTOPLASMIC ANTIBODY-ASSOCIATED SMALL VESSEL VASCULITIS

ANCA are found in the serum of 80% to 85% of patients with pauci-immune glomerulonephritis. ANCA antibodies are of two types: anti-proteinase 3 (anti-PR3) or anti-myeloperoxidase (anti-MPO). ANCA are implicated in the small vessel endothelial cell injury seen in Wegener granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome. Anti-PR3 ANCA is generally seen in a cytoplasmic pattern (c-ANCA) (Web Fig. 29-12) and is more common in Wegener granulomatosis. Anti-MPO ANCA is generally seen in a perinuclear pattern (p-ANCA) (Web Fig. 29-12) and is more common in microscopic polyangiitis or Churg-Strauss syndrome. Patients with Wegener granulomatosis may present with fever, rhinorrhea, nasal ulcers, sinus symptoms, pulmonary symptoms (hemoptysis), arthritis, microscopic hematuria, and mild proteinuria. It can present as limited disease with pulmonary and no renal involvement, pulmonary-renal syndrome, asymptomatic microscopic hematuria, or RPGN. Microscopic polyangiitis may present with many of the same symptoms as Wegener granulomatosis, but upper airway or pulmonary symptoms are rare. In Churg-Strauss syndrome, patients may have eosinophilia, purpura, mononeuritis multiplex, and respiratory involvement manifested as asthma or allergic rhinitis. The presentation may also be a pulmonary-renal syndrome with pulmonary infiltrates and RPGN. In most cases, renal biopsies associated with any of the above conditions reveal pauci-immune glomerulonephritis with only a few immune complexes in the small vessels and either a crescentic glomerulonephritis or a focal necrotizing glomerulonephritis. The biopsy is typically consistent with, but not diagnostic of, ANCA-associated vasculitis. Treatment is aggressive with plasmapheresis, high-dose steroids, and cyclophosphamide for induction therapy. Maintenance therapy appears important in these diseases to prevent relapse and usually involves lower doses of steroids and cytotoxic drugs.

CRYOGLOBULINEMIA

Cryoglobulinemia presents in middle age, more commonly in women than men, with manifestations of purpura, fever, Raynaud phenomena, arthralgias, fatigue, and renal involvement (40% to 50% of patients). Renal manifestations may range from mild (with isolated hematuria or proteinuria) to severe (with acute nephritic syndrome and RPGN). Serologic testing may reveal a positive rheumatoid factor, low levels of C₄, and evidence of hepatitis C infection. Up to 50% of patients with cryoglobulinemia have hepatitis C virus. Renal biopsy most commonly reveals a membranoproliferative pattern of injury with intraluminal hyaline thrombi. Treatment is not well established, but plasmapheresis and the use of cytotoxic agents have been reported to induce remissions; however, relapses are common. Often, treating the hepatitis C infection (if present) ameliorates the cryoglobulinemia.

IgA nephropathy, Henoch-Schönlein purpura, and membranoproliferative glomerulonephritis also may present as an acute nephritic syndrome or RPGN but are discussed later because acute nephritic syndrome is not their most common presentation.

Nephrotic Syndromes

MINIMAL CHANGE DISEASE

Minimal change disease (MCD) is the most common cause of nephrotic syndrome in children. Seventy to 90% of nephrotic syndrome cases in children and 10% to 15% in adults are due to MCD. MCD is typically idiopathic but can rarely be associated with Hodgkin disease or nonsteroidal anti-inflammatory drugs. MCD presents clinically with the abrupt onset of proteinuria in the nephrotic range, acellular urine, and edema. In children, the proteinuria is primarily albumin and is called *selective proteinuria*. Diagnosis in children is usually presumptive, and a renal biopsy is only done in nonresponders to steroid therapy. Renal biopsy is the only definitive diagnostic test and reveals normal light microscopy (Web Fig. 29-13), negative immunofluorescent microscopy, and effacement of the foot processes (Web Fig. 29-2B) supporting the epithelial podocytes on electron microscopy. Although it has been reported that up to 30% of children will have a spontaneous remission, most children today are treated with steroids. Ninety to 95% of children develop a complete remission (<0.2 mg per 24 hours of proteinuria) after 8 weeks of steroid therapy. Eighty to 85% of adults achieve remission, but only after 20 to 24 weeks of therapy. Steroid-dependent patients relapse as their steroid dose is tapered. Other less common clinical features include hypertension (30% in children, 50% in adults), atopy (40% in children, 30% in adults), microscopic hematuria (20% in children, 30% in adults), and renal failure (<5% in children, 30% in adults). Relapses are common in children after the first remission. Frequent relapsers are defined as having two or more relapses in 6 months. The frequency of relapses decreases after puberty. In adults, relapses are less common but more resistant to therapy. Steroid-resistant patients fail to respond to steroid therapy. Cytotoxic drugs such as cyclophosphamide, chlorambucil, and mycophenolate mofetil are given to frequent relapsers and to steroid-dependent or

Table 29-5 Etiology of Focal Segmental Glomerulosclerosis (FSGS)

<i>TRPC6</i> (cation channel) mutation
<i>ACTN4</i> (α -actinin 4 mutation)

steroid-resistant patients. Cyclosporine has been reported to induce remissions, but relapse is frequent when it is withdrawn. Overall, the prognosis is better in children than adults.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Focal segmental glomerulosclerosis (FSGS) accounts for 10% to 15% of nephrotic syndrome in children, and in adults it represents one third of non-diabetes-associated nephrotic syndrome. It is even more common in African American adults, in whom it is the etiology of more than 50% of cases of nephrotic syndrome. FSGS can either be primary and idiopathic or secondary to either a familial or systemic process (Table 29-5). Patients present with proteinuria, frequently microscopic hematuria, hypertension, edema, and impaired kidney function. Although there is much overlap in clinical presentations, adults with FSGS are more likely to present with hematuria, hypertension, and impaired renal function than adults with MCD. Children with nephrotic syndrome who fail empiric steroid therapy often have FSGS on renal biopsy. Renal biopsy changes (Fig. 29-3) are most prominent in glomeruli located at the cortico-medullary junction and include focal and segmental scarring. A cellular lesion with endocapillary hypercellularity and heavy proteinuria has also been described. A collapsing glomerulopathy with segmental or global glomerular collapse (**Web Fig. 29-14**), massive proteinuria, and rapidly advancing renal failure has been described in heroin users, patients with HIV, and African Americans. FSGS rarely remits spontaneously, and patients treated with steroids achieve remission far less often than patients with MCD. Treatment of primary FSGS should include inhibitors of the renin-angiotensin system and, in patients with a high risk for progressive loss of renal function, 6 to 9 months of steroid therapy. Patients at high risk include those with nephrotic range proteinuria, African Americans, males, and patients with renal insufficiency. It is estimated that 50% of these patients will reach ESRD in 6 to 8 years without treatment. With steroid therapy, proteinuria remits in 20% to 45% of patients. In secondary FSGS, the underlying cause should be treated, and steroid therapy is not indicated.

Figure 29-3 Glomerulus demonstrating a focus of sclerosis and hyalinosis.

Figure 29-4 Membranous glomerulopathy showing “spikes” on capillary loops.

MEMBRANOUS GLOMERULONEPHRITIS

Membranous glomerulonephritis (MGN) accounts for 25% to 30% of nephrotic syndrome in adults and is the most common cause of nephrotic syndrome in elderly people. Most cases of MGN are idiopathic, but 20% to 30% of cases are associated with malignancies (solid tumors of the breast, lung, colon), infection (hepatitis B, schistosomiasis, malaria), or rheumatologic diseases (systemic lupus, rheumatoid arthritis). Eighty percent of patients present with nephrotic syndrome with nonselective proteinuria, and 50% of patients present with microscopic hematuria. Because of the thrombogenic conditions associated with nephrotic syndrome, thrombotic events can be a feature of many glomerular diseases. However, MGN has the highest reported incidence of renal vein thrombosis, pulmonary embolism, and deep vein thrombosis. The diagnosis of MGN relies on the renal biopsy. Light microscopy reveals uniform thickening of and “spike” formation in the basement membranes (Fig. 29-4)

along the capillary loops, whereas immunofluorescence demonstrates granular glomerular deposits of IgG (Web Fig. 29-15) and C₃. Electron microscopy reveals electron-dense subepithelial deposits that distinguish MGN stages I to V. One third of patients with MGN have spontaneous remissions even 1 to 2 years after diagnosis. One third of patients have proteinuria without loss of renal function, and one third have nephrotic syndrome with a progressive decline in renal function. All patients should have treatment of edema, dyslipidemia, and hypertension and should receive drugs that inhibit the renin-angiotensin system. Patients with primary MGN who do not have a spontaneous remission should be treated with steroids and a cytotoxic agent or cyclosporine.

DIABETIC NEPHROPATHY

Diabetic nephropathy is the single most common cause of chronic kidney disease in the United States, representing 45% of all patients enrolled in the Medicare ESRD program. About 40% of patients with either type 1 or type 2 diabetes mellitus (DM) develop diabetic nephropathy. African American, Native American, Polynesian, and Maori patients with type 2 diabetes are far more likely to develop diabetic nephropathy than Caucasian patients with type 2 DM. The natural history of diabetic nephropathy is similar in patients with type 1 or type 2 DM. However, the time of onset of DM is often difficult to determine in patients with type 2 DM, and in newly diagnosed patients, even advanced diabetic nephropathy may be present. In patients with newly diagnosed diabetes, renal hypertrophy and glomerular hyperfiltration are present. Within 1.5 to 3 years, morphologic changes develop (Fig. 29-4), including glomerular basement thickening, mesangial expansion, hyaline arteriosclerosis, and in some patients, nodular glomerulosclerosis or Kimmelstiel-Wilson nodules. In the about 40% of patients with DM who develop clinically significant diabetic nephropathy, the earliest manifestation is an increase in urinary albumin excretion. Albuminuria in the range of 30 to 300 mg per 24 hours is arbitrarily referred to as *microalbuminuria*. Albuminuria greater than 300 mg per 24 hours is termed *overt nephropathy* or *proteinuria*. Current recommendations are to test patients with type 1 DM for microalbuminuria after 5 years of diabetes and yearly thereafter. Patients with type 2 DM should be tested at the time of diagnosis of DM and yearly thereafter.

Patients with microalbuminuria, if untreated, increase their urinary albumin losses and develop frank proteinuria. Proteinuria can be as little as 500 mg per 24 hours or greater than 20 g per 24 hours. Once proteinuria is present, renal function declines, with up to 50% of patients reaching ESRD in 5 to 10 years. However, many patients with microalbuminuria or proteinuria and type 2 DM die from adverse cardiovascular events before they reach ESRD. Ninety to 95% of patients with type 1 DM and diabetic nephropathy have diabetic retinopathy, whereas only 60% to 65% of patients with type 2 DM and nephropathy have retinopathy. In contrast to other glomerular diseases, patients with diabetic nephropathy often have normal-sized to enlarged kidneys despite even advanced renal disease. In the absence of other clinical or serologic data suggesting an alternate cause of glomerular disease, the diagnosis of dia-

betic nephropathy is usually a clinical one, not requiring a renal biopsy.

In type 1 DM, intensive blood sugar control has been unequivocally demonstrated to prevent both development and early progression of diabetic nephropathy. The data supporting intensive blood sugar control in type 2 DM are less compelling. Guidelines recommend controlling systemic blood pressure to about 130/80 mm Hg. Most patients with overt diabetic nephropathy require three or more antihypertensive drugs to achieve this goal. Multiple large clinical trials have demonstrated that drugs that inhibit the renin-angiotensin system slow the progression of early or overt nephropathy independent of their effect on systemic blood pressure.

Other glomerular diseases that can present as nephrotic syndrome, such as lupus nephritis (WHO class V), ANCA-associated vasculitis, deposition diseases, nail-patella syndrome, Fabry disease, and infection-associated glomerular disease are discussed in other sections.

Primarily Hematuria Manifested Glomerular Diseases

IMMUNOGLOBULIN A NEPHROPATHY AND HENOCH-SCHÖNLEIN PURPURA

IgA nephropathy is one of the most common causes of glomerulonephritis worldwide. There are well-described geographic and racial differences in the prevalence of IgA nephropathy. IgA nephropathy is more common in Asia and Southern Europe than in North America. In addition, IgA nephropathy is rarely familial (<10% of cases of IgA nephropathy), and clusters of cases have been associated with a founder effect. It has a peak incidence in the second and third decades of life and a male preponderance.

IgA nephropathy classically presents as recurrent episodes of gross hematuria during or immediately after an upper respiratory infection (synpharyngitic hematuria). Alternatively, it can present as persistent microscopic hematuria. Proteinuria, which can be in the nephrotic range, if it occurs at all, typically occurs late in the disease course. Rarely, IgA nephropathy can present as RPGN. In most patients, IgA nephropathy is a benign disease, with only 25% to 30% of patients progressing to ESRD over 20 years. Risk factors for progression include hypertension, the absence of macroscopic hematuria, proteinuria, and male gender. Specific diagnosis requires a renal biopsy that demonstrates characteristic dominant IgA mesangial staining on immunofluorescent microscopy (Web Fig. 29-16).

Inhibition of the renin-angiotensin system has been demonstrated to slow the progression of multiple glomerular diseases associated with proteinuria, including IgA nephropathy. There is no consensus on multiple other therapies that have been tried in small studies, including fish oil, tonsillectomy, steroid therapy, or cytotoxic therapy. The recommended treatment of IgA nephropathy when it presents as RPGN is plasmapheresis, steroids, and cytotoxic agents.

Henoch-Schönlein purpura is a closely related glomerular disease with indistinguishable biopsy findings. Clinically, it is distinguished from IgA nephropathy by prominent

systemic symptoms (including arthralgias), a younger age of onset (usually in childhood), and abdominal complaints.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

Membranoproliferative glomerulonephritis (MPGN) is a grouping of morphologically related but pathogenically distinct glomerular diseases. MPGN can be idiopathic or secondary to a systemic process. MPGN is rare in African Americans, and the idiopathic disease usually presents in childhood and adolescence. MPGN is subdivided into type I, type II (dense deposit disease), and type III disease. Type I MPGN is associated with hepatitis B, hepatitis C, cryoglobulinemia, systemic lupus, sickle cell anemia, antiphospholipid antibody syndrome, and less commonly, neoplastic diseases. Patients with MPGN type II or dense deposit disease commonly have C_3 nephritic factors, which are antibodies that stabilize the C_3 convertase and allow it to activate serum C_3 . Type II is also associated with partial lipodystrophy and factor H deficiency. Type III disease has been reported with complement receptor deficiencies and may also have associated “nephritic factors.” Patients with MPGN present with hematuria, proteinuria (nephrotic syndrome most common in type I), pyuria (30%), low C_3 levels (50% to 70%) (see Table 29-3), and in type I, frequent systemic symptoms of fatigue and malaise. Fifteen to 20% of patients with MPGN present with acute nephritis and RPGN (more common in type II). Renal biopsy findings include capillary loop thickening with basement membrane duplication and mesangial hypercellularity, often with lobular segmentation (Web Fig. 29-17). In type I, mesangial interposition between the capillary basement membrane and endothelial cells produces a double contour, “tram-tracking” appearance. Fifty percent of patients with MPGN develop ESRD within 10 years after diagnosis, and 90% have renal insufficiency after 20 years. In the presence of proteinuria, treatment with inhibitors of the renin-angiotensin system is indicated. In patients with RPGN, treatment with plasmapheresis, steroids, and cytotoxic agents is often empirically done. Patients with infection-associated MPGN have been reported to respond to treatment of the primary infection. Evidence for specific treatments for idiopathic MPGN is not well established.

THIN BASEMENT MEMBRANE DISEASE

Thin basement membrane disease (TBMD), also known as *benign familial hematuria*, is estimated to affect 1% of the general population. About 50% of patients with TBMD have an autosomal dominant pattern of transmission, and 40% to 50% of patients have mutations in either the *COL4A3* or *COL4A4* gene. These mutations cause subtle decreases in the $\alpha_3\alpha_4\alpha_5$ collagen IV networks in the GBM. This is in distinction to Alport syndrome, in which the collagen IV networks are lost or severely distorted, but has led some authors to view TBMD as a mild form of collagen IV glomerulopathy and Alport syndrome as a severe form. Patients present with isolated microscopic hematuria. Proteinuria is absent. The diagnosis is confirmed by a renal biopsy revealing attenuated GBM lamina densa, usually less than 250 nm in adults. Distinguishing classic TBMD from Alport syndrome is impor-

tant because in contrast to Alport syndrome, TBMD has a completely benign prognosis.

ALPORT SYNDROME

Alport syndrome, also known as *hereditary nephritis*, encompasses a spectrum of patients with mutations in collagen IV who present with hematuria. About 85% of patients have an X-linked mutation of *COL4A5*, causing a reduction or distortion in $\alpha_3\alpha_4\alpha_5$ (IV) and in $\alpha_5\alpha_5\alpha_6$ (IV) collagen. Female carriers have variable penetrance depending on the type of mutation or degree of mosaicism. Autosomal recessive disease with mutations in *COL4A3* or *COL4A4* causing loss of the $\alpha_3\alpha_4\alpha_5$ (IV) networks and autosomal dominant disease with mutations in *COL4A3* or *COL4A4* causing aberrations of the $\alpha_3\alpha_4\alpha_5$ (IV) network have been reported as well. Patients present with microscopic hematuria, mild proteinuria, and varying degrees of sensorineural deafness; some patients develop lenticonus of the anterior lens capsule. Rarely, mental retardation or leiomyomatosis is associated with Alport syndrome. Male patients are more affected than female patients and far more commonly progress to chronic glomerulosclerosis and ESRD. In the juvenile X-linked form of Alport syndrome, male patients reach ESRD before 30 years of age, and in the adult form, ESRD occurs after 30 years of age. Early severe deafness or lenticonus suggests a poorer prognosis. On skin biopsy, 80% of males with X-linked Alport syndrome have negative staining for α_5 (IV) in the epidermal basement membrane, and mosaic immunostaining is found in 50% of X-linked females with Alport syndrome. When skin biopsies are nondiagnostic in X-linked Alport syndrome (20% to 50%) and in patients with autosomal recessive or dominant Alport syndrome, renal biopsy is performed. Alport syndrome patients early in the disease have thin GBMs, which thicken over time into multilamellations surrounding lucent areas, the so-called split basement membrane. Primary treatment is control of systemic blood pressure using inhibitors of the renin-angiotensin system.

Sickle cell anemia–associated glomerulopathy, ANCA-associated vasculitis, and lupus nephritis can also present with hematuria but are discussed in other sections.

Glomerular Deposition Diseases

SYSTEMIC AMYLOID AND NONAMYLOID MONOCLONAL IMMUNOGLOBULIN DEPOSITION DISEASES

Of patients affected by systemic amyloidosis, about 63% have AL amyloid with deposits of immunoglobulin light chains, 29% have AA amyloid with deposits of serum amyloid A protein fragments, 2% have hereditary familial amyloid, and 5% are undetermined. In primary AL amyloidosis, light chains produced in excess by clonal plasma cell dyscrasias are most commonly of the lambda class (75%). About 10% of these patients have multiple myeloma. In AA amyloidosis, also known as *secondary amyloidosis*, serum amyloid A, an acute-phase reactant, forms deposits in

patients with a chronic inflammatory process. Rheumatoid arthritis is the most common inflammatory process and is seen in 40% of patients with AA amyloidosis. Amyloid fibrils can infiltrate the liver, heart, peripheral nerves, carpal tunnel, and kidney. Patients with renal involvement present with proteinuria, often of nephrotic range, and associated renal vein thrombosis can occur. Biopsy of the kidney is diagnostic with positive Congo red staining, positive staining for monoclonal light or heavy chains (30% false-negative results), and 10- to 12-nm nonbranching fibrils seen on electron microscopy (Web Fig. 29-18). Hereditary amyloidosis is negative for both monoclonal heavy and light chains and is diagnosed with stains specific for the abnormal protein deposited (e.g., fibrinogen, transthyretin, apolipoprotein, or lysozyme). Proper identification of hereditary amyloidosis is important because specific therapy such as liver transplantation may be indicated. Treatment of AA and AL amyloidosis is undergoing much change. In patients with AA amyloid, primary treatment of the systemic inflammatory process is critical (colchicine or anticytokine therapies), coupled with new therapeutic strategies such as eprodisate (an amyloid formation-inhibiting compound). AL amyloid treatment is directed at treating the underlying plasma cell dyscrasia, and although high-dose melphalan and steroid treatment with autologous stem cell transplantation have been used, they have been associated with significant toxicity in older patients and in patients with significant renal dysfunction. If multiple myeloma is present, therapy is directed towards this.

The nonamyloid monoclonal immunoglobulin deposition diseases (MIDDs) constitute a varied group of disorders that form Congo red negative deposits. Light-chain (light-chain nephropathy), light-heavy chain, and heavy-chain diseases represent disorders in which granular (not fibrillary) deposits that stain positive for monoclonal light or heavy chains are found on kidney biopsy. Light-chain nephropathy is most commonly seen and is associated with nephrotic syndrome, with 70% of patients progressing to ESRD. Light-chain nephropathy, in contrast to amyloidosis, is associated with predominant κ light chains. Treatment is directed at the plasma cell dyscrasia, and high-dose melphalan and prednisone with autologous stem cell transplantation have been used successfully. Thalidomide and its congeners have also been used as primary therapy. In immunotactoid and fibrillary glomerulonephritis, deposits of oligoclonal or oligotypic immunoglobulins form organized fibrils or tubules. Both disorders appear in adults in the fourth decade, with moderate to heavy proteinuria, hematuria, and a wide variety of associated renal histologic lesions. Treatment is control of systemic blood pressure and proteinuria with agents that block the renin-angiotensin system.

FABRY DISEASE

Fabry disease is an X-linked inborn error of globotriaosylceramide metabolism secondary to deficient lysosomal α -galactosidase A activity. Affected organs include the vascular endothelium, nerves, heart, brain, and kidneys. Renal manifestations of Fabry disease may include mild to moderate proteinuria and sometimes microscopic hematuria or nephrotic syndrome. Renal biopsy is diagnostic with enlarged glomerular visceral epithelial cells packed with vacuoles containing globotriaosylceramide, and focal and segmental scler-

osis. Treatment with recombinant α -galactosidase A has been demonstrated to clear the microvascular endothelial deposits in the kidneys, heart, and skin.

Glomerular Vascular Syndromes

HYPERTENSIVE NEPHROSCLEROSIS

Although only about 6% of patients with systemic hypertension develop kidney disease, up to one third of patients with ESRD have hypertensive nephrosclerosis as a primary cause. The risk for ESRD from hypertension is far higher in African Americans than Caucasians. Patients present with hypertension, less than 1 to 2 g of proteinuria, and less commonly microscopic hematuria. Episodes of malignant hypertension can be associated with acute kidney injury, nephrotic range proteinuria, or a thrombotic microangiopathic picture that can accelerate the path to ESRD. The diagnosis of hypertensive nephrosclerosis is usually inferred without a renal biopsy. Treatment is blood pressure control. In African Americans with hypertensive nephrosclerosis, antihypertensive therapy initiated with an angiotensin-converting enzyme (ACE) inhibitor has been demonstrated to slow the rate of decline of renal function.

CHOLESTEROL EMBOLI

Patients with underlying atherosclerosis may shower cholesterol crystals into the circulation, most commonly in the presence of a precipitating factor such as angiography or systemic anticoagulation, or less commonly spontaneously. Clinical manifestations include hematuria, mild proteinuria, loss of renal function (often in a stepwise fashion), livedo reticularis, fever, eosinophilia, eosinophiluria, and hypocomplementemia. Biopsy reveals characteristic biconvex clefts in vessels (Web Fig. 29-19). Although no specific therapy is of demonstrated benefit, blood pressure control, lipid-lowering agents, and cessation of smoking are reasonable recommendations.

THROMBOTIC THROMBOCYTOPENIC PURPURA AND HEMOLYTIC UREMIC SYNDROME

Thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) share the clinical features of thrombocytopenic purpura and microangiopathic hemolytic anemia (the combination of which is called *thrombotic microangiopathy*) (Table 29-6), fever, acute renal failure, and neurologic disturbances. The differentiation between TTP and HUS is difficult and is sometimes based on prominent renal symptoms or an association with diarrheal illness (Shiga toxin-induced diarrhea) in HUS, in contrast to prominent neurologic symptoms in TTP. In renal biopsy specimens, there is evidence of glomerular capillary endotheliosis with platelet thrombi and the formation of fibrin in and around the glomeruli. The cornerstone of therapy is plasma exchange, which is hypothesized either to remove antibodies to ADAMTS13, a metalloprotease that cleaves large multimers of von Willebrand factor, or to replace a

deficiency of ADAMTS13. Decreased activity of ADAMTS13 has been implicated in the pathogenesis of TTP and HUS.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

Antiphospholipid antibody syndrome is a systemic disease etiologically related to the presence of antibodies to anionic phospholipids. It can be idiopathic or associated with systemic lupus, pregnancy, or another primary renal disease. Thrombocytopenia, spontaneous venous or arterial occlusions, and renal manifestations may occur. Kidney injury occurring in about 25% of patients with this syndrome can present as acute renal failure, acute flank pain with renal vein thrombosis, or subacute proteinuria (1 to 2 g per 24 hours) and hematuria. Renal biopsy characteristically reveals occluded vessels, ischemic mesangiolysis, and glomerulosclerosis. The mainstay of treatment is anticoagulation with warfarin.

SICKLE CELL DISEASE

Patients with homozygous SS sickle cell anemia develop chronic vaso-occlusive disease that manifests commonly in the kidney as hyposthenuria early in the disease. Over time, microscopic hematuria, gross hematuria, hyperten-

sion, FSGS, interstitial nephritis, renal infarction or MPGN may appear. Treatment involves reducing the frequency of sickle crises and administering inhibitors of the renin-angiotensin system.

Infection-Associated Syndromes

Viral infections can be associated with many different kidney diseases, including glomerulonephritis and the nephrotic syndrome, hematuria, and acute and chronic renal failure. Viruses involved in kidney disease include HIV, hepatitis C, hepatitis B, parvovirus, polyomaviruses, cytomegalovirus, hantavirus, and coronavirus.

HIV-associated nephropathy presents after at least 2 to 3 years of HIV infection and is more common in patients with low CD4 counts and in African Americans. Distinguishing features include the absence of hypertension and well-preserved kidney size despite advanced renal failure, nephrotic syndrome, and a relatively rapid decline in renal function. Renal biopsy most commonly reveals FSGS, typically the collapsing form, but MPGN, IgA nephropathy, MCD, and MGN have all been reported. Because HIV replicates in the kidney, aggressive management to reduce the HIV burden with antiretroviral therapy is indicated. Use of ACE inhibitors has also been reported to slow the rate of decline of renal function.

Chronic hepatitis C infection is strongly associated with MPGN type I with or without mixed IgG and IgM cryoglobulins. Chronic hepatitis B infection can be associated with polyarteritis nodosa, MGN, or less commonly MPGN. Treatment of both these conditions aims at reducing the level of infection.

A variety of other infections can be associated with one or more glomerular lesions. Syphilis can be associated with nephrotic syndrome from MGN; leprosy with focal glomerulonephritis or renal amyloidosis; malaria with mild proteinuria and a mesangioproliferative glomerulonephritis; and schistosomiasis with MPGN.

Prospectus for the Future

The most common cause of glomerular disease and progressive kidney disease is diabetic nephropathy. A strong effort is underway to detect patients at risk for diabetic nephropathy using genetic and other urinary biomarkers through proteomics. By early identification of individuals at risk for kidney failure, novel treatment strategies may be developed that can prevent the progressive loss of kidney function and ESRD.

Additionally, better understanding of the mechanisms of glomerular injury in the various forms of glomerulonephritis has paved the way for development of disease-specific therapy, rather than systemic immunosuppression, to limit the extensive side effects and result in higher remission and cure rates for the disease.

Major Nonglomerular Disorders

James L. Pirkle, Amanda W. Basford, and Roy Zent

The tubulointerstitial compartment comprises the majority of the tissue mass of the kidney and can be affected by a diverse group of disorders, including acute and chronic tubulointerstitial nephritis, stone and cyst formation, and tumors. These disorders can present as acute or chronic renal failure, severe pain, or as incidental radiographic findings. Primary vascular disorders and some forms of acute tubular injury will be discussed in separate chapters.

Acute Interstitial Nephritis

Acute interstitial nephritis (AIN) is a clinicopathologic entity defined as a sudden decrease in renal function caused by acute infiltration of inflammatory cells into the interstitial compartment of the kidney (**Web Figs. 30-1 and 30-2**). AIN accounts for up to 10% to 20% of all cases of acute kidney injury (AKI).

CLINICAL PRESENTATION

The typical presentation of AIN is a sudden decrease in renal function in an otherwise asymptomatic patient recently begun on a new medication. The classic clinical triad of fever, rash, and eosinophilia are manifestations of a systemic hypersensitivity reaction, and any or all of these may be seen in AIN. Another fairly common symptom is lumbar or flank pain, possibly due to distention of the renal capsule. It is important to note that most patients do not have any of these features, and their absence does not preclude the diagnosis of AIN. Importantly, hypertension and edema, features of acute glomerulonephritis, are uncommon in AIN.

Characteristic laboratory tests include elevation of serum creatinine, consistent with acute kidney injury, sterile pyuria, and white blood cell casts. Hansel stain of the urine may demonstrate eosinophils. Although eosinophiluria is strongly suggestive of AIN, it is often not observed. Patients com-

monly have non-nephrotic range proteinuria (<1 g per day) and microscopic hematuria. Red blood cell casts are rarely seen. Eosinophilia may be seen on the peripheral blood smear.

ETIOLOGY

Drug reactions are the most common cause of AIN. Antibiotics are the most common offenders, most notably penicillins, cephalosporins, trimethoprim-sulfamethoxazole, and ciprofloxacin. Nonsteroidal anti-inflammatory drugs (NSAIDs) are a well-described cause of AIN, as are proton pump inhibitors such as omeprazole. The second most common cause of AIN is systemic infection. AIN may also be associated with acute pyelonephritis and autoimmune disease. A list of frequent causes of AIN is shown in Table 30-1.

TREATMENT AND PROGNOSIS

Treatment of AIN consists of removal of any suspected offending drug or treatment of the underlying infection or disorder. In cases in which antibiotics are being used to treat infection, another appropriate drug should be substituted. A short treatment with high-dose corticosteroids (prednisone, 1 mg/kg per day for a minimum of 2 weeks) may accelerate recovery if used early in the clinical course.

Most cases of AIN resolve completely after the offending factor has been removed. However, the longer the patient remains in renal failure, the less likely it is that complete recovery of renal function will occur.

Chronic Interstitial Nephritis

Chronic interstitial nephritis (CIN) is a clinicopathologic entity defined as slowly progressive renal insufficiency due to tubular cell atrophy and progressive interstitial fibrosis

caused by a chronic interstitial mononuclear cell infiltrate (**Web Fig. 30-3**). CIN is responsible for 15% to 30% of all cases of end-stage renal disease (ESRD).

CLINICAL PRESENTATION

Patients with CIN are usually asymptomatic until they develop advanced chronic kidney disease (CKD), which is characterized by symptoms of uremia: fatigue, malaise, nausea, nocturia, and sleep disturbance. Patients, might, however present earlier with features of the primary disease that has caused the CIN (see “Etiology” below). CIN is sometimes found incidentally on routine laboratory work (Table 30-2).

Laboratory studies reveal a glomerular filtration rate (GFR) that falls over time, characterized by a slowly rising serum creatinine. Urinalysis commonly reveals non-nephrotic range proteinuria (<1 g per day) and may show microscopic hematuria and pyuria. Because CIN is primarily a disease of the tubules, specific findings of tubular dysfunction might be out of proportion to the degree of renal insufficiency. Examples include lead toxicity and multiple myeloma, which primarily affect the proximal tubule and may present as a proximal renal tubular acidosis (RTA), glycosuria, aminoaciduria, and uricosuria. Chronic urinary obstruction usually causes distal tubular damage and may result in distal RTA, salt wasting, and hyperkalemia. Diseases such as analgesic nephropathy, sickle cell disease, and polycystic kidney disease affect the medullary collecting

Table 30-2 Clinical Findings that Suggest Chronic Interstitial Nephritis

Hyperchloremic metabolic acidosis (out of proportion to the degree of renal insufficiency)
Hyperkalemia (out of proportion to the degree of renal insufficiency)
Reduced maximal urinary concentrating ability (polyuria, nocturia)
Partial or complete Fanconi syndrome (phosphaturia, bicarbonaturia, aminoaciduria, uricosuria, glycosuria)
Modest proteinuria (<2 g/day)

tubules and may cause polyuria due to urinary concentrating defects.

ETIOLOGY

Many conditions are associated with CIN (Table 30-3). This section highlights the more common causes and describes the appropriate treatment and prognosis for each.

Metabolic Disturbances

Disorders of calcium metabolism that create hypercalcemia can lead to nephrocalcinosis, a deposition of calcium around the tubules and collecting ducts. Nephrocalcinosis may also occur in settings of acute hyperphosphatemia, as has been reported after the use of sodium phosphate solutions for bowel cleansing. CIN associated with nephrocalcinosis may be only slowly and incompletely reversible after the hypercalcemia is resolved.

Prolonged hyperuricemia is associated with chronic renal insufficiency, but it is unclear whether elevated serum urate levels per se result in CIN because chronic hyperuricemia is often associated with stones, hypertension, or renal ischemic disease, all of which may also cause CIN. Primary hyperoxaluria, an inborn error of metabolism, and enteric hyperoxaluria, a syndrome resulting from jejunoileal bypass or other cause of gastrointestinal malabsorption, may lead to progressive CIN and ESRD.

Analgesic Nephropathy

Analgesic nephropathy is a common condition that is caused by medications containing aspirin in combination with acetaminophen, phenacetin, caffeine, or codeine. Acetaminophen (a metabolite of phenacetin) is concentrated in the papillary tips and metabolized to reactive metabolites that can injure cells in the renal papilla, leading to papillary necrosis. The effect is worsened by NSAIDs, which decrease the supply of glutathione and thus decrease reducing potential. CIN usually accompanies the papillary necrosis in this entity. Analgesic nephropathy usually occurs in young women who have co-morbidities of emotional stress, neuropsychiatric disturbances, and gastrointestinal disturbances. Plain computed tomography (CT) of the kidneys may show papillary calcification and an abnormal contour of the renal cortex.

Treatment involves cessation of analgesic use. Progression of renal function loss is usually slowed or even arrested with discontinuation of the offending agents. These offending combination drugs are no longer available in North America or in many other parts of the world.

Table 30-3 Conditions Associated with Chronic Interstitial Nephritis

Hereditary Diseases
Autosomal dominant polycystic kidney disease
Metabolic Disturbances
Hypercalcemia, nephrocalcinosis
Hyperuricemia
Hyperoxaluria
Hypokalemia
Cystinosis
Drugs and Toxins
Analgesics, nonsteroidal anti-inflammatory drugs

Obstruction
Tumors
Stones
Bladder outlet obstruction
Vesicoureteral reflux
Miscellaneous
Radiation nephritis
Hypertensive arterionephrosclerosis
Renal ischemic disease

Lead Nephropathy

Occupational lead exposure has declined in the United States owing to strict governmental regulations. Lead can be ingested as a result of contaminated drinking water (from old lead pipes or crystal) or from drinking alcohol made in stills constructed with lead-soldered radiators. Lead is taken up by the proximal tubule cells, where it causes aminoaciduria, glycosuria, and CIN. The classic triad of hypertension, gout, and chronic renal insufficiency may suggest lead nephropathy as the cause. Diagnosis is made by the finding of elevated 24-hour urinary excretion of lead after administration of two 1-g doses of ethylenediaminetetraacetic acid (EDTA).

Treatment of this condition is accomplished using chelation therapy with EDTA, which may arrest or even reverse the CKD.

Chinese Herb Nephropathy

Chinese herb nephropathy (CHN) was first reported in 1992 in a cohort of women from Belgium who had ingested diet

pills containing root extracts. Cases have since been reported around the world. CHN usually presents silently, with evidence of renal insufficiency found on routine laboratory studies. Some patients may present with Fanconi syndrome or fatigue from anemia, which tends to be marked in CHN. Aristolochic acid, found in the herb genus *Aristolochia*, was identified as the nephrotoxic component and has reproduced the findings of CHN when administered to rat models. The clinical course is that of a rapidly progressive CIN with accelerated interstitial fibrosis, often leading to ESRD. Treatment consists of discontinuing ingestion of the herbs. Patients should be monitored for urothelial malignancy, which has also been associated with aristolochic acid.

Sarcoidosis

The most common cause of renal dysfunction in patients with sarcoidosis is hypercalcemia. However, sarcoidosis can also cause a noncaseating granulomatous interstitial nephritis that may lead to renal insufficiency in a subset of patients. These patients may develop glycosuria, concentrating defects, and RTA.

Patients with CIN related to sarcoidosis often respond well to corticosteroid therapy. Repeat kidney biopsies after treatment have shown loss of granulomas and lymphocytic infiltrate.

Multiple Myeloma

Multiple myeloma may cause acute and chronic renal dysfunction in a variety of ways. This disease predominantly causes tubulointerstitial pathology, and the most common renal complication is light-chain cast nephropathy (myeloma kidney). Other tubulointerstitial complications include hypercalcemia with nephrocalcinosis, hyperuricemia, and amyloid deposition. In light-chain cast nephropathy, excess light chains produced by the myelomatous plasma cells become trapped in the tubules and associate with Bence Jones proteins to create casts. The tubular cells are damaged as they try to reabsorb the heavy load of filtered light chains. Casts clogging the tubules initiate a multinucleated giant cell inflammatory reaction.

Treatment of light-chain cast nephropathy requires chemotherapy to reduce excess light-chain production, volume repletion, and alkalization of the urine.

Urinary Tract Obstruction

Urinary tract obstruction is discussed in more detail elsewhere in this chapter. Both acute urinary obstruction and chronic urinary obstruction are associated with a mononuclear cell interstitial infiltrate. Urinary obstruction causes CIN accompanied by impaired excretion of hydrogen ions and potassium and a vasopressin-resistant concentrating defect.

Treatment is relief of the obstruction, which results in halting the progression of loss of renal function.

Radiation Nephritis

Radiation nephritis develops in most patients whose kidneys are exposed to more than 2300 cGy. It may present as an acute severe form of injury within 1 year of the radiation and is associated with the development of hypertension, anemia, and edema. A more insidious chronic form presents with mild renal insufficiency, hypertension, and mild proteinuria.

The pathogenesis of this condition is primarily that of injury to the vascular endothelium, followed by vascular occlusion, tubular atrophy, and eventually interstitial fibrosis.

Hypertensive Arterionephrosclerosis

One of the most common causes of chronic kidney disease in the United States, hypertensive arterionephrosclerosis, begins with arteriopathy in the afferent arterioles leading to interstitial and glomerular changes likely related to ischemia. Tubular atrophy and interstitial fibrosis are prominent causes of the loss of renal function in these patients. This topic is discussed in detail in Chapter 31.

Urinary Tract Obstruction

Obstruction to urine flow may occur at any point from the renal pelvis to the urethral meatus. Unilateral ureteral obstruction usually causes no detectable change in urine flow or serum creatinine levels, and renal failure occurs only if the drainage of both kidneys is significantly compromised. Total urinary tract obstruction is an important cause of ESRD.

CLINICAL PRESENTATION

A change in urinary habits is often the presenting symptom of urinary tract obstruction. The most common cause of true anuria is complete urinary obstruction and is usually observed in elderly males who present with anuria or symptoms of metabolic disturbance. These patients usually have AKI with markedly elevated creatinine levels accompanied by metabolic acidosis and significant hyperkalemia. Complete urinary obstruction should be considered in any patient who is anuric. Patients with partial bladder outlet obstruction present with urinary hesitancy, decreased urine flow rate, polyuria, and nocturia. This condition is typically found in an elderly male who complains of nocturia and may have a fluctuating serum creatinine. Tubular defects may or may not be evident. Physical examination often reveals an enlarged prostate.

In patients with complete urinary obstruction, renal ultrasound may demonstrate hydronephrosis or hydroureter. However, dilation of the urinary tract may not be evident within the first 24 hours of obstruction or in patients who are volume depleted. The bladder may not even appear distended in patients who have complete urinary obstruction at the bladder outlet. In patients with partial urinary obstruction, renal ultrasound may demonstrate chronically dilated urinary tract, but a normal study does not exclude the diagnosis. A postvoid residual of more than 200 mL is considered abnormal and may suggest bladder outlet obstruction.

ETIOLOGY

Table 30-4 lists the common causes of urinary tract obstruction. The most common cause in adults is prostatic hypertrophy in a male patient.

TREATMENT AND PROGNOSIS

Management of the acute urinary tract obstruction is directed toward identifying the site and cause of obstruction

Table 30-4 Causes of Urinary Obstruction

Congenital Urinary Tract Malformation

- Meatal stenosis
- Ureterocele
- Posterior urethral valves

Intraluminal Obstruction

- Calculi
- Blood clots
- Sloughed papillary tissue

Extrinsic Compression

- Pelvic tumors
- Prostatic hypertrophy
- Retroperitoneal fibrosis

Acquired Anomalies

- Urethral strictures
- Neurogenic bladder
- Intratubular precipitates

and alleviating it. In the case of bladder outlet obstruction, this usually involves placement of a urinary catheter. If a ureter is found to be obstructed, surgical intervention, either through a ureteral stent or percutaneous nephrostomy tube, is required. Infection behind an obstruction is considered a urologic emergency and must be relieved. After relief of a complete obstruction, a postobstructive diuresis may be observed and must be monitored closely and treated with volume repletion when necessary. This diuresis is caused partly by the sodium and urea retained during the obstruction and partly by the tubular concentrating defect. There is usually complete recovery of renal function after relief of the acute, complete obstruction.

Management of the chronic partial obstruction depends on the location of the obstruction. If the history and physical examination suggest prostatic hypertrophy, an α_1 antagonist such as tamsulosin or an α -reductase inhibitor such as dutasteride may be used to improve urine flow. This condition often requires surgery to relieve obstruction within the prostate.

Cystic Diseases of the Kidney

Renal cysts are epithelium-lined cavities filled with fluid or semisolid debris. Cysts result from genetic and nongenetic processes and occur in a variety of diseases in both adults and children. Cysts can be simple or complex, and a clear diagnosis of cyst type is required to plan intervention.

SIMPLE CYSTS

Simple cysts are benign, asymptomatic lesions commonly found in normal kidneys. Simple cysts are the most common renal mass, accounting for 65% to 70% of all renal masses, and there is an increasing incidence with age. Cysts may be solitary, multiple, and bilateral and range in size from less than 1 cm to greater than 10 cm.

On ultrasound, simple cysts appear anechoic, have a thin or almost invisible wall, and demonstrate through-transmis-

Table 30-5 Bosniak Renal Cyst Classification Scheme

Category	Description
I—Simple cyst	A benign simple cyst with a thin wall and no septa, calcifications, or solid components.
II—Minimally complicated	A benign cystic lesion with a few thin septa. The wall or septa may contain fine calcifications or short segment of a slightly thickened calcification. (This category also includes uniformly high-attenuating lesions that are less than 3 cm in diameter, well marginated, and nonenhancing.)
IIF—Complicated	Well-marginated cysts, but more complicated than category II. They have multiple thin septa or minimal smooth thickening of the septa or wall and may contain calcifications that may be thick and nodular. (This category also includes totally intrarenal, nonenhancing high-attenuating lesions that are more than 3 cm in diameter.)
III—Indeterminate	Indeterminate cystic masses that have thickened irregular or smooth walls or septa. These lesions are enhancing on computed tomography. Forty to 60% of these lesions are malignant (cystic renal cell carcinoma and multiloculated cystic renal cell carcinoma). The rest of these cysts are hemorrhagic, chronic infected cysts or multiloculated cystic nephroma and are benign.
IV—Malignancy	Eighty-five to 100% of these lesions are malignant. On computed tomography, they have characteristics of category III cysts and contain enhancing soft tissue components that are adjacent to and independent of the wall or septum on the cyst. These lesions should undergo surgical evaluation.

sion because of the rapid progression of the sound waves through fluid when compared with soft tissue.

EVALUATION OF THE COMPLEX CYST

Complex cysts contain calcifications, septations, and mural nodules. These cysts have internal echoes representing hemorrhage, pus, or protein. Complex cysts may be benign or malignant. Malignancy is more likely if the cyst has increased wall nodularity, septations, or vascularity.

With the increased use of various imaging procedures, more and more renal cysts are being identified. To help diagnose and manage these lesions, the Bosniak renal cyst classification system was created. Based on morphologic and enhancement characteristics on CT scanning, cystic renal masses are placed into one of five different categories (Table 30-5).

Category I and II cysts generally do not require further evaluation. In some instances, an ultrasound may be repeated in 6 to 12 months to ensure stability. There is no defined approach to renal cystic lesions with indeterminate findings on ultrasound and CT scanning. Category IIF cysts should be reimaged and followed. The absence of change would point toward a more benign process, whereas progression of the cyst would suggest a neoplastic process and should undergo surgical evaluation. Some authorities suggest all Bosniak category III lesions undergo surgical evaluation owing to the high incidence of malignancy.

Magnetic resonance imaging (MRI) is used to evaluate patients with indeterminate lesions. MRI is useful for characterizing the internal contents of the cysts, differentiating hemorrhage or mucin, and is more sensitive than ultrasound and CT in showing enhancement of the internal septations.

Renal masses are being increasingly identified with the wide use of CT and MRI, and as a result, the role of renal mass biopsy will likely increase. In patients with indeterminate imaging, percutaneous image-guided biopsy appears safe and can provide a diagnosis in up to 80% of cases. A biopsy is required before percutaneous cryoablation of all renal masses.

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common hereditary disorder that causes ESRD and accounts for 8% to 10% of all cases of ESRD. The disease is characterized by cyst formation in the ductal organs, especially the kidney and liver. Patients also have noncystic, extrarenal manifestations such as mitral valve prolapse, intracranial aneurysms, and hernias. Patients usually present in adulthood but may have disease manifestations in infancy.

Polycystic kidneys are diffusely cystic and enlarged. Diagnostic criteria for individuals with a 50% risk by positive family history include two cysts, either bilateral or unilateral, in patients younger than 30 years. The criteria expand to two cysts in both kidneys in patients 30 to 59 years old and at least four cysts in each kidney in patients older than 60 years.

CLINICAL PRESENTATION

ADPKD is a multisystem disorder. Patients can have a reduction in urinary concentrating ability and glomerular hyperfiltration early in the disease. The kidneys will increase in size with age, and the structural abnormalities can lead to pain, hematuria, hypertension, and renal insufficiency. Hematuria occurs in up to 40% of patients at some time during the disease process and can be due to cyst hemorrhage, stone, infection, or tumor. Occasionally, a hemorrhagic cyst will rupture, leading to a significant retroperitoneal bleed that necessitates transfusion. Urinary tract infections are a common occurrence in ADPKD, being more common in women than men. Cyst infections and abscess formation are usually due to retrograde flow of bacteria; therefore, cystitis and asymptomatic bacteriuria should be promptly treated. Nephrolithiasis due to uric acid and calcium oxalate stones occurs in 20% of patients with ADPKD. Urinary stasis in the cysts, along with decreased ammonia excretion, low urinary pH, and low urinary citrate concentration, precipitate stone formation.

Hypertension is a major complication of ADPKD and is present in at least 75% of patients. Undiagnosed hypertension can lead to end-organ damage and has been shown to significantly affect the life expectancy of patients with ADPKD. Hypertension also accelerates the loss of GFR.

Polycystic liver disease is the most common extrarenal manifestation of ADPKD and occurs in both *PKD-1* and non-*PKD-1* genotypes (see “Etiology” below). Liver cysts arise from abnormal development and differentiation of the bile ducts. There is usually preserved liver function, but patients may have biliary hamartomas, biliary fibroadenomas, cystic dilation of peribiliary glands, and dilation of intrahepatic and extrahepatic bile ducts. Estrogen likely contributes to cyst growth, but the use of oral contraceptive pills and hormone replacement therapy is contraindicated only in those patients with significant liver enlargement. Symptoms of polycystic liver disease are usually due to massive liver enlargement or mass effect from a single large or multiple dominant cysts.

Intracranial aneurysms occur in 8% of the ADPKD population and appear to cluster within families. Patients with ADPKD should be screened for intracranial aneurysms if there is a family history of intracranial aneurysm or subarachnoid hemorrhage, previous aneurysm rupture, preparation for elective surgery that may involve hemodynamic instability, or high-risk occupations. Other vascular abnormalities appear to exist, such as thoracic aortic and cervicocephalic arterial dissections and coronary artery aneurysms. Mitral valve prolapse is the most common valvular abnormality and has been found in up to 25% of patients with ADPKD.

ETIOLOGY

The disease is expressed in an autosomal dominant pattern with variable penetrance. Two genes have been identified; *PKD-1* and *PKD-2*, and a third gene may exist. The *PKD-1* and *PKD-2* genes encode the proteins polycystin 1 and polycystin 2, and both proteins are thought to play an important role in the regulation of intracellular calcium homeostasis (Web Fig. 30-4). Polycystin 1 is a membrane receptor protein capable of binding and interacting with many proteins, carbohydrates, and lipids and eliciting intracellular responses through phosphorylation pathways. Polycystin 2 is thought to act as a calcium-permeable channel.

Both ADPKD type I and II have similar pathologic and physiologic features, but type II usually has a later onset of symptoms and a slower disease progression. Patients with mutations in both the *PKD-1* and *PKD-2* genes (transheterozygotes) have a more severe clinical course than patients with a mutation in only one of the genes.

TREATMENT AND PROGNOSIS

Treatment is directed at preventing complications of the disease and preserving renal function. Patients with flank pain should be evaluated for infection of cysts, stones, or tumor. If multiple cysts are contributing to pain, surgical decompression is effective in 80% to 90% of patients at 1 year, and 62% to 77% have sustained relief for greater than 2 years. Laparoscopic and retroperitoneoscopic nephrec-

tomy and arterial embolization can be used to treat symptomatic polycystic kidneys.

Blood pressure control is essential to prevent end-organ damage and delay progression of CKD. ACE inhibitors or angiotensin receptor blockers may have renoprotective properties in addition to blood pressure lowering properties.

ESRD occurs in 50% of patients by the age of 57 to 73 years. Risk factors for progressive renal failure include *PKD-1* genotype, male gender, diagnosis before the age of 30 years, first episode of hematuria before 30 years old, and onset of hypertension before 35 years old.

Patients who progress to ESRD tend to have a better prognosis on dialysis than those patients with ESRD from other causes. Females also tend to have a better prognosis. Patients also have higher endogenous erythropoietin and have better maintenance of hemoglobin. Peritoneal dialysis can be performed despite renal size, but patients are at increased risk for inguinal and umbilical hernias.

Autosomal Recessive Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease (ARPKD) is much rarer than the autosomal dominant form; the incidence is about 1 in 20,000 live births and often leads to fetal or neonatal death due to significant bilateral renal enlargement resulting in impaired lung function and pulmonary hypoplasia.

CLINICAL PRESENTATION

The diagnosis of ARPKD can be suggested on fetal ultrasound. The fetus may have enlarged echogenic kidneys and oligohydramnios, and decreased bladder urine may be seen as early as 16 weeks.

ETIOLOGY

ARPKD is due to mutations in the *PKHD-1* gene. The disease typically starts in utero, and cystic development is superimposed on a normal developmental sequence. The tubules develop a fusiform dilation of the collecting ducts. Patients present with biliary abnormalities due to defective remodeling of the ductal plate in utero, and primitive bile duct configuration will persist, leading to progressive portal fibrosis and congenital hepatic fibrosis.

TREATMENT AND PROGNOSIS

The estimated perinatal mortality rate is 30% to 50%. For infants who survive past 1 year of life, the mean 5-year patient survival rate is 80% to 95%. Progression to ESRD is highly variable. Hypertension usually develops in the first months of life and affects 70% to 80% of patients. Children who present later in childhood or adolescence frequently have portal hypertension as the predominant feature. These patients can develop hepatosplenomegaly and bleeding esophageal or gastric varices, thrombocytopenia due to hypersplenism, anemia, and leukopenia. In patients with

ESRD and severe portal hypertension, combined liver-kidney transplantation may be indicated.

Juvenile Nephronophthisis–Medullary Cystic Disease Complex

CLINICAL PRESENTATION

Juvenile nephronophthisis (NPHP) and medullary cystic disease complex share the same histopathologic features. These two disorders differ only in their mode of transmission and onset. Both are characterized by small, shrunken kidneys with cysts restricted to the medulla. Decreased urinary concentrating capacity, polyuria, and polydipsia are common symptoms in both.

Juvenile nephronophthisis is an autosomal recessive disorder that presents in childhood, and medullary cystic kidney disease is an autosomal dominant disorder that occurs in adults. Juvenile nephronophthisis is much more common than medullary cystic kidney disease.

ETIOLOGY

Six genes (*NPHP-1* to *NPHP-6*) have been identified in juvenile NPHP. The disease accounts for 6% to 15% of ESRD in children and adolescents. Three different forms have been described based on the age of onset of ESRD (infantile, juvenile, and adolescent). The juvenile and adolescent forms are nearly indistinguishable with regard to clinical, pathologic, and genetic analyses and therefore are referred to as *juvenile NPHP*.

TREATMENT AND PROGNOSIS

In juvenile NPHP, the most common form, ESRD occurs at a mean age of 13 years; the onset of ESRD in the infantile form usually occurs before 5 years old. Decreased urinary concentrating capacity usually precedes the decline in renal function; onset occurs in the school-aged child. Salt wasting develops in most patients with renal insufficiency, and sodium supplementation is often required until ESRD occurs.

Ten to 15% of children with juvenile NPHP have extra-renal abnormalities. Retinal abnormalities are the most common finding. Short stature, oculomotor apraxia (Cogan syndrome), mental retardation, and bone abnormalities have also been described. Congenital hepatic fibrosis occasionally occurs.

Acquired Cystic Kidney Disease

CLINICAL PRESENTATION

Acquired cystic kidney disease (ACKD) is a complication of CKD and is defined as more than three to five macroscopic

cysts in each kidney of a patient who does not have a hereditary cystic kidney disease. There is a high association with renal neoplasms, and it has been suggested that ACKD should be considered preneoplastic.

The prevalence of ACKD in dialysis patients ranges from 5% to 20%, and it is seen in about 80% to 100% of patients on dialysis for 10 years or longer. There is equal occurrence in patients on hemodialysis or peritoneal dialysis. The course of ACKD is variable after transplantation. If the renal allograft has good long-term function, cyst growth may slow or regress. However, if the graft function is impaired or failing, there may be further progression in the native kidneys and possible development of *de novo* ACKD in the graft.

ETIOLOGY

Various factors are thought to be involved in the development of ACKD, but the slow, progressive parenchymal loss appears to be the most important process. The loss of nephrons with CKD stimulates compensatory growth of remaining, intact nephrons, which is characterized by initial hypertrophy followed by hyperplasia. A cyst will develop from these hyperplastic tubules if transepithelial fluid secretion continues with impairment of distal outflow.

TREATMENT AND PROGNOSIS

There is nearly a 40-fold increased risk for renal cell carcinoma (RCC) in patients with ACKD compared with the general population. There is an increased risk for malignant transformation in males, African Americans, long duration of dialysis, and severe ACKD with significant organ enlargement. Compared with sporadic RCC, ACKD-associated RCC is characterized by younger patient age, male predominance, more frequent multiple and bilateral manifestations, and less aggressive behavior.

Up to 25% of kidneys with acquired cystic disease harbor tumors, about one third of which are carcinomas. Because of the high risk for malignant transformation, screening for ACKD is advocated, but there is no consensus screening strategy. Screening during transplantation evaluation is recommended with ultrasonography followed by CT of suspicious lesions based on the prevalence of renal cancer in up to 4% of the patients and concerns about the role of immunosuppression in accelerating tumor growth.

Renal Tumors

RENAL CELL CARCINOMA

The most common primary renal neoplasm is RCC, and it accounts for 85% of all primary renal malignancies. RCC accounts for 2% to 3% of all cancers and 2% of cancer deaths worldwide.

The clinical presentation of RCC may vary widely, from an incidental finding on imaging obtained for other clinical indications to the classic clinical triad of flank pain, hematuria, and palpable abdominal renal mass. Fever occurs in up to 20% of patients with RCC and is one of the most

common presenting symptoms. Other common presenting symptoms include anorexia, weight loss, and fatigue. Many RCCs are clinically occult for much of their courses and end up presenting with signs and symptoms of metastatic disease. Anemia is one of the most common laboratory findings, occurring in 20% to 40%. Paraneoplastic syndromes may occur with RCC, including hepatic dysfunction thought due to cytokine overproduction (Stauffer syndrome), hypercalcemia due to parathyroid-like hormone production, and erythrocytosis due to erythropoietin overproduction.

RCCs are classified according to cell type, of which there are five: clear cell, chromophilic, chromophobic, oncocytic, and collecting duct. The clear cell type is the most common, making up 75% to 85% of all RCCs. Clear cell carcinomas are characterized by a deletion in one or both copies of chromosome 3p. As mentioned later, patients with a mutated *VHL* tumor suppressor gene are at increased risk for clear cell RCC.

Treatment and prognosis are based on staging. Prognosis is excellent for disease that is confined to the kidney. The mainstay of treatment is nephrectomy, which has been shown to be beneficial even in locally invasive disease. Traditional chemotherapy has been largely ineffective in treating RCC. Immunotherapy using interleukin-2 (IL-2) gives somewhat better results, with response rates between 20% to 40%. IL-2 therapy is often limited by toxicity, with a major side effect being renal failure. Molecular targeted therapy directed against the vascular endothelial growth factor (VEGF) pathway and mammalian target of rapamycin (mTOR) have shown some promise in treating RCC. In general, if RCC can be completely surgically resected, the prognosis is good; however, if metastatic disease is present, prognosis is poor, with a 5-year survival rate of 10%.

TUBEROUS SCLEROSIS COMPLEX

Tuberous sclerosis complex is an autosomal dominant, tumor suppressor gene syndrome with tumor-like malformations, hamartomas, which can be found in the brain, kidneys, heart, lungs, and skin. TSC is due to an inactivating mutation in one of two genes, *TSC-1* on chromosome 9 and *TSC-2* on chromosome 16, adjacent to the *PKD-1* gene. Mutations lead to disruption of cell migration and differentiation of neural crest derivatives.

TSC affects 1 in 6000 people with variable disease penetrance. Two thirds of TSC cases appear to result from new mutations, and new mutations are more common in the *TSC-2* gene. The clinical manifestations of *TSC-2*-linked disease tend to be more severe. Patients may have seizures, mental retardation or autism, and skin lesions, and tumors in the brain, retina, kidney, and heart are common. Kidney involvement frequently occurs in TSC with angiomyolipomas, cysts, and renal malignancies. Angiomyolipomas are hamartomatous structures composed of abnormal, thick-walled vessels, varying amounts of smooth muscle cells, and adipose tissue. Angiomyolipomas are seen in about 80% of patients with TSC by the age of 10 years and increase in frequency and size with age. These tumors are benign and often require no treatment. However, they can grow and become locally invasive and may cause bleeding, pain, and hypertension. Annual evaluation with either ultra-

sound or CT is recommended. Female sex hormones may accelerate the growth of these lesions, and patients should be cautioned about the use of estrogen treatment and pregnancy.

Renal cysts occur less frequently than angiomyolipomas, but similarly increase in size and number with age. The occurrence of both cysts and angiomyolipomas is strongly suggestive of TSC. Strict blood pressure control is the mainstay of treatment for cystic disease.

Benign and malignant tumors of the kidney can occur in patients with TSC. The lifetime risk of a malignancy in the kidney in a patient with TSC is about 2% to 3%. TSC-associated renal carcinomas include clear cell, papillary, and chromophobe carcinomas. These carcinomas are often bilateral and occur with a higher frequency and earlier age of onset than in the general population.

CKD can occur but is rare. Decline in renal function is usually due to angiomyolipoma-parenchyma destruction, progressive renal cystic disease, interstitial fibrosis, and focal segmental glomerulosclerosis.

VON HIPPEL-LINDAU DISEASE

Von Hippel-Lindau disease (VHL) is an autosomal dominant disease that predisposes patients to tumors of the eyes, cerebellum, spinal cord, adrenal glands, pancreas, and epididymis, as well as renal and pancreatic cysts. RCC is one of the most common tumors in VHL, and reports indicate RCC occurs in up to 75% of patients by age 60 years. A germline mutation in the *VHL* tumor suppressor gene on chromosome 3 has been found; VHL is familial in 80% of cases and due to a new mutation in the remaining 20%. The incidence is 1 in 36,000 newborns.

The disease is subclassified by the risk for pheochromocytoma. Type I has a low risk for developing pheochromocytomas, whereas type II carries a high risk for developing pheochromocytomas. Type II is further divided according to the risk for developing RCC. There is a low risk for RCC in type 2A and a high risk in type 2B. In type 2C, patients will have familial pheochromocytoma without other VHL-associated malignancies.

In an individual at risk for VHL, the diagnosis is made if a single retinal or cerebellar hemangioblastoma, RCC, or pheochromocytoma is present. In presumed sporadic cases, diagnosis requires two or more retinal or central nervous system hemangioblastomas or a single hemangioblastoma and a characteristic visceral tumor.

The RCCs are usually the clear cell type, multiple and bilateral. They are often detected as an incidental finding on imaging or routine screening in patients with a family history of VHL. RCCs usually present by 35 to 40 years of age. VHL-associated RCC metastasizes to the lymph nodes, liver, lungs, and bones and accounts for about 50% of all VHL deaths.

Nephrolithiasis

Nephrolithiasis is a common disease, and the prevalence is rising in the United States and other developed countries. Up to 10% of all Americans will develop a stone in their lifetime. Lifestyle factors, medical conditions, and medications all contribute to stone formation. Population-based

Table 30-6 Medications Associated with Stone Formation

Medication	Mechanism
Acetazolamide	Hypocitraturia
Vitamin C	Hypocitraturia
Calcium supplements	
Vitamin D	Hypercalciuria
Antacids	Hypercalciuria
Theophylline	Hypercalciuria
Nifedipine	Hypercalciuria
Probenecid, ASA	Hyperuricosuria
Topamax	Hypocitraturia
Indinavir	Precipitation within the tubule
Acyclovir	Precipitation within the tubule

studies suggest that diabetes mellitus, obesity, and hypertension are associated with nephrolithiasis. Kidney stone disease occurs more frequently in men than women and is more common in white than African American populations.

CLINICAL PRESENTATION

The risk for recurrence after the initial episode is about 50% within 5 years, and nearly two thirds of patients have recurrence by 10 years. Patients present with severe flank pain with or without hematuria, and a possible history of passing “gravel” in their urine. Nephrolithiasis may sometimes be associated with polyuria, dysuria, and vomiting.

When eliciting the patient’s history, one should inquire about prior hematuria or kidney stones, urinary tract infection, past medical history, medications (Table 30-6), family history, and a lifestyle and dietary analysis. Laboratory examinations should include serum electrolytes, creatinine, calcium, phosphorous, and uric acid levels. Urinalysis is needed for determination of pH, hematuria, evaluation of possible infection, and identification of the type of crystal. Urinalysis findings seen in stone disease are indicated in Table 30-7. It is recommended to capture and analyze passed kidney stones.

The diagnosis is initially suspected by clinical presentation. A noncontrast helical CT scan with 3- to 5-mm sections is currently the preferred diagnostic test in patients with suspected nephrolithiasis and will also show urinary tract obstruction. Renal ultrasonography is an alternative in pregnant women, but routine ultrasound cannot localize ureteral stones, which can be detected by transvaginal ultrasonography.

There is disagreement on the extent of evaluation after the first episode of kidney stones; however, because of the high rate of recurrence, a full metabolic evaluation after the first episode should be completed in any patient willing to make lifestyle changes and should always be undertaken in those with recurrent stone disease. Routine chemistries, calcium, and parathyroid hormone level should be obtained. About 2 months after the initial stone episode, at least two separate 24-hour urine collections should be obtained while the patient maintains his or her usual diet and physical activities. The urine volume, pH, and excretion of calcium, uric acid,

Table 30-7 Urinalysis and Radiographic Findings of Renal Calculi

Stone Type	Urine Microscopic	Radiologic
Calcium oxalate monohydrate Calcium oxalate dehydrate	Dumbbell shaped; under polarized light appear coarse, needle shaped Envelope shaped	Opaque, round, multiple calculi
Struvite, magnesium ammonium phosphate	Coffin lid	Opaque, may be staghorn
Uric acid	Pleomorphic, often rhombic plates or rosettes	Radiolucent
Cystine	Hexagonal	Opaque

citrate, oxalate, sodium, and creatinine (to assess completeness of collection) should be measured. Monitoring kidney stones should be performed initially at 1 year, and if negative, every 2 to 4 years unless the patient develops new symptoms consistent with recurrent stones. If multiple stones are present, the radiologist should document the number of stones to monitor progression.

ETIOLOGY

Kidney stones are more likely to occur when one or more factors that lead to supersaturation of the urine, precipitation of crystals, and subsequent aggregation into a clinically detectable stone are present. The main nonsystemic causes of stones include idiopathic hypercalciuria, hypocitraturia, hyperoxaluria, hyperuricosuria, and low urine volume and low pH. The specific types of stones are outlined in more detail later.

TREATMENT AND PROGNOSIS

Stone size is the major determinant of the likelihood of spontaneous stone passage; however, location of stone is also important. Stones less than 4 mm in diameter pass spontaneously. As stone size increases above 4 mm, there is a progressive decrease in the spontaneous passage rate. Stones greater than 10 mm in diameter are unlikely to pass. Proximal ureter stones are also less likely to pass spontaneously.

All patients with stones should be instructed to drink enough fluid to make at least 2 L per day of urine. This will increase urine flow rate and lower the urine solute concentration, both of which protect against stone formation. Both calcium channel blockers (nifedipine) and α blockers (tamsulosin) have been shown to increase the likelihood of stone passage when compared with conservative treatment. Studies comparing the two medications have reported similar or slightly higher rates of stone passage with tamsulosin. Specific treatment modalities may be implemented when the metabolic risk factors for stone formation are identified (Table 30-8). Urgent urologic consultation is indicated in patients with urosepsis, acute renal failure, anuria, unyielding pain, nausea, or vomiting.

Table 30-8 Treatment Modalities for Different Nephrolithiasis Risk Factors

Urinary Abnormality	Dietary Change	Medication
High calcium	Adequate dietary calcium intake Reduce animal protein intake Reduce sodium intake to <3 g/day	Thiazide
High oxalate	Avoid high oxalate foods Adequate dietary calcium intake	Consider vitamin B ₆
High uric acid	Reduce purine intake	Allopurinol
Low citrate	Increase fruit and vegetable intake Reduce animal protein intake	Alkali (K citrate)
Low volume	Increase total fluid intake; goal to produce at least 2 L/day of urine	N/A

Calcium Stones

About 80% of patients with kidney stone disease form calcium stones. These stones are predominantly made of calcium oxalate, but a majority also contain calcium phosphate, mainly as apatite. Calcium phosphate and calcium oxalate stones are associated with the same risk factors. These are shown in Table 30-9.

Hypercalciuria can occur in the presence or absence of hypercalcemia. Hypercalcemia can be due to primary hyperparathyroidism, sarcoidosis, immobilization, neoplasms, excess vitamin A, excess vitamin D, or calcium supplementation. However, about 50% of patients have hypercalciuria in the absence of any identifiable cause of hypercalcemia and exhibit normal serum calcium and parathyroid hormone levels. Hypercalciuria tends to be familial and can be due to increased intestinal absorption (“absorptive hypercalciuria”), increased bone resorption (“resorptive hypercalciuria”), and increased renal losses (“renal hypercalciuria”), in which there is a defect in renal tubular calcium reabsorption. Most individuals with hypercalciuria exhibit more than one abnormality. The underlying mechanisms for idiopathic hypercalciuria are unknown, but 1,25-dihydroxyvitamin D and the vitamin D receptor may play an important role.

The urine pH contributes to the likelihood of formation of certain stones. Acidic urine favors uric acid precipitation, and calcium stones can form around a uric acid stone nidus. Increased animal protein intake leads to an increased acid load and results in increased urinary calcium excretion. The high protein intake also increases urinary calcium excretion by increasing the GFR.

Low urinary citrate excretion is a risk factor for calcium stone formation. Urinary citrate binds to urinary calcium forming a soluble complex and decreasing free ionic calcium for calcium oxalate stone formation. Urinary citrate also acts as an inhibitor of calcium oxalate crystal aggrega-

Table 30-9 Principle Risk Factors for Calcium Stone Formation

Higher urine calcium
Higher urine oxalate
Lower urine citrate
Lower urine volume
Dietary factors, including a low intake of fluid, calcium, potassium, and phytate, and a high intake of sodium, sucrose, and protein
Medical conditions, including primary hyperparathyroidism, obesity, gout, diabetes, and medullary sponge kidney

tion and growth. Citrate is normally reabsorbed in the proximal tubule, and reabsorption is increased in the presence of acidosis. Hypocitraturia is defined as citrate excretion below 320 mg per day. Several causes of hypocitraturia have been identified, including RTA, chronic diarrhea and malabsorption, metabolic acidosis, and hypokalemia. Potassium depletion causes decreased intracellular potassium and decreased intracellular pH and increases hydrogen secretion into the tubular lumen, causing hypocitraturia. A diet high in animal protein can cause hypocitraturia due to increased acid generation and excretion. If a patient has hypocitraturia, supplementing citrate intake with potassium citrate will increase urinary citrate excretion. A higher potassium intake may increase urinary citrate excretion (potassium-rich foods tend to have a high alkali content), thereby increasing the inhibitory properties of urine.

Hyperoxaluria may be present in up to 40% of male and 15% of female stone formers and is usually only mildly elevated. Oxalate is a product of the normal metabolism of glycine and ascorbic acid. There is a significantly increased risk for stone formation with urinary oxalate excretion above 25 mg per day. Dietary calcium can decrease oxalate absorption in the gut by formation of insoluble calcium oxalate salts in the intestinal lumen. Dietary magnesium may also reduce the risk for stone formation by the same mechanism, but the effect may be minor.

Marked hyperoxaluria is usually associated with inflammatory bowel disease, jejunioileal bypass, or intestinal resection and malabsorption because these patients have malabsorption of fatty acids and bile salts. There is an increase in oxalate reabsorption and excretion due to binding of free calcium to fatty acids in the intestinal lumen and to increased colonic permeability to small molecules such as oxalate.

Patients with diarrhea and malabsorption may have additional risk factors for stone formation in addition to increased oxalate absorption. Diarrheal fluid losses can result in decreased urine volume and a metabolic acidosis, which leads to a low urine pH and a decrease in citrate excretion; low urine pH can also promote uric acid stone formation. Patients with partial ileal bypass for obesity may have an incidence of kidney stones as high as 4% per year. It is postulated that low urine volumes, high oxalate, and a high rate of other stone risk factors such as low citrate all contribute to the increased recurrence.

Primary hyperoxaluria is a rare disorder in which enzyme deficiencies lead to an overproduction of oxalate from glyoxylate.

Ingestion of high doses of vitamin C can cause increased oxalate generation due to metabolism of ascorbic acid. Metabolic studies have shown that ingestion of 2000 mg per day of vitamin C significantly increases oxalate excretion in a large proportion of calcium oxalate stone formers.

If hyperoxaluria is present, patients should be instructed to follow a low oxalate diet and limit vitamin C ingestion. A deficiency of oxalate degradation by *Oxalobacter formigenes* in the intestine may contribute to increased absorption and urinary excretion of oxalate.

If urine calcium is elevated, attempts to lower the urine calcium concentration should be instituted by using a thiazide diuretic. Thiazide diuretics, the drug of choice for treatment of hypercalciuria, work at the distal convoluted tubule to inhibit Na and Cl transport and increase renal calcium reabsorption. During chronic treatment with thiazide diuretics, patients develop extracellular fluid volume contraction, and patients will increase NaCl reabsorption, with an associated passive reabsorption of calcium in the proximal tubule. A high sodium intake will also enhance the excretion of calcium because passive reabsorption of calcium in the proximal tubule follows gradients established by NaCl and water reabsorption.

URIC ACID STONES

Uric acid stones are caused by the precipitation of uric acid in the urine. Risk factors include dehydration, persistently acidic urine, hyperuricosuria due to overproduction of uric acid, or increased secretion associated with RTA. Uric acid stones are radiolucent stones.

A high intake of animal protein may increase the risk for uric acid stone formation owing to its high purine content. Furthermore, metabolism of animal protein leads to increased acid production due to the higher sulfur-containing amino acid content of animal protein and subsequently lowers urinary pH.

Diabetes mellitus may be a risk factor for the development of uric acid stones. This hypothesis is based on the observation that patients with recurrent uric acid stones tend to have metabolic and clinical findings characteristic of metabolic syndrome, including obesity. In addition, insulin appears to stimulate ammoniogenesis and sodium-hydrogen exchange in the proximal tubule. Therefore, insulin resistance impairs renal ammoniogenesis, resulting in a net lower urinary pH and increased risk for uric acid stone formation.

Alkali therapy is the most effective treatment of existing uric acid stones. Pure uric acid stones dissolve if urine pH is maintained at or above 6.5. Low doses of alkali on a daily basis can prevent new uric acid stone formation. Allopurinol is an additional agent that can be used if a patient has marked hyperuricosuria.

STRUVITE STONES

Struvite stones are composed of magnesium ammonium phosphate with variable amounts of calcium carbonate-apatite. Struvite stones occur in the presence of chronic urinary tract infection with urease-producing bacteria (Table 30-10). Bacterial urease acts on urine urea to yield ammonia and carbon dioxide; these are further hydrolyzed into ammonium and carbonate, resulting in a urine pH greater

Table 30-10 Urease Producing Bacteria

<i>Staphylococcus</i>
<i>Corynebacterium</i>

than 7.2. The alkaline urine is ideal for struvite stone formation.

Struvite stones account for less than 10% of all stones and most often occur in patients with increased frequency of urinary tract infection, such as patients with spinal cord injuries, neurogenic bladder, urinary diversion, or chronic indwelling Foley catheters.

Clinically, patients present with urinary tract infection, hematuria, flank pain, or obstructive uropathy. In rare instances, patients with chronic renal obstruction and infection can develop xanthogranulomatous pyelonephritis, which is a rare inflammatory condition in which the renal parenchyma becomes atrophic and is replaced by fat, pus, and cellular debris.

All struvite stones are infected because they occur in the region surrounding bacterial colonies. When struvite stones are calcified, they present radiographically with a characteristic multilobular shape and laminated appearance and may extend to involve all calyces, forming staghorn calculi. The only curative treatment is eradication of the infection with antimicrobials and removal of all stone material. Percutaneous nephrostolithotomy and extracorporeal shock-wave lithotripsy are the first-line treatment. Chronic antibiotic therapy may limit stone growth and may lead to partial dissolution in nonsurgical patients.

CYSTINE STONES

Cystinuria is an autosomal recessive trait in which patients have excess excretion of cystine into the urine and form cystine stones. The incidence of cystinuria varies from 1 in 20,000 to 1 in 15,000 live births and is highest in Scandinavia. The solubility of cystine in the urine is about 300 mg/L, and when overexcretion leads to higher concentrations than the solubility limit, cystine stones tend to form.

Clinically, patients present during the second or third decade of life with nephrolithiasis. Urinary tract obstruction, recurrent infection, and hypertension can occur, and on occasion the patient may have progressive kidney failure and require dialysis or transplantation. If transplantation is required, the disease does not appear to recur in the transplanted kidney.

Treatment is aimed at reducing the excretion and increasing the solubility of cystine. Lowering urinary cystine concentrations by increasing urinary volume reduces the likelihood of precipitation of cystine stones. An intake of more than 4 L per day may be required to reduce the solubility of cystine. The use of sulfhydryl agents to produce soluble mixed disulfides instead of cystine has been the mainstay of medical treatment. In the past, D-penicillamine was used for treatment because the drug forms a mixed disulfide with

cystine and reduces cystine excretion. However, long-term use is limited by the undesirable side effects of D-penicillamine, including nephrotic syndrome, membranous nephropathy, serum sickness, fever, rash, and pancytopenia.

A newer drug, mercaptopropionylglycine (Thiola), is also capable of reducing the free cystine concentration of the urine; side effects are less common, making it the preferable choice for the treatment of cystinuria.

Captopril, a sulfhydryl-containing angiotensin-converting enzyme II inhibitor, has been studied in the treatment

of cystine stones. Study results are mixed; some studies show a reduction in cystine excretion, whereas others do not. Cystine stones are refractory to extracorporeal shock-wave lithotripsy.

Cystinuria should not be confused with cystinosis. Cystinosis is also a genetic disorder, but patients have intracellular accumulation of cystine leading to widespread tissue damage, including renal failure. Patients with cystinuria only have increased excretion and accumulation of the amino acid in the tubular lumen.

Prospectus for the Future

- Vasopressin receptor antagonists may be a new treatment option in the future for polycystic kidney disease. Phase III, multicenter, randomized controlled trials are underway to evaluate the long-term safety and efficacy of oral tolvaptan in adults with PKD.
- Obstruction is a reversible cause of acute renal failure that can lead to CKD and should be evaluated as a possible cause in patients who present with renal insufficiency.
- Antibiotics and cytotoxic or immunosuppressive agents are useful therapeutic agents but can cause AIN. Patients should be monitored closely when these agents are used. Combination analgesics should be avoided. Efforts should be made to increase the public's awareness of the risk for AIN caused by over-the-counter and imported herbal remedies.

Vascular Disorders of the Kidney

James M. Luther and Gerald Schulman

Vascular disorders are the most common causes of chronic kidney disease (CKD) in the industrialized world, largely because of the increasing burden of diabetes and hypertension. Atherosclerotic renovascular disease is a common cause of CKD and hypertension, responsible for a syndrome of ischemic renal disease. Added to this are diseases of the vasculature that are mediated by inflammatory and immunologic processes.

Normal function of the microvasculature (arterioles, glomeruli, and capillaries) and vascular endothelium is essential for maintenance of all aspects of renal function but may be altered by a number of clinically important diseases. Preeclampsia, thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), and cholesterol emboli are the principal diseases altering microvascular function, each with its own distinct pathogenesis and clinical characteristics. Advances in molecular biology have led to a more detailed understanding of these processes, and now laboratory tests are available to aid in the diagnosis of TTP that were not possible even a decade ago. Similar insights into the pathogenesis of preeclampsia and HUS have also deepened our understanding of renal and endothelial function.

Renal Vascular Anatomy

The renal arteries arise directly from the aorta and enter the renal hilum. The right renal artery must pass anterior to the inferior vena cava (IVC) and is longer than the left renal artery. In a significant minority of the population, an accessory renal artery may also arise from the aorta to provide blood supply to a portion of the kidney, which may become important when evaluating patients for renovascular hypertension. The renal arteries give rise to segmental, interlobar, and then arcuate arteries (Fig. 31-1). Arcuate arteries course along the corticomedullary junction and give rise to interlobular arterioles, which extend outward into the cortex and provide the afferent arterioles. The glomeruli arise from these afferent arterioles, and then efferent arterioles con-

tinue and dive toward the medulla as the vasa rectae. The vasa rectae provide the sole blood supply for the renal medulla, making this portion of the kidney particularly susceptible to ischemic insults. Venules form from the ascending vasa rectae and eventually empty into the renal veins. The left renal vein returns to the IVC anterior to the aorta and inferior to the inferior mesenteric artery, which may rarely cause compression of this vein. The left gonadal vein also empties into the left renal vein, and thus a left varicocele may be evident if the renal vein is occluded by thrombosis or tumor involvement. The right renal vein is much shorter and directly empties into the IVC, whereas the right gonadal vein empties directly into the IVC and is not typically affected by right renal vein obstruction.

Renovascular Disease

Renovascular disease is the most common form of secondary hypertension, affecting up to 5% of patients with hypertension. Any process that narrows the renal arterial lumen beyond a critical point will elicit a humoral response from the ipsilateral kidney to increase intravascular pressure in an attempt to normalize blood flow to the kidney. Although many clinicians define renal artery stenosis (RAS) as a stenosis of at least 50%, some have attempted to define criteria for a “hemodynamically significant” stenosis using direct flow measurements, although the clinical utility of these measurements is uncertain. The hormonal response to a critical stenosis is initially characterized by renin and aldosterone secretion (secondary hyperaldosteronism), renal sodium and fluid reabsorption, and resultant hypertension. The end result is to raise perfusion pressure in the affected kidney and maintain glomerular filtration rate (GFR). The contralateral kidney, which is initially unaffected, cannot prevent this humoral response from the ischemic kidney but may allow a pressure natriuresis. Hypertension is maintained by increased vasoconstriction due to angiotensin II, and a pressure natriuresis is induced in the normal contralateral kidney. If the renal arteries to both kidneys are

Figure 31-1 Section of the human kidney showing the renal arteries and a schematic of the microcirculation of each nephron. (From Guyton AC, Hall JE: *Textbook of Medical Physiology*, 11th ed. Philadelphia, Elsevier, Saunders, 2006, p 309.)

narrowed, there will be a period of sodium retention due to vasoconstriction and angiotensin II–stimulated aldosterone production. Hypertension will be mediated by volume expansion rather than by increased total peripheral resistance. The same situation is seen when the initially normal contralateral kidney suffers microvascular damage after long-term exposure to the hypertensive state.

Thus, ischemic renal disease may be seen with unilateral or bilateral stenosis of the renal arteries or with unilateral RAS and a contralateral kidney damaged by hypertension (Fig. 31-2). Stenosis of a single kidney leads to hypertension that is sensitive to blockade of angiotensin II. Stenosis of both renal arteries or microvascular damage to the contralateral kidney leads to hypertension that is sensitive to volume reduction and blockade of angiotensin II.

In addition, successful hypertension treatment may produce renal ischemia and reduce the glomerular filtration of the affected kidney, but this may not be detectable by measurement of the serum creatinine if the contralateral kidney is functioning normally. However, a decline in GFR may be evident if there is underlying renal dysfunction, as is often the case with long-standing hypertension, diabetes, or vascular disease. In the case in which either a solitary kidney or both kidneys (bilateral RAS) are affected, acute renal failure may result. Renal function may improve after stopping angiotensin I–converting enzyme (ACE) inhibitor or angiotensin II, type I receptor (ARB) treatment or revascularization if detected promptly.

Figure 31-2 Anatomy of renal artery stenosis. Renal artery stenosis may be unilateral (A), bilateral (B), or unilateral with a solitary kidney (C). Aortic disease may also serve functionally as bilateral renal artery stenosis (D).

Atherosclerosis is the primary cause of RAS, although any process that narrows one or both renal arteries may also cause renal ischemia. The cause of RAS is not necessarily distinguishable based on clinical or laboratory findings alone, but the history may provide important clues. Atherosclerotic disease is rarely present in patients younger than 40 years, and is more common in males (2:1) and Caucasians.

CLINICAL EVALUATION FOR RENAL ARTERY STENOSIS

RAS should be suspected in patients with refractory hypertension or new-onset hypertension in patients older than 50 years (Table 31-1). Evaluation should always begin with a thorough history and physical examination, including particular attention to blood pressure and pulse amplitude in each extremity. A significant discrepancy between extremities may indicate peripheral vascular disease and increase clinical suspicion for RAS. An abdominal bruit is present in about 50% of subjects but is not specific for RAS. Edema is not typically present unless significant renal insufficiency exists. Laboratory evaluation may reveal hypokalemia ($K^+ < 3.5$ mEq/L) or metabolic alkalosis ($HCO_3^- > 28$ mEq/L). Renal insufficiency may be present, but its absence does not rule out RAS. Plasma renin activity and aldosterone are typically elevated. Urinalysis is usually normal, but low-grade proteinuria (usually < 1 g/day) may result from long-standing hypertension.

Table 31-1 Clinical Findings Suggestive of Renovascular Disease

Onset of hypertension at <30 years of age (FMD) or severe hypertension at >55 years of age (atherosclerotic RAS)
Accelerated, resistant, or malignant hypertension
Unexplained atrophic kidney or size discrepancy >1.5 cm between kidneys
Sudden, unexplained pulmonary edema
Unexplained renal dysfunction, including individuals starting renal replacement therapy
Development of new azotemia or worsening renal function after administration of an ACE inhibitor or ARB agent
Multivessel coronary artery disease or peripheral arterial disease
Unexplained congestive heart failure or refractory angina

ACE, angiotensin-converting enzyme; ARB, angiotensin II, type I receptor blocker; FMD, fibromuscular dysplasia; RAS, renal artery stenosis.

Adapted from Hirsch AT, Haskal ZJ, Hertzler NR, et al: ACC/AHA 2005 Practice Guidelines for the management of patients with peripheral arterial disease (lower extremity, renal, mesenteric, and abdominal aortic). *Circulation* 113:e463-e654, 2006.

Radiologic evaluation of RAS is guided by the local expertise at the testing facility. Renal ultrasound provides only a limited window into the presence of RAS because this modality will likely only reveal a discrepancy in kidney size, which develops only after prolonged ischemia and irreversible renal injury. However, a change in kidney size on serial imaging in the setting of known RAS may be a harbinger of worsening renal function and should prompt the clinician to consider revascularization. Renal ultrasound provides an assessment of renal size, and when used with Doppler pulse wave analysis, may give information regarding flow velocity in the renal arteries. However, renal duplex ultrasound (US) is technically demanding and is best performed by an experienced ultrasonographer at a high-volume center. Despite a reported high sensitivity of renal duplex US in the literature, it is doubtful that most centers can reproduce these results.

Computed tomography (CT) with intravenous iodinated contrast permits evaluation of the arterial vasculature (CT angiography, CTA) and is more easily reproducible across centers, providing the highest resolution of the renal vasculature. However, the risk associated with intravenous contrast may preclude CTA in subjects with renal insufficiency. Magnetic resonance angiography (MRA) with intravenous contrast is also highly reproducible, but application is limited by implanted metallic medical devices. Gadolinium administration to patients with advanced renal insufficiency (GFR < 30 mL per minute) is also contraindicated owing to the potential risk for nephrogenic fibrosing dermopathy. Analyses of renal duplex, CTA, and MRA data suggest that CTA and MRA have similarly high sensitivity and specificity.

Nuclear imaging using technetium-DTPA or MAG3 can assess the uptake and excretion in each kidney, before and after the administration of a short-acting ACE inhibitor, captopril (captopril renogram). When unilateral RAS is present but is compensated by increased systemic pressure, captopril administration produces greater afferent arteriolar dilation and reduces renal perfusion to the ischemic kidney. However, this test has limited specificity and is insensitive in

Figure 31-3 Incidence of cardiovascular outcomes in patients older than 65 years with atherosclerotic renal artery stenosis (RAS), compared with an age-matched population. ASPVD, atherosclerotic peripheral vascular disease; CAD, coronary artery disease; CHF, congestive heart failure; CVA/TIA, cerebrovascular event or transient ischemic attack; ESRD, end-stage renal artery disease requiring dialysis. (Data from Kalra PA, Guo H, Kausz AT, et al: Atherosclerotic renovascular disease in United States patients aged 67 years or older: Risk factors, revascularization, and prognosis. *Kidney Int* 68:293-301, 2005).

the case of bilateral RAS. The most sensitive and specific test, but also the most invasive, is renal arteriography. One added advantage of arteriography is that angioplasty or stenting can be performed during arteriography. Because of the frequent occurrence of accessory renal arteries, an aortogram must be performed rather than selective renal angiography to ensure that all vessels are visualized.

TREATMENT OF ATHEROSCLEROTIC RENAL ARTERY DISEASE

Patients with atherosclerotic RAS almost always have coexistent cerebrovascular, coronary, or other peripheral vascular disease. Clinicians should recognize and treat this high cardiovascular risk associated with atherosclerotic renal disease. The absolute risk for developing end-stage renal disease (ESRD) is increased in these patients compared with those without RAS, but remains much less than the risk for developing coronary disease, symptomatic peripheral vascular disease, heart failure, or stroke (Fig. 31-3). As with other manifestations of peripheral arterial disease, atherosclerotic RAS is recognized as an ischemic heart disease equivalent because of this increased risk, and clinical guidelines recommend intensive lipid lowering and aspirin use for this subgroup. Therefore, attempts to modify other cardiovascular risk factors (smoking cessation, hypertension and diabetes control, and antiplatelet therapy) are an essential component of therapy.

Intervention for atherosclerotic RAS is controversial and is the subject of several ongoing randomized clinical trials to investigate medical management versus intervention with renal artery stenting. Generally accepted guidelines for intervention have been reported, but decisions should still be made on a case-by-case basis (Table 31-2). Smaller clinical

studies have suggested that percutaneous transluminal renal angioplasty with stenting may improve blood pressure control in atherosclerotic RAS, but carries a risk for worsening renal function in a significant percentage of patients. This may be due to atheroembolic disease, contrast nephropathy, or stent thrombosis and may lead to irreversible renal failure. Moreover, recent studies have failed to prevent the decline in renal function using distal protection devices or platelet inhibition to protect against atheroemboli.

FIBROMUSCULAR DYSPLASIA

Fibromuscular dysplasia (FMD) is a nonatherosclerotic, noninflammatory disease causing RAS in young female patients. The etiology of FMD is unclear, but it is believed to be a developmental abnormality. Depending on the population, FMD is responsible for 10% to 25% of renovascular hypertension cases. FMD affects the renal arteries most commonly (bilateral in about 35%), but carotid and vertebral arteries can also be affected and produce neurologic symptoms. The disease frequently afflicts younger patients, with a female preponderance, but may also come to clinical attention in patients older than 50 years.

Classification of FMD is based on the histologic layer of the artery involved (intima, media, or adventitia) (Table 31-3). Medial fibroplasia with mural aneurysm is the most common cause of FMD in adults (70% of cases), consisting of alternating fibromuscular ridges and aneurysmal segments in the distal two thirds of the renal artery and a classic “string-of-beads” appearance on angiography (Fig. 31-4). Perimedial fibroplasia of the outer half of the media produces severe multifocal stenosis and causes about 15% of FMD cases in adults. Medial subtypes of FMD generally have a benign course and are responsive to angioplasty. The intimal subtype may have a higher likelihood of ischemic events and multiorgan system involvement. Symptoms are usually precipitated by stenoses, but rarely FMD may cause dissection or macroaneurysms that require intervention.

Treatment for FMD depends on the severity of complications. Pharmacologic treatment alone may be adequate to

Table 31-3 Histologic Classification of Fibromuscular Dysplasia

Subtype	Proportion of Cases (%)	Radiologic Appearance
Medial fibroplasia	60-70	“String of beads” with aneurysms
Perimedial fibroplasia	15	“String of beads” without large aneurysms
Medial hyperplasia	5-15	Smooth tubular stenosis
Intimal fibroplasia	1-2	Focal or smooth stenosis
Adventitial fibroplasia	<1	Focal or smooth tubular stenosis

control hypertension in simple cases. Intervention should be considered in patients with severe or difficult-to-control hypertension, or decreasing renal mass. Success may differ for various subtypes, but further research is needed. Balloon angioplasty without stenting is successful in most patients, but recurrence is not uncommon. For this reason, serial monitoring with renal duplex ultrasonography is needed to assess for restenosis. In selected cases in which percutaneous intervention is impossible, surgical intervention may be an appropriate option. Prompt intervention is important because improvement of hypertension is most achievable in those with shorter duration of hypertension, those with normal renal cortical thickness, and those younger than 50 years.

AORTIC DISSECTION

Aortic dissection occurs after injury to the intimal layer and propagation of blood flow “dissects” within the wall of the aorta, producing a false lumen and compressing the true vessel lumen. Aortic dissection is classified by either the site of origin (DeBakey classification) or the segment of the aorta involved (Stanford classification) (Fig. 31-5). DeBakey type I and II dissections originate in the ascending aorta, and type III dissections originate in the descending aorta. Stanford type A refers to dissections involving the ascending aorta, and type B to all others not involving the ascending aorta.

Major branch vessels of the aorta, including the renal arteries, may become obstructed as a result of extension or obstruction of the vessel by the false lumen. Aortic dissection frequently compromises the renal arteries when it extends into the abdominal aorta and causes renal failure in 21% of patients with type B dissections. The left renal artery is more commonly involved than the right because of anatomic circumstances. When disease is extensive enough to cause acute renal failure, vascular compromise to the intestinal or cerebral vasculature, or severe aortic regurgitation usually coexists and contributes to a high mortality rate. A similar clinical picture occurs with an isolated aortic intramural hematoma (IMH), which is thought to originate from a ruptured vasa vasorum. IMH is estimated to cause 5% to 10% of acute aortic syndromes and generally carries the same risks for organ ischemia, with a higher incidence of aortic rupture.

Figure 31-4 A, Typical medial fibroplasia (“string-of-beads” appearance) on angiogram of a right renal artery. B, Gadolinium-enhanced magnetic resonance angiography in the same patient, revealing bilateral medial fibroplasia of the renal arteries and a large marginal artery of Drummond (arrow), indicating that there is disease of the superior mesenteric artery. (From Slovut DP, Olin JW: Fibromuscular dysplasia. *N Engl J Med* 350:1862-1871, 2004.)

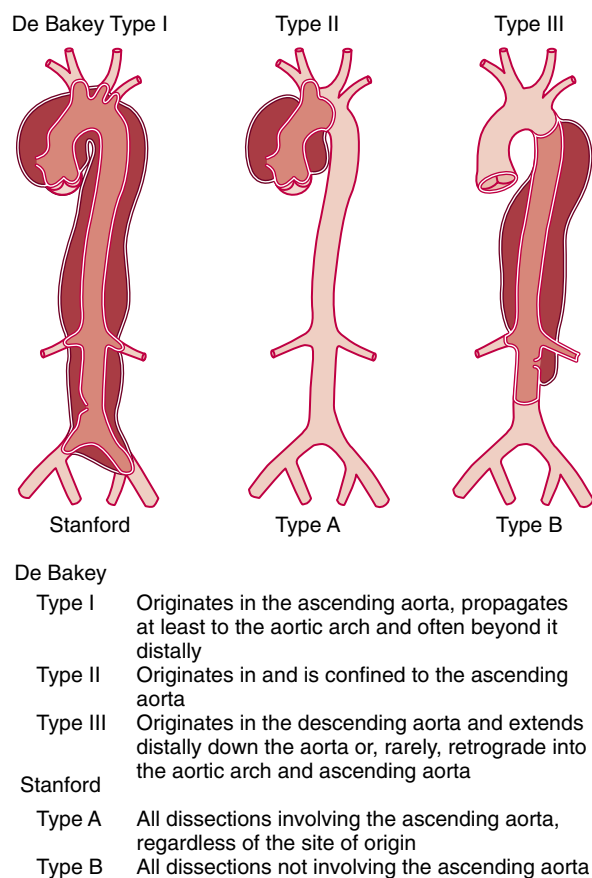

Figure 31-5 Classification of aortic dissection according to involvement of the thoracic, abdominal, or both portions of the aorta by the Stanford and DeBakey systems. (From Nienaber CA, Eagle KA: Aortic dissection: New frontiers in diagnosis and management: Part I: From etiology to diagnostic strategies. *Circulation* 108:628-635, 2003.)

Aortic dissection most frequently affects older patients (50 to 70 years of age) with coexistent vascular risk factors such as male sex, hypertension, smoking, and atherosclerosis. Occasionally a genetic connective tissue defect such as Marfan syndrome or Ehlers-Danlos syndrome type IV (about 5% of cases) may cause aortic dissection, and these should be considered in younger patients (<40 years of age). Trauma or procedures (e.g., aortic catheterization) can also cause dissection of the aorta or renal artery. Rarely, isolated renal artery dissection may occur spontaneously, most commonly in the setting of polyarteritis nodosa or FMD. Renal failure occurs in about 20% of patients diagnosed with acute type B aortic dissection and is an independent predictor of in-hospital mortality.

The initial diagnosis of aortic dissection is frequently missed, partly because of the widely varying clinical presentations, and may be discovered incidentally on unrelated imaging studies. The most frequent symptom during aortic dissection is chest pain, which may be described as a “ripping” sensation. Isolated loss of pulse in one or more extremities may be a clinical clue, and number of arteries involved correlates with severity of dissection. Aortic dissection should also be considered in patients during evaluation of acute renal failure. A common clue to the diagnosis on routine chest radiograph is a widened mediastinum, with or without a pleural effusion (most frequently on the left). Once the diagnosis of aortic dissection is established, evaluation of renal artery involvement is best undertaken noninvasively, in order to minimize further vascular injury. Contrast-enhanced CT or magnetic resonance imaging (MRI) or MRA usually provides images capable of confirming or excluding renal involvement, although each modality carries the same limitations as outlined for evaluation of RAS. Transesophageal echocardiography is useful for establishing the diagnosis of aortic dissection but does not provide information below the diaphragm. Similarly, renal duplex ultrasonography may be useful for evaluating renal perfusion in the setting of aortic dissection but is not recommended for initial investigation of aortic dissection. Aortography alone

is not a sensitive test for aortic dissection but could provide information regarding renal perfusion.

Aortic dissection is a hypertensive emergency and requires aggressive reduction of blood pressure into the normal range. Medical management of aortic dissection should focus on minimizing arterial blood pressure with antihypertensive agents. Medications that reduce the rate of increase in blood pressure during the cardiac cycle (dP/dT), such as β blockers, have theoretical benefit in aortic dissection to reduce the rate of progression. Surgical treatment options for renal involvement due to aortic dissection are dependent on individual circumstances, and careful evaluation by an experienced vascular surgeon is recommended. Thoracic aortic dissection requires surgical repair due to the high mortality rate if left untreated, but isolated abdominal aortic disease may be medically managed.

EMBOLIC DISEASE

Systemic arterial emboli, typically originating from the left atrium or left ventricle, may cause acute obstruction of the renal artery. Emboli usually originate in the heart, most commonly because of atrial fibrillation, bacterial endocarditis, valvular disease, or atrial myxoma. Rarely, a paradoxical embolus may occur from the venous system through an atrial septal defect. Symptoms of acute renal ischemia may include flank pain, hematuria, and fever. Laboratory findings are nonspecific but include elevated lactate dehydrogenase (LDH), microscopic hematuria, and leukocytosis. Diagnosis can be definitively made by presence of a focal nonenhancing region on contrast-enhanced CT. The area of affected kidney is usually not large enough to necessitate dialysis, although some worsening of renal function is commonly observed. The diagnosis of renal infarction is rarely made early enough to initiate treatment with intra-arterial thrombolysis, and it is questionable whether the risks and marginal benefit of this procedure warrant aggressive treatment. Therapy should instead address the underlying source of renal emboli.

LARGE VESSEL VASCULITIS

Systemic vasculitides such as Takayasu arteritis and polyarteritis nodosa (PAN) commonly affect large vessels such as the renal arteries but rarely cause glomerulonephritis.

Takayasu arteritis is commonly referred to as “pulseless disease” because of obstructing lesions of the large vessels of the aorta, most commonly the subclavian arteries, and frequently involves the main renal arteries (65% to 75% of cases), producing RAS, renal ischemia, or renal infarction. Takayasu arteritis is giant cell arteritis affecting mainly women of reproductive age. Common clinical features are constitutional symptoms, decreased pulses, claudication, bruits, and hypertension. Blood pressures are often unreliable in these patients because of the focal arterial lesions, and the arm with the highest obtainable blood pressure should be used. Diagnosis is made on clinical grounds, and treatment with corticosteroids may be beneficial.

PAN is a medium-large vessel vasculitis with no gender predilection, affecting predominantly older patients (40 to 60 years of age). It commonly causes both large vessel disease and necrotizing vasculitis of the renal parenchymal vessels,

such as renal artery microaneurysms, which are evident on renal angiogram or CT angiography in 40% to 90% of cases. By definition, PAN does not involve the arterioles or glomeruli. Most patients present with fever, malaise, and weight loss in addition to specific organ complaints related to skin, joint, nerve, and gut involvement. Symptoms specific to renal involvement may include loin pain and hematuria. Rarely, a renal artery aneurysm may produce renal ischemia, renal artery dissection, or spontaneous rupture. Diagnosis is made on clinical grounds and by angiography; there are no confirmatory serologic tests. Progressive renal disease is not typical, and most patients have complications related to other organs, most notably the gastrointestinal tract. Treatment with corticosteroids and immunosuppressive drugs is effective in reducing disease severity and mortality.

HYPERTENSIVE NEPHROSCLEROSIS

Hypertension is highly prevalent in the U.S. population, increasing with age and affecting 50% of adults aged 60 to 69 years. Uncontrolled hypertension is responsible for about 60% of cerebrovascular disease and about 50% of ischemic heart disease in the United States and is the leading attributable risk for death worldwide. Renal failure due to hypertension is relatively rare in the general population, but owing to the high prevalence of disease, a large proportion of renal failure is thought to be due to hypertension.

CKD is also a common cause of secondary hypertension, and it is often difficult to determine which disease preceded the other. Hypertension causes CKD in African Americans at a much higher rate than Caucasians, even at similar levels of blood pressure control. This fact has been accepted by nephrologists and could cause an overestimate of hypertension as the cause of ESRD or CKD in African Americans. However, the renal biopsy pilot study of the African American Study of Kidney Disease (AASK) trial documented the accuracy of this diagnosis based on history alone. Pharmacologic treatment of hypertension reduces the risk for progression to ESRD and worsening of creatinine in multiple patient populations, providing further evidence for the causative role of hypertension. The markedly increased risk for hypertensive nephrosclerosis in African Americans is being intensely investigated for possible genetic factors.

Diagnosis is typically made on clinical grounds, with a history of long-standing or severe hypertension preceding the development of renal insufficiency. The urinary sediment is typically bland with only low-grade proteinuria (<1 g per day). Symmetrical loss of renal cortical thickness on renal imaging with a generally smooth surface is typically found. Renal biopsy findings include afferent arteriolar medial thickening and hyalinization, and intimal fibrosis. Glomeruli are focally or globally sclerotic, with wrinkled glomerular basement membrane due to glomerular ischemia. Hypertensive nephrosclerosis is often found on renal biopsy in patients with other vascular disorders (e.g. diabetes, atheroembolic disease, or RAS).

An accelerated or “malignant” phase of hypertension with progressively increasing blood pressure and development of end-organ damage may occur if hypertension is not treated. Renal biopsy in this situation reveals arteriolar fibroid necrosis and “onion-skinning” of the interlobular arteries. These pathologic findings can overlap somewhat

with scleroderma renal crisis and thrombotic microangiopathy, although malignant hypertension tends to affect smaller arteries such as the afferent arterioles. The clinical history is necessary to differentiate these diseases.

Treatment is aimed at lowering blood pressure to levels recommended for other high-risk populations such as diabetics (<130/80 mm Hg) when CKD is present. Blood pressure reduction prevents future development of congestive heart failure, stroke, and ESRD. Many studies suggest that ACE inhibitors or ARBs are more effective in preventing morbidity, but other drug classes are almost always needed. Thiazide-type diuretics (e.g., hydrochlorothiazide) are recommended in most patients, and loop diuretics (e.g., furosemide) are needed when renal function worsens (GFR < 30 mL per minute).

ATHEROEMBOLIC DISEASE

Even the most astute clinician may fail to make the diagnosis of cholesterol emboli, and they are sometimes revealed only after renal biopsy or at autopsy. Cholesterol emboli originate from aortic atherosclerotic plaque, typically dislodged during an invasive arterial procedure (e.g., cardiac catheterization or vascular or cardiac surgery, particularly abdominal aortic aneurysm resection). In patients with severe atherosclerosis, cholesterol emboli may occur spontaneously or may even be precipitated by heparin anticoagulation. Because patients must have underlying atherosclerosis, the incidence increases with age and rarely occurs before age 40 years.

Cholesterol crystals are disrupted and lodge in small arterial vessels, including the arcuate or interlobular arteries of the kidney. In many cases, emboli also occur in the extremities, causing skin changes (livedo reticularis, digital ischemia), or the gastrointestinal tract, causing intestinal ischemia. Symptoms are typically related to organ ischemia but may also include fever by an unknown mechanism. Massive cholesterol embolization may cause acute renal ischemia leading to renin release and severe hypertension. If the embolic burden is lower, a decline in renal function typically occurs after 7 to 14 days as a result of the vascular inflammation and remodeling response to the cholesterol crystals. Typical laboratory findings include peripheral blood or urinary eosinophilia, elevated erythrocyte sedimentation rate, hypocomplementemia, and elevated amylase or liver enzymes. On renal biopsy, the fixation process washes out cholesterol crystals, leaving a typical needle-shaped disruption in the arterial lumen surrounded by reactive endovascular cells. These lesions may be seen on only a few sections, and even then may be overlooked by experienced pathologists. Cholesterol crystals may be visible on frozen sections if they are available because they do not undergo the same fixation process. Diagnosis is usually made clinically in the appropriate setting, but confounding features may necessitate renal biopsy.

The degree of renal insufficiency is determined by the magnitude of the embolic burden and the acuity of the process, owing to the degree of inflammation induced by the material from the plaque. Many patients may have stabilization after the insult, whereas others will progress to advanced renal failure or ESRD. There is no specific treatment for cholesterol emboli. Because an inflammatory reaction may

be associated with the emboli, some researchers advocate corticosteroids, but their use is unproved for preventing progression of renal failure. Statin therapy is appropriate for most patients for treatment of underlying atherosclerotic disease. Treatment with ACE inhibitors is effective for hypertension control in the acute setting, but worsening renal function may limit their use. Supportive care for renal failure may necessitate acute or long-term dialysis.

PREECLAMPSIA

Preeclampsia affects 3% to 5% of pregnancies and causes about 50,000 worldwide maternal deaths each year. It is the principal renal complication of pregnancy, characterized by the onset of hypertension (blood pressure > 140/90 mm Hg) and proteinuria (>300 mg per day) typically in the third trimester. Earlier development (<20 weeks' gestation) of preeclampsia is associated with reduced placental blood flow, reduced fetal growth, and more severe maternal disease. Although hypertension and proteinuria are the principal signs of preeclampsia, it is a systemic vascular disease with potential central nervous system, gastrointestinal, hepatic, and hematologic involvement. In severe cases, the disorder may cause seizure (eclampsia, in about 2% of cases), cerebral hemorrhage, pulmonary edema, placental abruption, or renal failure. The HELLP syndrome, characterized by hemolysis, elevated liver enzymes, and low platelets, is thought to be a manifestation of severe preeclampsia and is also associated with increased maternal and fetal mortality. Clinicians should be aware that although most cases of eclampsia occur before delivery, one third of cases may occur during the immediate postpartum period.

Multiple risk factors have been identified for preeclampsia (Table 31-4), and recent progress has been made in the pathogenesis. Placenta-derived circulating angiogenic factors have been described that precede the onset of preeclampsia, such as soluble fms-like tyrosine kinase-1 (sFlt1), or soluble endoglin (sEng), which inhibit circulating angiogenic hormones. These factors may be causative of widespread endothelial injury, and their role in preeclampsia is being further investigated. Endothelial dysfunction in turn causes increased sensitivity to vasopressor agents, systemic vasoconstriction, and reduced fibrinolytic function. Renal biopsy reveals endothelial cell swelling (endotheliosis) and,

Table 31-5 Antihypertensive Medications in Pregnancy

Medication	Serious Adverse Effects
Commonly Used	
Methyldopa	None definite
Clonidine	Fetal bradycardia
Hydralazine	None definitely reported
Labetalol, β blockers	Fetal bradycardia
Thiazide diuretics	Volume contraction
Calcium channel blockers	None definite
Contraindicated	
Angiotensin-converting enzyme inhibitors	Teratogenicity and fetal death
Angiotensin II receptor antagonists	Teratogenicity and fetal death

Note: There is a direct relationship between magnitude of blood pressure change and risk for small-for-gestational-age infants, regardless of drug choice. All drugs are category C for treatment of hypertension in pregnancy.

in severe cases, fibrin microthrombi with ischemia and necrosis.

Despite several clinical trials for the prevention of preeclampsia, no therapy is very effective. The only effective treatment for preeclampsia remains placental delivery. Proper obstetrical care is essential to balance the risk to the mother against the risk for prematurity of the fetus. Treatment of severe hypertension with antihypertensive agents can reduce cerebrovascular events due to elevated blood pressure, but will not treat the underlying disorder or reverse the disease. Methyldopa has long been the drug of choice for hypertension in pregnancy, whereas β blockers such as labetalol are common second-line drugs (Table 31-5). As with many medications in pregnancy, the risk profile of these medications is poorly defined. Treatment with magnesium sulfate in severe cases of preeclampsia effectively reduces the risk for progression to eclampsia, but does not reduce maternal or fetal mortality. The benefits of magnesium sulfate in mild or moderate cases of preeclampsia are less certain. Most cases gradually resolve after delivery of the placenta. However, even after delivery, preeclampsia is a risk factor for future hypertension, renal disease, and cardiovascular events.

SCLERODERMA RENAL CRISIS

Systemic sclerosis (scleroderma) is an idiopathic connective tissue disorder that produces inflammation and fibrosis of the skin and internal organs (skin, heart, lungs, and gastrointestinal tract). Proliferative endovascular lesions may lead to obliteration of the vascular internal lumina and renal ischemia, with severe hypertension, increased renin activity, angiotensin II, and aldosterone. In severe cases, microangiopathic hemolytic anemia may also occur. Acute oliguric renal failure or rapidly worsening hypertension in the setting of underlying scleroderma is clinically referred to as *scleroderma renal crisis*.

The annual incidence of renal crisis in patients with scleroderma is about 7% to 10%, primarily in patients with diffuse disease, rather than the more limited local cutaneous systemic sclerosis. The incidence of renal crisis also increases

with the severity of skin involvement and joint contractures and frequently occurs early in the course of disease (within first 1 to 2 years of diagnosis). Because this may occur early during the course of disease, or even before the clinical diagnosis of scleroderma is made, clinicians must be alert to this possibility.

The renin-angiotensin system appears to play an important role in the progression of the disease, although no clear trigger has been found. Clinical predictors of impending renal crisis include new-onset anemia, rapidly worsening skin findings, and cardiac involvement. There are presently no clinically recommended serologic tests that reliably predict or confirm the diagnosis of renal crisis. Renal biopsy may reveal interlobular artery involvement with intimal thickening, endothelial cell proliferation, and edema. In the afferent arterioles, fibrinoid necrosis may occur with intravascular fibrin accumulation extending into the glomeruli, often with ischemic collapse. The classic onion-skinning appearance of the larger arteries occurs in chronic disease.

Before the advent of ACE inhibitors and hemodialysis, renal crisis was almost universally fatal, even with multidrug antihypertensive regimens, and was a major cause of mortality in patients with scleroderma. If the diagnosis of scleroderma renal crisis is made before advanced renal failure is established, ACE inhibition may halt or even reverse the decline in renal function. Some experts recommend continuing ACE inhibitors even if renal function declines and temporary dialysis is necessary, citing increased chance of renal recovery even after temporary dialysis during continuation of treatment. With the advent of ACE inhibitor therapy, the mortality rate of scleroderma renal crisis has improved from near 90% to close to 10%.

Thrombotic Microangiopathy

Thrombotic microangiopathy encompasses the clinical syndromes of TTP, secondary TTP, diarrhea-related hemolytic uremic syndrome (D+HUS), and diarrhea-negative HUS (D-HUS, or atypical HUS). The common feature among these disorders is microvascular thrombosis that produces microangiopathic hemolytic anemia and organ dysfunction, although each syndrome has distinct clinical, pathophysiologic, and epidemiologic features (Table 31-6).

Although many processes cause microvascular endothelial injury (Table 31-7), these affect the vasculature at different levels. Thrombosis due to HUS and TTP primarily affects the glomeruli. Scleroderma often extends to the interlobular arteries, as opposed to malignant hypertension, which more often affects the afferent arterioles. However, there is significant overlap and similar histologic features among these diseases, making careful clinical evaluation essential for accurate determination of the etiology.

THROMBOTIC THROMBOCYTOPENIC PURPURA

TTP is characterized by microangiopathic hemolytic anemia and thrombocytopenia without an identifiable cause.

Table 31-6 Characteristics that Differentiate Shiga Toxin–Related HUS from TTP

Feature	Shiga Toxin–Related HUS	TTP
Epidemiology	Endemic areas (commonly, not exclusively)	Endemic regions not reported
Similar cases in family	If yes, synchronous	If yes, separated in time and space
Recurrences	Rare	Common
Gastrointestinal prodrome	Painful diarrhea, frequently bloody	Nondiarrheal abdominal symptoms predominate, but not as prodrome
von Willebrand factor profile	Increased degradation to smaller multimers	Ultralarge forms (assay not universally available); depletion of large and ultralarge forms in advanced stage
ADAMTS 13	Normal or slightly decreased	Deficient (<0.1 U/mL)
Characteristics of intravascular thrombi	Fibrin predominates	von Willebrand factor predominates
Endothelial cell appearance	Swollen	Not swollen
Response to plasma therapy	Not demonstrated	Yes
Diagnosis	Isolation of STEC; antibody response to <i>Escherichia coli</i> O157:H7 LPS antigen	ADAMTS 13 activity; inhibitors of ADAMTS 13 activity; genetic analysis for mutations of ADAMTS 13 gene

ADAMTS 13, a disintegrin and metalloproteinase, with thrombospondin-1-like domains; HUS, hemolytic uremic syndrome; LPS, lipopolysaccharide; STEC, Shiga-toxigenic *E. coli*; TTP, thrombotic thrombocytopenic purpura.

Data from Tarr PI, Gordon CA, Chandler WL: Shiga-toxin-producing *Escherichia coli* and haemolytic uraemic syndrome. *Lancet* 365:1073-1086, 2005.

Table 31-7 Disorders Associated with Thrombocytopenia and Microangiopathic Hemolysis

Condition	Example
Pregnancy	Preeclampsia, HELLP syndrome
Medications	Cyclosporine, tacrolimus, chemotherapeutic agents (e.g., mitomycin C), quinine, cocaine, ticlopidine, heparin, statins
Transplantation	Allogeneic bone marrow, solid organ
Neoplastic diseases	Metastatic cancers
Disseminated intravascular coagulation	Consumption of fibrinogen and other clotting factors
Prothrombotic disorders	Paroxysmal nocturnal hemoglobinuria, antiphospholipid antibody syndrome
Cardiovascular procedures	Cardiac catheterization, angioplasty, vascular bypass operations, artificial aortic valve with perivalvular leak
Infectious diseases	Rocky Mountain spotted fever, anthrax
Intravascular devices	Prosthetic heart valves, prosthetic aortic valve with perivalvular leak
Malignant hypertension	Blood pressure >200/120 mm Hg

Data from Tsai HM: Advances in the pathogenesis, diagnosis, and treatment of thrombotic thrombocytopenic purpura. *J Am Soc Nephrol* 14:1072-1081, 2003.

Patients may also have fever, renal dysfunction, and neurologic impairment, although these occur late in the disease and may be prevented by early diagnosis and treatment. Purpura is only rarely observed and is not necessary to make the diagnosis. Idiopathic TTP is thought to have an autoim-

mune mechanism in many cases. Other causes of hemolytic anemia with thrombocytopenia, such as autoimmune hemolysis, disseminated intravascular coagulation (DIC), cancer, eclampsia, drug toxicity (e.g., ticlopidine, cyclosporine, tacrolimus), stem cell transplantation, or malignant hypertension, may also have evidence of microangiopathic hemolysis and are classified as secondary TTP. The annual incidence of TTP is 4 cases per 1,000,000, with a 3:2 female ratio with a peak incidence in the third and fourth decades of life.

Idiopathic TTP is thought to be caused by a deficiency of ADAMTS 13 (a disintegrin-like and metalloproteinase with thrombospondin repeats), a plasma protease that normally cleaves von Willebrand Factor (vWF) and limits the extent of intravascular thrombosis (Fig. 31-6). Microthrombi composed primarily of platelets and vWF accumulate within the vascular bed of multiple organs, leading to microangiopathic hemolytic anemia. Deficiency in ADAMTS 13 may be either acquired (e.g., immunoglobulin G [IgG] autoantibodies) or genetic. Other laboratory abnormalities are reflective of microangiopathic hemolytic anemia, such as thrombocytopenia, elevated LDH, indirect bilirubin, reticulocyte count, and low haptoglobin. Coagulation laboratory tests (prothrombin time [PT], activated partial thromboplastin time [aPTT], fibrinogen) are typically normal, although fibrin split products may be elevated. Renal dysfunction may not occur, but microscopic hematuria and proteinuria are frequently present.

Without treatment, TTP has a mortality rate of about 90%, with most deaths occurring within 3 months of onset of symptoms. Treatment with plasma infusion normalizes ADAMTS 13, reducing intravascular hemolysis, and reduces mortality. Plasmapheresis and replacement with fresh-frozen plasma carries the advantage of removing inhibitory autoantibodies in addition to normalizing ADAMTS 13 levels because of the large volume of plasma that can be

Figure 31-6 Relation between ADAMTS 13 activity, excessive adhesion and activation of platelets, and thrombotic thrombocytopenic purpura. **A**, In normal subjects, ADAMTS 13 (von Willebrand factor–cleaving metalloprotease) molecules attach to binding sites on endothelial cell surfaces and cleave unusually large multimers of von Willebrand factor as they are secreted by stimulated endothelial cells. The smaller von Willebrand factor forms that circulate after cleavage do not induce the adhesion and aggregation of platelets during normal blood flow. **B**, Absent or severely reduced activity of ADAMTS 13 in patients with thrombotic thrombocytopenic purpura prevents timely cleavage of unusually large multimers of von Willebrand factor as they are secreted by endothelial cells. The uncleaved multimers induce the adhesion and aggregation of platelets in flowing blood. (From Moake JL: Thrombotic microangiopathies. *N Engl J Med* 347:589-600, 2002.)

infused. Assay for ADAMTS 13 activity must be sent before therapy is initiated to obtain accurate results, but treatment should not be delayed for these results to return. Severity of ADAMTS 13 deficiency (<5%) is predictive of future relapse, although those with severe deficiency are just as likely to respond initially to plasmapheresis as those with mild deficiency. In patients with relapsing TTP, treatment with vincristine may reduce the need for plasmapheresis. Secondary TTP is not associated with ADAMTS 13 deficiency and will not respond to plasmapheresis or plasma infusion. Likewise, patients with HUS typically do not have severe ADAMTS 13 deficiency.

HEMOLYTIC UREMIC SYNDROME

Infection with the Shiga-toxicogenic *Escherichia coli* strain O157:H7 may be complicated in about 15% of cases by thrombotic microangiopathy limited to the renal vasculature, termed the HUS. HUS is defined as anemia with schistocytes, thrombocytopenia, and renal dysfunction in the absence of other causes of coagulopathy. *Shigella dysenteriae* serotype 1 or other Shiga toxin–producing strains of *E. coli* may also cause HUS. HUS most commonly affects infants and children, although adults may also be affected. Cases of HUS often cluster owing to outbreaks of *E. coli* O157:H7, with peaks in summer and autumn. *E. coli* is endemic within the gastrointestinal tract of cattle, and cases are often tracked to undercooked meat, exposure to bovine

fecal matter, animal exposure, or other contaminated food products.

Shiga-toxicogenic bacterial strains commonly produce a prodrome of painful, bloody diarrhea, which precedes the development of HUS by 2 to 12 days (median of 3 days). Shiga toxin is directly thrombogenic within the renal vasculature (Fig. 31-7). Although intravascular coagulation HUS is often limited to the kidney, the heart, gastrointestinal tract, and central nervous system (seizures, stroke, and coma) are also affected in a significant minority of cases and carry a worse prognosis.

Laboratory abnormalities in HUS commonly include elevated creatinine, anemia, schistocytes on peripheral smear, elevated reticulocyte count, and thrombocytopenia. In contrast to DIC, fibrinogen levels are normal or high, and the prothrombin time is normal or only slightly prolonged. Fresh stool should be sent for culture of *E. coli* O157:H7, which can potentially aid in tracing the source of an outbreak. Stool studies should also be performed in patients without diarrhea because *E. coli* O157:H7 may rarely cause HUS in the absence of intestinal symptoms. If *E. coli* O157:H7 is not detected on culture, then repeat culture for other Shiga-toxicogenic organisms should be pursued. The pathologic renal lesions of HUS include vessel wall thickening with endothelial cell swelling and intraglomerular thrombosis with platelet- and fibrin-rich thrombi. Fragmentation of red blood cells may be seen within the renal vasculature and within the vessel wall.

Figure 31-7 Mechanism of platelet-fibrin formation in hemolytic uremic syndrome. **A**, Platelets activated by Shiga toxin may adhere by means of the glycoprotein Iba components of glycoprotein Ib/IX/V complexes to unusually large multimers of von Willebrand factor that are secreted from toxin-stimulated renal endothelial cells. The adherence of platelets to endothelial cells is especially likely if the cleavage of multimers extruding from endothelial cells by von Willebrand factor–cleaving metalloprotease, ADAMTS 13, is impaired by the interactions of Shiga toxin with globotriaosylceramide (Gb₃) receptors on endothelial cell surfaces. The activation of platelets that is mediated by Shiga toxin may contribute to the aggregation of additional platelets. **B**, Endocytosis and activation of the A subunits of Shiga toxin may cause the death and desquamation of endothelial cells, exposing unusually large multimers of von Willebrand factor entwined with collagen in the subendothelium. Platelets from flowing blood in the renal microcirculation may then adhere and aggregate on the exposed multimers and collagen. Local exposure of tissue factor and binding and activation of factor VII may occur on fibroblasts, invading phagocytic cells, and injured renal endothelial and epithelial cells. These actions may, in turn, induce the activation of factors IX and X, cleavage of prothrombin to thrombin by the complex of activated factor X and activated factor V, and the thrombin-induced formation of fibrin polymers, thus potentiating renal microvascular thrombosis. (From Moake JL: Thrombotic microangiopathies. *N Engl J Med* 347:589-600, 2002.)

Treatment of D+HUS is supportive, including adequate volume repletion with isotonic intravenous fluids, transfusion for severe anemia, and avoidance of other nephrotoxic agents (e.g., nonsteroidal anti-inflammatory drugs, aminoglycoside antibiotics, iodinated contrast). Platelet transfusion is generally not recommended because it may worsen the ongoing microvascular thrombosis. Antibiotic treatment of patients with bloody diarrhea is not recommended because it is not effective in reducing the incidence of HUS, and may actually increase the risk. Corticosteroids, anticoagulation (aspirin, heparin), thrombolytic agents, and plasma administration have also proved ineffective for the treatment of HUS. With supportive care alone, most patients with D+HUS will recover with normalization of renal func-

tion or only mild renal insufficiency, although about 25% may develop advanced renal failure or ESRD over the next 1 to 2 decades of life. Risk for chronic renal failure is increased with cortical necrosis and involvement of more than 50% of glomeruli on renal biopsy. The risk for complications and death increases with age, with mortality increasing from about 5% to 10% in children to about 30% in adults.

D–HUS (atypical HUS) accounts for a small percentage (about 5%) of cases and has a higher likelihood of recurrence, ESRD, or death. Many cases are due to genetic defects in the complement pathway (complement H, factor I, or CD46). With modern testing for ADAMTS 13 levels, laboratory testing may help distinguish cases of atypical HUS from TTP.

Data from Lim W, Crowther MA, Eikelboom JW: Management of antiphospholipid antibody syndrome: A systematic review. *JAMA* 295: 1050-1057, 2006.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

Anti-phospholipid antibodies (APAs) refer to autoantibodies that interfere with phospholipid-binding proteins, such as lupus anticoagulants (LA) or anticardiolipin antibodies (aCL), that interfere with in vitro phospholipid-dependent clotting assays (Table 31-8). The diagnosis of APS is a clinical diagnosis that requires the presence of arterial or venous clotting events or fetal loss during pregnancy (after 10 weeks' gestation) because LA and aCL are detectable in up to 10% of healthy populations. APAs are detectable in 30% to 50% of patients with systemic lupus erythematosus (SLE), and renal involvement is often observed in this setting. In the absence of an underlying autoimmune disease, the syndrome is referred to as primary antiphospholipid antibody syndrome (APS), and secondary APS when associated with other diseases such as SLE.

The procoagulant effect of APAs may be due to interference with the anticoagulant β_2 -glycoprotein 1, inhibition of fibrinolysis, direct endothelial injury, accelerated atherosclerosis, and activation of platelet, monocyte, and endothelial cells. APS has been associated with thrombotic events at any level within the renal vasculature (arteries, arterioles, glomeruli, or veins). The most commonly associated events are renal vein thrombosis, renal artery thrombosis, focal cortical atrophy, and thrombotic microangiopathy (including during pregnancy). APS nephropathy associated with SLE is often the only associated renal biopsy finding and appears to correlate more with the presence of LA than aCL.

Clinical signs of APS include livedo reticularis, thrombocytopenia, hemolytic anemia, and valvular heart disease. Laboratory screening for APAs is recommended in patients with unexplained venous or arterial thrombosis or multiple spontaneous abortions. One clinical clue to the presence of LA is a prolonged aPTT in the absence of heparin therapy or other anticoagulant therapy. Pathologic changes on renal biopsy of patients with primary APS are small vessel vaso-occlusive disease with fibrous intimal hyperplasia of interlobular arteries, recanalizing thrombi in arteries and arterioles, focal cortical atrophy, and thrombotic microangiopathy.

Long-term warfarin anticoagulation with a target international normalized ratio (INR) of 2 to 3 is indicated for patients with primary or secondary APS and prior DVT, arterial thrombosis, or recurrent spontaneous abortion. Warfarin is contraindicated during pregnancy, so heparin therapy with or without low-dose aspirin (81 mg) is necessary until the end of pregnancy in those cases. Treatment of APA-positive patients in the absence of prior clinical events is more controversial because of the high false-positive rate for these tests. Aspirin therapy for primary prevention in patients with persistently positive APA has been advocated, but not proved. In addition, plasmapheresis, prednisone, and hydroxychloroquine have been advocated for treatment of thrombotic microangiopathy due to APS and should be considered in severe cases.

RENAL VEIN THROMBOSIS OR OCCLUSION

Renal vein thrombosis (RVT) occurs rarely but is a potentially treatable cause of renal dysfunction. Although clinicians consider the diagnosis of RVT in the setting of nephrotic syndrome, most cases are associated with malignancy (66%), whereas a minority are caused by the nephrotic syndrome (20%) or an unidentifiable cause (12%). Other precipitating causes include surgery, trauma, and genetic or acquired hypercoagulable states (e.g., protein C or S deficiency, anti-thrombin gene mutation, factor V Leiden mutation). Most malignancy-associated cases of RVT (78%) are caused by renal cell carcinoma, often spreading to the contralateral kidney causing bilateral renal vein occlusion.

The nephrotic syndrome is associated with risk for venous thrombosis including RVT, which positively correlates with increasing severity of disease assessed by 24-hour urinary protein excretion and serum albumin (<2 g/dL). Some studies have documented about a 25% to 30% incidence of RVT in patients with nephrotic syndrome. Hypercoagulability is thought to be due to loss of antithrombotic proteins in the urine, increased procoagulant factors, or platelet activation. Glomerular diseases most commonly associated with RVT are membranous nephropathy, focal segmental glomerular sclerosis, membranoproliferative glomerulonephritis, and minimal change disease.

Patients may present with symptoms attributable to renal cell carcinoma, such as flank pain, gross hematuria, nausea, anorexia, or lower extremity swelling. In males, a left renal vein occlusion may cause a left varicocele, a result of the venous drainage of the left gonadal vein. In patients without a malignancy, symptoms of RVT depend on the acuity of the thrombosis. Acute, complete thrombosis is more likely to present with signs and symptoms, including hematuria, flank pain, abdominal distention, and acute renal failure. RVT in adults usually occurs gradually and allows time to develop collateral venous return. In gradual occlusion, most patients do not develop symptoms or acute renal failure, although a mild elevation of proteinuria and creatinine is often noted. Because patients often do not have symptoms, RVT is likely more common than reported in the literature, and some have suggested screening high-risk patients by CT scan.

The gold standard method for diagnosis is renal venography, but it has a risk for clot dislodgment, bleeding, and

Figure 31-8 Magnetic resonance venography demonstrating left renal vein thrombosis in a patient with membranous glomerulonephritis and nephrotic syndrome (urine protein excretion 7 g per 24 hours). The thrombosis can be seen as a dark void within the left renal vein (*large arrow*) extending into the inferior vena cava (*small arrow*).

iodinated contrast, so less invasive methods are now commonly used. Contrast-enhanced CT appears to have a relatively high sensitivity and specificity, although it carries some risk for contrast nephropathy. MRI using either gadolinium-based contrast (Fig. 31-8) or “time-of-flight” sequencing is promising but needs further characterization. Intravenous pyelography may detect RVT but has a low sensitivity and specificity. Renal Doppler ultrasound is useful but is user dependent and has a lower sensitivity than CT venography.

Treatment with systemic anticoagulation (warfarin) is recommended in the absence of contraindications and may be associated with improved long-term survival. RVT does not appear to increase mortality in the absence of underlying malignancy. Most clinicians maintain anticoagulation for 6 to 9 months, similar to the approach with nonrenal deep vein thrombosis and pulmonary embolism. The long-term recurrence risk is low if the underlying predisposition is successfully treated, and patients are unlikely to require indefinite anticoagulation. Direct intravenous thrombolysis or operative thrombectomy may be considered in severe cases. Prophylactic anticoagulation in high-risk patients has been proposed and may be considered in appropriate candidates.

Prospectus for the Future

The burden of obesity, hypertension, and diabetes continues to increase at an alarming rate in the industrialized world, contributing significantly to the incidence of CKD. Atherosclerotic RAS remains a common cause of secondary hypertension and carries with it a markedly increased risk for future cardio-

vascular events. Revascularization should be used in limited situations until results from ongoing clinical trials are available. Other vascular disorders of the kidney are less commonly encountered but should be considered in the appropriate clinical setting in order to initiate early treatment.

Acute Kidney Injury

Didier Portilla and Sudhir V. Shah

Definition and Etiology

Acute renal failure (ARF) is a syndrome that can be broadly defined as an abrupt decrease in glomerular filtration rate (GFR) sufficient to result in retention of nitrogenous waste products (blood urea nitrogen [BUN] and creatinine) and perturbation of extracellular fluid volume and electrolyte and acid-base homeostasis. In the absence of a universally accepted definition of acute renal failure, and in recognition that ARF as previously defined includes a spectrum of clinical conditions, the term *acute kidney injury* (AKI) has been proposed to reflect the entire spectrum of the syndrome. In addition, a consensus conference involving key societies in nephrology and critical care worldwide has recommended the diagnostic criteria for AKI as outlined in Box 32-1.

Despite technical advances in renal replacement therapy and supportive care during the past few years, the mortality rate of patients with AKI remains high. Several recent studies highlight the clinical importance of AKI (Table 32-1).

Acute kidney injury can result from (1) diseases that cause a decrease of renal blood flow (*prerenal azotemia*), (2) diseases that directly involve renal parenchyma (*renal azotemia*), or (3) diseases associated with urinary tract obstruction (*postrenal azotemia*) (Fig. 32-1).

The most common intrinsic renal disease that leads to AKI is an entity referred to as *acute tubular necrosis* (ATN), which is a clinical syndrome characterized by an abrupt and sustained decline in GFR occurring within minutes to days in response to an acute ischemic or nephrotoxic insult. The clinical recognition of ATN is largely predicated on exclusion of prerenal and postrenal causes of sudden azotemia, followed by exclusion of other causes of intrinsic AKI (glomerulonephritis, acute interstitial nephritis, and vasculitis). The other defined renal syndromes must be excluded before concluding that ATN is present. Although the name *acute tubular necrosis* is not an entirely valid histologic description of this syndrome, the term is ingrained in clinical medicine and is therefore used in this chapter.

Box 32-1 Diagnostic Criteria for Acute Kidney Injury

An abrupt (within 48 hours) reduction in kidney function, currently defined as an absolute increase in serum creatinine of more than or equal to 0.3 mg/dL ($\geq 26.4 \mu\text{mol/L}$), a percentage increase in serum creatinine of more than or equal to 50% (1.5-fold from baseline), or a reduction in urine output (documented oliguria $<0.5 \text{ mL/kg}$ per hour for more than 6 hours). The above criteria include both an absolute and a percentage change in creatinine to accommodate variations related to age, gender, and body mass index and to reduce the need for a baseline creatinine, but do require at least two creatinine values within 48 hours. The urine output criterion was included based on the predictive importance of this measure but with the awareness that urine outputs may not be measured routinely in non-intensive care unit settings. It is assumed that the diagnosis based on the urine output criterion alone will require exclusion of urinary tract obstructions that reduce urine output or of other easily reversible causes of reduced urine output. The above criteria should be used in the context of the clinical presentation and following adequate fluid resuscitation when applicable. Note: Many acute kidney diseases exist, and some (but not all) may result in AKI. Because diagnostic criteria are not documented, some cases of AKI may not be diagnosed. Furthermore, AKI may be superimposed on or lead to chronic kidney disease.

Differential Diagnosis and Diagnostic Evaluation of the Patient

ACUTE AZOTEMIA DURING HOSPITALIZATION

AKI complicates about 5% of hospital admissions and up to 30% of admissions to intensive care units. Despite the exhaustive list of conditions that can cause acute azotemia in hospitalized patients, a thorough history and physical

examination and simple laboratory tests often suffice for diagnosis. In hospitalized adults, prerenal azotemia is the single most common cause of acute azotemia, and ATN is the most common intrinsic renal disease that leads to AKI. Thus, the most important differential diagnosis is between prerenal azotemia (e.g., volume depletion) and ATN (secondary to ischemia or nephrotoxins). In the elderly male patient, bladder outlet obstruction must also be excluded. In addition, depending on the clinical setting, other diagnoses to be considered are acute interstitial nephritis (secondary to antibiotics), atheromatous emboli (from prior aortic surgery or aortogram), ureteral obstruction (pelvic or colon surgery), or intrarenal obstruction (acute uric acid nephropathy).

Table 32-1 Clinical Importance of Acute Kidney Injury

Increasing incidence of acute kidney injury
Even minor (0.3 mg/dL) increases in serum creatinine levels are associated with increased in-hospital mortality
Acute kidney injury indicates a poor prognosis associated with a poor, long-term morbidity and mortality
A relatively unrecognized effect of acute kidney injury is the subsequent development of chronic kidney disease and progression to dialysis dependency in about 15% of the patients

APPROACH TO DIAGNOSIS: CHART REVIEW, HISTORY, AND PHYSICAL EXAMINATION

Determination of the cause of AKI depends on a systematic approach, as depicted in Table 32-2. The difficulty in arriving at a correct diagnosis in a hospitalized patient is not the failure to identify a possible cause of the AKI; the problem is often just the opposite in that several causes of AKI may be possible. The correct diagnosis depends on a thorough analysis of available data concerning the patient with AKI

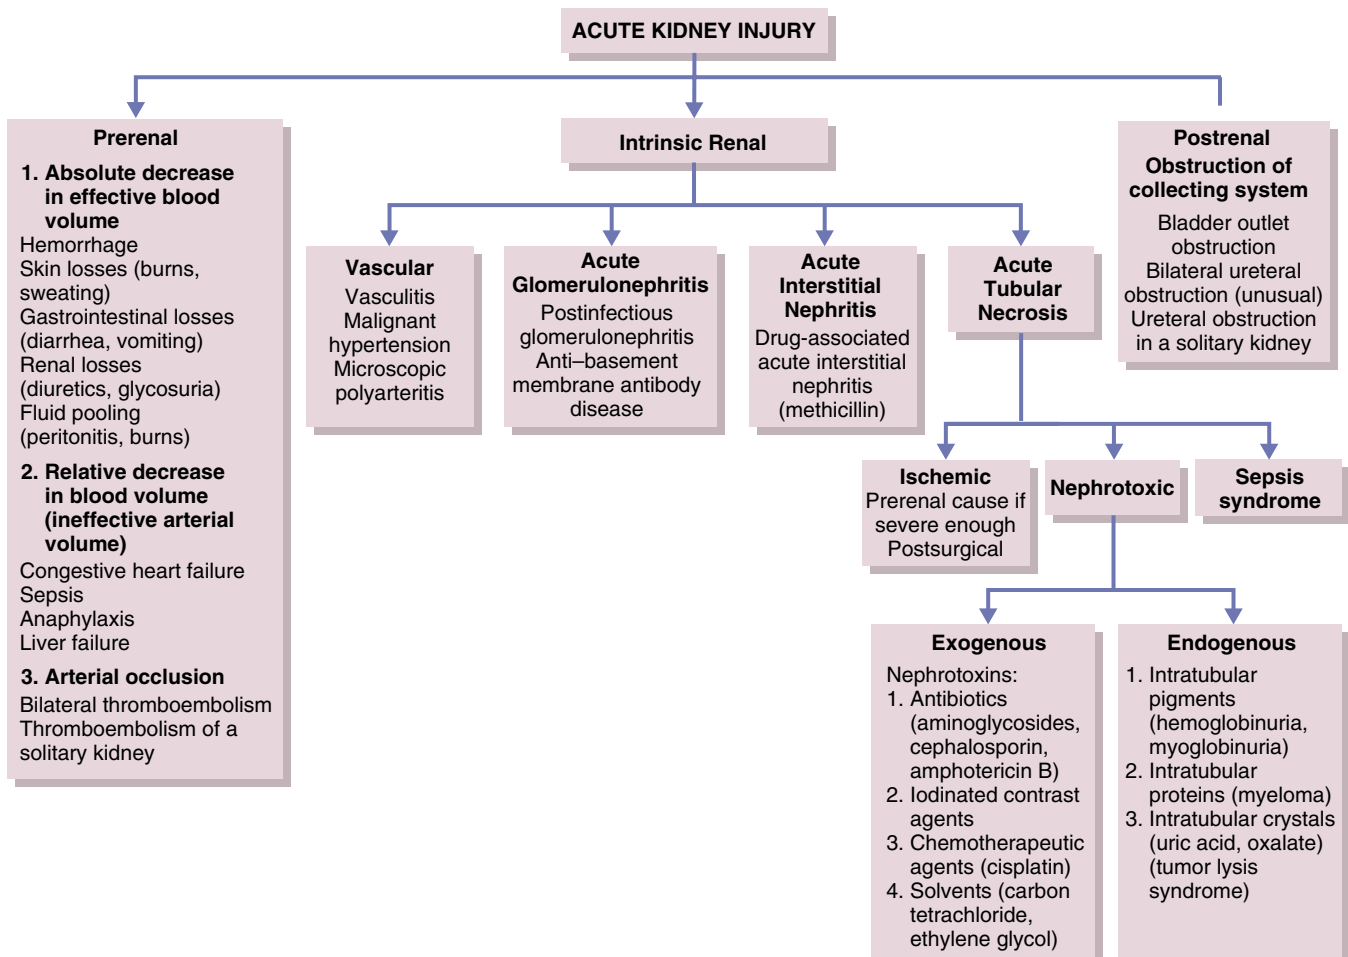

Figure 32-1 Causes of acute kidney injury.

and on examination of the sequence of deterioration in renal function in relation to chronology of the potential causes of AKI. The correct diagnosis also requires knowledge of the natural history of the different causes of AKI. Some of the important data that should be sought from the patient's chart review are presented in Table 32-3.

Reduced body weight, postural changes in blood pressure and pulse, and decreased jugular venous pulse all suggest a reduction in extracellular fluid volume. Prerenal azotemia may also develop in states in which extracellular fluids are expanded (cardiac failure, cirrhosis, and nephrotic syndrome), but the *effective* blood volume is decreased. Thorough abdominal examination may show a distended, tender bladder that indicates lower urinary tract obstruction. When lower urinary tract obstruction is suspected as a cause of acute azotemia, examination of the prostate and a sterile *in-and-out* diagnostic postvoid bladder catheterization

should be performed as a part of the physical examination. The urine volume should be recorded and a specimen saved for studies described later.

Additional findings that may be helpful are the occurrence of fever and rash in some patients with acute interstitial nephritis. A history of recent aortic catheterization and the finding of livedo reticularis are diagnostic clues for cholesterol or atheromatous emboli.

Differentiating prerenal azotemia from ATN may be difficult, partly because evaluation of volume status in a critically ill patient is not easy, and any cause of prerenal azotemia, if severe enough, may lead to ATN. Evaluation of the urine volume and urine sediment and of certain urinary indices is particularly helpful in making the correct diagnosis.

URINE VOLUME

The urine volume is often less than 400 mL per day in oliguric ATN. Normal urine output does not exclude the diagnosis of ATN because many patients with ATN have urine outputs as high as 1.5 to 2 L per day. This nonoliguric ATN is frequently associated with nephrotoxic antibiotic-induced AKI. In contrast, anuria (no urine output) should suggest a diagnosis other than ATN, the most important being obstruction. Widely varying daily urine outputs also suggest obstruction.

URINE SEDIMENT

In prerenal failure, a moderate number of hyaline and finely granular casts may be seen, but coarsely granular and cellular casts are infrequent. In ATN, the sediment is usually quite characteristic: *dirty* brown granular casts and renal tubular epithelial cells, free and in casts, are the most striking elements and are present in 70% to 80% of patients with ATN

Table 32-2 Diagnostic Approach to Acute Kidney Injury

1. Record review (see Table 32-3); special attention to evidence of recent reduction in glomerular filtration rate and sequence of events leading to deterioration of renal function to determine possible causative factors
2. Physical examination, including evaluation of hemodynamic status
3. Urinalysis, including thorough sediment examination
4. Determination of urinary indices
5. Bladder catheterization
6. Fluid diuretic challenge
7. Radiologic studies, particular procedure dictated by clinical setting (e.g., ultrasonography to look for obstruction)
8. Renal biopsy

Table 32-3 Record Review in a Hospitalized Patient Who Develops Acute Kidney Injury

Record Finding	Comments
Prior renal function	Determination of whether the azotemia is acute; patients with prior renal insufficiency particularly susceptible to AKI, secondary to contrast dyes
Presence of infection	Sepsis a possible cause of AKI, even in the absence of hypotension
Nephrotoxic agents	Aminoglycosides (e.g., gentamicin) important cause of ATN in hospitalized patients, typically nonoliguric ATN during first 2 wk of therapy; antibiotics possible cause of acute interstitial nephritis; cytotoxic drugs (e.g., cisplatin) possible cause of AKI
Contrast studies including oral cholecystography, intravenous pyelography, angiography	Important cause of ATN in hospitalized patients; typically causes oliguric ATN within 24 to 48 hr after study
Episodes of hypotension	Suggestion of prerenal azotemia or ischemic ATN
History of blood transfusions	Incompatible blood transfusion an unusual cause of ATN
Review of chart for history of loss or sequestration of extracellular fluid volume, intake-output, and serial weights	Important clues to the possibility of prerenal azotemia
Type of surgery	Patients who have had cardiac or vascular surgery or with obstructive jaundice particularly susceptible to ATN
Type of anesthesia	Methoxyflurane and the related less toxic enflurane causes of nonoliguric ATN
Amount of blood loss during surgery and whether associated with hypotension	Suggestion of prerenal azotemia or ischemic ATN

AKI, acute kidney injury; ATN, acute tubular necrosis.

 (Web Fig. 32-1A and B). A benign sediment containing few formed elements should alert the physician to the possibility that obstruction is present. In AKI associated with intratubular oxalate (e.g., methoxyflurane anesthesia) or uric acid deposition (associated with acute hyperuricemia after chemotherapy of neoplastic disease), the sediment contains abundant oxalate or uric acid crystals.

URINARY INDICES

An important series of diagnostic tests relates to an assessment of renal tubular function. The most widely used and convenient tests are measurements of sodium and creatinine simultaneously obtained from plasma and urine serum samples to calculate the fractional excretion of sodium (Fe_{Na}). The rationale for the use of these indices is as follows: The ratio of urine to plasma creatinine (U/P_{Cr}) provides an index of the fraction of filtered water excreted. If the assumption is made that all of the creatinine filtered at the glomerulus is excreted into the urine and that relatively little is added by secretion (an oversimplification but an acceptable one), then any increment in the concentration of creatinine in urine over that in plasma must result from the removal of water.

In prerenal azotemia, owing to the reduction in the amount of glomerular filtrate entering each nephron and to an added stimulus to salt and water retention, U/P_{Cr} typically is considerably greater than it is in ATN, and urinary sodium concentrations characteristically are low (Table 32-4). In contrast, in the ATN variety of AKI, the nephrons excrete a large fraction of their filtered sodium and water, and the results are a lower U/P_{Cr} and a higher Fe_{Na} . An exception to the rule that low Fe_{Na} indicates prerenal and high Fe_{Na} indicates ATN is the use of a diuretic or the presence of glucosuria that decreases tubular sodium reabsorption and increases Fe_{Na} . Recent studies show that, in the presence of diuretics, the rate of fractional excretion of urea (Fe_{urea}) of less than 35 indicates intact tubular function, thus favoring prerenal rather than established ARF as a cause of the azotemia. Because of the adaptive responses, in a patient with advanced chronic kidney disease (CKD), prerenal azotemia may not be associated with a Fe_{Na} of less than 1%. Interpretations of these tests, therefore, must

be made in conjunction with other assessments of the patient because clinically important exceptions to these generalizations exist. For example, certain types of ATN, such as in the case of severe burns, sepsis, and radiographic dye-induced kidney injury, or conditions associated with vascular inflammation, such as acute glomerulonephritis, acute vasculitis, or kidney transplant rejection, may exhibit all of the clinical characteristics of ATN but with an Fe_{Na} of less than 1%.

INDICATIONS FOR OTHER DIAGNOSTIC TESTS AND RENAL BIOPSY

If the diagnosis of prerenal azotemia or ATN is reasonably certain, and if the clinical setting does not require the exclusion of other causes of acute azotemia, then no further diagnostic evaluation is necessary. Further assessment is indicated in the following situations: (1) when the diagnosis is uncertain, especially if the clinical setting, suggests other possibilities (obstruction or vascular accident); (2) when clinical findings make the diagnosis of prerenal azotemia or ATN unlikely (anuria); or (3) when oliguria persists beyond 4 weeks.

Ultrasonography of the urinary tract is a noninvasive way to determine the presence of dilation of the collecting system that would suggest postrenal AKI. Radionuclide methods are available to assess the presence or absence of renal blood flow, differences in flow to the two kidneys, and excretory (secretory) function. However, these studies have reduced accuracy in quantitating absolute rates of flow. Renal biopsy is useful in cases in which clinical and laboratory assessment suggest diagnoses other than ischemic or nephrotoxic injury that may respond to disease-specific therapy. These conditions include glomerulonephritis, vasculitis, hemolytic uremic syndrome (HUS), thrombotic thrombocytopenic purpura, and allergic interstitial nephritis.

Approach to the Patient with Renal Failure

Azotemia first discovered outside the hospital may be either chronic or acute in origin. Useful points in deciding whether renal failure is acute or chronic are summarized in Table 32-5. Most patients who have advanced azotemia have chronic renal failure. Before a detailed evaluation is carried out, priority should be given to identifying complications of renal failure that may be lethal without prompt treatment. Some of these complications, such as marked fluid overload and pericardial tamponade, may be detected on clinical examination. However, life-threatening complications such as severe hyperkalemia or extreme metabolic acidosis require laboratory evaluation.

Even before the nature of the underlying disease causing azotemia is known, a decision to initiate dialysis has to be made. Dialysis should be instituted promptly in patients with severe hyperkalemia, acidosis, marked fluid overload, or uremic manifestations. Many uremic manifestations are nonspecific. However, a pericardial rub and neurologic manifestations such as asterix are indications for prompt dialysis.

Table 32-4 Urinary Diagnostic Indices

Index	Prerenal Azotemia	Acute Tubular Necrosis
Urine sodium (U_{Na}) (mEq/L)	<20	>40
Urine creatinine (U_{Cr}) (mg/dL)/ P_{Cr} (mg/dL)	>40	<20
Urine osmolarity (U_{OSM}) (mOsm/kg H_2O)	>500	<350
Renal failure index (RFI) = $U_{Na}U_{Cr}/P_{Cr}$	<1	>1
Fractional excretion of filtered sodium (Fe_{Na}) $Fe_{Na} = U_{Na}P_{Cr}/P_{Na}U_{Cr}$ (100)	<1	>1

P_{Cr} , plasma creatinine; P_{Na} , plasma sodium; U_{Cr} , urine creatinine; U_{Na} , urine sodium.

Table 32-5 Useful Features that Suggest Acute or Chronic Kidney Disease

Feature	Acute Kidney Injury	Chronic Kidney Disease
Previous history	Normal renal function	History of elevated blood urea nitrogen or creatinine
Kidney size	Normal	Small, with exception of multiple myeloma, diabetes, amyloid, polycystic kidney disease
Bone film	No evidence of renal osteodystrophy	Possible evidence of renal osteodystrophy
Hemoglobin, hematocrit	Anemia possible, but normal hemoglobin level in a patient with advanced azotemia is presumptive evidence of acute renal failure	Anemia common

LABORATORY EVALUATION

In hospitalized adults in whom the diagnoses of prerenal and postrenal azotemia have been excluded, AKI is usually caused by ATN. By contrast, in an outpatient setting in which prerenal and postrenal causes have been excluded, other renal parenchymal diseases cause AKI more often. Examination of the urine for blood and protein and of the urine sediment can give valuable information that often helps narrow considerably the diagnostic possibilities and suggest further appropriate laboratory evaluation.

The presence of 3+ to 4+ protein, 2+ to 3+ blood, and an active sediment with red blood cells (RBCs) and RBC casts is characteristic of proliferative glomerulonephritis. A history of an underlying systemic disease and various laboratory tests such as complement levels, antinuclear factor, and protein electrophoresis may suggest the presence of glomerulonephritis, but a kidney biopsy is required for a definitive diagnosis (reviewed in Chapter 29).

The presence of only a few RBCs in the urine sediment with strongly heme-positive urine or a heme-positive supernatant (with the RBCs removed by centrifugation) most commonly results from myoglobinuria or hemoglobinuria. Patients with rhabdomyolysis have a marked increase in the muscle enzymes such as creatine phosphokinase (CPK). The urine sediment in patients with myoglobinuria may show RBCs, pigmented casts, granular casts, and numerous uric acid crystals.

IMAGING STUDIES

Kidney size gives important clues about whether the kidney failure is acute or chronic and whether obstruction is present. Renal ultrasonography is the initial procedure of choice because it is noninvasive and reliable. The finding of normal-sized kidneys in a patient with advanced azotemia generally suggests that the patient has acute rather than chronic kidney disease; however, several important causes of CKD, including diabetes mellitus, HIV nephropathy, multiple myeloma, and amyloidosis, may be associated with normal-sized kidneys. The renal ultrasound examination is also helpful in (1) making a diagnosis of polycystic kidney disease, (2) determining whether one or two kidneys are present, and (3) localizing the kidney for renal biopsy.

Normal kidney size in a patient with kidney failure is often an indication for renal biopsy. Before a renal biopsy is carried out, the patient's blood pressure must be controlled,

bleeding and coagulation parameters must be checked, and the presence of two kidneys must be confirmed.

CYSTATIN C: A NEW MARKER FOR KIDNEY FUNCTION?

Cystatin C is a nonglycosylated 13-kD basic cysteine protease that all nucleated cells produce, and inflammatory conditions or muscle mass do not alter the production rate; only thyroid dysfunction has been shown to alter serum levels independent of glomerular filtration rate (GFR). Serum cystatin C levels increase before serum creatinine levels in patients with progressive CKD. Recent data also suggests that cystatin C levels increase 1 to 2 days before serum creatinine in patients developing AKI in the setting of radiocontrast nephropathy, kidney transplantation, and AKI in the intensive care unit. Cystatin C is excreted by glomerular filtration and then undergoes essentially complete tubular reabsorption and catabolism, without secretion, so that it is not normally found in urine in significant amounts. Based on these preliminary studies, cystatin C holds a promise as a potential novel diagnostic test to indicate the early development of acute tubular injury.

Clinical Presentation, Complications, and Management of Acute Tubular Necrosis

AKI produces signs and symptoms that reflect loss of the regulatory, excretory, and endocrine functions of the kidney. The loss of excretory ability of the kidney is expressed by a rise in the plasma concentration of specific substances that the kidney normally excretes. The most widely monitored indices are the concentrations of BUN and creatinine in the serum. In patients without other complications, the BUN rises by about 10 to 20 mg/dL per day, and the bicarbonate level falls to a steady-state level of 17 to 18 mEq/L. The serum potassium level need not rise appreciably, except in the presence of a hypercatabolic state, gastrointestinal bleeding, or extensive tissue trauma.

Because ATN is inherently a catabolic disorder, patients with ATN generally lose about 0.5 lb per day. Providing adequate calories (1800 to 2500 kcal or 35 kcal/kg body

weight per day) and about 1 to 1.4 g/kg body weight of protein per day may minimize further weight loss. The use of hyperalimentation with 50% dextrose and essential amino acids has had little effect on minimizing mortality and morbidity in patients with ATN, except in patients who also have significant burns.

Hyperkalemia is a life-threatening complication of AKI and often necessitates urgent intervention. The electromechanical effects of hyperkalemia on the heart are potentiated by hypocalcemia, acidosis, and hyponatremia. Thus, the electrocardiogram, which measures the summation of these effects, is a better guide to therapy compared with a single potassium determination. The cardiac effects of hyperkalemia are primarily referable to blunting of the magnitude of the action potential in response to a depolarizing stimulus. The sequential electrocardiographic changes observed in hyperkalemia are peaked T waves, prolongation of the PR interval, widening of the QRS complex, and a sine wave pattern, and these changes are mandatory indications for prompt treatment. The most common biochemical abnormality responsible for death in patients with ATN is hyperkalemia.

Moderate acidosis is generally well tolerated and does not need treatment unless used as an adjunct to controlling hyperkalemia or when plasma bicarbonate levels fall to less than 15 mEq/L. Hyperkalemia and acidosis not easily controlled by medical therapy are indications for initiating dialysis.

In most patients, hypocalcemia is asymptomatic and does not require treatment. Phosphate-binding gels may be used in patients with significant hyperphosphatemia. Anemia regularly develops in patients with ATN and does not require treatment unless it is symptomatic or contributes to heart failure.

In a well-managed patient (with use of early dialysis), many of the uremic manifestations outlined in Table 32-6 either do not develop or are minimal. However, infection remains the main cause of death despite vigorous dialysis. Thus, meticulous aseptic care of intravenous catheters and wounds and avoidance of the use of indwelling urinary catheters are important in the management of such patients.

The indications for initiating dialysis are severe hyperkalemia and acidosis not easily controlled by medical treatment or fluid overload. In the absence of any of the foregoing conditions, most nephrologists advocate dialysis when the BUN reaches about 80 to 100 mg/dL because the goal of modern therapy is to avoid the occurrence of uremic symptoms. Therefore, the patient is dialyzed as frequently as is necessary to keep the BUN at less than 80 mg/dL. When this approach is used, most patients do not develop uremic symptoms, the diet and fluid intake can be liberalized, and the overall management of the patient is easier. Finally, the clinician must review thoroughly the indications for and the doses of all drugs administered to patients with ATN. Monitoring of blood concentrations of drugs is an important adjunct to effective treatment.

Outcome and Prognosis

The oliguric phase of ATN typically lasts for 1 to 2 weeks and is followed by the diuretic phase. About one fourth to

Table 32-6 Major Complications of Acute Kidney Injury

Impairment of Fluid and Electrolyte Excretion

Retention of urea and other solutes	Uremia
	<i>Cardiac:</i> pericarditis
	<i>Neurologic:</i> asterixis, confusion, somnolence, coma, seizures
	<i>Hematologic:</i> anemia, coagulopathy, bleeding diathesis
	Infection
	<i>Gastrointestinal:</i> nausea, vomiting, gastritis, bleeding
	<i>Skin:</i> pruritus
	Glucose intolerance
Synthetic Impairment	
1,25-Dihydroxyvitamin D ₃	Hypocalcemia
Erythropoietin	Anemia
Impaired drug metabolism and excretion	Drug toxicity, decreased diuretic effectiveness

one third of the deaths occur in the diuretic phase. This finding is not surprising because, with the availability of dialysis, the most important determinant of the outcome is not the uremia itself but rather the underlying disease that causes the ATN.

As noted previously, infection continues to be the most important cause of death in patients with ATN. In modern acute care hospitals, the outcome of patients who develop ATN is highly variable, and, depending on the nature of the underlying disease, mortality rates may be in excess of 50%. In patients who survive the acute episode, renal function returns essentially to normal, with the only residual findings being a modest reduction in GFR and an inability to concentrate and acidify urine maximally.

Prevention

The first principle of good management is prophylaxis. This approach requires recognition of the clinical settings in which ATN normally occurs (e.g., in patients undergoing cardiac or aortic surgery) and recognition of patients particularly susceptible to ATN. Useful measures include correcting fluid deficiencies before surgical procedures and keeping patients who are particularly at risk adequately

hydrated before radiocontrast studies. Nephrotoxic drugs should be used only when essential and then only with careful monitoring of the patient. Finally, pretreatment with allopurinol before chemotherapy of massive tumors diminishes uric acid excretion.

Pathogenesis of Acute Tubular Necrosis

Although an initial decrease in renal blood flow appears to be a requisite for the development of ischemic ATN, blood flow returns to near normal within 24 to 48 hours after the initial insult. Despite adequate renal blood flow, tubular dysfunction persists, and the GFR remains depressed. Despite the common use of the term *acute tubular necrosis*, necrosis of the tubules is seen infrequently in either ischemic or nephrotoxic AKI. In addition, although two kinds of cell death, *apoptosis* and *necrosis*, are recognized, one of the major advances in the medical community's understanding of cell death has been the recognition that the pathways traditionally associated with apoptosis may be critical in the form of cell injury associated with necrosis. Thus, evidence indicates that apoptotic mechanisms, including increased mitochondrial membrane permeability resulting in the release and activation of apoptogenic factors such as endonuclease, are important in renal tubular injury and that certain mediators (increased fatty acids, oxidants, caspases, and ceramide) regulate this process. The pathway that the cell follows depends on both the nature and the severity of insults. Integral to the path that is followed is thought to be the expression of many genes involved in cell cycle regulation, as well as a group of genes that are proinflammatory and chemotactic. The cascades that lead to the apoptotic or necrotic mode of cell death probably are activated almost simultaneously and may share some common pathways (see Table 32-4).

Various biochemical changes have been implicated in proximal tubule cell injury in ARF. These changes include mitochondrial dysfunction, adenosine triphosphate (ATP) depletion, phospholipid degradation, elevation in cytosolic free calcium, decrease in sodium Na^+ , K^+ -ATPase activity, alterations in substrate metabolism, lysosomal changes, and the production of oxygen-free radicals. Which changes are causative and which may simply be byproducts of advanced cell injury is not yet clear.

Recent studies provide support for the role of microvascular endothelium and inflammatory cells in the pathophysiology of ischemic AKI. An early elevation on circulating levels of von Willebrand factor (a marker for endothelial cell injury) is seen, as well as increases in F-actin aggregates in the basolateral aspects of renal microvascular endothelial cells, accompanied by increased leukocyte and perhaps T-cell endothelial-adhesive interactions. Leakage of glomerular ultrafiltrate from the tubular lumen into the renal interstitium across the damaged renal tubular cells, obstruction to flow resulting from debris or crystals in the lumen of the tubules, and a decrease in the glomerular capillary ultrafiltration coefficient have all been proposed to play a pathophysiologic role in sustaining the clinical picture of ATN.

Specific Causes of Acute Renal Failure

EXOGENOUS NEPHROTOXINS

Radiographic Contrast Agents

Contrast media-associated AKI has been associated with increased mortality, permanent loss of kidney function, kidney failure requiring dialysis, prolonged hospitalization, and increased cost of medical care. Contrast media-associated AKI is rare in patients who are not at high risk for contrast nephropathy. Risk factors associated with contrast media nephropathy are listed in Table 32-7. Patients with a combination of advanced CKD and diabetes are considered at extremely high risk for developing acute kidney disease.

The exact mechanism by which contrast medium causes acute kidney disease is not well understood. Suggested mechanisms include severe vasoconstriction of renal medullary vessels and direct renal tubular toxicity likely related to release of oxidants.

Although acute kidney disease in this setting is usually defined as an increase in serum creatinine of 0.5 mg/dL or 25% or more from the baseline, an increase in serum creatinine of as little as 0.3 mg/dL is associated with unfavorable outcomes. Most patients develop acute kidney failure within 24 to 96 hours after parenteral administration of contrast media and, in most of these patients, kidney function recovers within 7 to 10 days. In a small proportion of patients, kidney function may not recover completely, or the patients may require dialysis. A diagnosis of contrast media-associated AKI is made on the temporal association of exposure to contrast media and kidney injury without any other obvious cause for AKI. Most patients have an Fe_{Na} of less than 1%. To date, no treatment for contrast media-associated renal failure is available, and therefore prevention is the key (Table 32-8). Hydration with saline has proved beneficial. In high-risk groups, intravenous administration of saline 4 to 12 hours before and 8 to 12 hours after

Table 32-7 Major Risk Factors Associated with Contrast Media-Associated Nephropathy

Chronic kidney disease
Diabetes mellitus
Age > 65 yr
Volume depletion
Study requiring large volume of contrast
High osmolar contrast media

Table 32-8 Prevention of Contrast Media-Associated Nephropathy

Identify high-risk patients
Avoid volume depletion
Use adequate saline hydration before and after the procedure
Limit contrast volume
Use iso-osmolar contrast media

administering contrast media is recommended. Hydration with a solution containing bicarbonate has been shown to decrease the incidence of contrast nephropathy, but until more data are available, normal saline is recommended. Iso-osmolar contrast media has also been shown to have lower incidence of contrast nephropathy. Prophylactic use of *N*-acetylcysteine has not shown to be of consistent benefit.

Aminoglycosides

One of the most important manifestations of aminoglycoside (e.g., tobramycin, gentamicin, amikacin) nephrotoxicity is AKI, which occurs in about 10% of patients receiving these drugs. Maintaining blood levels in the therapeutic range reduces but does not eliminate the risk for nephrotoxicity. AKI is usually mild and nonoliguric and produces a rise in the serum creatinine level after about 1 week of therapy with one of the aminoglycosides. The prognosis for recovery of kidney function after several days is excellent, although some patients may need dialysis support before recovery.

Nonsteroidal Anti-Inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) have several acute renal effects. NSAIDs are potent inhibitors of prostaglandin synthesis, a property that contributes to their nephrotoxic potential in certain high-risk patients in whom renal vasodilation depends on prostaglandins. The most frequent pattern of injury related to NSAIDs is prerenal azotemia, particularly in patients who either are volume contracted or have a reduced effective circulating volume. Susceptible persons include those with congestive heart failure, cirrhosis, CKD, and volume depletion. Hyperchloremic metabolic acidosis, often associated with hyperkalemia, has also been recognized as an effect of the NSAIDs, particularly in persons with preexisting chronic interstitial kidney disease. Hyporeninemic hypoaldosteronism occurs in these persons in states of renal prostaglandin inhibition. Finally, NSAIDs have been associated with the development of acute interstitial nephritis, often associated with renal insufficiency and nephrotic-range proteinuria. This complication appears to be an idiosyncratic reaction to propionic acid derivatives such as ibuprofen, naproxen, and fenoprofen. In contrast to acute interstitial nephritis associated with other drugs, the incidence of hypersensitivity symptoms and eosinophilia is low. Discontinuation of the offending agent usually results in resolution of this disorder.

Cyclo-oxygenase-2 Inhibitors

Cyclo-oxygenase-2 (COX-2) inhibitors have recently become a frequently used component of drug therapy in the adult population to treat acute inflammatory states, including arthritis and pain. Results from recent clinical trials have indicated that prostaglandins formed by COX-2 have important roles in renal physiology under certain conditions and that the effects of COX-2 inhibitors on kidney function are similar to those of traditional NSAIDs. Patients who are considered at elevated risk for adverse kidney events, including those with advanced age, kidney or hepatic disease, congestive heart failure, and diuretic or angiotensin-converting enzyme inhibitor therapy, should be monitored with the same caution when receiving therapy with COX-2 inhibitors

as they would be when receiving NSAIDs. A total of 15 cases of AKI associated with the use of these drugs have been reported to date: 9 with celecoxib and 6 with rofecoxib. All cases occurred in patients with the risk factors listed previously, and all patients returned to baseline renal function within 3 days to 3 weeks after discontinuation of COX-2 inhibitor therapy.

Cisplatin

Kidney injury is a well-recognized and dose-dependent complication of cisplatin, an antineoplastic agent used in the treatment of several carcinomas. Hypomagnesemia resulting from renal losses of magnesium may be severe and can occur in as many as 50% of patients. Patients should be well hydrated before they receive cisplatin, and simultaneous treatment with other known nephrotoxins should be avoided whenever possible. The usual lesion is that of ATN, but with severe damage or recurrent administration of the drug, chronic interstitial disease may ensue.

ETHYLENE GLYCOL TOXICITY

Ethylene glycol is a colorless, odorless, sweet liquid found in solvents and antifreeze. Ingestion of ethylene glycol, usually in the form of antifreeze, produces a characteristic syndrome of severe high anion gap (Na^+) - $[(\text{Cl}^-) + (\text{HCO}_3^-)]$ metabolic acidosis with a large osmolar gap $[(2)(\text{Na}^+) + (\text{BUN})/2.8 + (\text{glucose})/18 + (\text{ethanol})/4.7]$. Ethylene glycol is metabolized by alcohol dehydrogenase to glycolic acid, which is believed to be the major contributor to acidosis. The key clinical findings in patients who have ingested ethylene glycol are disorientation and agitation initially, progressing to central nervous system depression, renal failure, metabolic acidosis, respiratory failure, and circulatory insufficiency. Hypocalcemia is a prominent feature attributed to the deposition of calcium oxalate in multiple tissues but may be aggravated by a decreased parathyroid hormone response. The typical urine sediment is calcium oxalate crystals. AKI generally follows after 48 to 72 hours.

Aggressive intervention with intravenous sodium bicarbonate to enhance renal clearance of glycolate through ion trapping, intravenous ethanol or fomepizole (Antizol) to block the metabolism of ethylene glycol, and hemodialysis for removing ethylene glycol and glycolate should be initiated at the time of diagnosis. Regular monitoring of the osmolar gap (corrected for ethanol level if intravenous ethanol is being used during treatment) and anion gap will help guide therapy during hemodialysis.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

AKI associated with angiotensin-converting enzyme inhibitors is thought to be hemodynamic in origin, resulting from loss of autoregulation of renal blood flow and GFR, and has been typically reported when these drugs are given to patients with bilateral renal artery stenosis or with moderately advanced azotemia. Allergic acute interstitial nephritis similar to that observed with antibiotic administration has also been reported.

ENDOGENOUS NEPHROTOXINS

Rhabdomyolysis

Since the first description of the causative association between rhabdomyolysis and AKI in persons with crush injuries during World War II, the spectrum of causes of rhabdomyolysis, myoglobinuria, and renal failure has broadened. Rhabdomyolysis is most frequently the result of trauma or other injury, leading to muscle compression, ischemia, excess muscle activity associated with exercise or seizures, metabolic derangements (hypokalemia and hypophosphatemia), drugs, and infections. Cocaine use, neuroleptic malignant syndrome, and the use of hydroxymethylglutaryl coenzyme A reductase inhibitors (statin drugs) in the treatment of hypercholesterolemia also contribute to or cause rhabdomyolysis. Muscle pain and dark-brown orthotoluidine-positive urine without RBCs are important diagnostic clues, but the diagnosis must be confirmed by elevations of CPK and myoglobin. About one third of patients with rhabdomyolysis develop ARF, frequently associated with hyperkalemia, hyperuricemia, hyperphosphatemia, early hypocalcemia, and a reduced ratio of BUN to creatinine because of excessive creatinine release from muscle. Late hypercalcemia is also a typical feature of the disease.

The most important aspect of management will be rapid volume repletion. When patients are encountered in the field, intravenous fluids of normal saline at 200 to 300 mL per hour should be initiated. If urine output increases in 4 to 6 hours, the solution should be continued to match the urine output until the rhabdomyolysis resolves. However, if the patient continues to be oliguric (urine output < 400 mL per day), the infusion should be discontinued and the patient treated conservatively for AKI. Experience from recent disasters documents that early aggressive hydration and alkalini-zation (3 ampules of sodium bicarbonate to 1 L of 5% dextrose in water at 250 mL per hour) are capable of preventing myoglobinuric AKI by protecting the kidney from the nephrotoxicity of myoglobin and urate. The metabolic alkalosis induced will help protect the patient from hyperkalemia, which can be a lethal complication of rhabdomyolysis.

Hyperuricemic Acute Kidney Injury

AKI may occur in patients with *high-turnover* malignant diseases (acute lymphoblastic leukemia and poorly differentiated lymphomas) who either spontaneously or, more frequently, after cytotoxic therapy release massive amounts of purine uric acid precursors. This process leads to uric acid precipitation in the renal tubules. During massive cell lysis, phosphate and potassium are also released in large amounts, with resulting hyperphosphatemia and hyperkalemia. The peak uric acid level is often greater than 20 mg/dL, and a ratio of urinary uric acid to creatinine concentrations greater than 1 : 1 suggests the diagnosis of acute uric acid nephropathy. Prevention of AKI includes establishing a urinary output of 3 L or more per 24 hours, and treatment with allopurinol before cytotoxic therapy is instituted. More recent studies suggest that crucial to the management of tumor lysis syndrome (TLS) is the prompt initiation of a hypouricemic agent such as rasburicase. An established dose of 0.2 mg/kg of rasburicase is effective at decreasing uric acid levels sig-

nificantly in 4 hours of administration and to undetectable levels in 48 hours of initiation. Rasburicase has excellent tolerability and is potentially cost-effective in patients at high risk for TLS. Rasburicase is a safe and effective hypouricemic agent for both adults and children at high risk for TLS and for this reason should be considered the uricolytic agent of choice in these patients.

Hepatorenal Syndrome

The hepatorenal syndrome (HRS) is defined as kidney failure in patients with severely compromised liver function in the absence of clinical, laboratory, or anatomic evidence of other known causes of kidney failure. It closely resembles prerenal failure, except it does not respond to conventional volume replacement. Type I HRS is characterized by rapid decline in renal function within weeks and is most often seen in patients suffering from acute liver failure, acute alcoholic hepatitis, or acute decompensation of chronic liver disease. These patients tend to have severe hyperbilirubinemia, prolongation of prothrombin time, hyponatremia, and clinical evidence of portal hypertension and hepatic encephalopathy. Arterial blood pressure is usually low. Acute decompensation in type 1 HRS may be precipitated by bacterial infections, that is, spontaneous bacterial peritonitis, abdominal paracentesis, use of nephrotoxic antibiotics or NSAIDs, overzealous use of diuretics, diarrhea, and gastrointestinal bleeding. If left untreated, it runs a rapid downhill course resulting in death of the patient within weeks. Type 2 HRS is characterized by insidious onset and slowly progressive deterioration of renal function. This is most often seen in patients with decompensated cirrhosis and portal hypertension. This group of patients has low to normal blood pressure, less jaundice, and also refractory ascites. It tends to run a slowly progressive downhill course over months. The hallmark of hepatorenal syndrome is oliguria with urine osmolality two to three times the concentration of plasma, as well as urine that is virtually sodium free, similar to that of patients with prerenal azotemia.

In patients with hepatorenal syndrome, there is marked splanchnic and systemic vasodilation that results in arterial hypotension, arteriolar baroreceptor unloading, and overstimulation of sympathetic nervous and renin-angiotensin systems. This reflex neurohumoral hyperactivity, through endogenous vasoconstrictors and vasopressors such as angiotensin II and noradrenaline, induces arterial vasoconstriction in different extrasplanchnic vascular beds, including preglomerular arteries in the kidney. Recent randomized clinical trials have shown that treatment with a combination of the vasopressin analogue terlipressin plus intravenous albumin improved renal function in patients with type 1 HRS.

Acute Kidney Injury Related to Pregnancy

AKI of pregnancy is presently a rare occurrence in industrialized nations, occurring in about 1 in 20,000 deliveries. This decreased incidence is directly related to legalization of abortion in many countries.

AKI associated with infection following an abortion may be precipitated by hypotension, hemorrhage, sepsis, and disseminated intravascular coagulopathy. Although many organisms can be involved, the most serious and common

infection associated with AKI is that caused by *Clostridium* species. The clinical picture may be associated with hemolysis as a result of the production of a toxin. Aggressive management with broad-spectrum antibiotics and dialysis support are the mainstays of therapy for this group of patients.

Pyelonephritis, or urinary tract infection, is one of the most common medical complications of pregnancy. About 25% of patients can develop a transient decline in GFR during pyelonephritis. These patients should be treated initially with intravenous antibiotics followed by oral antibiotics for up to 2 weeks of therapy.

In the third trimester, AKI is associated with and is secondary to complications of pregnancy, including preeclampsia, postpartum hemorrhage, amniotic fluid embolism, placental abruption, and retained fetal and placental parts. A renal failure pattern resembling ATN is seen in patients suffering from preeclampsia and peripartum hemorrhage. Bilateral cortical necrosis may occur in association

with any type of ischemic injury and appears to have a disproportionate incidence in pregnancy compared with the nonpregnant adult. Abruption placentae can also cause ATN but is most commonly associated with renal cortical necrosis. The syndrome involving hemolysis, elevated liver enzymes, and low platelets (HELLP syndrome) in association with preeclampsia has been associated with ARF in up to 7.7% of patients.

Postpartum AKI, also known as *postpartum hemolytic uremic syndrome*, is characterized by hypertension and microangiopathic hemolytic anemia and occurs 1 day to several months after delivery, the most common time frame being from 2 to 5 weeks postpartum. The mainstay of treatment is plasma exchange, with a maternal survival rate of 70% to 80%, compared with the 90% mortality rate that existed before the use of plasma exchange. Elevation of lactate dehydrogenase in HUS versus elevated transaminases in HELLP syndrome may provide help in distinguishing these two syndromes.

Prospectus for the Future

Members representing key societies in nephrology and critical care worldwide have organized a group called the *Acute Kidney Injury Network* to address many of the critical issues facing this field. Consensus conferences and research initiatives, as well as establishment of a clinical trials network emerging from such initiatives, are likely to provide significant advances in the field in the next decade. It is generally accepted that many of the clinical trials in AKI have failed because of late intervention. There is urgent need to identify biomarkers that indicate early kidney injury and predict development of renal failure before the changes in serum creatinine. There are several groups in the United States and elsewhere critically

evaluating biomarkers for this purpose and other biomarkers that may have prognostic and therapeutic implications. Patients at risk for AKI are likely to be identified by specific genetic differences that predispose patients to the development of AKI. For example, patients who develop repeated episodes of rhabdomyolysis-induced AKI have been found to have genetic polymorphisms of carnitine palmitoyltransferase enzymes, a series of mitochondrial enzymes involved in the metabolism of fatty acids. Similarly, it may be possible to detect why, for example, only about 15% of patients develop aminoglycoside nephrotoxicity. Thus, in the future, it may be possible to target specific therapies that minimize potential side effects.

Chronic Renal Failure

Kerri Cavanaugh and T. Alp Ikizler

Chronic kidney disease (CKD) is defined as progressive and irreversible loss of renal function. The spectrum of CKD ranges from proteinuria to elevated serum creatinine, representing a decrease in the glomerular filtration rate (GFR), and finally complete loss of kidney function, that is, end-stage renal disease (ESRD). According to the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI), CKD is classified into stages 1 to 5, based on GFR and irrespective of the underlying etiology (Table 33-1). In stages 1 and 2, in which GFR is more than 60 mL/1.73 m² per minute, evidence of kidney damage, such as proteinuria, hematuria, or other abnormalities in blood, urine, or imaging tests, must be present to meet the diagnostic criteria of CKD. Additionally, evidence of kidney damage must be present and persistent for at least 3 months to differentiate CKD from acute kidney injury.

CKD is a worldwide public health problem. First, in the United States, the prevalence of CKD estimated by population-based studies is about 20 million people. Many people with CKD will progress to kidney failure and require dialysis or a kidney transplantation. ESRD is the term used in the United States to describe people with kidney failure who are eligible to receive either dialysis or a kidney transplantation. Trends in the incidence and prevalence of ESRD suggest a continuing increase in the numbers of patients requiring care at least for the next few decades (**Web Fig. 33-1**). Care of the ESRD patient is costly, accounting for \$23 billion (6.4%) of the U.S. Medicare budget in 2006. Second, elevated serum creatinine has been increasingly recognized as an independent risk factor for cardiovascular disease and death. Thus, classification of CKD will identify the patient at risk not only for renal loss but also for decreased survival.

The most common causes of ESRD are listed in Table 33-2. During the evaluation of CKD, every attempt should be made to arrive at the specific cause of kidney disease. Laboratory measurements of the serum creatinine concentration over a period of time (at least 3 months) will help differentiate between acute kidney injury and CKD. Renal biopsy is the most specific tool to reach a definitive diagnosis and guides treatment of the underlying cause, assessment of the prognosis, and determination of suitability for kidney transplantation. However, the procedure itself has potential

complications, and clinical information, including present, past, and family histories, serology, examination of the urine sediment, and renal imaging may be sufficient to provide a conclusive diagnosis.

Pathophysiology of Chronic Kidney Disease

To ensure adequate solute, water, and acid-base balance, the surviving nephrons must adjust by increasing their filtration and excretion rates. Patients with CKD, especially at stages 3 to 5, are vulnerable to edema formation and severe volume overload, hyperkalemia, hyponatremia, and azotemia. During progressive kidney disease, sodium balance is maintained by increasing fractional excretion of sodium by the nephrons. Acid excretion is maintained until the late stages of CKD, when the GFR falls to less than 15 mL per minute. Initially, increased tubular ammonia synthesis provides an adequate buffer for hydrogen in the distal nephron. Later, a significant decrease in distal bicarbonate regeneration results in hyperchloremic metabolic acidosis. Further loss of nephron mass leads to the retention of organic ions such as sulfates, which results in an anion gap metabolic acidosis.

It has been appreciated for several decades that once GFR has decreased to below a critical level, CKD tends to progress relentlessly toward ESRD, regardless of the initial insult. This observation suggests that loss of a critical number of nephrons provokes a vicious cycle of further nephron loss. Figure 33-1 shows how risk factors may interact with pathophysiologic mechanisms to accelerate CKD progression. Detailed studies have elucidated a number of interrelated mechanisms that together contribute to CKD progression, including glomerular hemodynamic responses to nephron loss, proteinuria, and proinflammatory responses. Tubular hypertrophy is associated with increased energy expenditure, a metabolic event related to generation of reactive oxygen metabolites. Reactive oxygen metabolites have been proposed as a mechanism of tubulointerstitial damage in animal models. In addition, hyperlipidemia is believed to play a role in progressive kidney disease through mesangial

Table 33-1 Classification of Chronic Kidney Disease and U.S. Prevalence Rates

Stage	Description	GFR, (mL/1.73 m ² /min)	U.S. Prevalence* (millions) (%)	U.S. Prevalence
1	Kidney damage† with normal or increased GFR	≥90	3.6	1.8
2	Kidney damage† with mildly decreased GFR	60-89	6.5	3.2
3	Moderately decreased GFR	30-59	15.5	7.7

proliferation and sclerosis. Activation of the renin-angiotensin-aldosterone system (RAAS) pathway and increased transforming growth factor- β (TGF- β) also play critical roles in leading to renal fibrosis. The observation that interventions that reduce intraglomerular pressure, such as protein restriction and the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin-receptor blockers (ARBs), help attenuate progression of renal disease further support the importance of glomerular hemodynamics and RAAS in progressive kidney disease.

Care of the Patient with Chronic Kidney Disease

Comprehensive care of kidney disease includes screening, diagnosing, and treating CKD and complications of CKD to prevent CKD development and progression (**Web Fig 33-2**). Screening for CKD is recommended in patients with high-risk co-morbid disease, including diabetes mellitus and hypertension, and also those with a family history of kidney disease. Once a diagnosis of CKD is established, management goals include (1) prevention of progression of CKD, (2) identifying and treating symptoms and complications of CKD, and (3) preparing patients for renal replacement therapy (RRT).

PREVENTION OF PROGRESSION

In addition to treatment of the specific underlying cause of kidney disease, methods used to slow progression of CKD include optimal control of hypertension, diabetes, and other cardiovascular disease risk factors (i.e. tobacco cessation), use of medications that block the RAAS pathway, diet modifications, avoidance of nephrotoxins, and addressing potentially reversible causes of acute kidney injury in the setting of CKD.

MANAGEMENT OF HYPERTENSION AND DIABETES

Several controlled trials have conclusively confirmed that aggressive management of hypertension attenuates the rate of progression of kidney disease, with significant benefits being shown in patients with diabetic kidney disease and other etiologies of CKD. The present recommendation is to target blood pressure to lower than 130/80 mm Hg in patients with diabetes or kidney disease. In addition, studies demonstrate that medications that block the production or effect of angiotensin II prevent the progression of CKD above and beyond control of hypertension in patients with diabetic and nondiabetic kidney disease and proteinuria. Dihydropyridine calcium channel blockers have not been shown to be as beneficial as ACE inhibitors or ARBs in slowing the progression of kidney disease. To reach optimal blood pressure control, an average of 2.7 antihypertensive medications will be needed per patient. When using a patient-centered multidisciplinary approach, it is important to evaluate the impact of therapy on a person's lifestyle to minimize side effects and maximize adherence to recommended therapies.

Diabetes mellitus is the leading cause of CKD in developed countries and is increasing in prevalence worldwide because of the epidemics of type 2 diabetes mellitus and obesity. For patients with diabetes mellitus, it is essential to screen annually for evidence of proteinuria as an indicator of CKD because an estimated GFR alone may not adequately reflect kidney damage due to diabetes. Adequate glycemic control in patients with diabetes mellitus and CKD is shown to prevent progression of CKD. Recommended goal glycosylated hemoglobin (A1C) measures are less than 7% irrespective of a concurrent diagnosis of CKD. For patients with diabetes mellitus and hypertension, ACE inhibitors and ARBs are the preferred medications for therapy because they

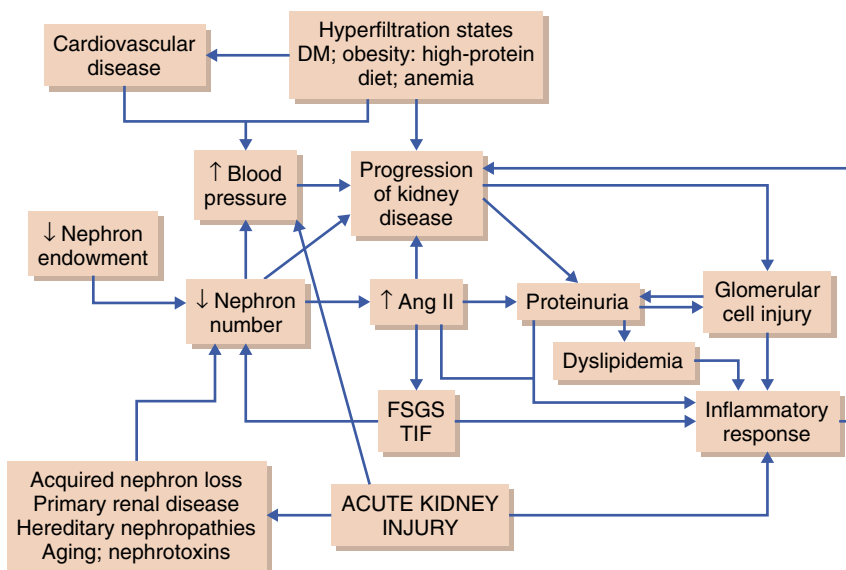

Figure 33-1 A simplified depiction of risk factors interacting with pathophysiologic mechanisms to accelerate chronic kidney disease progression. (Adapted from Taal MW, Brenner BM: Predicting initiation and progression of chronic kidney disease: Developing renal risk scores. *Kidney Int* 70:1694-1705, 2006.)

slow the progression of CKD. ACE inhibitors and ARBs may also be considered in patients with diabetes and proteinuria, but without hypertension, to slow CKD progression.

Diet

Dietary protein restriction is advocated to reduce uremic symptoms and slow progression of CKD. Several meta-analyses indicate that reduced protein diets may be modestly beneficial to slow CKD progression, but the largest clinical trial, the Modification of Diet in Renal Disease (MDRD) study, did not show a significant benefit. The recommended dietary protein intake in advanced CKD (stage 4 or 5) is 0.60 g/kg per day and, if this is not accepted or tolerated, can be increased to 0.75 g/kg per day, with at least 50% of the protein being of high biologic value (Table 33-3). The primary concern of applying a low-protein diet in patients with advanced CKD is the risk for predisposition to poor nutritional state, which is a strong predictor of increased mortality if present at the initiation of dialysis. The present consensus is that aggressive dietary management in patients with CKD, with proper restriction of sodium, potassium, phosphorus, and protein intake, may reduce progression of CKD, albeit to a small extent. Such dietary interventions should be instituted only under closely supervised patients in whom dietary behaviors such as protein and caloric intake can be monitored and maintained in conjunction with a specialized dietician.

Avoiding Toxic Drug Effects

Many drugs that are excreted by the kidney should be avoided, or their doses should be reduced, in patients with renal insufficiency, as shown in Table 33-4. Drugs may injure the kidney in many ways, including direct toxicity leading to acute tubular necrosis, induction of interstitial nephritis, or development of urinary crystals that may obstruct the kidney. Common classes of medications that injure the kidney include antibiotics, specifically aminoglycosides; nonsteroidal anti-inflammatory drugs, including cyclo-oxygenase-2 (COX-2) inhibitors; and antiretroviral

Table 33-3 Recommended Intake of Protein and Energy in Kidney Failure

Chronic Kidney Disease	Protein	Energy
Stage 1-3 (GFR > 30 mL/min)	No restriction	No restriction
Stage 4-5 (GFR < 30 mL/min)	0.60-0.75 g/kg/day*	35 kcal/kg/day†
Dialysis		
Hemodialysis	>1.2 g/kg/day	35 kcal/kg/day†
Peritoneal dialysis	>1.3 g/kg/day	35 kcal/kg/day†

medications. Over-the-counter herbal medications, including aristolochic acids, have been suggested to cause CKD and kidney failure. Herbal supplements, such as St. John's Wort, may interact with kidney transplant medications and should be avoided. Additionally, iodinated radiocontrast agents can cause acute or acute-on-chronic kidney injury. Iso-osmolar contrast agents are less toxic than high-osmolar agents. Risk factors for contrast-induced acute kidney injury include volume depletion and underlying CKD. Patients at high risk for contrast-induced kidney injury should receive intravenous fluid hydration with normal saline, and the volume of the contrast should be minimized. Some studies appear to indicate that 0.45% saline with 50 mEq of sodium bicarbonate per liter 8 to 10 hours before and after the procedure is beneficial, but large-scale controlled studies are still needed because a meta-analysis showed controversial results. Recent studies have also suggested a protective role of *N*-acetylcysteine, 600 mg orally given twice a day, the day before and the day of the contrast exposure, suggesting a role of reactive oxygen species in the injury. More recently, an association between the contrast agent gadolinium, used in magnetic resonance imaging (MRI), has been associated

Propoxyphene	Triamterene	Phosphate-containing bowel-preps

NSAIDs, nonsteroidal anti-inflammatory drugs.

with the severe fibrotic skin condition of nephrogenic systemic fibrosis in patients with CKD, but with the majority with ESRD receiving dialysis therapy. Caution must be exercised when considering MRI evaluations requiring contrast in patients with advanced CKD.

Reversible Causes of Acute Deterioration in Kidney Function

The rate of decline in GFR for individual patients is log linear. Accordingly, plotting $1/\text{serum creatinine}$ against time usually predicts the rate at which a specific patient will reach ESRD, as shown in Figure 33-2. When such a patient suddenly shows acceleration of kidney failure, the differential diagnosis for such acceleration should be considered and investigated, as presented in Table 33-5. Recent evidence indicates that diagnosis of in-hospital acute kidney injury is associated with a higher rate of progression of kidney disease and increased incidence of ESRD, emphasizing the importance of detection and prevention of acute kidney injury.

CLINICAL MANIFESTATIONS

General Features of Uremic Syndrome

Patients with CKD usually do not become symptomatic until the GFR is less than 15 mL per minute. *Uremia* is a syndrome that affects every organ system. Uremic syndrome is likely the consequence of a combination of factors, including retained molecules, deficiencies of important hormones, and metabolic factors, rather than the effect of a single uremic

toxin (Fig. 33-3). Among these toxins, urea can cause symptoms of fatigue, nausea, vomiting, and headaches. Its breakdown product (cyanate) can result in carbamylation of lipoproteins and peptides and adverse effects, leading to multiple organ dysfunctions.

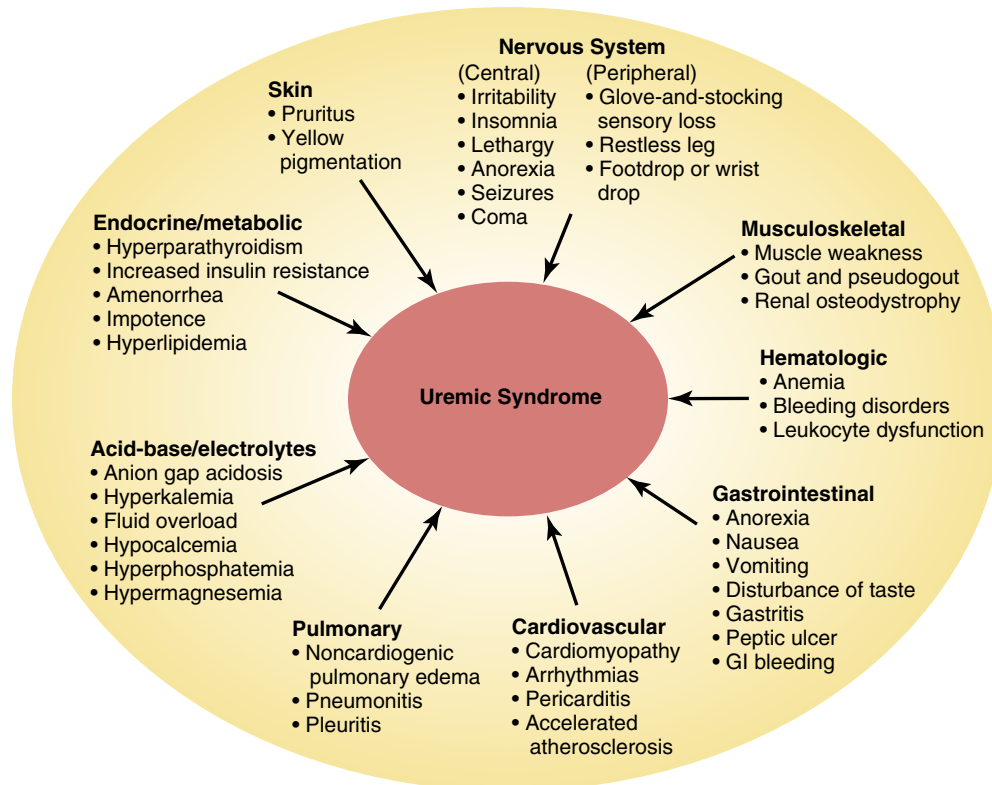

Figure 33-4 Diagrammatic summary of the major manifestations of the uremic syndrome. GI, gastrointestinal.

Guanidines, byproducts of exogenous or endogenous protein metabolism, are increased in renal failure. These byproducts can inhibit α_1 -hydroxylase activity within the kidney and can lead to deficient calcitriol production and secondary hyperparathyroidism. High parathyroid hormone levels have been implicated in various manifestations of uremia, especially in cardiomyopathy and metastatic calcifications. β_2 -microglobulin accumulation in patients with ESRD has been associated with neuropathy, carpal tunnel syndrome, and amyloid infiltration of the joints.

Signs and Symptoms of Uremia

Major manifestations of uremia are shown in Figure 33-4.

Cardiovascular

In addition to hypertension, cardiovascular disorders are common in patients with CKD. Mortality from cardiovascular disease in CKD patients, especially those with stage 3 to 5 disease, is 3.5 times that of an age-matched population (Web Fig. 33-3). Heart disease accounts for more than 50% of the deaths in ESRD patients. More than 60% of patients who start dialysis have echocardiographic manifestations of left ventricular hypertrophy, dilation, and systolic or diastolic dysfunction. Anemia and hypertension contribute to left ventricular hypertrophy and congestive heart failure. Secondary hyperparathyroidism can lead to metastatic calcification in the myocardium, cardiac valves, and arteries. Accelerated atherogenesis is responsible for the high prevalence of coronary artery disease in this population and the high rate of recurrent coronary artery stenosis after angioplasty. Arrhythmias, including those resulting in sudden death, may result from electrolyte abnormalities or are

related to ischemic cardiovascular disease. Pericarditis can occur in patients with uremia before they start dialysis, as well as in patients who are already undergoing dialysis, usually related to inadequate dialysis. Initiation of dialysis or intensifying dialysis therapy usually successfully treats pericarditis.

Gastrointestinal

Gastrointestinal disturbances are among the earliest and most common signs of the uremic syndrome. Patients with kidney failure usually describe a metallic taste and loss of appetite. Later, they experience anorexia, nausea, vomiting, and weight loss, and those with severe uremia may also experience stomatitis and enteritis. Several pathologic processes due to uremia can lead to a higher risk for gastrointestinal bleeding. This may be caused by gastritis, peptic ulceration, and arterial venous malformations in addition to platelet dysfunction.

Neurologic

Central nervous system (CNS) manifestations are frequent and occur rather late, often with development of fatigue and anorexia. They are mostly characterized by changes in cognitive function and memory and by disturbances in sleep. Lethargy, irritability, asterixis, seizures, and frank encephalopathy with coma are late manifestations of uremia and are usually avoided by early initiation of dialysis. Peripheral neurologic manifestations appear as a progressive symmetrical sensory neuropathy in a glove-and-stocking distribution. Patients have decreased distal tendon reflexes and loss of vibratory perception. Peripheral motor impairment can result in restless legs, footdrop, or wristdrop. Optimal

Figure 33-5 Calcium and phosphate homeostasis in the setting of renal failure. The decreased excretion of phosphate initiates the cycle directed at normalization of the serum calcium concentration. PTH, parathyroid hormone.

dialysis or transplantation has been shown to reverse most of the CNS peripheral neurologic manifestations.

Musculoskeletal

Alterations in calcium and phosphate homeostasis and renal osteodystrophy, with hyperparathyroidism and disturbance of vitamin D metabolism, are common manifestations of CKD and kidney failure. Hypocalcemia and secondary hyperparathyroidism are the results of phosphate retention and the lack of α_1 -hydroxylase activity in the failing kidney, with consequent deficiency of the most active form of vitamin D. Over time, the adaptive parathyroid hypertrophy becomes maladaptive and leads to bone disease and tissue calcification. Calcium and phosphate homeostasis in the setting of kidney failure is demonstrated in Figure 33-5. Control of hyperparathyroidism is achieved with dietary phosphate restriction, oral phosphate-binding medications, calcium and vitamin D supplementation, and dialysis therapy. Calcimimetics are a novel class of drug that targets calcium-sensing receptors on the parathyroid gland and sensitizes them to the inhibitory effect of serum calcium. This action inhibits parathyroid hyperplasia and treats secondary hyperparathyroidism related to kidney disease.

Hematologic and Immunologic

Erythropoietin (EPO), a hormone produced by the kidney that regulates erythrocyte production, becomes progressively deficient as kidney failure progresses and renal mass declines. EPO and iron deficiency are common causes of anemia in CKD. Administration of synthetic EPO every 1 to 2 weeks to patients results in correction of anemia, improved

quality of life and anemia-related symptoms, and decreased dependence on blood transfusions. Caution must be exercised because high doses of EPO resulting in elevations of the serum hemoglobin to more than 13 g/dL may be associated with a higher risk for adverse cardiovascular events. Bleeding disorders, primarily from defects in platelet adherence and aggregation, are common in patients with uremia. Uremic bleeding can be generally controlled with cryoprecipitate, 1-deamino-(8-D-arginine)-vasopressin, conjugated estrogens, and dialysis.

Defects occur in both the humoral and cellular immune systems in patients with kidney failure. Although the leukocyte count is normal and appropriately responsive in advanced kidney failure, patients are generally immunosuppressed and susceptible to infections. This may be due to functional abnormalities of polymorphonuclear leukocytes, lymphocytes, and other cellular host defenses. Additionally, because of these immune abnormalities, patients with CKD may not respond adequately to vaccination. However, it is still recommended that patients with CKD receive influenza and pneumococcal vaccinations, and as their kidney disease progresses, vaccination against hepatitis B virus.

Endocrine and Metabolic

Alterations in thyroid function testing may contribute to difficulty diagnosing thyroid disease in patients with uremia. Common laboratory findings may include an increased triiodothyronine resin uptake, a low triiodothyronine level resulting from the impaired conversion of thyroxine to triiodothyronine peripherally, and normal thyroxine levels. Thyroid-stimulating hormone levels are usually normal. On occasion, the use of a thyrotropin-releasing hormone stimulation test may be needed for a diagnosis of thyroid disorders in uremia. Interestingly, goiter is present in up to one third of patients with chronic renal failure.

A deranged pituitary-gonadal axis can result in sexual dysfunction exhibited by impotence, decreased libido, amenorrhea, sterility, and uterine bleeding. Hyperprolactinemia may be responsible for some of the abnormalities of the pituitary-gonadal axis. Patients have decreased plasma levels of testosterone, estrogen, and progesterone, with normal or increased levels of follicle-stimulating hormone and luteinizing hormones. Pregnancy is uncommon in female patients who have a GFR of less than 30 mL per minute.

As renal function diminishes, many patients with diabetes have a decreased insulin requirement. This change is partly a result of the increased half-life of exogenously administered insulin secondary to decreased renal insulin clearance, which may lead to development of frequent episodes of hypoglycemia in a person with diabetes who was well controlled on a stable insulin regimen. However, increased peripheral insulin resistance in patients with uremia has also been described. Insulin resistance occurs secondary to tissue insensitivity to insulin due to a postreceptor defect, as well as metabolic acidosis and hyperparathyroidism, which impair insulin release and secretion.

Lipid abnormalities are common findings in the early course of kidney disease. They are most consistent with type IV hyperlipoproteinemia, with a marked increase in plasma triglycerides and less of an increase in total cholesterol. The activity of lipoprotein lipase is decreased

in uremia, with a reduction in the conversion of very-low-density lipoprotein to low-density lipoprotein and thus hypertriglyceridemia. These abnormalities of lipid metabolism are considered contributors to accelerated atherosclerosis and contribute to mesangial proliferation and progressive kidney disease. The treatment of choice is the hydroxymethylglutaryl-coenzyme A reductase (HMG-CoA) inhibitor class of drugs because of their pluripotent effects on inflammation and atherosclerosis.

Acidosis and Electrolytes

As CKD progresses to a moderate impairment of kidney function, the kidney is unable to generate and excrete adequate acid, and a chronic metabolic acidosis may develop. This is typically an anion gap acidosis due to retained anions. Once the serum bicarbonate falls below 20 mEq/L, treatment with sodium bicarbonate or sodium citrate should be considered to prevent the exacerbation of bone disease or nutritional metabolic derangements.

Hyperkalemia occurs in patients with CKD as a result of progression of CKD resulting in oliguria and decreased renal clearance of potassium, intracellular to extracellular shifts of potassium in the setting of metabolic acidosis related to kidney failure, and also the concomitant use of medications such as ACE inhibitors, ARBs, or other medications that alter potassium clearance. The primary method of treatment is dietary reduction of potassium but may also include use of loop diuretics or potassium-binding medications. Hypokalemia is much less common in CKD but may occur in the setting of very poor nutritional intake or use of high-dose potassium-wasting diuretic medications.

Hyperphosphatemia is also very common as CKD progresses because of a reduction in renal clearance of phosphate. As described previously, this contributes to the development of secondary hyperparathyroidism in the kidney patient. Dietary reduction of phosphorus and use of phosphate-binding medications taken at each meal can successfully control serum phosphorus levels.

Skin

Uremic hue, a yellowish skin color, is likely the result of retained liposoluble pigments, such as lipochromes and carotenoids. Uremic hue usually responds to dialysis, control of hyperparathyroidism, improved calcium and phosphate balance, and, occasionally, ultraviolet rays. Calciphylaxis, or calcific uremic arteriolopathy, results in painful skin calcification and is often seen in patients with a serum calcium x phosphate product that exceeds 70 mg/dL in the presence of severe hyperparathyroidism. Nail findings include the half-and-half nail, characterized by red, pink, or brownish discoloration of the distal nail bed, pale nails, and splinter hemorrhages. Other common signs and symptoms include pruritus, pallor related to anemia, and ecchymoses due to disorders of bleeding.

Care of the Patient with End-Stage Renal Disease

As CKD progresses to kidney failure, it is important to prepare for the initiation of renal replacement therapies. Patients with moderately advanced kidney disease (CKD

stage 4) should be referred to a nephrologist for co-management. This may include evaluation of risk for CKD progression, estimation of timing until kidney failure, and introduction of and preparation for the modalities of renal replacement therapy. Late referral (<3 months before ESRD) to a nephrologist is associated with a higher risk for death after initiation of renal replacement therapy.

RENAL REPLACEMENT THERAPIES

A plan for a modality of RRT should be discussed with the patient early in the course of kidney failure and before the appearance of uremic symptoms. The two primary treatments for ESRD are dialysis and transplantation. There are two types of dialysis, hemodialysis and peritoneal dialysis. Kidney transplants may be from either deceased or living donors. In the United States in 2006, 101,306 patients began hemodialysis, whereas only 6,758 (6%) elected peritoneal dialysis. First kidney transplantations were performed in 15,918 people, although most of these patients (83%) received dialysis for some period of time before receiving a kidney transplant. This distribution of patients on various modalities differs in other countries. Chronic dialysis is usually initiated when the GFR is 15 mL per minute or less and there are no apparent reversible causes of kidney failure. However, chronic dialysis may be started at any time when complications of ESRD, such as fluid balance and potassium levels, cannot be controlled medically. The choice of dialysis modality largely depends on the patient's physical characteristics, social support exposure to pre-ESRD patient education, and lifestyle choices. In medically eligible patients, kidney transplantation is encouraged because it allows a better quality of life, increased survival rate, and greater chance for rehabilitation.

Hemodialysis

As illustrated in Figure 33-6, blood is pumped from a temporary or permanent vascular access into tubing that leads to a large number of capillaries bundled together in a dialyzer (**Web Fig. 33-4**). The capillaries are made up of semi-synthetic materials that are biocompatible. This membrane is semipermeable and is capable of allowing exchange of small molecules across the concentration gradient by diffusion. Moving in the opposite direction to blood is a dialysate solution that is passing through outside the capillaries, thus allowing countercurrent exchange. This solution contains sodium chloride, bicarbonate, and varying concentrations of potassium. Diffusion through the membrane allows low-molecular-weight substances such as urea, potassium, and organic acids to move across according to the concentration gradient. Fluid is removed by *ultrafiltration*, which is achieved by applying transmembrane hydrostatic pressure across the dialyzer.

In the setting of ESRD, an average patient undergoing *intermittent* chronic hemodialysis requires 4 hours of dialysis 3 times a week to adequately remove toxins. The treatment requires a blood flow of about 400 mL per minute from the access to the dialysis machine. Common complications associated with hemodialysis treatments include hypotension and muscle cramping. Avoiding excessive weight gain (more than 2 to 3 kg) between treatments can minimize these complications.

Figure 33-6 Essential components of a dialysis delivery system that, together with the dialyzer, make up an *artificial kidney*. In isolated ultrafiltration, no dialysis fluid is used (bypass mode). Also shown is the apparatus for using a single needle for inflow and outflow of blood from the patient (From Keshaviah PR: Hemodialysis monitors and monitoring. In Maher JF [ed]: Replacement of Renal Function by Dialysis, 3rd ed. Boston, Kluwer Academic Publishers, 1989. Reprinted by permission of Kluwer Academic Publishers.)

Access for Hemodialysis

The recommended access for hemodialysis is a permanent access such as an arteriovenous fistula (AVF) or arteriovenous graft (AVG) (**Web Fig. 33-5**, **Web Table 33-1**). In certain instances, a temporary or permanent indwelling catheter can be used for hemodialysis. Although the goal is for at least 66% of prevalent dialysis patients to use an AVF for dialysis access (<http://www.fistulafirst.org>), many patients continue to use AVGs or catheters. Temporary catheters are placed into internal jugular, subclavian, or femoral veins the way central venous lines are placed and can be used for a short time. Permanent catheters have a cuff around the outer wall of the tubing and tunnel under the chest wall skin for some distance before entering the internal jugular vein. The cuff causes local fibrosis in the subcutaneous tissue, thus sealing the access of skin flora into the catheter and reducing the infection rates. However, catheters have much higher rates of infection, lower blood flow rates, and a higher risk for mortality compared with AVF and AVG.

Peritoneal Dialysis

Peritoneal dialysis is a type of RRT in which the peritoneal capillaries act as a semipermeable membrane similar to a hemodialysis filter. This technique has several advantages over hemodialysis because it allows independence from the long time spent in dialysis units, it does not require as stringent dietary restrictions as in hemodialysis, and rehabilitation rates are better than those observed in hemodialysis, with more patients returning to full-time employment. Residual renal function is maintained for a longer period (e.g., 1 to 2 years) while the patient receives peritoneal dialysis, thus improving morbidity and mortality. In continuous ambulatory peritoneal dialysis, dialysate of 2- to 3-L volumes

is instilled through a peritoneal catheter (**Web Fig. 33-6**) into the peritoneal cavity for varying amounts of time and exchanged 4 to 6 times daily. In continuous cyclic peritoneal dialysis, the patient is connected to a machine referred to as a *cycler* that allows inflow of smaller volumes of dialysate with shorter dwell time overnight while the patient sleeps. This process allows patients to be actively working during the day. Several modifications in this regimen can be made to fit specific patients to achieve adequate clearance of toxins and fluid. The rate of removal of various solutes depends on the concentration gradient, surface area, and permeability of the peritoneal membrane to the solute. Smaller molecules move across the peritoneal membrane with ease and are influenced by ultrafiltration rates. Ultrafiltration is achieved through increasing dextrose concentration in the dialysate. The two major drawbacks of peritoneal dialysis are peritonitis and difficulty in achieving adequate clearances in patients with excess body mass. Peritonitis in patients undergoing peritoneal dialysis can be treated with intraperitoneal antibiotics, most often as outpatients. Catheter removal is indicated in some cases of peritonitis, for instance, bacterial peritonitis that is not responding to antibiotics and fungal peritonitis. Additionally, a slow deterioration occurs in the permeability of the membrane, especially after one or more peritonitis episodes, leading to inadequate dialysis and, ultimately, to the need to change the modality of RRT to hemodialysis.

Management of Complications in Dialysis

As with CKD, patients receiving dialysis therapy experience similar abnormalities in many related organ systems. The risk for cardiovascular disease, and cardiovascular events, remains very high in this complex patient population. Efforts to minimize cardiovascular risk, such as treatment of hypertension and screening for evidence of cardiac ischemia, are recommended. Tobacco cessation remains an important component of reducing cardiovascular risk. Recent studies in prevalent dialysis patients have not demonstrated that lowering lipid levels with statins reduces cardiovascular risk and mortality, although it may be that the greatest impact of lipid lowering can be made in the CKD patient before reaching ESRD. Anemia, hyperphosphatemia, and hyperparathyroidism are also common in patients receiving dialysis therapy, and treatment strategy is similar to that recommended for patients with CKD, albeit with minor differences in dosing and target levels.

Kidney Transplantation

Kidney transplantation is the preferred modality of RRT, although hemodialysis or peritoneal dialysis often is required before, during, or after transplantation. When cyclosporine became available in 1983, the success rate of kidney transplantation from deceased donors improved significantly, with an 85% to 90% 1-year graft survival rate, compared with 65% with azathioprine and steroids. A decrease in the incidence of acute rejection and some improvement in long-term allograft survival have been seen secondary to the introduction of newer immunosuppressive agents that include rapamycin, mycophenolate mofetil, tacrolimus, and anti-interleukin-2 receptor antibodies (daclizumab and basiliximab).

Table 33-6 Comparison of Donor Sources for Kidney Transplantation

Advantages	Disadvantages
Living Donor Better tissue match with less likelihood of rejection Smaller doses of drugs for immunosuppression Waiting time for transplant reduced Sequelae of long-term dialysis avoided Elective surgical procedure Better early graft function with shorter hospitalization Better short-term and long-term success	Small potential risk of operation to donor Requirement of willing, medically suitable family member or other person
Deceased Donor Availability to any recipient Availability of other organs for combined transplants (i.e., kidney-pancreas transplant) Availability of vascular conduits for complex vascular reconstruction	Tissue match not as similar Waiting time variable Operation performed urgently Early graft function possibly compromised Short-term and long-term success not as good as from living donor

Types of Kidney Transplants

Kidney transplant donors may be deceased or living and, among those living, may be related or unrelated.

Advantages and disadvantages of deceased versus living donors are listed in Table 33-6. Because the deceased donor organ supply is inadequate, the pressure for living kidney donation has increased. Unrelated donors with a stable and close emotional relationship with the recipient or who have agreed to an equitable kidney exchange as part of a kidney transplant program may be appropriate for donation. Survival of grafts from living unrelated donors is better than survival of grafts from deceased donors, despite less histocompatibility matching of human leukocyte antigen (HLA). The main advantages of a living related donor transplant are less ischemic injury and histocompatibility matching. Figure 33-7 is a representation of the inheritance pattern of HLA within a family. HLA-identical matches consistently demonstrate superior graft survival and reduced chance for rejection than less well-matched living or deceased donor renal transplants. However, with procedures to reduce antibodies, including plasmapheresis and pre-transplantation immunosuppressive therapy, it is possible to successfully perform kidney transplantations in ABO blood group-incompatible pairs.

Immunosuppressant Drug Therapy

Prophylaxis against and treatment of graft rejection are at the heart of the success of kidney transplantation. All protocols for immunosuppression aim at disruption of the lymphocyte cell cycle, and many include some period of exposure to corticosteroids. Since the introduction of cyclosporine in the early 1980s, the number of drugs capable of suppressing the immune system has increased steadily. These agents, by virtue of their specific mode of action, have succeeded in preventing most patients from having early and irreversible graft rejections without severe toxic effects. The mechanism of action of some of the most commonly used immunosuppressants is illustrated in Figure 33-8.

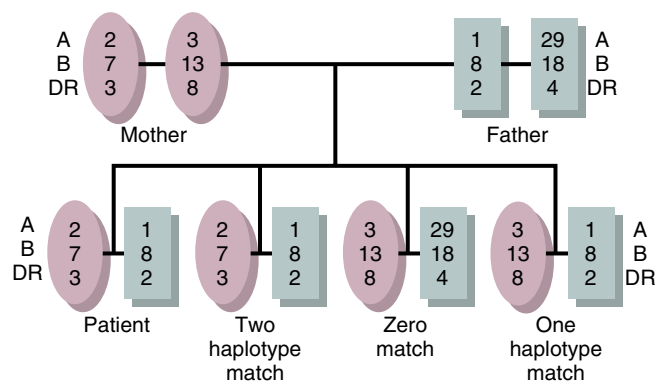

Figure 33-7 Diagrammatic representation of inheritance of human leukocyte antigen tissue types in a family with four siblings.

The hepatic cytochrome P-450 system is essential for cyclosporine, tacrolimus, and rapamycin metabolism. Significant changes in the levels of these drugs may occur when patients start or discontinue taking any of several drugs that can induce or inhibit this system. Therefore, evaluation for drug-drug interactions is critical to prevent toxic or even subtherapeutic effects of either the immunosuppressant drug or the other prescribed therapy.

Cyclosporine exerts its specific immunosuppressive activity by inhibiting immunocompetent lymphocytes in the G₀ and G₁ phases of the cell cycle. Some of the most important side effects of cyclosporine include hematologic suppression, hyperkalemia, seizures, exacerbation of gout, dyslipidemia, and gingival hypertrophy. Most effects respond to an appropriate dose reduction. The most significant of these effects is nephrotoxicity, and this is often related to decreased glomerular blood flow.

Tacrolimus has a mechanism of action and side-effect profile similar to those of cyclosporine but with the additional problems of hyperglycemia and an increased tendency

Figure 33-8 Pathways of T-cell activation and site of action of immunosuppressive agents. ATG, antithymocyte globulin; AZA, azathioprine; IL, interleukin; MHC, major histocompatibility complex; MMF, mycophenolate mofetil; MTOR, mammalian target of rapamycin; NFAT, nuclear factor of activated T-cells; TCR, T-cell receptor.

toward neurotoxicity. Both cyclosporine and tacrolimus can cause calcineurin inhibitor nephrotoxicity, which may contribute to chronic allograft nephropathy and ultimately graft loss.

Mycophenolate mofetil or *mycophenolic acid* specifically inhibits T-lymphocyte and B-lymphocyte proliferation by interfering with purine synthesis and thus DNA synthesis. Mycophenolate mofetil has been associated with a 60% to 70% reduction in acute transplant rejection compared with conventional therapies and thus promotes long-term graft survival. Side effects include anemia and leucopenia as well as gastrointestinal symptoms.

Rapamycin is a macrolide antibiotic produced by the fungus *Streptomyces hygroscopicus*. Rapamycin binds to the mTOR (mammalian target of rapamycin) receptor, thus blocking the phosphorylation of *p70(s6)* kinase and the eukaryotic initiation factor 4E-binding protein, PHAS-I. This action leads to the dampening of cytokine and growth factor activity on T, B, and nonimmune cells. The major side effects are thrombocytopenia and dyslipidemia (primarily hypertriglyceridemia).

Acute Rejection

T lymphocytes survey the human body and are capable of recognizing foreign antigens when these antigens are presented in association with HLA antigens, especially class II histocompatibility antigens. When the recipient's helper cells identify foreign HLA class II antigens presented by dendritic or other antigen-presenting cells in the transplanted kidney, lymphocyte activation occurs. Activated cytotoxic lymphocytes invade the tubular interstitial region of the transplanted kidney, with resulting tubulitis. Clinically, acute rejection is detected by graft tenderness, rise in serum creatinine levels, oliguria, and, in some instances, fever. Frequent monitoring of kidney function has allowed early detection of acute rejection based on rising serum creatinine before any clinical signs or symptoms become apparent.

Acute rejection episodes have a negative impact on long-term graft survival. Acute humoral rejection involves the intrarenal arteries and leads to vasculitis, carrying a poor prognosis. This type of rejection is usually resistant to steroids, thus necessitating antilymphocyte and possibly plasmapheresis therapy.

Post-transplantation Infection

Infection is second only to cardiovascular disease as the leading cause of mortality in kidney transplant recipients. Prophylaxis therapies are often used immediately after kidney transplantation to prevent infectious diseases that are of particularly high risk, including *Pneumocystis jirovecii* pneumonia, urinary tract infections, and cytomegalovirus infection. In addition to common community-acquired bacterial and viral infections, kidney transplant recipients are also susceptible to numerous viral, fungal, and other opportunistic infections that normally do not cause severe illness in the immunocompetent host. Fortunately, the timetable of these infections is predictable, and an educated guess based on the time of infection after transplantation, together with the specific set of syndromes associated with each infection, can help early recognition and prompt empirical treatment pending confirmatory tests. Figure 33-9 shows the temporal relationship of infections in renal transplantation.

Post-transplantation Malignant Disease

Immunosuppression increases the risk for developing malignant disease. Skin cancer (mostly squamous cell) has the highest incidence in transplant recipients compared with all other types of malignancy. Sun exposure is the most significant risk factor, and skin protection provides excellent primary prevention. With continuous surveillance and aggressive management, metastasis from skin cancers is rare.

Transplant recipients are also at high risk for developing non-Hodgkin lymphoma and Kaposi sarcoma, a rare

Figure 33-9 Timetable for the occurrence of infection in the renal transplant recipient. Exceptions to this timetable should initiate a search for an unusual hazard. CMV, cytomegalovirus; CNS, central nervous system; EBV, Epstein-Barr virus; HSV, herpes simplex virus; TB, tuberculosis; UTI, urinary tract infection; VZV, varicella-zoster virus. (From Rubin RH, Wolfson JS, Cosimi AB, et al: Infection in the renal transplant recipient. *Am J Med* 70:405-411, 1981. Copyright 1981 by Excerpta Medica, Inc.)

occurrence in the immunocompetent host. In addition to age-appropriate screening, cancer surveillance should be an essential part of post-transplantation follow-up. Transplant

recipients should be educated to recognize and report early changes in bowel habits, respiratory symptoms, hematuria, musculoskeletal symptoms, skin changes, or weight changes.

Prospectus for the Future

In the CKD population, the major challenges will be to slow the progression of kidney disease by identifying novel targets and development of new immunosuppressive regimens or therapies to achieve tolerance after transplantation. Other efforts include the following:

- Biomarkers of chronic kidney disease
- More sensitive markers of kidney function such as serum cystatin-C

- Development of an artificial kidney
- Development of laboratory tests to measure the overall immune reactivity of solid organ transplant recipients in order to customize treatment protocols without the risk for rejection or opportunistic infections
- Genetic manipulation of animals to succeed in xenotransplantation

Common Clinical Manifestations of Gastrointestinal Disease

A. Abdominal Pain

Charles M. Bliss, Jr. and M. Michael Wolfe

Abdominal pain is a frequent manifestation of intra-abdominal disease. Abdominal pain is difficult to localize or grade because the sensation of pain is colored by emotional and physical factors. Abdominal pain may be classified as acute or chronic. Acute pain occurs suddenly and suggests serious physiologic alterations. Conversely, chronic pain may be present for several months; although it does not mandate immediate attention, chronic pain may lead to prolonged evaluation. Appropriate evaluation of abdominal pain requires knowledge of pain mechanisms, close attention to history and physical examination findings, and recognition of important accompanying symptoms as well as awareness of the strengths and weaknesses of the tests that might be used.

Physiology

Abdominal pain results from stimulation of receptors specific for thermal, mechanical, or chemical stimuli. Once these receptors are excited, pain impulses travel through sympathetic fibers. Abdominal pain can be characterized as somatic or visceral. Somatic pain originates from the abdominal wall and parietal peritoneum, whereas visceral pain originates in internal organs and from the visceral peritoneum. Two types of neurons carry pain: A fibers, which have rapid conduction, and C fibers, which have slow conduction. Most visceral neurons are of the C type, and the pain resulting from their stimulation tends to be variable with regard to sensation and localization. In contrast, fibers originating from the parietal peritoneum and abdominal wall are of

both the A and the C types, and the pain tends to be sharp and distinctly localized.

Because of this pattern of innervation, abdominal viscera are not sensitive to cutting, tearing, burning, or crushing. However, visceral pain results from stretching of the walls of hollow organs, or of the capsule of solid organs, as well as from inflammation or ischemia.

Causes of Abdominal Pain

Multiple intra-abdominal and extra-abdominal disorders can produce abdominal pain. Distinguishing acute from chronic abdominal pain is helpful. The approach varies with each specific cause, but acute abdominal pain generally demands prompt intervention.

Clinical Features

HISTORY

The differential diagnosis of abdominal pain, whether acute or chronic, requires thorough history taking with regard to pain characteristics, location and radiation, timing, and the presence of any other accompanying symptoms.

Pain location often indicates the organ responsible for the problem. For instance, epigastric pain is usually typical of peptic ulcer or dyspepsia, whereas right upper quadrant pain

Table 34-1 Key Abdominal Pain Syndromes

Condition	Type	Location	Radiation
Acute Abdominal Pain			
Appendicitis	Crampy, steady	Periumbilical, RLQ	Back
Cholecystitis	Intermittent, steady	Epigastric, RUQ	Right scapula
Pancreatitis	Steady	Epigastric, periumbilical	Back
Perforation	Sudden, severe	Epigastric	Entire abdomen
Obstruction	Crampy	Periumbilical	Back
Infarction	Severe, diffuse	Periumbilical	Entire abdomen
Chronic Abdominal Pain			
Esophagitis	Burning	Retrosternal	Left arm, back
Peptic ulcer	Gnawing	Epigastric	Back
Dyspepsia	Bloating, dull	Epigastric	None
IBS	Crampy	LLQ, RLQ	None

IBS, irritable bowel syndrome; LLQ, left lower quadrant; RLQ, right lower quadrant; RUQ, right upper quadrant.

is more suggestive of cholecystitis and other biliary disorders. Early in the course of illness, pain may be perceived in one location and subsequently felt in another; this pattern of progression may be suggestive of specific pain syndromes. In acute cases, abdominal pain tends to be sharp and severe. The pain of a perforated viscus is intense, and the pain from a dissecting aneurysm may be described as tearing or crushing. Chronic pain may be less severe; pain from irritable bowel or dyspepsia is constant and dull, and the pain of chronic peptic ulcer is described as gnawing or hunger pain. The pattern of pain relief is helpful for diagnosing some conditions. The physician should also inquire about whether pain is steady or intermittent and whether it occurs at night. For nocturnal pain, a distinction should be made between pain that awakens the patient and pain that is felt when the patient wakes up for other reasons.

Table 34-1 outlines characteristics, location, and radiation of pain for a few common acute and chronic abdominal conditions.

PHYSICAL EXAMINATION

Examination of the abdomen may provide invaluable clues to the diagnosis, but the examination should start with the general appearance of the patient. A patient writhing in bed and unable to find a comfortable position may be suffering from obstruction. In contrast, a patient lying with the lower extremities flexed and avoiding any motion may be suffering from peritonitis. Abdominal distention indicates obstruction or ascites. Visual inspection for peristalsis is helpful for the diagnosis of small bowel obstruction, but this sign is present only in the early stages. Focal areas of distention may indicate hernias; note should also be made of any scars from previous surgery.

Auscultation should be performed in several areas to evaluate the timber and pattern of bowel sounds as well as to search for bruits or hums. Absence of bowel sounds suggests ileus, whereas the presence of hyperactive, high-pitched sounds may indicate obstruction. Multiple bruits alert the examiner to the possibility of significant vascular disease, suggesting ischemia.

The abdomen should be palpated gently, starting in an area away from the area of pain. The physician searches for

areas of localized tenderness and rebound as well as for masses and enlarged organs. Percussion is performed to identify size of organs or to determine the presence of ascites. Pain on percussion of the abdomen indicates peritoneal reaction, as does severe rebound tenderness.

A rectal examination is important for identifying a rectal tumor in the case of colon obstruction or tenderness high in the rectum in acute appendicitis. Pelvic examination should be performed in women to rule out pelvic inflammatory disease.

Acute Abdomen

The acute abdomen is a challenging condition in medical practice. The first question to be answered is whether immediate surgery is needed. Therefore, a quick evaluation is necessary to avoid undue delay in intervention for patients who require surgery. Early surgical consultation should be obtained, even in doubtful cases, rather than awaiting confirmation of the diagnosis via laboratory or radiologic studies.

The acute abdomen is caused by sudden inflammation, perforation, obstruction, or infarction of various intra-abdominal organs. However, many extra-abdominal conditions such as pneumonia, myocardial infarction, nephrolithiasis, and metabolic disorders may cause acute abdominal pain.

In some instances, the acute abdomen, in its early stages, may show few findings. The examiner should be aware that patients with benign chronic conditions might come to the emergency department with severe pain that is out of proportion to any physical findings. With the acute abdomen, inquiring about medical history, particularly previous abdominal surgery, is important. Indeed, a patient with sudden crampy pain and abdominal distention may have intestinal obstruction caused by adhesions or an incarcerated hernia. Performing an entire examination of the patient, looking for jaundice, skin lesions, or evidence of chronic liver disease, is also important.

A complete blood cell count with differential, a urinalysis, and measurements of serum amylase, lipase, bilirubin, and electrolytes are necessary components of the laboratory

examination. Additional studies may be done but usually do not aid in the rapid decision making required in the evaluation of the acute abdomen. An elevated white blood cell count may indicate inflammatory disease, and extremely high values are quite typical of acute intestinal ischemia. An elevated serum amylase concentration usually indicates acute pancreatitis, although a perforated ulcer or mesenteric thrombosis may also cause hyperamylasemia.

Radiographic examination is an important part of the evaluation of the patient with an acute abdomen. An abdominal film is important in revealing the intra-abdominal gas pattern, and an upright film that includes the diaphragm or left lateral decubitus film may identify intra-abdominal air. Ultrasonography can be helpful in the diagnosis of acute cholecystitis or appendicitis. Computed tomography (CT) scans have become more helpful with technologic improvements in scanners; early CT scans allow prompt diagnosis of sometimes unsuspected abdominal diseases. Examination with a radiopaque medium should be used judiciously, especially if surgery is anticipated. **Web Figures 34-1 through 34-4** are CT images of appendicitis, diverticulitis, pancreatitis, and ulcerative colitis.

Chronic Abdominal Pain

Chronic abdominal pain poses a challenge for the physician to distinguish organic pain resulting from a specific pathologic process from functional pain. The location and characteristics of pain, as already discussed, serve as important guides, as do other accompanying symptoms. The presence of postprandial nausea and vomiting suggests chronic peptic ulcer, disorders of gastric emptying, or outlet obstruction. The documentation of weight loss mandates the search for

an organic cause, such as inflammatory bowel disease or celiac disease. If anorexia accompanies weight loss, particularly in elderly patients, cancer must be excluded. If no cancer can be found and all objective tests are normal, the possibility of chronic depression must be entertained.

The most frequent causes of chronic abdominal pain are *functional*. Dyspepsia is characterized by chronic intermittent epigastric discomfort, sometimes accompanied by nausea or bloating. These symptoms are not always relieved by acid suppression and may be the result of an underlying motor disorder. Furthermore, the eradication of *Helicobacter pylori*, when found in a patient with dyspeptic symptoms, may not necessarily lead to the resolution of symptoms. Controversy thus presently exists regarding the most effective strategy for the treatment of dyspepsia when *H. pylori* organisms are found in the absence of peptic ulcer disease.

Irritable bowel syndrome (IBS) is a common disorder. Estimates are that 15% of Americans suffer from IBS on a regular basis and that 40% to 50% of referrals to gastroenterologists are related to IBS. The syndrome consists of abdominal distention, flatulence, and disordered bowel function. The abdominal pain of IBS tends to be in the left lower quadrant, but it can be located elsewhere or be more generalized. Any patient with weight loss, anemia, nocturnal symptoms, steatorrhea, or onset of symptoms after age 50 years should be carefully evaluated for organic disease. The Rome criteria, developed for research studies, may be helpful in the diagnosis of IBS. These criteria include pain associated with change in bowel habits, relieved with defecation or accompanied by distention or bloating. Patients are reassured, counseled, and treated with anticholinergic agents and stool softeners. Alosetron, a serotonin 5-HT₃ antagonist, has been shown to help relieve symptoms in patients with diarrhea-predominant IBS. Tegaserod, a serotonin 5-HT₄

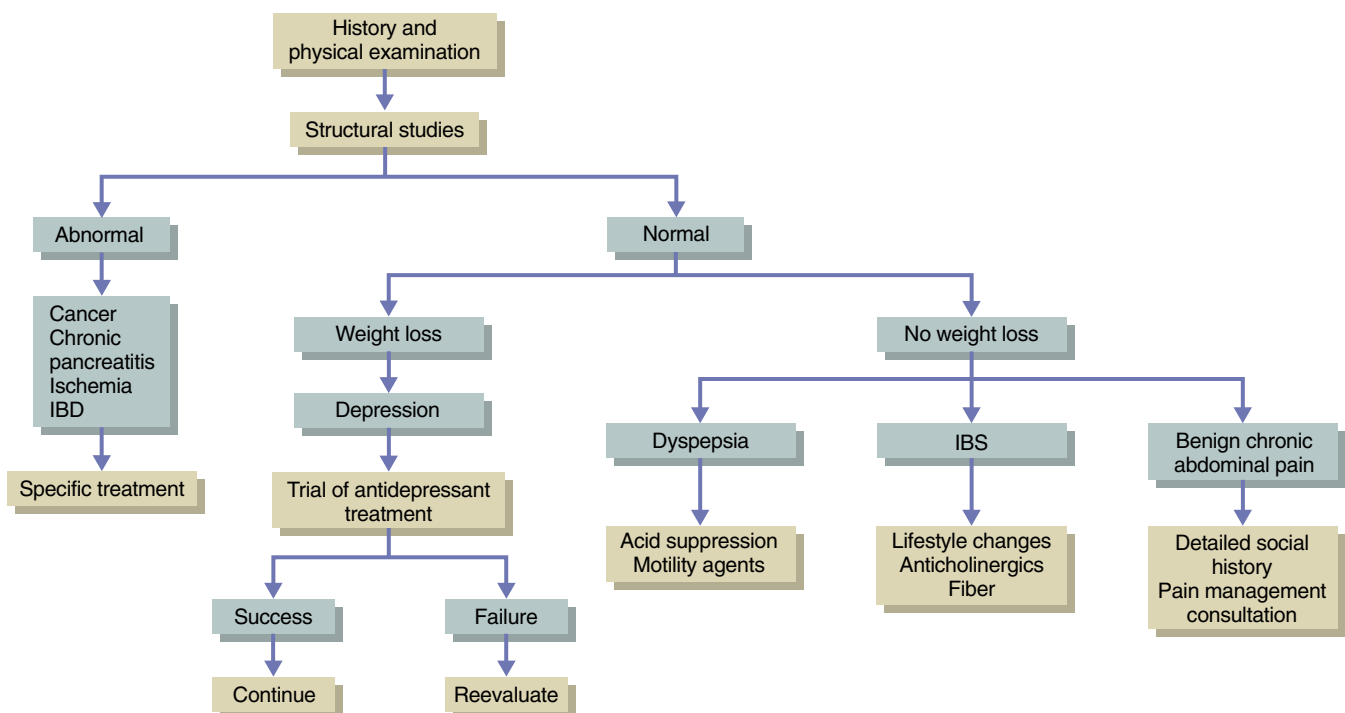

Figure 34-1 Approach to the patient with chronic abdominal pain. IBD, inflammatory bowel disease; IBS, irritable bowel syndrome.

agonist, has been found to be effective in relieving pain and constipation in constipation-predominant IBS and has recently been approved for use in both men and women.

The more challenging clinical problem is the one of functional abdominal pain syndrome. This term describes a condition in which the pain has been present for months or years. The complaints of pain are often not related to eating, defecation, or menses, unlike other causes of chronic pain. The patient is likely to be a woman who has undergone numerous examinations and diagnostic studies with negative findings and, in many cases, surgical operations without any relief. Lengthy or repeated diagnostic work-ups are counterproductive and only convince the patient that one more test is what is needed to determine the source of the pain. The physician must establish that organic disease is not present and must also realize that the pain is real. The patients are not malingerers despite the fact that the pain does not fit any familiar pattern. Depression may be the result rather than the cause of the pain.

Chronic abdominal pain is a clinical situation requiring as much tact, diplomacy, and compassion as it does scientific knowledge. An effort should be made to inquire about social factors, including history of physical and sexual abuse, particularly in women. Psychiatric evaluation may be necessary,

but the suggestion for such a consultation may be interpreted by the patient as a belief from the physician that the “pain is in my head.” A referral to a competent pain management specialist is helpful in a certain number of cases. This approach offers the possibility of providing relief with nerve blocks when the pain is localized or other pain-relieving devices. If this approach fails, referral to a psychologist or psychiatrist may be acceptable to the patient.

For a practical approach to chronic abdominal pain, see the algorithm in Figure 34-1.

B. Gastrointestinal Hemorrhage

T. Carlton Moore, Chi-Chuan Tseng,* and M. Michael Wolfe

Acute Gastrointestinal Hemorrhage

Acute gastrointestinal (GI) bleeding remains a common and major medical problem, despite recent advances in diagnosis and treatment. Bleeding occurs as the result of a variety of diseases, and adequate treatment depends on assessing hemodynamic stability, determining blood loss, and identifying sources of bleeding. Although advancements in medical and surgical intensive care, pharmacologic therapy, and the prompt deployment of endoscopic therapies have significantly decreased the rate of rebleeding, the overall mortality rate from acute bleeding episode has remained essentially unchanged during the past half century, at about 5% to 10%, owing to an aging population and an increased prevalence of serious concomitant illnesses.

PRESENTATION OF GASTROINTESTINAL BLEEDING

When massive GI bleeding occurs, patients generally present with any combination of weakness, dizziness, lightheaded-

ness, shortness of breath, postural changes in blood pressure or pulse, cramping abdominal pain, and diarrhea. The characteristics of bleeding may help to localize the source of bleeding to the upper or lower GI tract. Patients with acute bleeding commonly present with one of the following symptoms:

Hematemesis. The patient usually presents with vomiting of bright red blood or of material that resembles coffee grounds. After excluding swallowed blood from the nasopharynx or secondary to hemoptysis, the source of bleeding is likely proximal to the ligament of Treitz.

Melena. As little as 50 to 100 mL of blood in the stomach can produce melena. Black, tarry, usually foul-smelling stools are most often a manifestation of upper GI bleeding; however, a small bowel or proximal colonic source of bleeding may on occasion lead to melanic stools.

Hematochezia. The passage of bright-red blood or maroon stools per rectum frequently indicates a lower GI source of bleeding. However, about 10% to 15% of patients presenting with acute severe hematochezia have an upper GI source of bleeding. This group of patients commonly displays signs of hemodynamic instability.

*Deceased.

ETIOLOGY OF GASTROINTESTINAL BLEEDING

A major goal during early management of bleeding is to distinguish between upper and lower GI bleeding. In addition to the symptoms and signs stated previously, certain aspects of the history, physical examination, laboratory studies, and age of the patient may assist in localizing the site of bleeding. However, the site of bleeding frequently remains undetermined after initial evaluation. Common sources of acute GI hemorrhage are listed in Table 34-2.

APPROACH TO THE PATIENT WITH ACUTE GASTROINTESTINAL BLEEDING

Assessment of Vital Signs and Resuscitation

The first step in the evaluation and therapy for the patient with acute GI hemorrhage is to determine the severity of blood loss (Fig. 34-2). Vital signs with postural changes

should be recorded immediately. If the systolic blood pressure drops more than 10 mm Hg or the pulse increases more than 10 beats per minute as the patient changes positions from supine to standing, it is likely the patient has lost at least 800 mL (15%) of circulating blood volume. Hypotension, tachycardia, tachypnea, and mental status changes in the setting of acute GI hemorrhage suggest at least a 1500-mL (30%) loss of circulating blood volume.

The goals of resuscitation are to restore the normal circulatory volume and to prevent complications from red blood cell loss, such as cardiac, pulmonary, renal, or neurologic consequences. Initially, at least two large-bore intravenous catheters are used to administer isotonic solutions (e.g., lactated Ringer solution, 0.9% NaCl), and blood products if indicated. If the patient is in shock, central venous access should be established. The amount of blood products to be transfused must be individualized, and in view of a potential risk for blood transfusion, it is not appropriate to simply transfuse until an arbitrary hematocrit is achieved. If coagulation studies are abnormal, as commonly observed in cir-

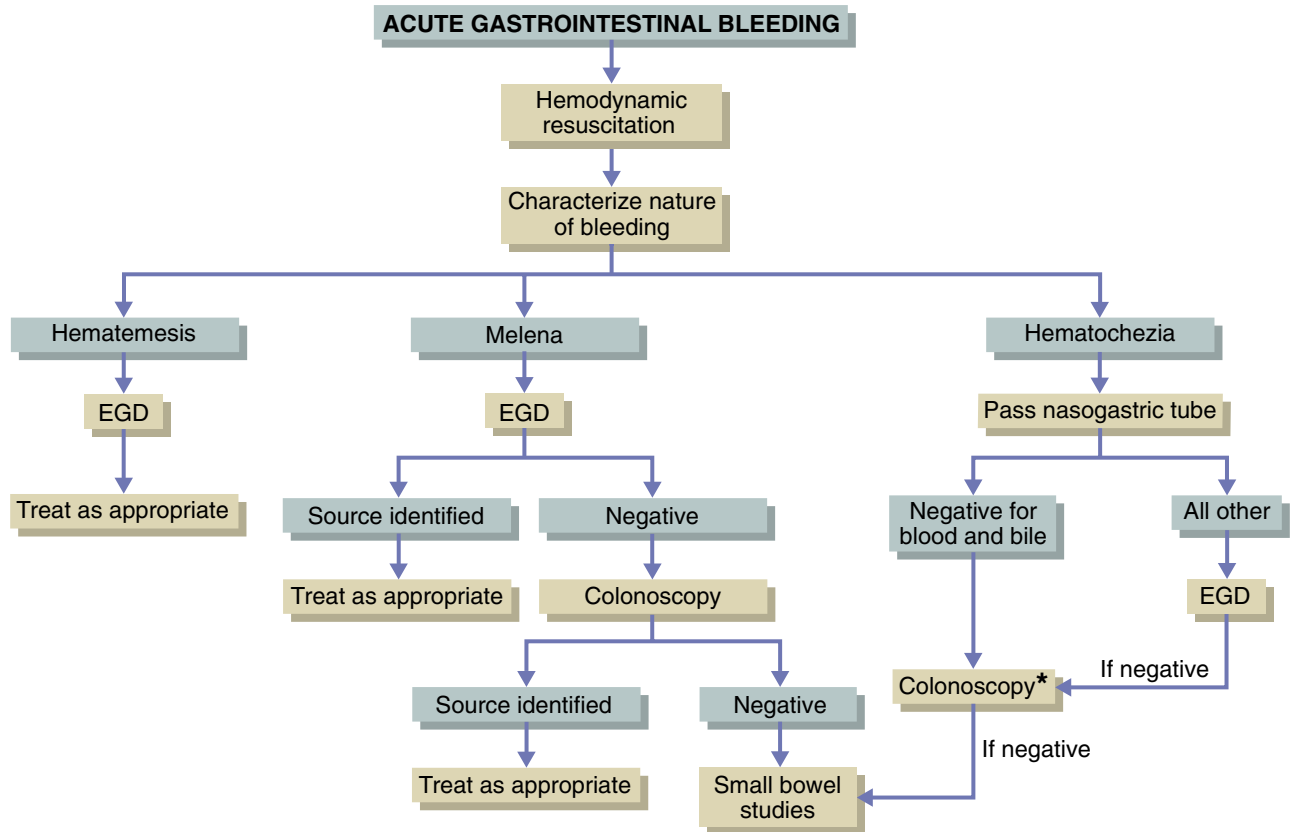

Table 34-2 Common Sources of Acute Gastrointestinal Hemorrhage

Source	Associated Clinical Features	Treatments
Upper Gastrointestinal Tract		
Esophagitis	Heartburn, dysphagia, odynophagia	Medication* Antireflux surgery or procedures
Esophageal cancer	Progressive dysphagia, weight loss	Chemoradiotherapy, surgery Palliative endoscopy procedures
Gastritis, gastric ulcer	Aspirin, NSAID use	Withdraw NSAIDs
Duodenitis, duodenal ulcer	Abdominal pain, dyspepsia <i>Helicobacter pylori</i> infection	Medication† Endoscopic therapy for acute bleeding
Gastric cancer	Early satiety, weight loss, abdominal pain	Surgery, chemotherapy
Esophagogastric varices	History of CLD Stigmata of CLD on examination	Variceal banding, sclerotherapy Vasopressin, octreotide TIPS or decompressive surgery
Mallory-Weiss tear	History of retching before hematemesis	Supportive (usually self-limited) Endoscopic therapy
Lower Gastrointestinal Tract		
Infection	History of exposure, diarrhea, fever	Supportive, antibiotics
Inflammatory bowel diseases	History of colitis, diarrhea, abdominal pain, fever	Steroids, 5-ASA, immunotherapy Surgery if unresponsive to medication
Diverticula	Painless hematochezia	Supportive Surgery for recurrent disease
Angiodysplasia	Painless hematochezia Often in ascending colon Commonly involves stomach and small bowel as well	Endoscopic therapy Supportive Surgery for localized disease
Colon cancer	Change in bowel habit, anemia, weight loss	Surgery
Colon polyp	Usually asymptomatic	Endoscopic or surgical removal
Ischemic colitis	Typically elderly patients History of vascular disease May produce abdominal pain	Supportive (self-limited)
Meckel diverticulum	Painless hematochezia in young patient Located at distal ileum	Surgery
Hemorrhoids	Rectal bleeding associated with bowel movement	Supportive Surgery, banding

*Proton pump inhibitors or histamine-2 receptor antagonists.

†Proton pump inhibitors or histamine-2 receptor antagonists in the absence of *H. pylori* infection; various combinations of antibiotics, proton pump inhibitors, and bismuth products in the presence of *H. pylori* infection.

Figure 34-2 Approach to the patient with acute gastrointestinal bleeding. EGD, esophagogastroduodenoscopy.

rhotic patients, fresh-frozen plasma, platelets, or both may be required to control ongoing hemorrhage.

Initial Evaluation

As the patient is being fluid resuscitated, the following information should be obtained by history and physical examination in order to determine the source of bleeding:

1. The nature of bleeding: melena, hematemesis, hematochezia, or occult blood. A digital rectal examination is essential for the determination of stool color and the identification of anal fissures or rectal neoplasms.
2. The duration of GI bleeding, which helps dictate the appropriate pace of the evaluation to determine the bleeding source
3. The presence or absence of abdominal pain; for example, hematochezia caused by diverticula or angiodysplasia is typically painless, but when due to ischemia, it may be accompanied by abdominal pain.
4. Other associated symptoms, including fever, urgency or tenesmus, recent change in bowel habits, and weight loss
5. Current or recent medication use, particularly nonsteroidal anti-inflammatory drugs (NSAIDs) or aspirin (which may predispose to ulceration or gastritis; see Chapter 37), anticoagulants, and alcohol. Many over-the-counter products may contain aspirin or NSAIDs.
6. Relevant past medical and surgical history, including a history of GI bleeding, abdominal surgery (prior abdomi-

nal aorta repair should raise suspicion for an aortoenteric fistula), history of radiation therapy (radiation proctitis), history of major organ disease (including cardiopulmonary, hepatic, or renal disease), history of inflammatory bowel diseases, and recent polypectomy (postpolypectomy bleeding).

The physical examination must include an assessment of vital signs, cardiac and pulmonary examination, and abdominal and digital rectal examination. The initial laboratory examination should include complete blood cell count, blood typing and cross-matching, and measurements of serum electrolytes, blood urea nitrogen, creatinine, and coagulation factors. The first hematocrit measurement may not reflect the degree of blood loss, but it will decrease gradually to a stable level over 24 to 48 hours.

The initial disposition of the patient must also be considered. Patients older than 60 years, those with severe blood loss or with continued bleeding (as reflected by a significant decrease in hematocrit or postural changes in blood pressure or pulse rate), and those with significant comorbid illness are at the greatest risk for complications of GI hemorrhage and are best managed in an intensive care setting until stabilized.

Identification of the Bleeding Source

In about 80% to 90% of cases, acute GI hemorrhage resolves spontaneously without recurrence. Nevertheless, it is prudent to localize the bleeding source. Proper identification allows

for direct treatment in cases in which bleeding does not spontaneously resolve and allows for the identification of the patient at risk for further bleeding. For example, in a patient with a bleeding gastric or duodenal ulcer, acid suppression with an intravenous proton pump inhibitor may maximize clot stability and enhance platelet aggregation. Proton pump inhibitors, in combination with appropriate endoscopic management, decrease the risk for ulcer rebleeding, the need for urgent surgery, and death. Direct visualization of the bleeding site by endoscopy can alter patient management because various stigmata of hemorrhage may be identified within the ulcer crater. Stigmata that carry a high risk for rebleeding are active bleeding and the presence of a pigmented protuberance (artery visible within the ulcer crater). The patient with a “clean base” ulcer exhibiting no such stigmata has an excellent prognosis for cessation of bleeding. The patient found to have high-risk stigmata is likely (>50%) to have continued or recurrent bleeding. In such a patient, the site of bleeding may be treated by injection therapy with vasoconstrictors or saline, thermal therapy by electrocautery, or mechanical therapy by placement of endoscopic clips. These endoscopic therapies decrease rates of rebleeding, mortality, need for transfusion, need for surgery, and length of hospital stay. Thermal or mechanical therapy applied alone, or in combination with injection therapy, is more effective than injection therapy alone.

An approach to the patient with acute GI bleeding is outlined in Figure 34-2. Historical points and objective findings often enable localization of the bleeding site to the upper GI tract (proximal to the ligament of Treitz) or to the lower GI tract (distal to that point). For the patient with melena or hematemesis, the upper GI tract should be examined first. Patients with hematochezia more commonly have lower GI bleeding, but when the pace of bleeding is brisk, an upper GI tract lesion may manifest with hematochezia. Placement of a nasogastric tube with aspiration of contents is a reasonable first step. The absence of blood does not by itself rule out the presence of an upper GI source because blood from a duodenal bulb ulcer may not flow back into the stomach and allow for sampling by the nasogastric tube. In general, in patients who present with acute GI hemorrhage and have significant blood loss, an upper endoscopy should be the initial step in the evaluation. Once the lower GI tract has been identified as the source of bleeding, sigmoidoscopy or colonoscopy is the test of choice. In cases of lower GI bleeding in which the pace of bleeding is so brisk as to preclude endoscopic visualization of the colon and rectum, scintigraphic ^{99m}Tc -sulfur colloid- or ^{99m}Tc -pertechnetate-labeled erythrocyte scans can localize the bleeding site if the rate of blood loss exceeds 0.5 mL per minute. Although the bleeding site identified by scintigraphic examination may not be accurate, it will direct visceral arteriographic search while minimizing the dye used. There is *no* role for barium studies in the evaluation of acute GI hemorrhage.

Chronic Gastrointestinal Hemorrhage

This condition may manifest as self-limited, recurrent episodes of melena or hematochezia, usually not with the degree of hemodynamic compromise discussed earlier. Patients may also have no overt evidence of blood loss, but rather may have persistent anemia and consistent occult blood loss.

The evaluation of this condition differs from that of acute GI hemorrhage. Obviously, the pace of the evaluation is less urgent. Furthermore, the likely causes for this bleeding differ from those of acute GI bleeding. Patients with this condition usually have undergone upper and lower endoscopy at least once, with no bleeding source identified. Therefore, the bleeding must have either an upper GI tract or colonic source that is difficult to identify or that emanates from the small intestine. The small intestine is a difficult area to examine in this regard because of its length and configuration. In general, the small intestine is initially evaluated radiographically. The patient may ingest barium, which is followed through the length of the small intestine. To distend the small bowel and give greater mucosal detail, an enteroclysis tube may be placed with its distal tip near the ligament of Treitz, allowing more forceful administration of barium and air. Computed tomographic and magnetic resonance enterography are rapidly replacing fluoroscopic imaging. However, all these imaging techniques have limited diagnostic utility. Flat mucosal lesions such as vascular ectasias, a common cause of obscure bleeding, may easily be missed. When radiographic studies are unrevealing, endoscopic evaluation of the small bowel may be attempted by push or double-balloon enteroscopy, or by “capsule endoscopy” (see Chapter 35). For the patient with persistent blood loss, no source of bleeding in the upper GI tract or colon as determined by endoscopy, and negative findings on radiologic studies, the entire small intestine may be examined at laparotomy with endoscopy in the operative suite. In addition, angiographic evaluation of the whole GI tract may reveal the source of chronic blood loss.

C. Malabsorption[†]

Marcos C. Pedrosa and Elihu M. Schimmel

The main purpose of the GI tract is the digestion and absorption of major nutrients (fat, carbohydrate, and protein), essential micronutrients (vitamins and trace minerals), water, and electrolytes. Digestion involves both mechanical and enzymatic breakdown of food. Mechanical processes include chewing, gastric churning, and the to-and-fro mixing in the small intestine. Enzymatic hydrolysis is initiated by intraluminal processes requiring gastric, pancreatic, and biliary secretions and is completed at the intestinal brush border. The final products of digestion are absorbed through the intestinal epithelial cells. The regulation of gastric emptying, normal intestinal progression, and adequate intestinal surface area are additional important factors.

Most food components can be absorbed throughout the length of the small intestine, but some can be absorbed only at specific areas (e.g., vitamin B₁₂ and cholesterol are absorbed only in the terminal ileum). Several molecules undergo an enterohepatic circulation with release into and reabsorption from the intestine, notably the bile acids needed for fat absorption. The primary absorptive function of the colon is the absorption of water and electrolytes; in addition, there is colonic salvage of much of the carbohydrate from indigestible fiber through bacterial enzymatic activity. This section discusses normal assimilation of the major nutrients and the approach to patients with maldigestion or malabsorption.

Digestion and Absorption of Fat

Dietary fat is composed predominantly of triglycerides (about 95%) with long-chain fatty acids (16- and 18-carbon molecules). In animal fat, the constituent fatty acids are mostly saturated (e.g., palmitic and stearic), whereas those of vegetable origin are rich in unsaturated fatty acids (i.e., having one or more double bond in the carbon chain; e.g., oleic and linoleic acids). Fats are insoluble (hydrophobic), and digestion begins with emulsification (i.e., fat droplets are dispersed in the aqueous medium of the lumen). Bile salts and pancreatic enzymes are bound to the surface of these globules by colipase, resulting in the release of fatty acids and a monoglyceride. These are taken up as mixed micelles with bile salts, allowing these hydrophobic particles to cross the unstirred water layer that overlies the epithelial brush border. Within the cell, the fatty acids are resynthesized into triglycerides and, together with cholesterol and phospholipids, are

packaged into chylomicrons and very-low-density lipoproteins (VLDLs) to be exported through lymphatic channels. Bile salts remain in the lumen, are recycled into new micelles, and are finally reabsorbed in the terminal ileum with 95% efficiency. Most dietary lipids are absorbed in the jejunum, together with the fat-soluble vitamins (A, D, E, and K). Whereas fat constitutes up to 40% to 45% of diet calories in developed countries, a goal of 35% or less is set as a dietary recommendation for reduction of risk from cardiac disease and some cancers.

Digestion and Absorption of Carbohydrates

The bulk of dietary carbohydrates consist of starch, a glucose polymer, and the disaccharides sucrose and lactose, but only monosaccharides are absorbed. Salivary and pancreatic amylases release oligosaccharides from starch, and the final hydrolysis to glucose monomers occurs at the brush border, including disaccharide hydrolysis by sucrase and lactase. Glucose and galactose are actively transported in conjunction with sodium, whereas fructose absorption occurs by facilitated diffusion. About half of dietary energy is ordinarily derived from carbohydrate, with a nutritional goal of 55% and an increased component of insoluble fiber (i.e., that which is indigestible by mammalian enzymes, but variably broken down by colonic bacteria).

Digestion and Absorption of Proteins

Dietary proteins are the major source for amino acids and the only source for the essential amino acids. Digestion starts in the stomach with pepsins secreted by the gastric mucosa, but most of the hydrolysis is accomplished by pancreatic enzymes in the proximal small bowel. The pancreas secretes the proteases trypsin, elastase, chymotrypsin, and carboxypeptidase as inactive proenzymes. Enterokinase (more properly, enteropeptidase) is secreted by the intestinal brush border and splits trypsinogen to its active form, trypsin, which, in turn, converts the other proenzymes to their active forms. The products of luminal brush border peptidase digestion consist of amino acids and oligopeptides, which are transported across the epithelial cell. The transfer of most amino acids is sodium dependent and takes place in the proximal small bowel. Dietary need for amino acid nitrogen is met with about 15% of calories from protein.

Table 34-3 Pathophysiologic Mechanisms in Malabsorption

Luminal Phase	Mucosal Phase	Transport Phase
Reduced nutrient availability	Extensive mucosal loss (resection or infarction)	Vascular conditions (vasculitis; atheroma)
Cofactor deficiency (pernicious anemia; gastric surgery)	Diffuse mucosal disease (celiac sprue)	Lymphatic conditions (lymphangiectasia; irradiation; nodal tumor, cavitation, or infiltrations)
Nutrient consumption (bacterial overgrowth)	Crohn disease; irradiation; infection; infiltrations; drugs: alcohol, colchicine, neomycin, iron salts	
Impaired fat solubilization	Brush border hydrolase deficiency (lactase deficiency)	
Reduced bile salt synthesis (hepatocellular disease)	Transport defects (Hartnup cystinuria; vitamin B ₁₂ and folate uptake)	
Impaired bile salt secretion (chronic cholestasis)	Epithelial processing (abetalipoproteinemia)	
Bile salt inactivation (bacterial overgrowth)		
Impaired cholecystokinin release (mucosal disease)		
Increased bile salt losses (terminal ileal disease or resection)		
Defective nutrient hydrolysis		
Lipase inactivation (Zollinger-Ellison syndrome)		
Enzyme deficiency (pancreatic insufficiency or cancer)		
Improper mixing or rapid transit (resection; bypass; hyperthyroidism)		

Adapted from Riley SA, Marsh MN: Maldigestion and malabsorption. In Feldman M, Scharschmidt BF, Sleisenger MH (eds): Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management, 6th ed. Philadelphia, WB Saunders, 1998, pp 1501-1522.

Mechanisms of Malabsorption

The term *maldigestion* refers to defective hydrolysis of nutrients, whereas *malabsorption* refers to impaired mucosal absorption. In clinical practice, however, *malabsorption* refers to all aspects of impaired nutrient assimilation. Malabsorption can involve multiple nutrients or be more selective, and the clinical manifestations of malabsorption are thus highly variable. The complete process of absorption consists of a *luminal phase*, in which various nutrients are hydrolyzed and solubilized; a *mucosal phase*, in which further processing takes place at the brush border of the epithelial cell with subsequent transfer into the cell; and a *transport phase*, in which nutrients are moved from the epithelium to the portal venous or lymphatic circulation. Impairment in any of these phases can result in malabsorption (Table 34-3).

LUMINAL PHASE

Digestion is accomplished for the most part by pancreatic enzymes, particularly lipase, colipase, and trypsin; the gastric digestive enzymes do not play a major role. As a consequence, chronic pancreatitis can result in malabsorption, particularly for fat and protein. Deficiency in bile salts also contributes to fat malabsorption and may be the result of cholestatic liver disorders (impaired secretion of bile), bacterial overgrowth (resulting in luminal bile salt deconjugation), or ileal disease or resection (with loss of effective enterohepatic circulation of the bile acids). The major part of digestion occurs in the duodenum and most proximal jejunum.

tion), or ileal disease or resection (with loss of effective enterohepatic circulation of the bile acids). The major part of digestion occurs in the duodenum and most proximal jejunum.

MUCOSAL PHASE

Mucosal disease is a more common cause of malabsorption. It can occur because of diffuse small intestinal disease, such as in celiac sprue or Crohn disease, or from a decrease of surface area (e.g., after surgical resection for small bowel infarction). Selective defects in an otherwise normal intestine may result in specific entities such as lactase deficiency or abetalipoproteinemia.

TRANSPORT PHASE

After absorption, nutrients leave the cells through venous or lymphatic channels. Consequently, malabsorption may occur after mesenteric venous obstruction, lymphangiectasia, or lymphatic obstruction from malignancy or infiltrative processes (such as Whipple disease).

Multiple Mechanisms

Occasional disorders can impair the absorptive process at many stages. For example, patients with subtotal gastrectomy often have malabsorption. There are resultant defects at all phases: impaired gastric churning; premature empty-

ing; and impaired mixing (in the jejunum) of food with bile and pancreatic enzymes. The latter is a consequence of anatomic changes (gastrojejunostomy bypassing the duodenum) and reduced production of pancreatic enzymes (because cholecystokinin and secretin release are blunted when gastric contents bypass the duodenum). Finally, stasis may lead to bacterial overgrowth in the afferent loop, with changes in the bile acids needed for fat absorption. Another example of manifold mechanisms is diabetes mellitus, with delayed gastric emptying, abnormal intestinal motility, bacterial overgrowth, and pancreatic exocrine insufficiency.

Clinical Manifestations of Malabsorption

The clinical manifestations of malabsorption are usually nonspecific. A change in bowel movements—usually diarrhea—and weight loss may occur early. Later, symptoms and signs of nutrient deficiency develop. Muscle wasting and edema result from protein malabsorption. Nutritional anemia, due to iron and vitamin deficiency (folate and B₁₂), contributes to fatigue. Bleeding tendency, such as ecchymosis, may be attributed to prolonged prothrombin time (high international normalized ratio) from vitamin K deficiency. Bulky, oily stools are the hallmark of steatorrhea resulting from fat malabsorption, whereas bloating (abdominal distention) and soft diarrheal movements occur as a result of carbohydrate malabsorption. Signs associated with malabsorption are presented in Table 34-4.

Clinical Tests for Malabsorption

Blood assays of albumin, carotene, cholesterol, calcium, and folic acid and of the prothrombin time are useful screening studies for malabsorption. These tests are helpful in assessing the severity of malabsorption, but are not specific for the differential diagnosis. Many tests are available in the work-up of malabsorption; those that have been most useful clinically are discussed next.

FECAL FAT ANALYSIS

The simplest qualitative method for detecting stool fat is the microscopic examination of a Sudan stain of a drop of stool. Sensitivity is limited, but it is quick and easy and correlates well with the quantitative measurement of fecal fat when moderate to severe steatorrhea is present. To quantify fat, stool is collected for 3 consecutive days while the patient is on a diet containing 100 g of fat per day, and the specimen is analyzed for fat content. Normal fat excretion should not exceed 6 g/day. Although the test is cumbersome and nonspecific, it offers an accurate quantification of fecal fat excretion provided fat consumption is appropriate.

TESTS OF PANCREATIC EXOCRINE FUNCTION

Intubation study of the duodenum with a fluoroscopically placed double-lumen tube may be the best index of

pancreatic exocrine function. After stimulation of the pancreas, duodenal contents are aspirated and analyzed for bicarbonate and enzyme output. The test is invasive and time consuming; much experience is needed for its accurate interpretation; and it remains more of a research tool than a useful clinical test. The measurement of pancreatic enzymes in the blood (trypsinogen) or in the stool (chymotrypsin or elastase) is simple and provides helpful laboratory evidence for the diagnosis of moderate to severe pancreatitis. Pancreatic calcifications seen on abdominal films or computed tomography (CT) scan indicate the presence of chronic pancreatitis. Magnetic resonance cholangiopancreatography is a sensitive, noninvasive imaging procedure that may supplement CT scan for diagnostic purposes. Abnormal ductal anatomy can be best demonstrated by an endoscopic retrograde cholangiopancreatography (ERCP), but this test is invasive and has significant adverse side effects.

SMALL INTESTINAL BIOPSY

Peroral small intestinal mucosal biopsy is a key diagnostic test for diseases that affect the cellular phase of absorption. In some diseases, the histologic features are diagnostic; in others, the findings may be highly suggestive (Table 34-5). Endoscopic duodenal biopsies have largely replaced the more cumbersome jejunal sampling obtained by aspiration biopsy tubes. Several tissue samples should be taken from the distal duodenum to enhance the diagnostic accuracy.

D-XYLOSE TEST

D-xylose is a 5-carbon monosaccharide that is transported across the intestinal mucosa largely by passive diffusion. In this test, a patient ingests 25 g of D-xylose, and urine is collected for the next 5 hours. Healthy subjects excrete more than 4.5 g of D-xylose in 5 hours (or $\geq 20\%$ of the ingested load). The test reflects intestinal transport function and surface area; it serves as an indicator of mucosal absorption. Abnormally low (false-positive) results may occur in the presence of impaired renal excretory function, massive peripheral edema, or ascites. Abnormal results can also be seen in the presence of bacterial overgrowth, but this “pseudomalabsorption” may be corrected after treatment with antibiotics serving as a therapeutic trial.

RADIOGRAPHIC STUDIES

Barium studies of the small bowel in malabsorption are usually nonspecific. Occasionally, however, distinct anatomic changes are seen in jejunal diverticulosis, lymphoma, Crohn disease, strictures, or enteric fistulas; also, there may be a distinctive barium pattern of thin-walled, dilated loops, suggestive of celiac sprue.

SCHILLING TEST

Absorption of vitamin B₁₂ requires several steps. First, the ingested vitamin binds to salivary R-factor protein; gastric parietal cells secrete intrinsic factor that mixes with the ingested meal. In the duodenum, pancreatic trypsin hydro-

Table 34-4 Signs Associated with Malabsorption Syndromes

Signs	Associated Syndromes
Gastrointestinal	
Mass	Crohn disease, lymphoma, tuberculosis, glands
Distention	Intestinal obstruction, gas, ascites, pseudocyst (pancreatic), motility disorder
Steatorrheic stool	Mucosal disease, bacterial overgrowth, pancreatic insufficiency, infective or inflammatory, drug induced
Extraintestinal	
Skin	
Nonspecific	Pigmentation, thinning, inelasticity, reduced subcutaneous fat
Specific	Blisters (dermatitis herpetiformis), erythema nodosum (Crohn disease), petechiae (vitamin K deficiency), edema (hypoproteinemia)
Hair	
Alopecia	Gluten sensitivity
Loss or thinning	Generalized inanition, hypothyroidism, gluten sensitivity
Eyes	
Conjunctivitis, episcleritis	Crohn disease, Behçet syndrome
Paleness	Severe anemia
Mouth	
Aphthous ulcers	Crohn disease, gluten sensitivity, Behçet syndrome
Glossitis	Deficiencies of vitamin B ₁₂ , iron, folate, niacin
Angular cheilosis	Deficiencies of vitamin B ₁₂ , iron, folate, B complex
Dental hypoplasia (pitting, dystrophy)	Gluten sensitivity
Hands	
Raynaud phenomenon	Scleroderma
Finger clubbing	Crohn disease, lymphoma
Koilonychia	Iron deficiency
Leukonychia	Inanition
Musculoskeletal	
Monoarthropathy and polyarthropathy	Crohn disease, gluten sensitivity, Whipple disease, Behçet syndrome
Back pain (osteomalacia, osteoporosis, sacroiliitis)	Crohn disease, malnutrition, gluten sensitivity
Muscle weakness (low potassium, magnesium, vitamin D, generalized inanition)	Diffuse mucosal disease, bacterial overgrowth, lymphoma
Nervous System	
Peripheral neuropathy (weakness, paresthesias, numbness)	Vitamin B ₁₂ deficiency
Cerebral (seizures, dementia, intracerebral calcification, meningitis, pseudotumor, cranial nerve palsies)	Whipple disease, gluten sensitivity, diffuse lymphoma

From Riley SA, Marsh MN: Maldigestion and malabsorption. In Feldman M, Scharschmidt BF, Sleisenger MH (eds): Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management, 6th ed. Philadelphia: WB Saunders, 1998, pp 1501-1522.

lyzes the R protein, freeing the vitamin to bind with intrinsic factor. The vitamin B₁₂-intrinsic factor complex is then absorbed by specific receptors found on enterocytes in the distal ileum. Consequently, malabsorption of vitamin B₁₂ can occur because of lack of intrinsic factor (e.g., pernicious anemia or gastric resection), pancreatic insufficiency, bacterial overgrowth, or ileal resection or mucosal disease (i.e., Crohn disease). The Schilling test quantifies vitamin B₁₂ absorption using radiolabeled vitamin B₁₂ as a marker. The test may be expanded to several stages to amplify its diagnostic spectrum. In stage 1, after the injection of 1000 mcg of unlabeled vitamin B₁₂ to saturate hepatic storage, the patient ingests 0.5 mcg of radiolabeled vitamin. Urine is then collected for the measurement of radioactivity; reduced radioactivity suggests B₁₂ malabsorption. The test is repeated

(stage 2) with the addition of oral intrinsic factor to the ingested vitamin B₁₂; if urinary excretion of the radiolabel is corrected, pernicious anemia is diagnosed. If malabsorption is still present, the patient is given a short course of oral antibiotics (stage 3), and the test is repeated; correction of radiolabeled B₁₂ excretion establishes bacterial overgrowth. If the test result remains abnormal, oral pancreatic enzymes are given (stage 4), and the test is repeated; correction of the abnormality implies pancreatic deficiency. Finally, if all these interventions fail, ileal disease or the absence of transcobalamin protein is determined by other diagnostic tests. This long outline serves more as an example of an algorithm of clinical analysis; the usual routine in clinical settings is to administer parenteral vitamin B₁₂ while the etiology is delineated by other modalities.

BREATH TESTS

Breath tests rely on bacterial degradation of luminal compounds, which releases metabolic byproduct gases (such as hydrogen, methane, and CO₂) that can be measured in the exhaled breath. In the case of disaccharidase deficiency, a specific disaccharide (such as lactose) that is orally ingested but not properly absorbed in the small intestine is delivered to the colon, where bacterial fermentation liberates metabo-

lites; hydrogen gas is the marker assayed in the breath. In the presence of bacterial overgrowth of the small intestine, orally ingested glucose ferments in the proximal small bowel (instead of being absorbed), resulting in increased breath hydrogen; here, the timing of exhaled hydrogen aids in the diagnosis. The measurement of radioactive CO₂ (tested with a nutrient labeled with ¹⁴C) in the breath has been used to estimate the malabsorption of fat or bile acids and for measurement of bacterial overgrowth (¹⁴C-xylose). The radioactive tests are cumbersome, and their usefulness in clinical practice is limited.

Table 34-5 Utility of Small Bowel Biopsy Specimens in Malabsorption

Often Diagnostic
Whipple disease
Amyloidosis
Eosinophilic enteritis
Lymphangiectasia
Primary intestinal lymphoma
Giardiasis
Abetalipoproteinemia
Agammaglobulinemia
Mastocytosis
Abnormal but Not Diagnostic
Celiac sprue
Systemic sclerosis
Radiation enteritis
Bacterial overgrowth syndrome
Tropical sprue
Crohn disease

Data from Trier JS: Diagnostic value of peroral biopsy of the proximal small intestine. *N Engl J Med* 285:1470, 1971.

Approach to the Patient with Suspected Malabsorption

A large number of diagnostic tests are available for the work-up of malabsorption, necessitating the use of a rational algorithm (Fig. 34-3). The most accurate test for fat malabsorption remains the 72-hour fecal fat analysis; however, the test is difficult to carry out in clinical practice. Surrogate screening for steatorrhea is done with the qualitative stool fat examination (Sudan stain) and serum carotene. If the stool fat content is normal, the patient may still have selective impairment of the absorption of a specific carbohydrate. This latter condition should be suspected if the primary symptoms are cramps, flatulence, and diarrhea. The most common example of carbohydrate malabsorption is lactose intolerance; specific tests include the oral lactose tolerance test, but measurement of breath hydrogen is more sensitive

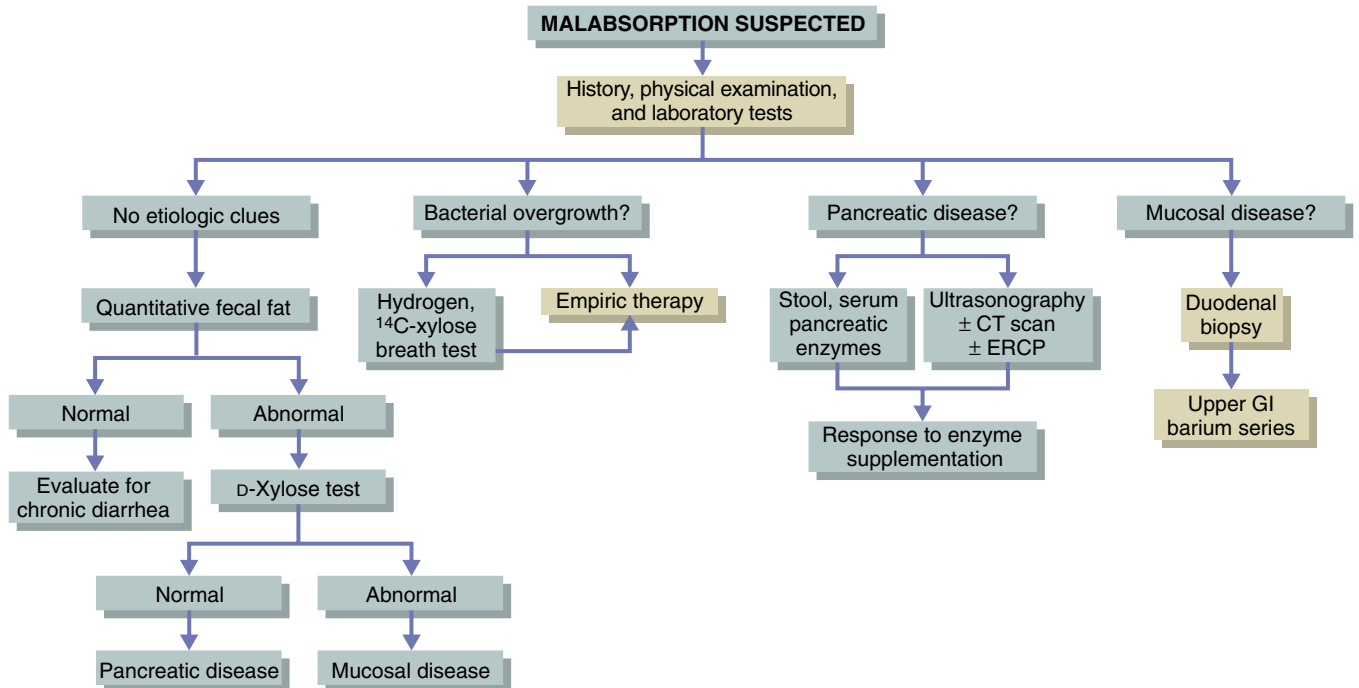

Figure 34-3 Approach to the patient with suspected malabsorption. CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; GI, gastrointestinal. (Adapted from Riley SA, Marsh MN: Maldigestion and malabsorption. In Feldman M, Scharschmidt BF, Sleisenger MH [eds]: *Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management*, 6th ed. Philadelphia, WB Saunders, 1998, pp 1501-1522.)

and specific. More generally, an osmotic gap in fecal water suggests a dietary (rather than secretory) cause of the diarrhea related to luminal short-chain fatty acids or carbohydrates. The osmotic gap is calculated by the following formula: plasma osmolality – $[2 \times (\text{fecal Na}^+ + \text{fecal K}^+)]$. The osmotic gap is not calculated by directly measuring stool osmolality because it increases with time in the specimen container. In addition, luminal osmolality is equal to serum osmolality because the colon cannot establish a gradient against the serum concentration of solutes.

When fat malabsorption is demonstrated (>6 g per 24 hours, or increased qualitative stool fat and decreased serum carotene), a D-xylose absorption-excretion test should be performed next. A normal D-xylose test makes diffuse mucosal disease unlikely and suggests maldigestion, principally pancreatic enzyme or bile salt deficiency. Clues to chronic pancreatitis include a history of alcohol abuse or previous episodes of pancreatitis; unusual causes of pancreatic malabsorption, such as cystic fibrosis, microlithiasis, or drug toxicity, require specific testing and a detailed history. In the search for maldigestion, serum enzyme tests and abdominal imaging (plain film or, with much greater sensitivity, abdominal CT scan) can be obtained next to identify pancreatic disease. If the urinary D-xylose excretion is abnormal, the breath hydrogen test may be used to diagnose bacterial overgrowth using glucose for the carbohydrate load. When no bacterial overgrowth is present, a mucosal biopsy should be performed (see Table 34-5). Radiologic studies of the small bowel with barium may be helpful on occasion.

When the etiology of malabsorption remains unclear, other considerations should include parasitic infection, such as *Giardia lamblia* or ascariasis involvement of the pancreatic duct (more common in undeveloped countries). These diagnoses require a careful stool examination for ova and parasites or fecal antigen studies. Occasionally, therapeutic trials for treatable conditions should be instituted, such as a gluten-free diet for celiac disease, pancreatic enzyme replacement for pancreatic exocrine function, metronidazole for *G. lamblia* infection, or broad-spectrum antibiotics for suspected bacterial overgrowth.

The specific treatment of malabsorption depends on identifying the underlying condition. Parenteral nutrition may have a role in maintaining an adequate nutritional status. Treatment modalities are discussed in the sections devoted to the corresponding diseases.

Specific Disorders

Malabsorption can be caused by a large number of disorders, some of them listed in Table 34-3. Two of these disorders, celiac sprue and bacterial overgrowth, are discussed in this section as illustrative of the pathophysiology. Cystic fibrosis of the pancreas may be the most common cause of malabsorption in the very young and is discussed in other sections.

CELIAC SPRUE (ALSO NONTROPICAL SPRUE, OR GLUTEN-SENSITIVE ENTEROPATHY)

Celiac disease is characterized by intestinal mucosal injury resulting from immunologic damage from gluten in persons

genetically predisposed to this condition. The prevalence of the disease among relatives of patients with celiac sprue is about 10%. There is a strong association of celiac sprue with human leukocyte antigen (HLA) class II molecules, particularly HLA-DQ2 and HLA-DQ8. The disease is induced by exposure to storage proteins found in grain plants such as wheat (which contains gliadin), barley, and rye and their products. Oats are implicated not because of gliadin but because of contamination with wheat during packaging and transportation. The exposure initiates a cellular immune response that results in mucosal damage, particularly in the proximal intestine. Results of investigations suggest that an enzyme, tissue transglutaminase, may be the autoantigen of celiac sprue.

Clinical Presentation

Celiac disease can manifest with the classic constellation of symptoms and signs of a malabsorption syndrome. Not uncommonly, the manifestation may be atypical, with non-specific GI symptoms such as bloating, chronic diarrhea (with or without steatorrhea), flatulence, lactose intolerance, or deficiencies of a single micronutrient, as in iron deficiency anemia. Extraintestinal complaints such as depression, weakness, fatigue, arthralgias, osteoporosis, or osteomalacia may predominate. A number of diseases, including dermatitis herpetiformis, type 1 diabetes mellitus, autoimmune thyroid disease, and selective immunoglobulin A (IgA) deficiency, are found in significant association with celiac disease.

Diagnosis

Although celiac disease is a leading consideration in every patient with the malabsorption syndrome, it should also be included in the differential diagnosis of patients with atypical manifestations. Fiberoptic or capsule endoscopy may show the typical features of broad and flattened villi; with the former instrument, tissue can be sampled for histology. Intestinal biopsy is the most valuable test in establishing the diagnosis, and the spectrum of pathologic changes ranges from normal villous architecture with an increase in mucosal lymphocytes and plasma cells (the infiltrative lesion) to partial blunting or total villous flattening. Although abnormal biopsy findings are not specific, they are highly suggestive, particularly because most other conditions that can mimic celiac disease (such as Crohn disease, gastrinoma, lymphoma, tropical sprue, graft-versus-host disease, or immune deficiency) may be distinguished clinically. A clinical response to a gluten-free diet establishes the diagnosis and precludes the need, in adults, to document healing by repeated biopsies. Serologic blood tests (antigliadin, antienteromyxial, and reticulin antibodies) are helpful in screening of patients with atypical symptoms or asymptomatic relatives of patients with celiac sprue.

Treatment

Strict, lifelong adherence to a gluten-free diet is the only treatment for celiac disease. Specific nutritional supplementation should be provided to correct deficiencies, particularly those of iron, vitamins, and calcium. A clinical response may be seen within a few weeks. Patients should be monitored to ensure adequate response and proper adherence to the diet. The long-term prognosis is excellent in patients who adhere

to the diet, although there may be a slight increase in the incidence of malignancies, particularly lymphoma.

BACTERIAL OVERGROWTH SYNDROME

The proximal small bowel normally contains fewer than 10^4 bacteria per milliliter of fluid, with no anaerobic *Bacteroides* organisms and few coliforms. Overgrowth of luminal bacteria can result in diarrhea and malabsorption by a number of mechanisms: (1) deconjugation of bile salts, which leads to impaired micelle formation and impaired uptake of fat; (2) patchy injury to the enterocytes (small intestinal epithelial cells); (3) direct competition for the use of nutrients (e.g., uptake of vitamin B₁₂ by gram-negative bacteria or the fish tapeworm *Diphyllobothrium latum*); and (4) stimulated secretion of water and electrolytes by products of bacterial metabolism, such as hydroxylated bile acids and short-chain (volatile) organic acids.

Conditions Associated with Bacterial Overgrowth

The most important factors maintaining the relative sterility of the upper gut include (1) gastric acidity, (2) peristalsis, and (3) intestinal immunoglobulins (IgA). Thus, conditions that impair these functions can result in bacterial overgrowth. Impaired peristalsis can be caused by motility disorders (e.g., scleroderma, amyloidosis, or diabetes mellitus) or anatomic changes (e.g., surgically created blind loops, obstruction, jejunal diverticulosis). Achlorhydria (resulting from atrophic gastritis or the inhibition of gastric acid secretion), pancreatic insufficiency, and hypogammaglobulinemia are also associated with bacterial overgrowth, but uncommonly result in clinical steatorrhea.

Diagnosis

Direct culture of jejunal aspirate is the most definitive diagnostic test, but it is invasive, uncomfortable, and a costly laboratory undertaking. The ¹⁴C-xylose breath test is an accurate and sensitive laboratory test, whereas breath hydrogen after an oral challenge with glucose is simpler, although not as sensitive or specific. Empirical therapeutic trial with antibiotics is an acceptable alternative to diagnostic testing.

Treatment

When appropriate, specific therapy, such as surgery for intestinal obstruction, should be provided. More commonly,

patients are treated with antibiotics, the most appropriate being those effective against aerobic and anaerobic enteric organisms. Tetracycline, trimethoprim-sulfamethoxazole, or metronidazole, in combination with a cephalosporin or quinolone, is a suitable agent. A single course of therapy for 7 to 10 days may be therapeutic for months. In other patients, intermittent therapy (1 week of every 4 weeks) or even an extended period of continuous therapy may be the most effective management.

Malabsorptive Therapy

Cardiovascular disease and other consequences of obesity have reached epidemic proportions in the United States, and as a result, one approach to the problem has included the deliberate induction of malabsorption (primarily of fats) to reduce lipid levels and the body mass index (BMI). Medications used for this purpose include bile-acid binding resins, such as cholestyramine and colestipol, and more recently, the lipase inhibitors, orlistat (Xenical) and ezetimibe (Zetia). Surgical treatment usually consists of gastric partition combined with some degree of small intestinal bypass, which induces significant weight loss by several proposed mechanisms, including malabsorption, improved nutrient deposition, and enhanced satiety.

D. Diarrhea

Satish K. Singh

Definition

Diarrhea is both a symptom and a sign. As a symptom, diarrhea is most often reported as a decrease in stool consistency and an increase in stool volume; often, patients will use the term to describe frequency, urgency, and fecal incontinence as well. As a sign, diarrhea is defined as a stool weight (i.e., water content) that exceeds 200 g in 24 hours. This section discusses the physiologic aspects of intestinal solute and water transport and the pathophysiologic factors and management of diarrheal diseases.

Normal Physiology

About 8 to 9 L of fluid enter the small intestines daily: 1 to 2 L is derived from dietary intake, whereas the balance comes from normal salivary, gastric, pancreatic, biliary, and intestinal secretions. The small intestine absorbs most of this fluid so that only 1 to 1.5 L pass into the colon. In the colon, further water salvage results in a final stool output of only 100 to 200 mL per day.

Different types of specialized epithelial cells line the small and large intestines. However, all epithelial cells possess (1) polarity, in that they have distinct apical (facing the lumen) and basolateral (facing the blood) domains, (2) intercellular *tight* junctions that join their apical poles, and (3) a basolateral Na^+ pump (Na^+, K^+ -ATPase) that maintains an electrochemical gradient. Among different small and large intestinal segments, epithelial cells mediate a range of different transport processes but share the fact that ions are moved across the epithelium by transport processes, while water follows along passive osmotic gradients. Movement of ions across the epithelium can be either passive, along electrochemical and concentration gradients, or active, against such gradients, requiring energy expenditure. Active ion transport is always transcellular, that is, it occurs *through* cells. Because of their charge, ions do not readily penetrate lipid bilayers and are moved through the plasma membrane in a regulated fashion through specialized proteins known as *pumps*, *carriers*, and *channels*.

Pumps are energy (adenosine triphosphate [ATP])-requiring transporters capable of moving ions and solutes against an electrochemical gradient. The most important pump in the intestinal epithelium is Na^+, K^+ -ATPase, which removes Na^+ from the inside of the cell across the basolateral membrane against electrochemical gradients. With each cycle of the pump, three Na^+ ions are exported, and two K^+ ions are imported, creating an electronegative, Na^+ -poor cell interior that ultimately drives transepithelial Na^+ and water absorption (Fig. 34-4).

Figure 34-4 Apical sodium transporters. Sodium moves down its electrochemical gradient across the apical membrane of the epithelial cell. Pathways for apical sodium uptake include (1) channel proteins specific for sodium that can be blocked by amiloride, (2) carriers that couple the movement of sodium to the movement of nutrients such as glucose, and (3) antiport carriers that mediate electroneutral entry of sodium in exchange for intracellular hydrogen ion (i.e., acid). The common exit pathway across the basolateral membrane is the sodium pump. (From Sellin JH: Intestinal electrolyte absorption and secretion. In Feldman M, Scharschmidt BF, Sleisenger MH [eds]: Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management, 6th ed. Philadelphia: WB Saunders, 1998, pp 1451-1471.)

Fluid secretion throughout the gut depends on electrogenic chloride (Cl^-) secretion. Active Cl^- secretion is predominantly mediated by cells within the crypts that possess tandem pathways for basolateral uptake and apical exit of Cl^- . Typically, basolateral Cl^- -uptake mechanisms are coupled to the Na^+ gradient, thus maintaining intracellular Cl^- concentration above electrochemical equilibrium. As a result, increased apical Cl^- permeability following activation of an apical Cl^- -channel protein causes Cl^- to exit the cell into the lumen, resulting in Cl^- and water secretion. One Cl^- channel, in particular, has been identified as a defective gene product in cystic fibrosis. Known as the *cystic fibrosis transmembrane regulator* (CFTR), it is activated by elevations in intracellular cyclic adenosine monophosphate (cAMP) as well as by several other mediators implicated in secretory diarrhea. The process of active chloride secretion is shown in Figure 34-5. Of note, secretory diarrheas produce a fluid rich in Cl^- and HCO_3^- anions. Basolateral HCO_3^- uptake (through $\text{Na}-\text{HCO}_3^-$ cotransport [NBC] or $\text{Cl}:\text{HCO}_3^-$ exchange) in tandem with an apical exit pathway (through $\text{Cl}:\text{HCO}_3^-$ exchange or an HCO_3^- conductive pathway) have

been implicated in the process of active bicarbonate secretion in animal models.

Although the small bowel and the colon share many basic mechanisms with regard to ion transport, differences exist. As a result, the small intestinal fluid that enters the colon has a plasma-like electrolyte composition, whereas fecal fluid

contains twice as much K^+ as it does Na^+ . At no time does either the small or the large intestine maintain standing osmotic gradients.

Pathophysiologic Factors

A significant number of mechanisms can cause diarrhea, and these mechanisms are listed in Table 34-6. However, most diarrheal states are caused by either inadequate absorption of ions, solutes, and water or by increased secretion of electrolytes that result in water accumulation in the lumen.

Figure 34-5 Chloride secretion. Discrete basolateral entry steps and apical exit steps are integral to chloride secretion. A carrier couples the movement of sodium, potassium, and chloride in a 1:1:2 stoichiometry and permits chloride to accumulate in the cell above its electrochemical equilibrium. Chloride exits the cell across the apical membrane by means of a chloride channel. The sodium and potassium that entered with the chloride are recycled by, respectively, the sodium pump and a basolateral potassium channel. (From Sellin JH: Intestinal electrolyte absorption and secretion. In Feldman M, Scharschmidt BF, Sleisenger MH [eds]: *Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management*, 6th ed. Philadelphia, WB Saunders, 1998, pp 1451-1471.)

SECRETORY DIARRHEA

Secretory diarrhea is caused by abnormal ion transport across the intestinal epithelium, which results in decreased absorption, increased secretion, or both. Secretory diarrheas are typically caused by neurohumoral mediators or bacterial toxins that affect intracellular levels of cAMP, cyclic guanosine monophosphate (cGMP), and calcium. Elevated levels of these intracellular second messengers, in turn, typically inhibit electroneutral NaCl absorption and induce Cl^- secretion, the net result being increased water accumulation in the gut lumen. A classic example of a secretory diarrhea is cholera. A toxin produced by the bacterium binds to membrane receptors on enterocytes, irreversibly activating a guanine nucleotide-binding protein (G protein) that leads to enhanced cAMP production. The increased intracellular cAMP (1) inhibits apical electroneutral NaCl absorption (mediated by coupled Na^+ -hydrogen ion [H^+] and Cl^- -bicarbonate ion [HCO_3^-] exchange) and (2) simultaneously induces Cl^- secretion by activating apical Cl^- channels. These events result in massive diarrhea, intravascular volume loss, and, absent fluid resuscitation, eventual circulatory collapse. The hallmark of toxigenic and hormone-mediated secretory diarrheas is that there is no associated histopathologic

Table 34-6 Classification of Diarrhea

Type	Mechanism	Examples	Characteristics
Secretory	Increased secretion or decreased absorption of Na^+ and Cl^-	Cholera Vasoactive intestinal peptide-secreting tumor Bile salt enteropathy Fatty acid-induced diarrhea	Large-volume, watery diarrhea No gas or pus No solute gap Little or no response to fasting
Osmotic	Nonabsorbable molecules in gut lumen	Lactose intolerance (lactase deficiency) Generalized malabsorption (particularly carbohydrates) Mg^{2+} -containing laxatives	Watery stool; no blood or pus Improves with fasting Stool may contain fat globules or meat fibers and may have an increased solute gap
Inflammatory	Destruction of mucosa Impaired absorption Outpouring of blood, mucus	Ulcerative colitis Shigellosis Amebiasis	Small frequent stools with blood and pus Fever Variable
Decreased absorptive surface	Impaired reabsorption of electrolytes or nutrients	Bowel resection Enteric fistula	
Motility disorder	Increased motility with decreased time for absorption of electrolytes or nutrients Decreased motility with bacterial overgrowth	Hyperthyroidism Irritable bowel syndrome Scleroderma Diabetic diarrhea	Variable Malabsorption

Na^+ , sodium; Cl^- , chloride; Mg^{2+} , magnesium.

epithelial injury, leaving intact apical Na^+ -coupled nutrient transporters (Na^+ -glucose, Na^+ -amino acid) that are not inhibited by intracellular second messengers. The persistence of these intact, alternative Na^+ -absorption pathways can be exploited effectively by glucose and starch-based oral rehydration therapies.

Clinically, secretory diarrheas (1) are high output (often >1 L per day), (2) persist during fasting, and (3) display a minimal (<50 mOsm) stool osmotic gap (i.e., the amount by which stool osmolality exceeds what is accounted for by measured electrolytes, estimated from $2[\text{Na}^+] + 2[\text{K}^+]$) because salt secretion alone is causing the diarrhea. Some causes of secretory diarrhea are listed in Table 34-7. Although these features are classic for cases of pure secretory diarrhea, a more complex picture can result when mixed mechanisms coexist, for example, in malabsorptive syndromes such as celiac disease. Osmotic forces from malabsorbed fatty acids interfere with normal fluid absorption from both the small intestine and the colon, whereas bile acids interfere with absorption of water and electrolytes in addition to inducing Cl^- secretion in the colon. Thus, the component of water loss from fat malabsorption may fall substantially during fasting (see "Osmotic Diarrhea" next), an osmotic gap might be present as a result of carbohydrate malabsorption, fermentation and organic anion production, and a secretory component may exist as well if, for example, bile acids are substantially malabsorbed causing colonic Cl^- secretion.

OSMOTIC DIARRHEA

Water and solute movement is coupled throughout the GI tract, and no standing osmotic gradients are maintained across the mucosa. As a result, osmotic diarrhea is simply caused by excessive levels of poorly absorbed, osmotically active solutes in the lumen. Some causes of osmotic diarrhea are presented in Table 34-8. Osmotic diarrhea has two important clinical features. First, diarrhea stops when patients fast because they are no longer taking in poorly absorbed osmoles or the nutrients that they are malabsorbing. Second, stool analysis reveals an elevated osmotic gap because of the presence in stool of osmotically active or nonabsorbed agents.

ABNORMAL INTESTINAL MOTILITY

Altered GI motility can cause diarrhea by two mechanisms:

1. Enhanced motility, resulting in rapid gut transit and decreased contact time between luminal contents and absorptive epithelial cells. Decreased transit time and enhanced propulsive contractions contribute to postvagotomy, postgastrectomy, carcinoid, hyperthyroid, and diabetic diarrheas as well to diarrhea-predominant IBS.
2. Decreased motility, caused by diseases such as scleroderma or diabetes. These diseases promote small intestinal stasis that can result in overgrowth of largely anaerobic bacteria that inappropriately deconjugate bile acids, causing steatorrhea and diarrhea.

EXUDATIVE DIARRHEA

Inflammatory or infectious conditions that result in damage to the intestinal mucosa with disruption of the epithelial layer and intercellular junctions can cause diarrhea by numerous mechanisms. Blood, mucus, and serum proteins can be lost, the extent of which depends largely on the degree of injury. However, mucosal damage and attendant inflammation can interfere with absorption, induce secretion, and affect motility, all of which contribute to diarrhea.

Evaluation of Diarrhea**HISTORY AND PHYSICAL EXAMINATION**

A thoroughly obtained history will yield valuable clues that guide appropriate and cost-effective investigation of diarrheal diseases. The *duration* of diarrhea is particularly useful because most acute diarrheas are caused by microbial pathogens and typically resolve independent of intervention. Chronic diarrhea, defined as lasting more than 4 weeks, is unlikely to be infectious. The presence of blood is also a useful clue because it suggests inflammation, neoplasm, ischemia, or infection by invasive organisms. Large-volume diarrhea suggests small bowel or proximal colonic disease; in contrast, frequent small stools with associated urgency suggest left-sided colonic or rectal disease. All current and recent medications (specifically new medications, antibiotics, and antacids) and alcohol intake should be

reviewed. Intake of nutritional supplements should also be reviewed, including sugar substitutes that contain poorly absorbed carbohydrates, fat substitutes, milk products, shellfish, and heavy intake of fruits, fruit juices, and caffeine. The social history should include travel, source of drinking water (treated city water or well water), consumption of raw milk in rural populations, exposure to farm animals that may spread *Salmonella* or *Brucella*, and sexual practices. Familial occurrence of celiac disease, inflammatory bowel disease, or multiple endocrine neoplasia syndromes should be considered as well. Physical examination in acute diarrhea is helpful in determining severity of disease and hydration status. Physical findings are less helpful in chronic diarrhea, although certain findings have been associated with specific diseases: oral ulcers and pyoderma gangrenosum with inflammatory bowel disease, dermatitis herpetiformis with celiac disease, and lymphadenopathy with lymphoma.

Further evaluation with appropriate laboratory tests depends largely on the duration and severity of diarrhea and the presence of blood, overt or occult, in the stool.

ACUTE DIARRHEA

Acute diarrhea is defined as lasting less than 4 weeks and is most commonly caused by infectious organisms or toxins. It is usually self-limited and, in the absence of blood in the stool, usually remains undiagnosed. If a patient is seen early in the course of illness and has mild diarrhea without systemic symptoms or blood in the stool, expectant management with observation and follow-up is the most appropriate course of action. Otherwise, and certainly in the presence of blood, stool should be evaluated for infectious organisms, and antimicrobials should be initiated when appropriate. If organisms are not identified, sigmoidoscopy or colonoscopy should be performed and biopsies obtained. Further investigations should be guided by findings on sigmoidoscopy (e.g., if inflammatory bowel disease is suspected), severity of diarrhea, immunocompetence of the patient, and the presence of systemic toxicity. A general algorithm for the evaluation of acute diarrhea is shown in Figure 34-6.

CHRONIC DIARRHEA

Clinicians have numerous tests at their disposal for investigating a patient with chronic diarrhea, and a rational approach should be exercised in making the most appropriate choices. Duration of diarrhea, evidence of systemic involvement, nutritional deficiencies, and prior work-up should guide the evaluation of the patient. In contrast to acute diarrhea, infectious origin is uncommon with chronic diarrhea. However, certain persistent parasitic infections, such as giardiasis and postviral syndromes that result in persistently disturbed brush border enzyme, motility, and transport activities, can produce a chronic malabsorptive diarrheal picture.

Weight loss and evidence of nutritional deficiencies suggest malabsorption caused by a pathologic process in the small intestine or pancreas, the latter associated with a history of excessive alcohol intake or chronic pancreatitis. Chronic bloody diarrhea suggests inflammatory bowel disease, particularly ulcerative colitis. Chronic diarrhea with no evidence of nutritional or metabolic derangements suggests lactose intolerance (common); IBS, particularly when associated with abdominal pain (common); microscopic colitis (particularly in elderly women); eosinophilic enteritis (in young men); fecal incontinence; or surreptitious laxative abuse. Colon cancer should always be considered in older patients, especially those who have not had age-appropriate screening. Large-volume diarrhea in the absence of nutritional deficiencies, with features of a secretory process, usually prompts a search for hormone-producing tumors, although more often than not, they remain occult. Whenever possible, therapy is directed specifically toward the underlying cause. When no specific treatment is available (as in microscopic colitis) or no cause is determined, empiric therapies (e.g., antibiotics for possible bacterial overgrowth, *G. lamblia* infection, cholestyramine for bile acid malabsorption) with or without agents that decrease motility and secretion in general (e.g., loperamide, diphenoxylate and, in more severe cases, codeine, paregoric, long-acting somatostatin analogue), can be tried. A general algorithm for the approach to chronic diarrhea is presented in Figure 34-7.

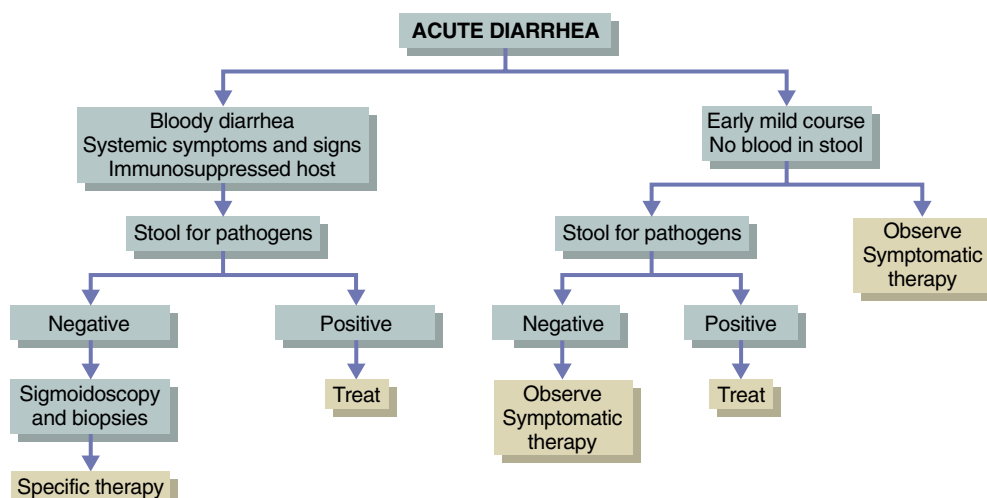

Figure 34-6 Algorithm for the evaluation of the patient with acute diarrhea.

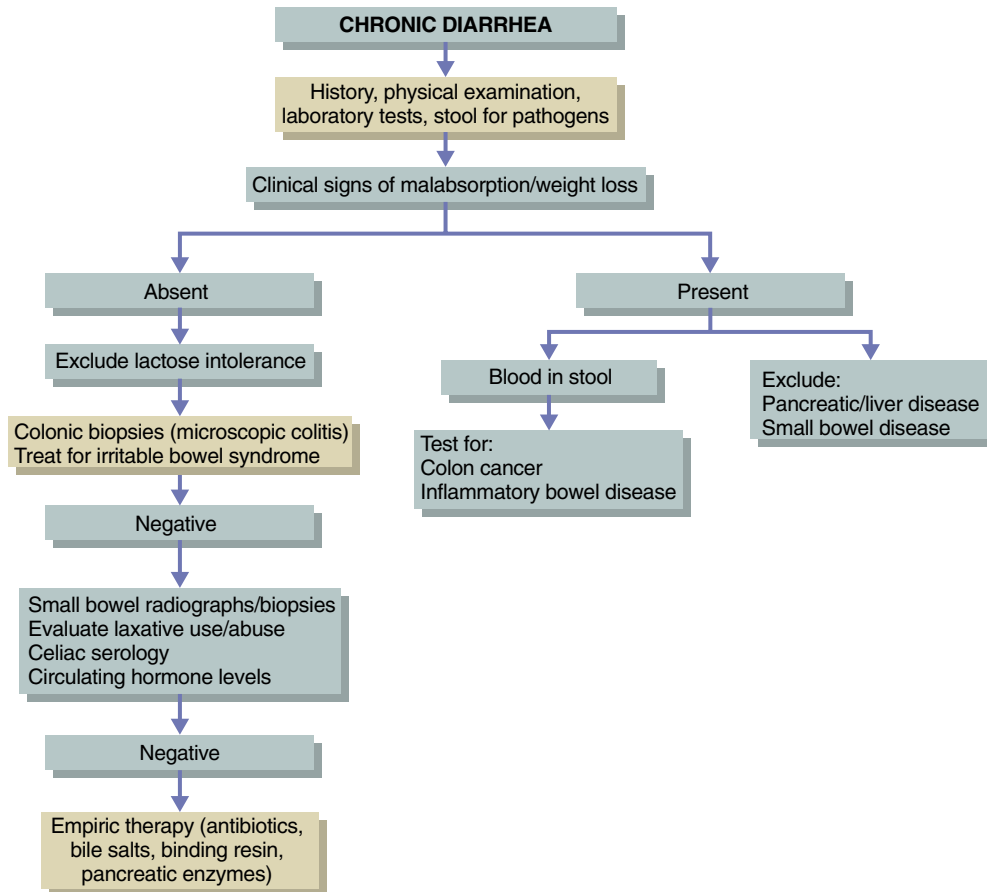

Figure 34-7 Algorithm for the evaluation of the patient with chronic diarrhea.

Prospectus for the Future

When viewed in a long-term perspective, the addition of diagnostic studies such as CT scanning, endoscopy, and most recently capsule endoscopy has clearly heightened diagnostic accuracy. The hope is that, in the future, even more sophisti-

cated diagnostic instruments, including biochemical measurements, will enhance our understanding of the complex manifestations of abdominal pain.

Endoscopic and Imaging Procedures

Brian C. Jacobson and Daniel S. Mishkin

Since Mikulicz first used a prototype esophagoscope to visualize the lumen of the esophagus in 1880, physicians have been attempting to peer into every portion of the gastrointestinal (GI) tract in an attempt to understand disease and to restore their patients to health. No other field in internal medicine is associated with as many imaging modalities as gastroenterology, with its broad focus on the GI tract, pancreas, liver, and biliary tree, including the gallbladder. A wide variety of both invasive and noninvasive imaging procedures is available for evaluating GI signs and symptoms, performing cancer screening, and providing therapeutic interventions. This chapter reviews the various endoscopic and radiographic procedures currently in use, including their indications and basic information regarding their performance.

Gastrointestinal Endoscopy

The once-rigid endoscope has been supplanted by today's flexible instruments. These instruments are composed of long shafts 6 to 12 mm in diameter (Fig. 35-1) that house wires for deflecting the endoscope's tip in multiple directions, digital imaging equipment, and an accessory channel for the passage of biopsy forceps or other tools. The distal end contains lenses for both lighting and visualization, and the proximal end includes a series of knobs and buttons used to deflect or *steer* the endoscope's tip, insufflate air into the GI lumen, wash the lens, and suction air or liquid from the GI lumen.

GI endoscopy can be performed in dedicated endoscopy suites or at a patient's bedside in emergency situations. After positioning the patient appropriately and providing sedation, if necessary, the lubricated endoscope is passed through the intended orifice and advanced manually by the endoscopist. Bends and turns in the GI lumen are navigated by deflecting the endoscope tip and by applying torque

to the instrument shaft (i.e. rotating the shaft along the long axis of the instrument). Endoscopy is generally safe, with complications that include bleeding (0.3% to 1% after colonoscopic polypectomy), perforation (0.05% in general, but 0.1% to 0.5% after polypectomy), and sedation-associated hypotension and hypoxia (1% to 5%). Death related to endoscopic procedures is exceedingly rare (0% to 0.01%).

Technologic advances continue to affect endoscopic imaging, such as the recent introduction of high-definition instruments, magnification endoscopy, and narrow band imaging (NBI). NBI incorporates specific filters into the endoscope's light source to limit the instrument's lighting to narrow wavelengths in the blue and green range of the visible spectrum. By eliminating red light, endoscopic images demonstrate greater mucosal detail that may highlight subtle neoplastic changes.

ESOPHAGOGASTRODUODENOSCOPY

Esophagogastroduodenoscopy (EGD), often referred to as *upper endoscopy*, is performed with a *gastroscope* and allows the endoscopist to visualize the esophagus, stomach, and duodenum to its third and sometimes fourth portions (Fig. 35-2). Diagnostic indications for EGD include dysphagia and odynophagia, screening for and surveillance of Barrett esophagus, screening for esophagogastric varices, upper GI symptoms suggestive of ulcer disease or malignancy, suspected upper GI bleeding, and occasionally investigation of less common entities, such as celiac sprue or protein-losing enteropathy. The therapeutic interventions performed during EGD include the treatment of esophageal varices; dilation of esophageal strictures; rupture of esophageal rings and webs; dilation of the gastroesophageal junction in the setting of achalasia; removal or ablation of neoplastic lesions such as polyps, foci of high-grade dysplasia, or small malignancies; therapy for upper GI bleeding; and the placement of palliative stents for malignant obstruction of the esophagus, pylorus, or duodenum.

Figure 35-1 Endoscopes used for upper GI endoscopy. Endoscopes of varying sizes are available for use in different situations. The uppermost endoscope (6-mm diameter) can be used for unsedated endoscopy. The middle endoscope (9-mm diameter) is used for standard diagnostic endoscopy. The lowermost endoscope (12-mm diameter) is used for therapeutic endoscopy, such as the placement of enteral stents. (Courtesy of Brian C. Jacobson.)

ENTEROSCOPY

Examination of the small intestine beyond the ligament of Treitz is not feasible with a standard gastroscope. More recently, greater strides have been made to gain direct visualization of the 6 meters or 22 feet of the small intestine. *Push* enteroscopy using a long (>200 cm) endoscope allows the endoscopist to both image and biopsy or cauterize lesions in the small intestine. Advancing this instrument beyond the first 50 cm of jejunum can be difficult. Balloon-assisted enteroscopy is an exciting new technique that provides endoscopic access to most of the small bowel. This method employs balloons, incorporated into overtubes or the endoscope itself, to permit pleating of the small bowel onto the endoscope. By inflating and deflating the balloons in sequence, the enteroscope can be advanced through extremely long stretches of small intestine. Combining an antegrade (through the mouth) and retrograde (through the anus) approach, the entire small intestine can be visualized. Intraoperative enteroscopy is yet another means for obtaining visualization of the deeper portions of jejunum or ileum. In this procedure, a surgeon will make an incision in the patient's abdomen and then pleat the small bowel onto the enteroscope while the endoscopist visualizes the luminal surface. Once a lesion is identified, the surgeon may elect to proceed directly to a resection of the affected intestine.

VIDEO CAPSULE ENDOSCOPY

The desire to obtain visualization of the GI lumen in the least invasive way has resulted in the development of video capsule endoscopy, the use of pill-size wireless cameras that

the patient swallows (**Web Fig. 35-1**; **Web Video 35-1**). Currently, capsule endoscopes are available for the evaluation of the esophagus and small intestine. Capsules are 11 × 26 mm and can transmit images wirelessly to a data recorder as they travel through a patient's GI tract, without the need for sedation. At the end of the study, the data recorder allows for stored images to be uploaded into a computer for viewing while the capsule is ultimately passed in the patient's stool. The esophageal capsule is helpful in patients being screened for esophageal varices or individuals with suspected complications of acid reflux, such as reflux esophagitis or Barrett esophagus. The small bowel capsule has become the gold standard for visualizing the small intestine, most commonly for the purpose of investigating obscure GI bleeding (**Web Figs. 35-2 and 35-3**; **Web Videos 35-2 and 35-3**) and suspected inflammatory bowel disease (**Web Figs. 35-4 and 35-5**).

SIGMOIDOSCOPY AND COLONOSCOPY

Flexible sigmoidoscopy allows visualization of the rectum, sigmoid colon, and descending colon to the level of the splenic flexure. Enemas are given before the procedure to clear stool from the distal colon. Because sigmoidoscopy is quick (<10 minutes) and not particularly painful, sedation is typically not provided, making it a convenient tool for colorectal cancer screening. Additional indications for sigmoidoscopy include acute and chronic diarrhea and rectal bleeding and for evaluating responses to therapies for colitis.

Colonoscopy allows direct visualization of the entire large bowel and even several centimeters of terminal ileum. Bowel cleansing for colonoscopy requires the ingestion of osmotically active solutions, such as sodium phosphate or polyethylene glycol, coupled with a liquid diet for 24 hours before the procedure. Colonoscopy is more uncomfortable for the patient than sigmoidoscopy, which requires sedation. Indications for colonoscopy include those for sigmoidoscopy, as well as iron deficiency anemia, frank and occult GI blood loss, and assessing inflammatory bowel disease, including surveillance for dysplasia. Therapeutic interventions possible during colonoscopy include polypectomy, thermal ablation of vascular ectasias, decompression of colonic dilation associated with pseudo-obstruction, and occasionally the endoscopic control of lower GI bleeding.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

Endoscopic retrograde cholangiopancreatography (ERCP) is a combined endoscopic and radiographic procedure for imaging the biliary and pancreatic ducts. A *duodenoscope* is a specially designed instrument for use during ERCP that includes an imaging lens oriented on the side of the endoscope's tip, allowing a direct view of the ampulla of Vater on the medial wall of the second portion of the duodenum. A tiny finger-like projection called an *elevator* helps the endoscopist guide a catheter into the duct of interest. Contrast is then injected through the catheter, filling the duct, and fluoroscopic images are obtained (**Fig. 35-3**). ERCP is indicated for evaluating obstructive jaundice with or without suppurative cholangitis, biliary colic with suspected bile duct stones, chronic or recurrent acute pancreatitis, and suspected

Figure 35-2 **A**, Endoscopic view of the distal esophagus. The distal esophagus contains an abrupt transition between its squamous-lined mucosa and the columnar-lined mucosa of the stomach. **B**, Endoscopic view of Barrett esophagus, in which the squamous epithelium of the distal esophagus is replaced by columnar-lined epithelium. Evident in this view is a tongue of columnar-lined mucosa extending proximally into the esophagus. **C**, Endoscopic view of a gastric ulcer. A yellow-based ulceration with a pigmented spot is visualized on the gastric wall at the transition between the corpus and the antrum. (Courtesy of M. Michael Wolfe.)

primary sclerosing cholangitis. Bile duct brushings and even biopsies may be obtained to determine whether a biliary stricture is neoplastic. With the use of a special manometry catheter, sphincter of Oddi pressures can also be measured in cases of suspected sphincter of Oddi dysfunction. Therapeutic interventions possible during ERCP include sphincterotomy (an incision through the sphincter of Oddi using a catheter with an electrocautery cutting wire), removal of bile duct stones, and placement of biliary or pancreatic duct stents to alleviate signs and symptoms of obstruction. ERCP carries a significant (5%) risk for complications, including pancreatitis, postsphincterotomy bleeding, and perforation.

Choledochoscopy and *pancreatography* are techniques in which an endoscope 3 mm or less in diameter is passed through the accessory channel of a duodenoscope and into the bile or pancreatic ducts. The use of this small endoscope permits direct visualization of ductal abnormalities, guides electrohydraulic lithotripsy of large stones, and allows for direct sampling of ductal lesions.

ENDOSCOPIC ULTRASOUND

Endoscopic ultrasound (EUS) or endosonography is performed with an endoscope containing an ultrasound transducer in its tip. Because this transducer can be placed within

A

B

the GI lumen, high-resolution images of the bowel wall can be obtained, revealing distinct layers that correspond to the mucosa, submucosa, muscularis propria, and serosa (Fig. 35-4). This technique allows the endoscopist to stage tumor depths and determine the layer of origin of subepithelial masses. In addition, EUS can penetrate the luminal wall, providing sonographic images of the mediastinum, pancreas, liver, gallbladder, and mesenteric vessels. Thin EUS probes can be passed through the accessory channel of a duodenoscope and into the biliary and pancreatic ducts to provide sonographic images of small tumors and stones. Fine-needle aspiration (FNA) can be performed under EUS guidance, enhancing the diagnostic capability of EUS. Tissue samples obtained by EUS-guided FNA are analyzed by cytopathologists and can distinguish benign from malignant lesions and metastatic spread of cancer to lymph nodes or the liver. FNA can also be performed to drain cystic lesions, such as pancreatic cystic neoplasms and pseudocysts.

Nonendoscopic Imaging Procedures

PLAIN ABDOMINAL RADIOGRAPHS

Plain abdominal radiographs include upright, supine, and lateral decubitus films obtained with standard x-ray equipment and without the use of contrast agents. Plain abdominal radiographs can reveal evidence of a pneumoperitoneum, dilated bowel loops and air-fluid levels, excessive amounts of stool, or displacement of bowel loops. These findings are indicative of a perforation, obstruction or ileus, constipation or fecal impaction, and volvulus or organ enlargement,

Figure 35-4 Endoscopic ultrasound of the gastrointestinal wall. A 12-MHz ultrasound probe, passed through the accessory channel of an endoscope, demonstrates the normal layers of the rectal wall. The mucosa (m) appears as a superficial, hyperechoic (white) band and a deeper hypoechoic (black) band. The submucosa (sm) appears as the next hyperechoic layer. The muscularis propria (mp) appears hypoechoic, and the serosa (s) appears as the outermost, hyperechoic layer. (Courtesy of Brian C. Jacobson.)

respectively (Fig. 35-5). Calcifications, such as those seen in chronic pancreatitis and gallstone disease, may also be visible on these radiographs. Plain films are most useful in the initial evaluation of abdominal pain or nausea and vomiting.

Figure 35-5 Upright plain radiograph of the abdomen. Air in dilated loops of colon and air-fluid levels can be seen in this patient with a sigmoid volvulus. (Courtesy of Brian C. Jacobson.)

CONTRAST STUDIES

Contrast agents such as barium or the water-soluble diatrizoate (e.g., Gastrografin) can be administered by mouth or rectum to detect mucosal abnormalities (ulcerations and masses), strictures, herniations, diverticula, and abnormal peristalsis. Contrast agents can be used alone (*single contrast*) or with the instillation of air or ingestion of gas-forming agents (*double contrast*). The former method is more useful for detecting obstructing lesions and motility disturbances, whereas the latter method aids in detecting more subtle findings such as small ulcerations or polyps.

A *video esophagogram* entails the filming of a patient's oral cavity and pharynx during the ingestion of contrast materials of various thicknesses and textures. This imaging modality permits careful assessment of a patient's ability to manipulate a food bolus, swallow effectively, and avoid aspiration events. A video esophagogram is indicated for evaluating patients with oropharyngeal dysphagia and recurrent aspiration pneumonia. A more generalized *barium esophagogram* focuses attention on the esophagus during the ingestion of a bolus of contrast. This study can detect esophageal rings, webs, strictures, and motility problems that endoscopy might miss. A barium esophagogram may be useful for evaluating nonoropharyngeal dysphagia as well as odynophagia.

An *upper GI series* includes serial radiographic images as an ingested contrast agent travels through the esophagus, stomach, and duodenum. This study can define gastric

Figure 35-6 Small bowel follow-through. Ingested barium defines the contours of the small and large bowel lumen. A long stricture (S) of the terminal ileum can be seen in this patient with Crohn disease. (Courtesy of Brian C. Jacobson.)

abnormalities, such as ulcerations and mucosal thickening. It is indicated in evaluating abdominal pain and suspected gastric outlet obstruction. If radiographic imaging continues as the contrast agent traverses the jejunum and ileum, the study is called a *small bowel follow-through* (Fig. 35-6). During this more involved procedure, a radiologist will obtain multiple films, including *spot films*, or close-up views of regions that appear abnormal. Fluoroscopy can be used to follow a contrast agent during the journey through the small bowel. Attention is paid not only to structural findings but also to the length of time required for contrast to reach and enter the colon. For more detailed small bowel images, *enteroclysis* can be performed. This method requires the infusion of concentrated contrast directly into the small bowel through a nasojejunal tube placed under fluoroscopic guidance. Because of its invasive nature, enteroclysis is becoming less common in this era of wireless capsule endoscopy. Indications for a small bowel follow-through include suspected small bowel obstruction or partial obstruction from any cause, suspected small bowel mucosal diseases such as Crohn disease, and obscure GI blood loss.

Single- and double-contrast barium enemas can detect colonic strictures, diverticula, polyps, and colonic ulcerations, and they can reduce an intussusception. A barium enema may be used in conjunction with flexible sigmoidoscopy to provide screening for colorectal cancer, or it may be used to visualize the proximal colon when colonoscopy cannot be completed for various reasons. In general, the upper GI series and barium enema have been superseded by upper endoscopy and colonoscopy because the endoscopic procedures offer increased sensitivity for detecting mucosal abnormalities, the ability to obtain mucosal biopsies, and the potential for resection of identified lesions.

TRANSABDOMINAL ULTRASOUND

Ultrasonography is often the first imaging study obtained in the evaluation of suspected biliary colic, jaundice, and

abnormal liver tests. Its use of sound waves to create an image avoids radiation exposure, and the addition of Doppler techniques permits the assessment of vascular patency. Ultrasound can detect parenchymal abnormalities, such as fatty liver or cirrhosis, focal masses or cysts, ascites, biliary ductal dilation, gallstones, and large vessel thromboses. It may detect thickening of the gut wall and areas of intussusception. Ultrasound is also used to guide needle placement for biopsies or fluid aspiration. Ultrasound cannot penetrate bone or air, preventing its use as a more general diagnostic tool for the GI tract.

COMPUTED TOMOGRAPHY, COMPUTED TOMOGRAPHY ENTEROGRAPHY, AND COMPUTED TOMOGRAPHY COLOGRAPHY

Computed tomography (CT) uses computer-aided reconstruction of multiple radiographic images obtained in a circular or helical course around a patient's vertical axis. Internal organs are visualized based on their inherent tissue densities compared with their surroundings. The GI lumen is usually opacified by having the patient drink an oral contrast agent. In addition, intravenous contrast agents can be administered to highlight regions with increased blood flow, thereby improving detection of pathologic lesions, such as tumors. CT can detect parenchymal lesions, such as tumors, cysts, and abscesses, as well as define the size, shape, and parenchymal characteristics of organs, such as the liver and spleen. Vascular abnormalities, such as perigastric varices or large vessel thromboses, and intra-abdominal fluid, such as ascites, can also be seen with CT. The caliber and contour of the GI tract wall are demonstrated by CT, aiding in the diagnosis of inflammatory lesions, such as colitis, diverticulitis, and appendicitis. CT can also be used to guide needle biopsies of abdominal masses and to place electrodes into tumors for ablative therapies such as radio-frequency ablation. The use of CT to guide placement of drainage catheters has made possible the percutaneous treatment of intra-abdominal abscesses, pseudocysts, and pancreatic necrosis.

CT enteroclysis and *CT enterography* are two emerging techniques developed to provide better images of the small intestine. *CT enteroclysis* uses a nasojejunal tube to deliver contrast into the small intestine, whereas *CT enterography* uses an orally ingested intraluminal contrast to highlight the small intestinal mucosa. With the advancement of this technology and its ability to reconstruct images in multiple planes, both luminal and extraluminal information can be obtained.

CT can also be used to obtain high-resolution images of the colon. *CT colography*, or *virtual colonoscopy*, makes use of special image reconstruction software to create accurate visualization of the colonic lumen, provided that the patient has completed a bowel-cleansing regimen identical to that used for colonoscopy. These CT images are 70% to 90% sensitive for detecting polyps or masses within the colon, helping to determine which patients need therapeutic colonoscopy. Virtual colonoscopy is presently being used in some centers to complete colonic visualization in the setting of an incomplete endoscopic colonoscopy.

MAGNETIC RESONANCE IMAGING AND MAGNETIC RESONANCE CHOLANGIOPANCREATOGRAPHY

Similar to CT, magnetic resonance imaging (MRI) provides multiple cross-sectional images of the abdomen and pelvis. These images are created using powerful field magnets to orient small numbers of nuclei within the body in such a way as to produce a measurable magnetic moment. MRI therefore avoids radiation exposure but requires the patient to lie nearly motionless, and often within a small enclosed tube, for prolonged periods. MRI can visualize parenchymal lesions such as masses and cysts and may better characterize abnormalities seen on CT, such as hemangiomas, hepatic focal nodular hyperplasia, and fatty liver. MRI is also helpful in better characterizing perirectal abscesses and fistulas in Crohn disease. Special rectal MRI probes or coils can provide detailed images of rectal cancer used for tumor staging.

MRI of the biliary and pancreatic ducts (*magnetic resonance cholangiopancreatography*, MRCP) is a noninvasive method that can detect ductal dilation, strictures, stones, pancreatic parenchymal changes in chronic pancreatitis, and congenital ductal abnormalities, such as pancreas divisum. Although MRCP techniques continue to improve, this technique fails to visualize small bile duct stones (<4 mm) and strictures, and it may be inaccurate for diagnosing primary sclerosing cholangitis. *Magnetic resonance angiography* is a magnetic resonance method for visualizing blood vessels and serves as an important noninvasive tool for evaluating patients with suspected mesenteric ischemia.

VISCERAL ANGIOGRAPHY

Angiography is an invasive technique whereby a catheter is introduced into a blood vessel, and intravascular contrast is injected during fluoroscopic imaging to visualize the vessel's lumen. Visceral angiography is used for evaluating mesenteric vessels in the setting of GI bleeding and suspected mesenteric ischemia. For GI bleeding, angiography is sensitive enough to detect 1 to 1.5 mL per minute of blood loss. Once the site of bleeding has been localized, the radiologist can infuse vasopressin (a vasoconstrictor) or embolize the vessel using tiny coils or gelatin sponges to ensure hemostasis. In the setting of mesenteric ischemia, angiography permits localization of a vascular stenosis or obstruction, followed by possible therapeutic interventions (e.g., balloon angioplasty, stent placement, infusion of vasodilators and thrombolytics). Other indications for angiography include the placement of transjugular intrahepatic portosystemic shunts (TIPS) in cirrhotic patients with intractable variceal bleeding or refractory ascites and for chemoembolization of liver tumors.

RADIONUCLIDE IMAGING

Technetium-99m (^{99m}Tc) is currently the major radionuclide used in GI imaging. Its 6-hour half-life and ready availability make it ideal for clinical use. ^{99m}Tc is used to label various substances for use in several imaging techniques. ^{99m}Tc -sulfur colloid scanning and ^{99m}Tc -labeled red blood cell scanning are two distinct methods that can be used to detect active GI bleeding. The latter uses the patient's own blood cells to carry the radionuclide throughout the body.

These methods can detect as little as 0.05 to 0.4 mL per minute of blood loss. However, localization of the site of bleeding is less accurate with these methods compared with angiography. ^{99m}Tc scans are often performed before angiography to document ongoing bleeding before subjecting a patient to the more invasive, less sensitive study. A ^{99m}Tc -labeled red blood cell scan can also be used to diagnose a hepatic hemangioma with an almost 100% positive predictive value.

Cholescintigraphy using ^{99m}Tc -iminodiacetic acid (IDA) analogs is the most commonly performed liver study in

nuclear medicine. The radionuclide is taken up by the liver, is excreted into bile, and passes through the biliary tree into the gallbladder and duodenum. Failure to visualize the gallbladder during a hepatobiliary IDA scan may indicate cholecystitis secondary to cystic duct obstruction by a gallstone. Meckel diverticulum can be a source of abdominal pain and bleeding, but it can be difficult to visualize with standard endoscopic and radiographic imaging. The agent ^{99m}Tc -pertechnetate has a high affinity for gastric mucosa and is therefore used to demonstrate the presence of this congenital anomaly.

Prospectus for the Future

Through continued technologic advances, improvements in both endoscopic and radiologic image quality and resolution will also continue. In addition, the gastrointestinal lumen will no longer be regarded as a boundary to therapeutic endoscopy. Examples of expected innovations include:

- *The implementation of transgastric endoscopically guided surgical procedures.* With the use of recently introduced instruments, an endoscopist will be able to incise the gastric wall, advance an endoscope into the peritoneal cavity, and then perform surgical procedures such as elective cholecystectomy. A new field of *endosurgery* will develop to accompany these advances and will require training in both surgical principles and gastroenterology.
- *Commercial availability of new endoscopic imaging methods, such as confocal microscopy and fluorescence endoscopy.* Confocal microscopy allows an endoscopist to obtain magnified endoscopic images similar to those seen with a low-power microscope. Fluorescence endoscopy entails the use of special wavelengths of light to excite naturally occurring fluorophores in benign and neoplastic tissue. These fluorophores, such as collagen and nicotinamide adenine dinucleotide plus hydrogen (NADH), then fluoresce in a predictable manner, thereby providing a means of identifying, by endoscopy, otherwise microscopic changes, such as dysplasia without the need for a biopsy.
- *Video capsule endoscopes with advanced diagnostic and possibly therapeutic capabilities.* Through further advances in nanotechnology, video capsule endoscopes will be able to sample gastrointestinal secretions, measure intraluminal pressures, take biopsy samples, and perhaps even provide focal ablation of lesions using thermal energy or radiofrequency ablation.

Esophageal Disorders

Robert C. Lowe and M. Michael Wolfe

The esophagus appears to be a simple organ with a single function, the transmission of ingested food and fluids to the stomach. This task is achieved, however, by a tightly coordinated pattern of motility, coupled with a protective barrier that prevents gastric secretions from entering the esophagus and pharynx. Derangement of these activities can cause a significant number of distressing symptoms that are among the most common reasons for patients to seek medical care.

Normal Function of the Esophagus

The esophagus is a hollow muscular tube designed to transport ingested materials from the mouth to the stomach in a coordinated fashion. It is composed of both striated muscle (the proximal one third) and smooth (the distal two thirds) muscle, bounded by two sphincters that are tonically contracted between swallows. The upper esophageal sphincter (UES) opens to admit a bolus into the esophagus and then closes rapidly to prevent aspiration of material into the trachea. The lower esophageal sphincter (LES) opens at the initiation of a swallow and remains open until the bolus passes into the stomach. It then closes to prevent reflux of ingested material into the esophageal body.

The act of swallowing begins with propulsion of the chewed bolus into the posterior oropharynx by the tongue. During the next phase of swallowing, several actions occur:

- The soft palate elevates to close off the nasopharynx.
- The epiglottis closes over the larynx, sealing off the trachea.
- The larynx is pulled upward to facilitate esophageal opening.
- The UES relaxes.
- The pharyngeal constrictors contract to propel the bolus into the esophagus.

Once the bolus has entered the esophagus, it is propelled downward by a series of coordinated contractions (primary peristalsis). The motility of the esophagus is mediated by local neurotransmitter release from enteric neurons. Con-

traction of esophageal segments above a bolus is induced by acetylcholine, whereas relaxation of segments below the bolus is mediated by both nitric oxide (NO) and vasoactive intestinal peptide (VIP).

Symptoms of Esophageal Disease

Heartburn (pyrosis) is the most common symptom of esophageal disease, occurring in 44% of Americans at least once a month. About 10% of persons in the United States experience heartburn every day. It is most often described as a burning sensation in the epigastrium that rises into the chest. Patients often move their hand up and down between the xiphoid and sternal angle when describing this symptom. Given that heartburn is a cardinal sign of gastroesophageal reflux, it tends to occur after meals, when a patient is lying supine, or after an increase in intra-abdominal pressure (bending or lifting). Specific types of food, including fatty or spicy foods and chocolate, may also induce heartburn. Symptoms are often relieved temporarily by antacid preparations. Heartburn may be accompanied by regurgitation of bitter or sour fluid into the back of the throat or by excessive saliva production (the so-called water brash, which is caused by a vagal reflex induced by the presence of acid in the esophagus).

Dysphagia refers to a sensation of difficulty swallowing; patients report that a food bolus “gets stuck” or “goes down slowly.” Although patients may point to their neck or chest when describing where the bolus gets held up, the location to which they point is poorly correlated with the actual level of obstruction. Dysphagia may result from a mechanical obstruction of the esophagus, inflammation of the esophageal mucosa, or an abnormality of motility of the esophagus.

Odynophagia, or pain on swallowing, needs to be differentiated from dysphagia in the patient history because it can be an important clue to the cause of the swallowing disorder. Painful swallowing is most often associated with infectious esophagitis or pill-induced esophageal ulcers but is only rarely present in acid-mediated esophageal disease.

Chest pain may also be a sign of esophageal disease, most often caused by gastroesophageal reflux or esophageal dysmotility. Unfortunately for the clinician, the symptoms of cardiac and esophageal chest pain overlap because of the shared neural pathways mediating pain sensation to these organs. Typical features of angina may occur in reflux-induced chest pain, including radiation to the neck and jaw, relief with nitrates, which modulate esophageal motility, and onset of symptoms with exertion. Chest pain that wakes a patient from sleep, however, is uncommon in true cardiac disease and may suggest an esophageal disorder, as does pain that is relieved with antacids or pain that lasts for several hours without associated symptoms. Esophageal chest pain is often thought to occur in response to esophageal spasm, but most data suggest that gastroesophageal reflux is responsible for most cases.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is the most common disorder of the esophagus, causing occasional heartburn in nearly one half of the population and daily symptoms in nearly 15% of Americans. GERD is responsible for about \$10 billion to \$12 billion in direct medication costs per year, and acid antisecretory therapies used in the treatment of GERD are among the most commonly prescribed drugs in the United States.

PATHOGENESIS

GERD occurs when the esophageal mucosa is bathed in acid-containing gastric secretions. Under normal conditions, several defensive mechanisms exist to minimize esophageal acid exposure. The most important of these mechanisms is the LES, which remains closed between swallows, separating the gastric and esophageal compartments. In a minority of patients with GERD, the LES is tonically weak, whereas the most common abnormality seen in these patients is an increase in transient LES relaxations (TLESRs). These brief relaxations occur in all persons, but those with GERD have a large number of episodes, allowing excessive acid exposure to the esophagus. The presence of a hiatal hernia contributes to deficient LES function by removing the added constriction of the diaphragmatic crura; thus, hiatal hernia is often noted in patients with GERD. However, reflux and hiatal hernia may occur independently of one another. Other factors contributing to esophageal protection include the following:

- Esophageal bicarbonate secretion
- Esophageal motility. Acid in the esophagus induces contractions (so-called secondary peristalsis) to clear the refluxate. Patients with motility disorders cannot empty refluxed acid into the stomach, leading to increased esophageal exposure to acid and symptoms of GERD.
- Saliva. Salivary bicarbonate helps neutralize refluxed acid. Patients with sicca syndrome, therefore, have an increased incidence of GERD symptoms.

These factors are summarized in Figure 36-1.

Figure 36-1 Pathogenesis of gastroesophageal reflux disease: (1) impaired lower esophageal sphincter—low pressures or frequent transient lower esophageal sphincter relaxation; (2) hypersecretion of acid; (3) decreased acid clearance resulting from impaired peristalsis or abnormal saliva production; (4) delayed gastric emptying or duodenogastric reflux of bile salts and pancreatic enzymes.

CLINICAL FEATURES

Heartburn is the cardinal clinical feature of GERD, and, when present, the diagnosis of GERD is made easily. Complaints of bitter regurgitation or water brash add to the diagnostic accuracy, but these features are not always present. In some cases, atypical symptoms dominate in patients with no history of heartburn. Most cases of noncardiac chest pain, which can mimic angina, are believed to be caused by GERD. In addition, a significant number of additional symptoms, including chronic cough, asthma, hoarseness, chronic sore throat, and globus sensation, may be the result of occult gastroesophageal reflux (**Web Table 36-1**).

DIAGNOSIS

The diagnosis of GERD is most often made on clinical grounds in patients with typical symptoms. Endoscopy is not a sensitive means of diagnosing GERD, given that only 15% of patients with GERD will have endoscopic evidence of esophagitis; endoscopy is useful, however, in identifying complications of GERD, including esophageal ulcers, strictures, and Barrett esophagus. A barium upper gastrointestinal series may demonstrate reflux of contrast material, but this, too, is insensitive as a diagnostic test for GERD. If a diagnosis of GERD is in question owing to the presence of atypical symptoms or comorbid illnesses, the appropriate diagnostic test is a 24-hour ambulatory pH study. In the past, this study was performed with a nasogastric probe that is placed into the stomach for 24 hours; transducers continuously monitor the pH of the esophagus while the patient participates in his or her usual daily routine. Symptomatic episodes are recorded in a diary and compared with the recorded pH values. More recently, an endoscopically

placed esophageal probe has been developed that can measure pH for 48 hours; this probe is clipped to the esophageal mucosa, and the patient can perform his or her activities without the nuisance of a nasogastric tube. Although pH monitoring is the most accurate means of diagnosing GERD, it is not often used because an empiric trial of antisecretory therapy that leads to symptom resolution is considered diagnostic and is often used in place of expensive and invasive pH monitoring.

THERAPY

Many modalities are used in the treatment of GERD; these are outlined in Table 36-1. Therapy begins with lifestyle modifications that reduce the incidence of reflux. These maneuvers are often not completely successful, and most patients require the addition of medical therapy to achieve relief of symptoms. The pathophysiologic process underlying GERD is primarily an abnormality of LES motility, but current therapies directed at augmenting motility are rarely successful. Promotility agents such as metoclopramide have been used in GERD but with limited efficacy and a preponderance of side effects. Consequently, the mainstays of therapy for GERD are acid-neutralizing and antisecretory therapy, which neutralize or inhibit gastric acid secretion and render the refluxate less irritating to the esophageal mucosa. Magnesium and aluminum-based antacids (Mylanta, Maalox, Rolaids) offer temporary relief of symptoms, but lasting relief is better achieved with histamine-2 (H_2) receptor antagonists and proton pump inhibitors (PPIs). Provided their optimal administration, PPIs are the

most effective preparations, controlling GERD symptoms in greater than 85% of patients with daily (before breakfast) or twice-daily (before breakfast and dinner) dosing.

SEQUELAE OF GASTROESOPHAGEAL REFLUX DISEASE

Common complications of GERD include esophagitis, ulceration, and esophageal stricture. Strictures typically produce progressive dysphagia to solids and often require endoscopic dilation to relieve the obstruction followed by intensive antisecretory therapy to prevent recurrence.

BARRETT ESOPHAGUS

Barrett esophagus is a condition in which the squamous mucosa of the esophagus undergoes metaplasia, becoming a columnar-lined epithelium with features of intestinal mucosa (goblet cells, Paneth cells). This specialized intestinal epithelium appears to occur as a result of years of acid exposure and is present in 5% to 15% of patients who undergo endoscopy for chronic GERD symptoms (**Web Fig. 36-1**). Barrett esophagus changes may be localized to the area of the gastroesophageal junction or may extend several centimeters proximally. The clinical significance of Barrett metaplasia lies in its propensity to undergo neoplastic change and develop into adenocarcinoma (**Web Fig. 36-2**). The risk for cancer in Barrett esophagus is estimated to be 40 to 100 times that of the general population, with a 0.5% risk for developing cancer per patient-year. Neither acid suppression therapy nor fundoplication leads to regression of Barrett metaplasia. At present, endoscopic surveillance is recommended for all patients with Barrett esophagus. Endoscopy is performed every 2 years, and biopsies are taken from the area of abnormal mucosa. If the biopsies reveal low-grade dysplasia, the frequency of endoscopies is increased. If high-grade dysplastic changes are seen and confirmed by a second pathologist, the risk for subsequent adenocarcinoma is greater than 25%, and surgical resection or ablative therapies should be considered.

Dysphagia

Evaluation of a patient complaining of difficulty swallowing begins with the discrimination between oropharyngeal and true esophageal disease. Oropharyngeal dysphagia is a disorder of initiation of swallowing caused by neurologic or muscular disease, including Parkinson disease, stroke, multiple sclerosis, myasthenia gravis, and amyotrophic lateral sclerosis (ALS). Patients with oropharyngeal dysphagia may complain of an inability to move the bolus to the back of the mouth and may note pooling of food in the cheeks after a swallow. Coughing or sputtering while eating may indicate aspiration of food, and nasal regurgitation is a classic sign of oropharyngeal dysphagia caused by a lack of coordination of the soft palate, which fails to close off the nasopharynx during swallowing. Treatment of oropharyngeal dysphagia consists of treating the underlying disorder, if possible, along with intensive speech and swallowing therapy that teaches patients techniques for improving their swallowing function.

Table 36-1 Treatment of Gastroesophageal Reflux Disease

Simple (Lifestyle) Measures

Elevation of the head of the bed
 Avoidance of food or liquids 2 to 3 hr before bedtime
 Avoidance of fatty or spicy foods
 Avoidance of cigarettes, alcohol
 Weight loss
 Liquid antacid (aluminum hydroxide, magnesium hydroxide), 30 mL, 30 minutes after meals and at bedtime, or over-the-counter H_2 receptor blockers

Persistent Symptoms

Without Esophagitis

Alginic acid antacids (Gaviscon), 10 mL, 30 minutes after meals and at bedtime
 Promotility drugs
 Cisapride, 10 mg 4 times daily (qid)
 Metoclopramide, 10 mg qid
 H_2 receptor blockers
 Cimetidine, 400 mg twice daily (bid)
 Ranitidine, 150 mg bid
 Famotidine, 20 mg bid
 Nizatidine, 150 mg bid

With Esophagitis

H_2 receptor blockers—regular or double dose depending on severity
 H_2 receptor blocker and promotility agent
 Proton pump inhibitor
 Omeprazole, 20 mg every morning
 Lansoprazole, 30 mg every morning
 Antireflux surgery

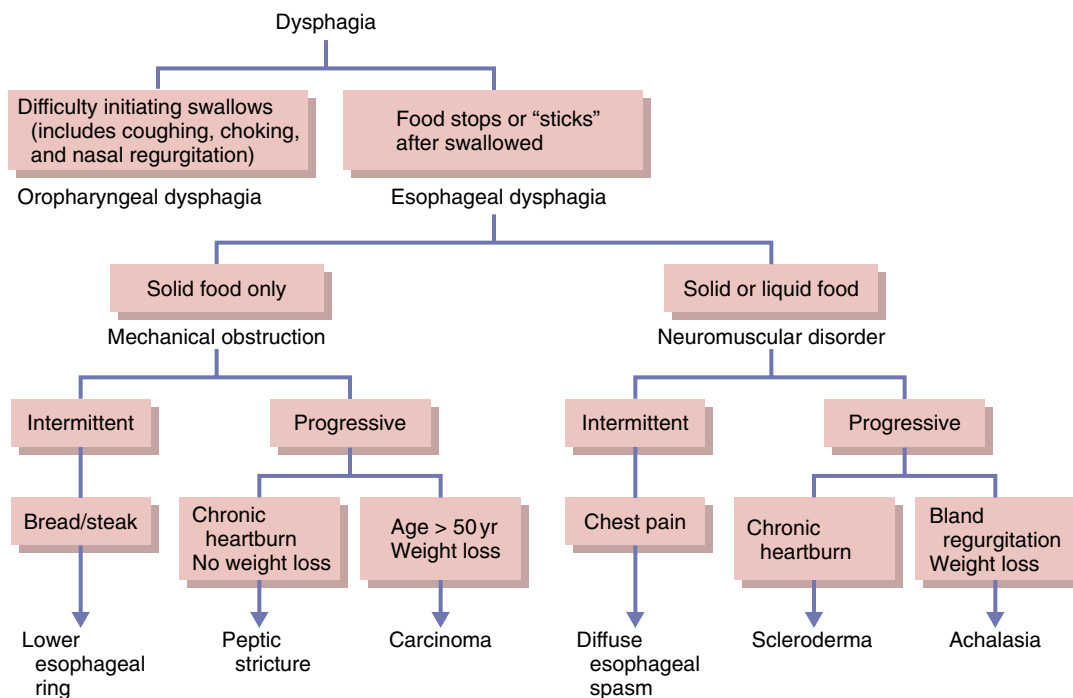

Figure 36-2 Algorithm for the differential diagnosis of dysphagia.

If a patient is found to truly have esophageal dysphagia, the next step in evaluation is to distinguish between mechanical obstruction of the esophagus and an abnormality of esophageal motility. Patients with motility disorders often describe dysphagia to both solids and liquids, whereas patients with obstruction generally have progressive obstruction only to solids until very late in their disease, when the obstruction becomes so narrow as to interfere with the passage of liquids. An important diagnostic feature in patients with dysphagia to solids is whether the dysphagia is intermittent or progressive. Intermittent dysphagia indicates the presence of an esophageal ring or web, whereas progressive symptoms are more likely to be caused by a stricture or mass lesion. A barium swallow is useful in outlining obstructive lesions of the esophagus, although endoscopy will then be necessary for purposes of biopsy and possible dilation; many gastroenterologists choose to evaluate dysphagia with an initial upper endoscopy to avoid numerous diagnostic tests.

If radiologic testing or endoscopic examination fails to demonstrate an obstructing lesion, the motility of the esophagus should be evaluated using esophageal manometry, a procedure in which a nasogastric tube with pressure transducers is placed in the esophagus, and pressures are measured during a specific number of swallows. This procedure permits diagnosis of motility disorders such as achalasia, diffuse esophageal spasm, or other nonspecific motility disorders. An algorithm for the management of patients with dysphagia is presented in Figure 36-2.

Esophageal Motility Disorders

Many patients with esophageal dysmotility have a nonspecific disorder that cannot be definitively characterized;

however, three of the more common disorders of esophageal motility are achalasia, diffuse esophageal spasm, and scleroderma. The features of these three diseases are outlined in Table 36-2.

ACHALASIA

Achalasia is a rare disorder of esophageal motility characterized by a tonically contracted LES that fails to relax appropriately during swallows, along with a dilated, aperistaltic esophagus. The disorder is caused by a degeneration of neurons in the myenteric plexus of the esophagus and in the vagal nuclei supplying the esophagus. Patients with achalasia typically have progressive dysphagia and weight loss and commonly experience chest pain and regurgitation of undigested food. Diagnosis is made using esophageal manometry, which reveals a tightly contracted LES that fails to relax with swallowing, along with poor or absent peristalsis in the esophageal body. Endoscopy is indicated to rule out an obstructing lesion of the lower esophagus or gastric cardia, which can mimic achalasia. Barium study in achalasia demonstrates a characteristic pattern shown in Figure 36-3. The widely dilated esophagus that tapers to a narrow “bird’s beak” is highly suggestive of achalasia but does not obviate the need for endoscopy and manometric evaluation. Treatment is directed at opening the contracted LES, either by balloon dilation or by surgical myotomy. Botulinum toxin injections are also used to relax the LES, but relief is usually transient, and retreatment is almost always necessary.

DIFFUSE ESOPHAGEAL SPASM

Diffuse esophageal spasm is a motility disorder of the esophagus that usually produces episodes of chest pain and intermittent dysphagia to both solids and liquids. Manometric examination of the esophagus reveals uncoordinated,

Table 36-2 Esophageal Motor Disorders

	Achalasia	Scleroderma	Diffuse Esophageal Spasm
Symptoms	Dysphagia Regurgitation of nonacidic material	Gastroesophageal reflux disease Dysphagia	Substernal chest pain (angina-like) Dysphagia with pain
Radiographic appearance	Dilated, fluid-filled esophagus Distal <i>bird-beak</i> stricture	Aperistaltic esophagus Free reflux Peptic stricture	Simultaneous noncoordinated contractions
Manometric findings			
Lower esophageal sphincter	High resting pressure Incomplete or abnormal relaxation with swallow	Low resting pressure	Normal pressure
Body	Low-amplitude, simultaneous contractions after swallowing	Low-amplitude peristaltic contractions or no peristalsis	Some peristalsis Diffuse and simultaneous nonperistaltic contractions, occasionally high amplitude

Figure 36-3 Radiologic appearance of achalasia (A) and diffuse esophageal spasm (B). In achalasia, the esophageal body is dilated and terminates in a narrowed segment or bird beak. The appearance of numerous simultaneous contractions is typical of diffuse esophageal spasm.

nonperistaltic contractions of normal or increased amplitude. This disorder is difficult to treat, given that pharmacologic therapy with nitrates and calcium channel blockers often proves minimally effective. Balloon dilation of the esophagus has been associated with relief in a minority of patients, as has surgical myotomy.

SCLERODERMA (PROGRESSIVE SYSTEMIC SCLEROSIS)
