Esophageal dysmotility is a cardinal feature of scleroderma, occurring in up to 80% of patients. Scleroderma affects the distal two thirds of the esophagus (i.e., the smooth muscle portion), leading to fibrosis, atrophy, aperistalsis of the distal esophagus, and decreased LES tone. The manometric features of scleroderma include poor peristalsis in the distal

esophageal body and a weak LES. As a result of this dysmotility, gastroesophageal reflux is typically present and is often severe; erosive esophagitis and peptic strictures are not uncommon, and patients may exhibit dysphagia caused by the primary dysmotility or to mechanical obstruction associated with stricture. The use of PPIs has significantly decreased the incidence of erosive GERD and its sequelae in patients with scleroderma.

Other Esophageal Disorders

ESOPHAGEAL RINGS AND WEBS

Esophageal rings (also called *Schatzki* or *B rings*) are rings of fibrous tissue that occur in the lower esophagus and cause intermittent dysphagia to solids. Classically, patients experience dysphagia when eating a large piece of meat or soft bread (leading to the name *steakhouse syndrome*). Between episodes of dysphagia, patients report normal swallowing and no associated symptoms. On endoscopic examination, rings are visible in the distal esophagus and may be partial or completely circumferential (**Web Fig. 36-3**). Treatment with balloon or bougie dilation is effective in relieving symptoms, although some patients require repeated dilations to remain symptom free. Esophageal webs are similar to rings but tend to occur in the proximal esophagus. An association between esophageal webs and iron deficiency anemia (sideropenic dysphagia) has been described (also known as *Plummer-Vinson* or *Patterson-Kelly syndrome*).

EOSINOPHILIC ESOPHAGITIS

Eosinophilic esophagitis (EE) is an inflammatory disorder of the esophagus characterized by a dense eosinophilic infiltration of the mucosa that leads to structural abnormalities in many patients. EE was originally described in the pediatric population but in recent years has been increasingly recognized in adults. The eosinophilia is believed to be the result of a delayed hypersensitivity reaction to food antigens or other allergens outside of the gastrointestinal tract. Dysphagia is the most commonly reported symptom, but patients

may complain about heartburn, chest pain, or nausea; a food impaction may be the first presentation of EE. Endoscopic findings may include a narrowed esophageal lumen, longitudinal furrows or circular ridges in the mucosa, and discrete luminal strictures. The esophagus in EE is friable and prone to tearing with simple passage of the endoscope, during biopsy or after dilation. Diagnosis is established if biopsies from the proximal esophagus demonstrate 15 to 25 eosinophils per high-power field. Current treatment consists of swallowed topical steroids; fluticasone inhalers are used, but the contents are sprayed into the mouth and swallowed to coat the esophagus with the steroid preparation. This has proved effective in reducing symptoms and improving histology in pediatric clinical trials, and it is currently used in adults as well; oral steroids may be necessary in refractory cases.

ESOPHAGEAL INFECTIONS

Infections of the esophagus occur but are uncommon in patients who are immunocompetent. They are, however, a major source of morbidity in patients with compromised immunity, including organ transplant recipients, patients infected with HIV and patients on chronic steroids. Infectious esophagitis tends to produce both dysphagia and odynophagia, with the latter being the predominant symptom. *Candida* esophagitis is often associated with oral thrush and tends to produce dysphagia and only mild pain on swallowing. *Candida* has a characteristic appearance on endoscopic examination, and esophageal brushings and biopsies dem-

onstrate fungal hyphae (Web Fig. 36-4). Treatment with oral fluconazole is generally effective. Herpes simplex virus (HSV) causes multiple esophageal ulcers and exhibits clinically severe odynophagia. Acyclovir is the treatment of choice for herpes esophagitis. Cytomegalovirus (CMV) also causes esophageal ulceration and odynophagia. Endoscopic examination usually demonstrates a single large ulcer in the distal esophagus, and biopsies often detect viral inclusions that confirm the diagnosis. Both ganciclovir and foscarnet are effective treatments for CMV esophagitis. HIV infection is associated with esophageal ulceration and odynophagia, although much less commonly in the era of effective antiretroviral therapy.

PILL ESOPHAGITIS

Several medications can cause esophageal ulceration following prolonged contact with the esophageal mucosa. The most common medications associated with this condition include tetracyclines, potassium preparations, nonsteroidal anti-inflammatory drugs, iron sulfate, and the bisphosphonate alendronate. Patients report epigastric pain, sometimes radiating to the back, and both dysphagia and odynophagia. Treatment is symptomatic, and topical preparations such as viscous lidocaine may be helpful in relieving discomfort. Prevention of pill esophagitis is accomplished by ensuring that patients drink sufficient fluid (>120 mL) when taking oral medications. Patients should also be counseled to avoid lying down immediately after swallowing pills.

Prospectus for the Future

Our understanding of a significant number of issues regarding GERD, including extraesophageal manifestations and disease sequelae, will continue to evolve in the future, leading to progress in the treatment options for this common disorder. These issues include the following:

- The development of effective and safe prokinetic agents aimed at treating the pathophysiologic motor abnormalities underlying GERD and the development of new medication aimed at providing prompt and sustained improvement in symptoms associated with GERD, such as episodic heartburn
- Improvements in the understanding of the precise role and contribution of gastric contents to the development of noncardiac chest pain and tracheopulmonary symptoms attributed to GERD
- Improvement in the early detection of Barrett metaplasia, dysplasia, and early esophageal adenocarcinoma (including

chemoprevention) in patients with GERD. These improvements will include a better understanding of the cellular and molecular pathways that underlie metaplastic and neoplastic transformation and tumor progression, which will serve to provide additional targets for selective pharmacologic or immunologic forms of therapy.

- Technologic advances in the performance of both instrument and capsule endoscopic methods, including endoscopic spectrophotometry, for the diagnosis and treatment of Barrett esophagus-associated dysplasia and esophageal adenocarcinoma
- A better definition of the roles of surgical and endoscopic methods to treat GERD and its complications and the precise role of photodynamic therapy and other novel methods for the ablation of dysplastic and neoplastic mucosa

Diseases of the Stomach and Duodenum

Wanda P. Blanton, Jaime A. Oviedo, and M. Michael Wolfe

The stomach, a J-shaped dilation of the alimentary tract, acts as a reservoir for recently ingested food and initiates the process of digestion. By storing large quantities of food (1.5 to 2 L in the adult), the stomach allows intermittent feeding. Once solid particles have been reduced in size to accommodate the much smaller capacity of the duodenum, the gastric contents are released through the pylorus in a controlled fashion. This chapter focuses on the anatomy and physiology of the stomach and duodenum as well as on the most common disease processes that may involve these two organs.

Gastroduodenal Anatomy

The stomach is in continuity with the esophagus proximally and the duodenum distally. A circular smooth muscle structure, the *lower esophageal sphincter*, located at the distal end of the esophagus, creates a high-pressure zone that, under normal conditions, prevents gastric contents from refluxing into the esophagus. Similarly, the pyloric sphincter, the most distal portion of the stomach, plays an important role in the trituration of solid food particles and ensures the downstream propulsion of the food bolus, preventing duodenogastric reflux. The stomach is divided into four regions (Fig. 37-1; **Web Video 37-1**). The cardia is a poorly defined transition from the esophagogastric junction to the fundus. The dome-shaped fundus projects upward above the cardia and is the most superior part of the stomach in contact with the left hemidiaphragm and the spleen. The body, or corpus, located immediately below and continuous with the fundus, is the largest part of the stomach and is characterized by the presence of longitudinal folds known as rugae. The antrum extends from the incisura angularis, a fixed sharp indentation that marks the end of the gastric body, to the *pylorus*, or *pyloric channel*, a tubular structure that joins the stomach to the duodenum.

The mucosa, or inner lining of the stomach, is formed by a layer of columnar epithelium. The submucosa, immediately deep to the mucosa, provides a skeleton of dense con-

nective tissue in which lymphocytes, plasma cells, arterioles, venules, lymphatics, and the myenteric plexus are contained. The third tissue layer, the muscularis propria, is a combination of an inner oblique, a middle circular, and an outer longitudinal smooth muscle layer. The serosa, a thin, transparent continuation of the visceral peritoneum, is the final layer of the stomach wall. The autonomic innervation of the stomach stems from both the sympathetic and parasympathetic nervous systems. The anterior and posterior trunks of the vagus nerve provide parasympathetic innervation, whereas the celiac plexus, coursing along the vascular supply of the stomach, provides sympathetic innervation.

The gastric mucosal surface is composed of a single layer of mucus-containing columnar epithelial cells. The surface lining is invaginated by gastric pits, which provide access to the gastric lumen for gastric glands. The gastric glands of different regions of the stomach are lined with different types of specialized cells. The oxyntic or acid-producing region of the stomach is found in the fundus and body, where gastric glands contain characteristic parietal cells, which secrete both acid and intrinsic factor. These glands also contain zymogen-rich chief cells, which synthesize pepsinogen, and enterochromaffin-like endocrine cells, which secrete histamine. Antral glands have different endocrine cells, including gastrin-secreting G cells and somatostatin-secreting D cells.

The duodenum, the most proximal portion of the small intestine, forms a C-shaped loop around the head of the pancreas and is in continuity with the pylorus proximally and the jejunum distally (see Fig. 37-1 and **Web Video 37-1**). Angular changes in course divide the duodenum into four portions. The first part of the duodenum is the duodenal bulb or cap and is characterized by a smooth, featureless luminal surface. The remainder of the duodenum has characteristic circular folds known as the *plica circularis* or *valvulae conniventes*, which increase the surface area available for digestion. Similar to the stomach, the duodenal wall is formed by mucosa, submucosa, muscularis, and serosa layers. The duodenal mucosa is lined with columnar cells forming villi surrounded by crypts of Lieberkühn. The

submucosa includes characteristic Brunner glands that produce bicarbonate-rich secretions involved in acid neutralization. The innervation of the duodenum is also similar to that of the stomach.

Gastroduodenal Mucosal Secretions and Protective Factors

Although hydrochloric acid (HCl) is the primary gastric secretion, the stomach also secretes water, electrolytes (hydrogen [H⁺], sodium [Na⁺], potassium [K⁺], chloride [Cl⁻], and bicarbonate [HCO₃⁻]), enzymes (pepsin and gastric lipase), and glycoproteins (intrinsic factors and mucin) to assist in a wide variety of physiologic functions. The digestion of proteins and triglycerides, as well as the complex process of vitamin B₁₂ absorption, begins in the gastric lumen. Gastric acid also prevents the development of enteric colonization and systemic infections. The normal human stomach contains about 1 billion parietal cells that secrete H⁺ ions into the gastric lumen in response to various physiologic stimuli. Parietal cells located in the oxyntic glands of the fundus and body of the stomach are stimulated

Figure 37-2 Schematic representation of acid secretion by the parietal cell. Each transmitter has a specific receptor located on the basolateral surface of the parietal cell. Stimulation of these receptors leads to activation of intracellular second messenger systems. Gastrin and acetylcholine promote the accumulation of intracellular calcium, whereas histamine causes a stimulatory G protein (G_s) to activate adenylate cyclase, which, in turn, generates cyclic adenosine monophosphate (cAMP). These intracellular messengers then activate protein kinases, which activate the proton pump (the H⁺, K⁺-ATPase enzyme), located at the apical surface of the parietal cell, to secrete H⁺ ion in exchange for K⁺ ions. Prostaglandins and somatostatin inhibit parietal cell function by binding to receptors that act through inhibitory G proteins (G_i) to inhibit adenylate cyclase. *Long arrows* indicate sites of action of various drugs that inhibit acid secretion. ECL, enterochromaffin-like endocrine cells.

to secrete H⁺ ions by three different pathways: neurocrine, paracrine, and endocrine (Fig. 37-2). The neurocrine pathway involves the vagal release of acetylcholine, which stimulates H⁺ ion generation through a parietal cell muscarinic M₃ receptor. The paracrine pathway is mediated by the release of histamine from mast cells and enterochromaffin-like (ECL) cells in the stomach. Histamine binds to histamine-2 receptors on parietal cells, activating adenylate cyclase, which, in turn, leads to an increase in adenosine 3',5'-cyclic monophosphate (cAMP) levels and subsequent generation of H⁺ ions. The secretion of gastrin from antral G cells constitutes the endocrine pathway and stimulates H⁺ ion generation both directly on the parietal cell and indirectly by stimulating histamine secretion from ECL cells. The hydrogen-potassium adenosine triphosphatase (H⁺, K⁺-ATPase) enzyme, or proton pump, located at the apical surface of the parietal cell, is the final step of acid secretion. A negative feedback loop governs both gastrin release and acid secretion, preventing postprandial acid hypersecretion. Somatostatin, produced by D cells in the gastric corpus and

fundus, inhibits release of gastrin from G cells and may also reduce acid secretion from parietal cells and histamine release from ECL cells. Acid is necessary to convert pepsinogen, secreted from gastric chief cells, into pepsin, a proteolytic enzyme that is inactive at a pH greater than 4. Parietal cells also secrete intrinsic factor, a glycoprotein that binds to ingested vitamin B₁₂, allowing its absorption in the terminal ileum.

Several mechanisms are involved in maintaining the protective mucosal barrier. Mucus and HCO₃ constitute the first line of defense. Mucus forms a stable layer that prevents H⁺ ion back-diffusion and lubricates the mucosa, protecting against mechanical damage and maintaining a significant pH gradient between the gastric lumen and the epithelial cell surface. Endogenous epithelial defensive factors, such as cell migration and proliferation, lead to a constant and rapid renewal of the mucosa and ensure the continuity of the epithelium and the integrity of the tight intercellular junctions. Subepithelial defensive factors such as an adequate mucosal blood flow constitute a second line of protection and play a crucial role in maintaining a normal pH environment and thereby the integrity of the gastroduodenal mucosa.

Gastroduodenal Motor Physiology

Based on electrophysiologic and functional characteristics, the stomach can be divided into two functional compartments. The proximal stomach (fundus and proximal third of the body) acts as a reservoir for recently ingested food, whereas the distal stomach grinds, mixes, and sieves food particles. The smooth muscle of the proximal stomach has a characteristic tonic contraction that allows for gastric accommodation, a process by which the fundus relaxes in response to incoming food and fluid, with little increase in intragastric pressure. In contrast, the distal stomach produces high-amplitude contractions originating from the pacemaker region in the midportion of the greater curvature.

Gastroduodenal motor events vary in response to fasting and food intake. During fasting, gastric motility is characterized by a pattern of phasic contractions known as the migrating motor complex (MMC). The MMC clears the stomach and small intestine of undigested food particles, mucus, and sloughed epithelial cells. The MMC begins in the stomach and migrates down the length of the small bowel with a combined duration of 84 to 112 minutes. Following a meal, irregular contractile activity propels the ingested material distally.

Gastric emptying of a mixed solid and liquid meal involves the coordinated actions of the distinct regions of the stomach with feedback from the small intestine. Although liquids empty from the stomach at a relatively linear rate, solids are propelled forward by gastric contractions toward the antrum, where particles are triturated by high-amplitude contractions. Once solids have been reduced in size to particles of 1 to 2 mm, they are emptied into the pylorus.

A variety of medications and foods that exert significant effects on gastroduodenal motility are described in Figure

37-1 (see Web Video 37-1). Agents that modify the lower esophageal sphincter and esophageal motility are explained in Chapter 36.

Gastritis

CLINICAL PRESENTATION

Gastritis represents a nonspecific inflammation of the mucosal surface of the stomach. Clinically, the three most common causes of gastritis are *Helicobacter pylori*, nonsteroidal anti-inflammatory drugs (NSAIDs), and stress-related mucosal changes.

Helicobacter pylori

Helicobacter pylori are curved, flagellated, gram-negative rods found only in gastric epithelium or in gastric metaplastic epithelium. It is the most common worldwide microbial infection, with an estimated 50% of the world's population being infected. *H. pylori* organisms clearly cause histologic gastritis and are found in 50% to 95% of patients with gastroduodenal ulcers. However, only a minority of patients with *H. pylori* gastritis develop peptic ulcer disease (PUD) or gastric cancer. In the Western world, a clear age-related prevalence of *H. pylori* infection exists in healthy individuals, increasing from 10% in those younger than 30 years to 60% in those older than 60 years, and the mode of transmission appears to be by the fecal-oral route. Improvements in sanitation and standards of living have been associated with a decline in the rate of infection. *H. pylori* colonization is more common in individuals in lower socioeconomic strata compared with other groups. In the developing world, infection is far more common, with more than 80% of the population being infected by age 20 years. *H. pylori* infection is typically lifelong, unless antimicrobial treatment is instituted.

H. pylori organisms reside in the mucus layer overlying gastric epithelium and are characterized as noninvasive organisms. Factors important in the organism's ability to colonize the stomach include its motility, production of urease, and bacterial adherence. Ammonia generated from urea by *H. pylori* urease neutralizes acid, creating a more hospitable microclimate in which the bacteria can survive. *H. pylori* also have the ability to bind specifically to gastric-type epithelium, which prevents the organisms from being shed during cell turnover and mucus secretion or gastric motility. Tissue injury is mediated by the production of lipopolysaccharide, leukocyte-activating factors, and CagA and VacA proteins, which have been associated with cytotoxic effects, inflammation, and cytokine activation. Colonization causes acute and chronic inflammation consisting of neutrophils, plasma cells, T cells, and macrophages accompanied by varying degrees of epithelial cell injury, all of which resolve after treatment.

Although predicting the ultimate outcome of *H. pylori* infection is impossible, the clinical manifestations can be correlated with various distributions of gastric histopathologic states. Antral-predominant *H. pylori* gastritis is associated with duodenal ulcers, whereas corporal and fundic colonizations are more likely to cause atrophic gastritis. Other important factors that may influence the outcomes of the infection include the host response, environmental

factors, and age at the time of infection. Virtually all patients with *H. pylori* infection have a chronic superficial gastritis; however, duodenal and gastric ulcers develop in only 20% of infected patients. Patients with *H. pylori* infection and severe atrophic gastritis, corpus-predominant gastritis, or both, along with intestinal metaplasia, are at increased risk for intestinal-type gastric cancer. Finally, the mucosal lymphocytic response to *H. pylori* infection may lead to a monoclonal B-cell proliferation in mucosa-associated lymphoid tissue (MALT). MALT lymphomas, also known as *maltomas*, are rare, with about 1 in 1 million infected patients developing the disease. Complete histologic regression has been demonstrated in 50% to 80% of maltomas following eradication of *H. pylori*. Flat, localized, nonbulky lesions of the distal stomach are associated with greater rates of cure after antibiotic therapy.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are one of the most widely used classes of drugs. Although generally well tolerated, NSAIDs are associated with a small but significant percentage of adverse gastrointestinal (GI) events. Concepts about NSAID-induced gastroduodenal mucosal injury have evolved from a simple notion of topical injury to theories involving multiple mechanisms with both local and systemic effects. According to the dual-injury hypothesis, NSAIDs have direct toxic effects on the gastroduodenal mucosa and indirect effects through active hepatic metabolites and decreased synthesis of mucosal prostaglandins. Hepatic metabolites are excreted into the bile and subsequently into the duodenum, where they may cause mucosal damage to the stomach by duodenogastric reflux and to the small intestine by antegrade passage through the GI tract. Prostaglandin inhibition, in turn, leads to reduction in epithelial mucus, decreased secretion of HCO_3^- , impaired mucosal blood flow, reduced epithelial proliferation, and decreased mucosal resistance to injury. The impairment in mucosal resistance facilitates mucosal injury by endogenous factors, including acid, pepsin, and bile salts.

Prostaglandins are derived from arachidonic acid, which originates from cell membrane phospholipids through the action of phospholipase A_2 . The metabolism of arachidonic acid to prostaglandins and leukotrienes is catalyzed by the cyclo-oxygenase (COX) pathway and the 5-lipoxygenase (LOX) pathway, respectively (Fig. 37-3). Two related but unique isoforms of COX, designated COX-1 and COX-2, have been demonstrated in mammalian cells. Despite their structural similarities, each is encoded by distinct genes that differ with regard to their distribution and expression in tissues; the COX-1 gene is primarily expressed constitutively, whereas the COX-2 gene is inducible. COX-1 appears to function as a housekeeping enzyme in most tissues, including the gastric mucosa, whereas the expression of COX-2 can be induced by inflammatory stimuli and mitogens in many different types of tissue. Theories have therefore suggested that the anti-inflammatory properties of NSAIDs are mediated through the inhibition of COX-2, whereas adverse effects, such as gastroduodenal ulceration, occur as a result of the effects on COX-1. The discovery of the two COX isoforms led to the development of COX-2-

Figure 37-3 Biosynthesis of prostaglandins and leukotrienes through the cyclo-oxygenase and lipoxygenase pathways.

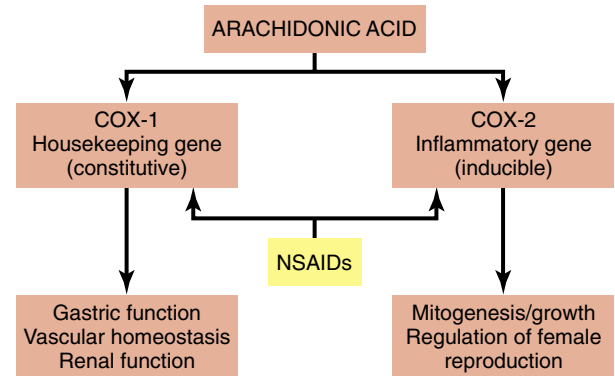

Figure 37-4 Depiction of the two cyclo-oxygenase (COX) isoenzymes that catalyze the synthesis of tissue prostaglandins from arachidonic acid.

specific inhibitors (e.g., celecoxib, rofecoxib, valdecoxib), drugs that maintain their anti-inflammatory properties while preserving the biosynthesis of protective prostaglandins (Fig 37-4).

The spectrum of NSAID-related mucosal injury includes a combination of subepithelial hemorrhages, erosions, and ulcerations that is often referred to as *NSAID gastropathy*. Erosions are likely to be small and superficial, whereas ulcers tend to be larger (more than 5 mm in diameter) and deeper. Although no area of the stomach is resistant to NSAID-induced mucosal injury, the most frequently and severely affected site is the antrum. Microscopically, a *reactive* pattern of injury can be found that is characterized by mucin depletion and little or no increase in inflammatory cells. Endoscopic studies have shown a prevalence of gastroduodenal ulcers of 10% to 25% in patients with chronic arthritis treated with NSAIDs, which is 5 to 15 times the expected prevalence in an age-matched healthy population.

Stress-Related Gastric Mucosal Damage

During critical illness, events such as shock, hypotension, and catecholamine release are associated with reduced blood flow and mucosal ischemia. When blood flow to the mucosa

is inadequate, the normal mucosal protective mechanisms, including epithelial turnover and mucus and HCO_3^- secretion, are altered. In addition, mediators such as cytokines and oxygen-free radicals are released. The combination of these events reduces the mucosal resistance to acid back-diffusion, causing erosions that may progress to ulceration and bleeding. Although mucosal damage develops in most critically ill patients, stress ulcers usually remain superficial and do not erode through the stomach wall to cause perforation. The major problem is blood loss, which is occult in most instances. Although occult stress ulcer bleeding occurs in 20% of patients in long-term intensive care units, gross hemorrhage occurs in only 5%.

TREATMENT

Aggressive volume resuscitation, control of sepsis, and adequate oxygenation in critically ill patients are important measures that may reduce the occurrence of low-flow states and subsequent mucosal damage. A wide variety of prophylactic strategies are used to prevent GI bleeding in critically ill patients. Pharmacologic agents used in this setting exert their effects through three main mechanisms: (1) acid neutralization, (2) mucosal protection, and (3) inhibition of gastric acid secretion. Acid neutralization with antacids is effective but requires administration every 1 to 2 hours through a nasogastric tube, which is inconvenient and increases nursing time. The side effects of magnesium-containing antacids include diarrhea, hypermagnesemia, and alkalemia, whereas aluminum-based antacids cause hypophosphatemia, constipation, and metabolic alkalosis, as well as potentially toxic plasma aluminum levels in patients with renal insufficiency. Mucosal protective agents such as sucralfate, an aluminum salt of sucrose sulfate, may improve mucosal blood flow through a prostaglandin-mediated mechanism. Sucralfate is well tolerated at doses of 1 g every 4 to 6 hours. Constipation occurs in 2% to 4% of patients, and aluminum toxicity has occurred in patients with chronic renal failure. Prostaglandin analogues (e.g., misoprostol) exert a protective effect on the gastric mucosa but have not been carefully studied for stress ulcer prophylaxis, and their use in this setting cannot be recommended. Antisecretory agents inhibit gastric acid secretion and are frequently used in the prevention of stress-induced mucosal damage in critically ill patients. Histamine-2 (H_2) receptor antagonists (e.g., cimetidine, ranitidine, famotidine, nizatidine), given either as a continuous infusion or by bolus injection, have been shown to reduce the incidence of clinically significant stress bleeding. An increase in intragastric pH to greater than 4 has been demonstrated with these agents; however, tolerance occurs rapidly and may limit their clinical efficacy. Although H_2 receptor antagonists are considered safe, they do possess both class-specific and individual side-effect potentials. The most prominent class-specific effect is central nervous system toxicity, which occurs more frequently in elderly patients compared with other age groups. Proton pump inhibitors (PPIs) irreversibly block parietal cell H^+ , K^+ -ATPase. These agents (e.g., omeprazole, lansoprazole, rabeprazole, pantoprazole, esomeprazole) are prokinetic agents that are normally activated following systemic absorption and localization to the highly acid milieu of the secretory canaliculus of *activated* parietal cells. Activation occurs after

Table 37-1 Indications for Stress Bleeding Prophylaxis

a meal, and because critically ill patients are generally fasting, PPIs administered orally or by nasogastric tube are significantly less active in this setting and are thus not recommended. However, in patients receiving enteral feeding, PPIs administered by the enteral route suppressed acid more effectively than intravenous PPIs. Pantoprazole, the first intravenous PPI available in the United States, has shown promising results in several small studies and may prove beneficial in stress bleeding prophylaxis. Intravenous preparations of lansoprazole and esomeprazole have recently become available.

Prophylaxis is recommended in patients with coagulopathy and in patients with respiratory failure requiring mechanical ventilation for more than 48 hours. Other patients in whom stress bleeding prophylaxis is indicated include those with central nervous system trauma, burns, organ transplantation, a history of PUD with or without bleeding, multiorgan failure, trauma, and major surgery (Table 37-1).

OTHER CAUSES OF GASTRITIS

Autoimmune atrophic gastritis exhibits an autosomal-dominant inheritance pattern and is associated with autoantibody formation. Histologically, autoimmune atrophic gastritis is characterized by chronic inflammation, gradual atrophy of glands, and loss of parietal cells. The process is usually confined to the corpus and fundus, where the gastric glands tend to undergo intestinal metaplasia. Loss of parietal cells results in achlorhydria, vitamin B_{12} deficiency, and megaloblastic anemia (pernicious anemia). These patients have an increased risk for carcinoma, especially in Scandinavian countries. No overall increased cancer risk has been documented in American patients, and routine surveillance has not been advocated in the United States.

Lymphocytic gastritis is characterized by a mononuclear infiltration of T cells, usually antral predominant, and is often associated with celiac disease, collagenous-lymphocytic colitis, and Ménétrier disease. Eosinophilic gastritis is characterized by an eosinophilic infiltration of the stomach, especially the antrum. All layers of the gastric wall may be affected, but selective predominance of eosinophilic infiltrates may be found in the submucosa, muscle layers, or subserosa, making biopsy diagnosis difficult. Clinical manifestations include delayed gastric emptying or manifestations of anemia from chronic blood loss caused by associated mucosal ulceration. Corticosteroids are used to control symptoms.

Ménétrier disease is a rare disease characterized by giant gastric folds in the fundus and the body of the stomach. Histologically, increased mucosal thickness, glandular atrophy, and an increase in the size of the gastric pits are characteristic findings. Hypochlorhydria and hypoalbuminemia are commonly seen. In children, *Ménétrier disease* is thought to be caused by cytomegalovirus (CMV), whereas overexpression of a tissue growth factor has been implicated in the adult form of the disease.

In addition to *H. pylori*, a variety of infectious pathogens may involve the stomach. Gastric infections are typically seen in patients who are immunocompromised in the settings of HIV infection, chemotherapy, and organ transplantation. Bacterial infections such as tuberculosis and syphilis rarely involve the stomach. CMV and herpesvirus infection, as well as fungal (e.g., *Candida*, histoplasmosis, mucormycosis, cryptococcosis, aspergillosis), and parasitic infections (e.g., *Cryptosporidium*, *Strongyloides*) are also possible. Other diseases such as sarcoidosis and Crohn disease may involve the stomach. The presence of granulomas on histologic specimens, along with systemic manifestations of the disease, confirms the diagnosis.

The stomach is occasionally involved by acute *graft-versus-host* disease. Gastric erosions or ulcers may be encountered in the investigation of bone marrow transplantation patients with abdominal pain or GI bleeding. Biopsy specimens should be obtained to rule out opportunistic infections (e.g., CMV).

Alcohol, drugs (e.g., cocaine, iron, potassium chloride), and physical agents (nasogastric tubes) are also associated with nonspecific forms of gastritis. Similarly, ischemia as a result of vascular injuries, embolization, vasculitis, and amyloidosis has been described as a cause of gastritis.

Peptic Ulcer Disease

Peptic ulcers are a common clinical problem characterized by mucosal defects of the GI mucosa of the stomach or the duodenum. The proteolytic enzyme pepsin and gastric acid were initially identified as the key factors involved in the pathogenesis of ulcers. Thus, the concept of *no acid, no ulcer* has been widely used and accepted for many years. However, in the past two decades, the roles of factors other than acid and pepsin in the development of ulcers have been recognized. Men and women are at equal risk for developing PUD, and the overall lifetime risk for both genders is 10%. Peptic ulcers are uncommon in children, but the risk increases with age. More than 70% of all ulcer cases occur in individuals between the ages of 25 and 64 years. However, whereas the incidence of PUD is decreasing in the young age groups, more persons 65 years and older are developing ulcers. These trends are likely related to the overall decrease in the prevalence of *H. pylori* infection and the increasing use of NSAIDs by the older population. The most important risk factors for the development of peptic ulcers are infection with *H. pylori* and use of NSAIDs. If neither of these factors is present, an alternative cause must be sought, such as hypersecretory states (e.g., Zollinger-Ellison syndrome [ZES]) or one of the other less common causes of ulcer disease, including Crohn disease, vascular insufficiency, viral infection, radiation therapy, and cancer chemotherapy.

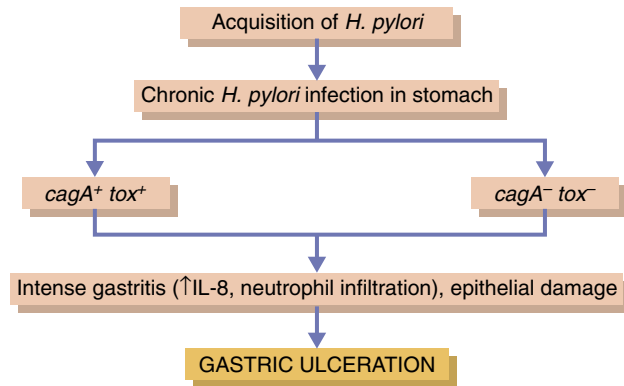

Although a significant number of environmental factors, including stress, personality, occupation, alcohol consumption, and diet, have been linked to the development of ulcers, no convincing evidence suggesting that any of these factors by itself can cause PUD has been found.

PATHOPHYSIOLOGIC FACTORS

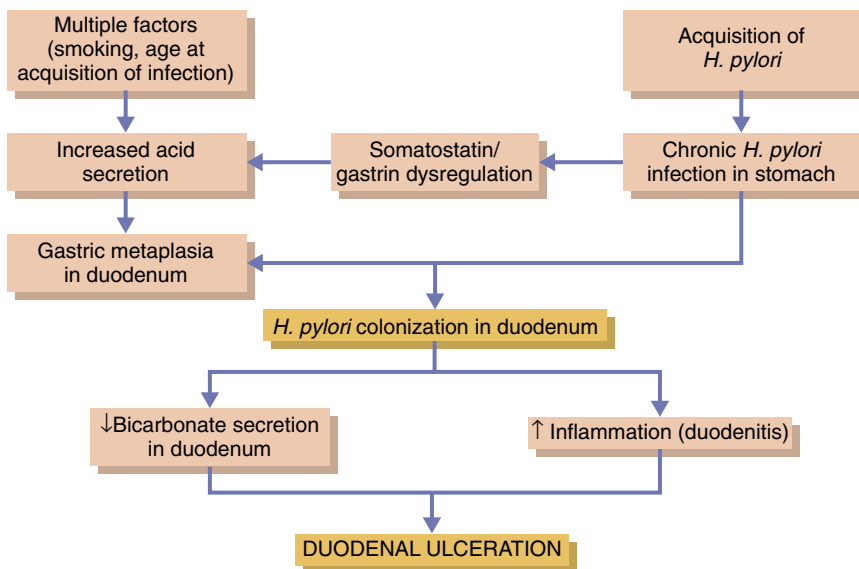

By killing ingested bacteria and other micro-organisms, gastric acid prevents the development of enteric colonization and ensures both efficient absorption of nutrients and prevention of systemic infections. Gastric acid is also an important factor in protein hydrolysis and digestion and, under various conditions, may play an etiologic role in inciting gastroduodenal mucosal injury. Postprandial gastric acid secretion is regulated primarily by increases in gastrin expression, which is controlled by a negative feedback loop wherein postprandial gastrin-mediated acid secretion stimulates the release of somatostatin from antral D cells. Somatostatin appears to act by a paracrine mechanism to inhibit further release of gastrin from G cells. Somatostatin produced by D cells in the gastric corpus and fundus may also directly inhibit acid secretion from parietal cells and may suppress histamine release from ECL cells. Although the presence of acid is necessary for ulcers to form, acid secretion is normal in nearly all patients with gastric ulcers and is increased in only one third of patients with duodenal ulcers. Therefore, acid is clearly not the only factor involved in the pathogenesis of peptic ulcers, and the balance between aggressive factors that act to injure the gastroduodenal mucosa and defensive factors that normally protect against corrosive agents is also important. When this delicate balance is disrupted for any reason, an ulcer may ensue.

In addition to the regulation of intragastric acidity, mechanisms involved in maintaining the protective mucosal barrier include mucus and HCO_3^- secretion, mucosal blood flow, cell restitution and repair, and changes in local immune factors. The mucosal defensive properties appear to be mediated to a large extent by endogenous prostaglandins, nitric oxide, and trefoil proteins. When the synthesis of any or all is diminished, the ability of the gastroduodenal mucosa to resist injury is reduced, and even normal rates of acid secretion may be sufficient to injure the mucosa. As stated previously, the pathogenesis of peptic ulcer is complex and involves an imbalance between defensive and aggressive factors. Individuals infected with *H. pylori* have been shown to have a diminished number of somatostatin-secreting D cells, which decreases the magnitude of the response to luminal acidification. Thus, in patients with *H. pylori* infection limited to the antrum, the negative inhibition of gastrin release is disrupted, resulting in higher postprandial gastrin levels and hypersecretion of acid. In addition, *H. pylori* organisms penetrate the mucous layer and adhere to surface epithelial cells by attaching to phospholipids and glycoproteins. Once attached, the bacteria synthesize and release phospholipases and proteases that are harmful to the mucous layers and the underlying cells. Interleukin-8 and other cytokines that contribute to mucosal injury are subsequently released from the gastric epithelium. About 65% of *H. pylori* isolates produce a vacuolating toxin. Toxin-producing strains may be more pathogenic than those that do not produce toxins, and their presence correlates with a more

A

B

Figure 37-5 Mechanisms by which *Helicobacter pylori* may cause gastric ulcers (A) and duodenal ulcers (B). IL-8, interleukin-8. (From Peek RM, Blaser MJ: Pathophysiology of *Helicobacter pylori*-induced gastritis and peptic ulcer disease. *Am J Med* 102:200-207, 1997.)

intense polymorphonuclear cell infiltration. A cytotoxin-associated gene (*cagA*) has been found to be a marker for strains that make the vacuolating toxin. Patients infected with *cagA*-positive strains are more likely to develop ulcers (Fig. 37-5).

Although a large number of gastroduodenal ulcers are associated with *H. pylori* infection, at least 60% of individuals with complicated ulcers (e.g., hemorrhage, perforation) report the use of NSAIDs, including aspirin. Topical injury caused by NSAIDs certainly contributes significantly to the development of gastroduodenal mucosal injury. However, the systemic effects of these agents appear to play the predominant role, largely through the decreased synthesis of mucosal prostaglandins. NSAID-induced ulceration occurs with all traditional NSAIDs, regardless of enteric coating or delivery as a prodrug formulation. The risk for NSAID-induced ulceration and complications is dose related and increases with age older than 60 years, concurrent corticosteroid use, increasing duration and dose of therapy, anticoagulant therapy, and a history of prior ulcer disease.

ZES, produced by gastrin-secreting tumors, accounts for 0.1% of patients who have PUD and should be considered in patients with ulcers in unusual sites (e.g., distal duodenum, jejunum); multiple, recurrent, or complicated duodenal ulcers; or ulcers associated with chronic diarrhea.

CLINICAL PRESENTATION

Peptic ulcers can exhibit in a variety of forms ranging from asymptomatic iron deficiency anemia to abdominal pain, obstruction, perforation, and hemorrhage. Symptoms may mimic those of other diseases, including cholecystitis, pancreatitis, gastric cancer, and gastroesophageal reflux. Myocardial ischemia or infarction, especially of the inferior wall, can cause abdominal pain that resembles peptic ulcer. Abdominal pain is generally epigastric and is usually described as a dull ache but may be sharp or burning. Less than 20% of patients report the hunger-like pain traditionally associated with both gastric and duodenal ulcers. Similarly, the character of the symptoms and their relation with

meals, specifically pain relief after food intake for duodenal ulcer and pain worsening for gastric ulcer, do not always correlate with endoscopic diagnosis and are less useful in predicting ulcer location. Nocturnal pain and pain relief with milk or antacids are common with duodenal ulcers but can also occur with gastric ulcers. NSAID-associated ulcers typically produce painless bleeding. Nausea and vomiting are commonly associated with peptic ulcers, being slightly more common with gastric ulcers. Gastric outlet obstruction may be caused by antropyloric or duodenal ulcers but should be differentiated from malignant obstruction resulting from gastric or pancreatic cancer. Weight loss, although suggestive of malignancy, is frequently reported by patients with peptic ulcers.

DIAGNOSIS

Because the clinical features of gastroduodenal ulcers may overlap with other disorders, and the physical examination is often not helpful in the diagnosis, imaging studies of the GI tract are required to confirm the presence of peptic ulcers. Although contrast radiology (barium upper GI series) can be used, endoscopy is usually preferred because, in addition to characterizing the ulcer, it allows tissue sampling to exclude malignancy, assessment of *H. pylori* infection, and, in cases of acute ulcer hemorrhage, delivery of endoscopic therapy for the control of hemorrhage.

DIAGNOSTIC TESTS FOR HELICOBACTER PYLORI

The fact that the eradication of *H. pylori* infection is associated with a significant reduction in ulcer recurrence is now recognized. *H. pylori* testing is thus essential in all patients with PUD. Diagnostic tests for detecting *H. pylori* infection and the indications for their use are summarized in Figure 37-6. Immunoglobulin G serologic testing is the noninvasive test of choice for diagnosing *H. pylori* infection in the untreated patient. However, because the antibodies may persist for several years, serologic analysis is not useful as a means to document cure of the infection. Positive results of antibody testing may thus indicate past exposure but not necessarily current infection with *H. pylori*. Another noninvasive mean of detecting *H. pylori* is the ^{13}C - or ^{14}C -labeled urea breath test. When present, *H. pylori* urease splits the urea, which may be detected as labeled carbon dioxide in the breath of a patient. The urea breath test is more accurate than serologic tests, and although more expensive and less widely available, it is the noninvasive test of choice to document successful *H. pylori* eradication after antibiotic therapy. Patients should not receive PPIs for at least 14 days before administration of breath tests to avoid false-negative results. Stool antigen testing is also available and useful in the initial diagnosis of *H. pylori* infection. If endoscopic examination is performed, the diagnosis is made by the rapid urease test or histologic testing. In the rapid urease test, mucosal biopsies are placed in a urea-containing medium with a pH-sensitive indicator that changes color when ammonia is produced from urea by the urease of the organism. The rapid urease test has high sensitivity and specificity equivalent to histologic analysis and is inexpensive. Recent treatment with antibiotics or PPIs may decrease the yield of the test. Histo-

logic analysis is frequently the standard for detecting *H. pylori* infection and can establish the degree, type, and location of inflammation. Gastric biopsy specimens should be taken from both the antrum and the corpus because the bacteria are not uniformly distributed throughout the stomach. The presence of chronic active gastritis is strongly suggestive of *H. pylori* infection, even if bacteria are difficult to identify.

Complications of Peptic Ulcer Disease

BLEEDING

PUD is the leading cause of upper GI bleeding, accounting for about 50% of instances and more than 150,000 hospital admissions annually in the United States. Although bleeding ceases spontaneously in 80% of patients, the mortality rate associated with bleeding ulcers is 5% to 10%. Patients with bleeding ulcers exhibit hematemesis, melena, or hematochezia, often without abdominal pain. The major risk factor for bleeding ulcers is NSAID use. Predictors for an adverse outcome include hemodynamic instability at presentation, bright red blood from the rectum or through the nasogastric tube, age older than 60 years, ongoing transfusion requirements, and an increasing number of underlying medical illnesses. All patients with upper GI bleeding should undergo early upper endoscopic examination, which allows for both therapeutic intervention and the determination of other predictors for rebleeding. Rebleeding rates are about 5% for clean-based ulcers, 10% for ulcers with flat spots, 22% for adherent clots, 43% for nonbleeding visible vessels, and 55% for active oozing or spurting from an ulcer (Fig. 37-7). Patients with large ulcers, greater than 1 to 2 cm in diameter, also have increased rebleeding and mortality rates. Endoscopic therapy with techniques such as multipolar or thermal coagulation or injection with epinephrine clearly improves the outcome in patients with bleeding ulcers by decreasing mortality, length of hospital stay, number of blood transfusions, and need for emergency surgery.

Because most ulcer bleeding recurs within 3 days of initial presentation, patients with active bleeding or stigmata of hemorrhage, such as raised pigmented spots in an ulcer crater or clot, can be discharged within 2 to 3 days if they are stable. Given the excellent prognosis for patients with clean-based ulcers, discharge within 24 hours of presentation or immediately after endoscopic examination appears to be safe. About 20% of patients rebleed after endoscopic therapy, and 50% of these can be successfully retreated. The remainder may be treated angiographically with either intra-arterial vasopressin or embolization techniques. Surgery is generally reserved for instances in which all other measures have failed. Although endoscopic therapy is the first treatment modality in the management of actively bleeding gastroduodenal ulcers, some evidence also suggests that adjuvant use of acid suppression therapy can reduce recurrent bleeding after initial endoscopic control. A continuous infusion of intravenous omeprazole has been shown to reduce the incidence of recurrent ulcer hemorrhage following endoscopic therapy. Thus, patients with significant

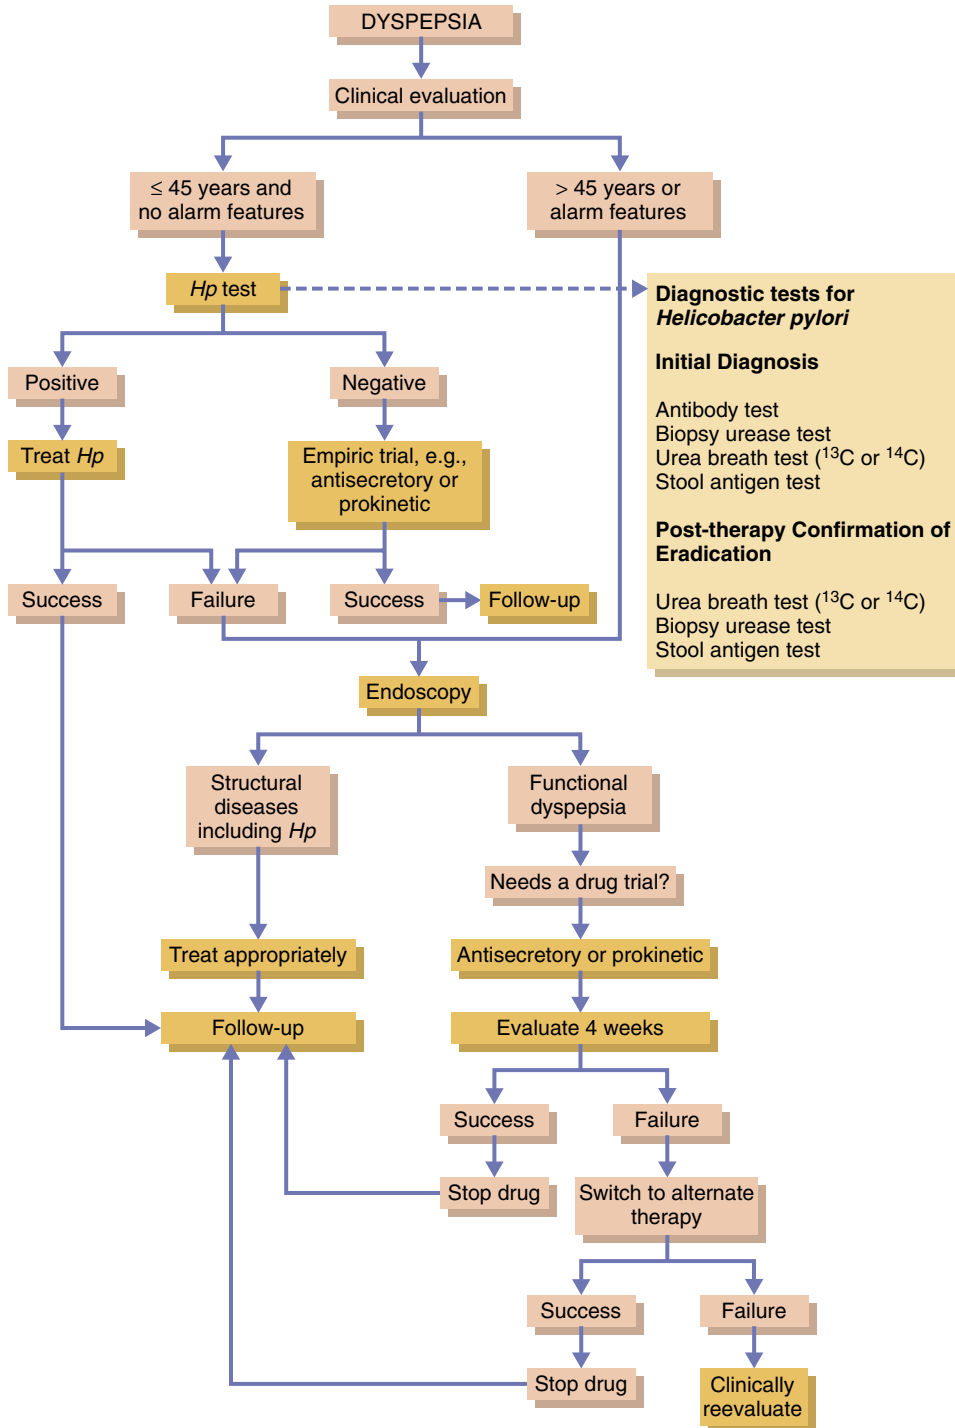

Figure 37-6 Diagnostic approach to patients presenting with uninvestigated dyspepsia. Alarm features include weight loss, vomiting, dysphagia, evidence of anemia, gastrointestinal bleeding, or an abdominal mass or lymphadenopathy. *Hp*, *Helicobacter pylori*. (Modified from American Gastroenterological Association medical position statement: Evaluation of dyspepsia. [No authors listed]. *Gastroenterology* 114:579-581, 1998.)

upper GI bleeding in whom a peptic ulcer is suggested should be treated with an intravenous PPI using a loading dose (80 mg of pantoprazole) followed by a continuous infusion (8 mg per hour of pantoprazole). If at the time of endoscopic examination, no evidence of recent or active bleeding can be found, and after feeding has been initiated, oral administration can be substituted for the parenteral route.

PERFORATION

Perforation, which occurs when a peptic ulcer erodes through the full thickness of the stomach or duodenum, is a far less common complication than bleeding. Ulcer perforation usually leads to peritonitis, which, if untreated, may result in sepsis and death. Patients exhibit sudden onset of

	Clean base	Flat spot	Adherent clot	NBVV*	Active bleed
					
Prevalence (%)	42	20	17	17	18
Rebleeding risk (%)	5	10	22	43	55
*Nonbleeding visible vessel

severe abdominal pain that typically begins in the epigastrium and radiates throughout the entire abdomen. When peritonitis has occurred, physical examination is remarkable for abdominal pain, guarding, rebound tenderness, and boardlike rigidity. The clinical suggestion of perforation may be confirmed in most cases by the presence of free intra-abdominal air (pneumoperitoneum) with either an upright chest radiograph or upright and supine abdominal radiographs. In less obvious instances, computed tomography (CT) or an upper GI water-soluble contrast study may be helpful. Perforation mandates surgical intervention. A perforated duodenal ulcer is typically repaired with an omental patch, whereas a perforated gastric ulcer necessitates either an omental patch or a resection.

GASTRIC OUTLET OBSTRUCTION

In the era before acid suppression and *H. pylori*, PUD accounted for 60% of the cases of gastric outlet obstruction. More recently, the incidence of both ulcers and obstruction requiring surgery has declined, and estimates indicate that fewer than 5% of patients with duodenal ulcer and less than 1% to 2% with gastric ulcer develop significant gastric outlet obstruction. Gastric outlet obstruction is typically caused by either pyloric channel or duodenal ulcers and may be seen in the setting of acute ulceration, in which edema, spasm, and inflammation lead to obstruction, or as a consequence of chronic ulceration with scarring and fibrosis. Patients usually exhibit symptoms of early satiety, bloating, nausea, vomiting, and weight loss. Endoscopy is the diagnostic test of choice but is frequently obscured by the presence of retained food residue. Patients in whom gastric outlet obstruction is suggested should undergo gastric decompression and lavage to remove retained gastric contents before endoscopic examination. Malignancy may now account for 50% of instances of gastric outlet obstruction and should be excluded with adequate biopsy and cytology samples. Occasionally, imaging techniques such as barium upper GI series and radionuclide gastric-emptying scans can also be used to determine the length of the obstructed area and to evaluate gastric emptying. In addition to the correction of fluid, electrolyte, and pH imbalances resulting from persistent vomiting, patients with gastric outlet obstruction should undergo nasogastric decompression for 3 to 5 days. During that time, acid suppression with an intravenous H_2 receptor antagonist or PPI should also be instituted. Adequacy of response may

be assessed empirically with a trial of refeeding. For patients failing to respond to medical therapy, treatment options include endoscopic balloon dilation and surgery.

Treatment of Peptic Ulcer Disease

HEALING ULCERS BY SUPPRESSING ACID SECRETION

Regardless of the cause, the inhibition of gastric acid secretion continues to be the cornerstone of therapy for PUD. Antacids are effective agents for healing ulcers and may provide some symptom relief. However, because of the need to take these drugs at least 4 times, and up to 7 times, every day, and the frequency of associated adverse effects, antacids are now rarely used in the healing of gastroduodenal ulcers.

H_2 receptor antagonists reduce acid secretion by competitively and selectively inhibiting the histamine receptor on the parietal cell. H_2 receptor antagonists increase intragastric pH and inhibit pepsin activity. In general, H_2 receptor antagonists are safe and well tolerated, although the occurrence of adverse effects is slightly increased with cimetidine because of binding to cytochrome P-450 and hence increased risk for drug interactions. H_2 receptor antagonists heal 90% to 95% of duodenal ulcers and 88% of gastric ulcers after 8 weeks. Given as a single full dose at bedtime, cimetidine (800 mg), ranitidine and nizatidine (300 mg), and famotidine (40 mg) have comparable efficacies for ulcer healing. The recommended duration of treatment is 4 weeks for duodenal ulcers and 8 weeks for gastric ulcers.

PPIs, the most potent inhibitors of gastric acid secretion available, heal gastroduodenal ulcers more rapidly than H_2 receptor antagonists. However, because they are most effective when the parietal cell is stimulated to secrete acid in response to a meal, PPIs should only be taken before a meal and should not be used in conjunction with H_2 receptor antagonists or other antisecretory agents. Moreover, because acid secretion must be stimulated for maximal efficacy, PPIs are administered before the first meal of the day. These agents are safe and well tolerated; adverse effects are unusual and include headache, diarrhea, and nausea. Single daily doses of omeprazole (20 mg), pantoprazole (40 mg), rabeprazole (20 mg), lansoprazole (30 mg), or esomeprazole

(40 mg), all before breakfast, are effective in healing gastroduodenal ulcers. The recommended duration of treatment is again 4 weeks for duodenal ulcers and 8 weeks for gastric ulcers.

HEALING BY ENHANCING MUCOSAL DEFENSE

Sucralfate, a complex salt of sucrose sulfate and aluminum hydroxide, appears to be as effective as H₂ receptor antagonists in the treatment of duodenal ulcer disease. The evidence for efficacy in healing of gastric ulcers is less compelling. Sucralfate has little or no effect on acid secretion and acts through several different mucosal protective mechanisms. In the gastroduodenal lumen, sucralfate becomes a gel-like substance that binds to both defective and normal mucosa, acting as a physical barrier to the diffusion of acid, pepsin, and bile acids. The recommended dose is 1 g 4 times daily, which makes it less convenient than other agents for treating PUD.

Although bismuth compounds and prostaglandin analogues have been shown to provide protective effects on the gastroduodenal mucosa and may have some effect on ulcer healing, these agents are not routinely used in the initial treatment of peptic ulcers.

TREATMENT OF HELICOBACTER PYLORI INFECTION

Eradication of *H. pylori* should be attempted in all patients with documented current or past PUD and evidence of infection. The various niches of *H. pylori* within the gastric mucosa provide a challenge for antimicrobial therapy. Successful therapy requires a combination of drugs that prevents the emergence of resistance and effectively reaches the bacteria. Therapy must be of sufficient duration to ensure that a small population of bacteria does not remain viable. Combinations of two antibiotics, plus either a PPI or ranitidine bismuth citrate, are used to maximize the chance of eradication. Current treatment regimens for *H. pylori* are shown in Table 37-2. Factors such as antibiotic resistance and noncompliance with therapy have been identified as predictors of treatment failure. Metronidazole resistance is most common, and both metronidazole and clarithromycin resistance are increasing in frequency, with rates of 37% and 10%, respectively. Because compliance is essential for treatment success, the current regimens offer simpler dosing than earlier options. A failed initial course of antibiotic therapy suggests antibiotic resistance, and it may be assumed that, if the patient received metronidazole or clarithromycin in the original regimen, resistance to that antibiotic is present. When possible, repeat use of the same antibiotic should be avoided. The recommended duration for repeat treatment courses is 14 days. An alternative initial approach involves a shorter, 10-day treatment course with PPI and sequential dosing of amoxicillin and clarithromycin, but further validation studies are needed before recommendation.

MAINTENANCE THERAPY

Before embarking on long-term maintenance therapy for PUD, careful attention must be paid to eliminating the most

Table 37-2 Treatment Regimens for *Helicobacter pylori* Infection

Triple therapy (cure rate, 85% to >90%)
BMT triple therapy for 14 days
Bismuth subsalicylate, 524 mg by mouth 4 times daily
Metronidazole, 250 mg by mouth 4 times daily
Tetracycline HCl, 500 mg by mouth 4 times daily + H ₂ -RA for additional 4 weeks
LAC for 10 or 14 days
Lansoprazole, 30 mg by mouth twice daily
Amoxicillin, 1 g by mouth twice daily
Clarithromycin, 500 mg by mouth twice daily
OAC for 10 or 14 days
Omeprazole, 20 mg by mouth twice daily
Amoxicillin, 1 g by mouth two times daily
Clarithromycin, 500 mg by mouth twice daily
RBC-AC (cure rate, >90%)
Ranitidine bismuth citrate + amoxicillin + clarithromycin
MOC (cure rate, >90% in the absence of metronidazole resistance)
Metronidazole + omeprazole + clarithromycin
H ₂ -RA, histamine-2 receptor antagonist; HCl, hydrochloric acid.

important risk factors for ulcer recurrence: *H. pylori* infection and NSAID use. Moreover, hypersecretory states, including gastrinoma, should be excluded before considering maintenance therapy in individuals with recurrent ulcers without *H. pylori* infection. Patients with a history of ulcer complications, frequent ulcer recurrence, continued NSAID use, or *H. pylori*-negative ulcers, and those who fail to clear *H. pylori* infection despite appropriate therapy, should be considered candidates for maintenance antisecretory therapy. However, even patients who have had a complicated ulcer may not require maintenance therapy, provided *H. pylori* infection is cured. Maintenance regimens include an H₂ receptor antagonist at bedtime at one half the dose required for initial healing or a PPI taken before breakfast.

TREATMENT AND PROPHYLAXIS OF NSAID-INDUCED ULCERATION

The optimal treatment in patients with NSAID-induced gastroduodenal ulcers is the discontinuation of the offending agent. If NSAIDs must be continued, therapy with an antisecretory agent should be instituted. Based on their superior safety profile and their ability to heal gastroduodenal ulcers at an accelerated rate whether or not NSAID use is continued, PPIs are preferred over both H₂ receptor antagonists and misoprostol in the treatment of NSAID-associated gastroduodenal ulcers.

Because of the significant rate of serious complications associated with NSAIDs and the poor correlation of dyspeptic symptoms (e.g., abdominal pain, distention, nausea, heartburn) with the presence of gastroduodenal mucosal injury, prevention of ulceration has become the principal goal in the management of NSAID-related GI toxicity. Risk factors for NSAID-related injury have been identified and include advanced age (>60 years), prior history of PUD or ulcer hemorrhage, concomitant use of anticoagulants or corticosteroids, significant comorbid conditions, and use of high NSAID doses (Table 37-3). Two strategies have been used to prevent ulcers: (1) the concomitant use of

Table 37-3 Risk Factors for Development of NSAID-Related Ulcers**Definite**

Advanced age
 History of ulcer
 Concomitant corticosteroid therapy
 Concomitant anticoagulation therapy
 High doses of NSAIDs
 Serious systemic disorders

Possible

Concomitant infection with *Helicobacter pylori*
 Cigarette smoking
 Consumption of alcohol

NSAIDs, nonsteroidal anti-inflammatory drugs.

medications such as misoprostol or PPIs, and (2) the development of safer anti-inflammatory agents, such as COX-2-specific inhibitors. Misoprostol, a prostaglandin E₁ analogue, significantly reduces the development of both gastric and duodenal ulcers in patients using NSAIDs. By augmenting prostaglandin-dependent pathways, misoprostol reduces gastric acid secretion and enhances mucosal defenses. However, misoprostol is associated with significant adverse effects and a high frequency of therapy discontinuation as a result of these effects, especially when administered 4 times a day. The most frequent symptom is diarrhea, although symptoms such as abdominal pain, nausea, and bloating may also occur. A lower dose of misoprostol (200 mcg 3 times daily) is nearly as effective as 4 times daily dosing for preventing duodenal and gastric ulcers, with a slight reduction in the occurrence of adverse effects.

The second strategy to prevent NSAID-induced ulcers involves the co-administration of an antisecretory agent, usually a PPI, or the substitution of the traditional NSAID with one of the newer COX-2-specific inhibitors.

According to available evidence from clinical trials, PPIs are superior to H₂ receptor antagonists in preventing gastroduodenal ulceration as well as in improving dyspeptic symptoms during continued NSAID use. Similarly, PPIs provide protection against endoscopic NSAID ulcers at a rate at least comparable with that of misoprostol, with fewer associated GI symptoms. However, misoprostol, but not PPIs, has been shown in a prospective analysis to decrease the prevalence of ulcer complications.

COX-2-specific inhibitors (e.g., celecoxib, rofecoxib, valdecoxib) have shown an improved GI safety profile with reduced incidence of ulcers and ulcer complications and at least similar effectiveness when compared with traditional NSAIDs.

However, recent evidence suggesting an increased risk for cardiovascular events, specifically myocardial infarctions and strokes, associated with the use of selective COX-2 inhibitors, has led to significant public concern with subsequent market withdrawal of some of these agents and restricted use of others. These adverse effects are thought to be related, at least in part, to the inhibition of prostacyclin with the resultant unopposed *thrombogenic* effects of thromboxane A₂. Recommendations for use of nonselective NSAID versus COX-2 inhibitor and use of either PPI or misoprostol involve risk stratification of the patient's cardiovascular risk and GI risk by the clinician.

More recent meta-analysis demonstrated that concomitant *H. pylori* infection and NSAID use double the risk for ulcer complications. Therefore, in patients who require chronic NSAID use, the current recommendation is to test for and eradicate *H. pylori*, given that it is a treatable risk factor.

SURGERY

Because of the remarkable progress in pharmacologic acid suppression therapy and the recognition that ulcer disease can be cured by eliminating *H. pylori* infection and NSAIDs, surgery now plays a marginal role in treating uncomplicated PUD. Surgical intervention is now mostly reserved for managing the complications of peptic ulcers, especially gastric outlet obstruction and perforation. Some of the different surgical approaches are shown in Figure 37-8.

NONULCER DYSPEPSIA

Dyspepsia, a classic symptom of PUD, is a common clinical problem and may be seen in 25% to 40% of adults. However, only 15% to 25% of patients with dyspepsia are found to have a gastric or duodenal ulcer. The remainder of patients have nonulcer or functional dyspepsia, a condition most likely related to an abnormal perception of events in the stomach caused by afferent visceral hypersensitivity. Recent evidence suggests that about 40% of patients with nonulcer dyspepsia (NUD) have impairment in the fundic accommodation response of the stomach. Dyspeptic symptoms may be chronic, recurrent, or of new onset. The diagnostic work-up should focus on excluding other causes of dyspepsia such as gastroparesis and gastric cancer.

MANAGEMENT

Three possible strategies for managing patients with NUD have been formulated (see Fig. 37-6). Immediate endoscopic evaluation is indicated for individuals older than 45 years and persons exhibiting alarm features (*red flags*) such as weight loss, recurrent vomiting, dysphagia, GI bleeding, anemia, a strong family history of GI cancer, or an abdominal mass. Urgent endoscopic examination is indicated to exclude a serious underlying disease process, particularly gastric and esophageal carcinoma. If a gastric ulcer is found during endoscopic examination, multiple biopsies and cytologic analysis should be obtained to exclude malignancy. Ulcer treatment is subsequently employed, and ulcer healing should be confirmed with a follow-up endoscopic examination because nonhealing ulcers can occasionally be a manifestation of gastric carcinoma. Barium radiography offers poor sensitivity and specificity and is thus no longer recommended in the evaluation of dyspepsia.

The second option when treating patients younger than 45 years with NUD but without alarm features is an empirical trial of antisecretory therapy for 1 to 2 months. Endoscopy is indicated in patients who fail to respond to this regimen. Avoiding the introduction of long-term drug use in this situation is important, particularly because of the considerable benefit of placebo in such individuals.

The third strategy for managing NUD involves initial noninvasive testing for *H. pylori* followed by antimicrobial

Figure 37-8 Operations for peptic ulcer disease.

therapy in patients with positive tests. This strategy is presumed to heal ulcers if present, eliminate the ulcer diathesis, and save on resources, particularly in patients younger than 45 years without alarm symptoms. The frequency of *H. pylori* infection in the community should also be taken into account because noninvasive tests show decreased accuracy when the prevalence of *H. pylori* is less than 10%. This approach, although advocated by some physicians, has not been proved effective in relieving NUD. Moreover, indiscriminate use of antimicrobial therapy may be associated with altering normal intestinal flora, increasing resistance of *H. pylori* and other bacteria that are not a target of therapy, and producing a series of adverse events such as antibiotic-associated and *Clostridium difficile* colitis.

Zollinger-Ellison Syndrome

ZES is characterized by elevated levels of serum gastrin produced by gastrin-secreting tumors that are most often located in the pancreas and duodenum. Hypergastrinemia stimulates hypersecretion of gastric acid and pepsin, which may produce peptic ulcers, duodenojejunitis, esophagitis, and diarrhea. ZES is an uncommon cause of PUD, accounting for less than 1% of the instances. The gastrin-secreting

tumor in ZES, referred to as a *gastrinoma*, is frequently located in the *gastrinoma triangle*, an area encompassed by the second and third portions of the duodenum, the junction of the head and neck of the pancreas, and the cystic duct. Seventy-five percent of all gastrinomas are sporadic; the remaining 25% are part of the type I multiple endocrine neoplasia (MEN-I) syndrome, an autosomal-dominant condition with a locus on chromosome 11, typically associated with hyperparathyroidism and pituitary tumors. All patients with sporadic gastrinomas without evidence of liver metastases should be surgically explored with the intent of removing local and regional disease. Unfortunately, despite careful diagnostic testing, no tumor is found in at least 10% of diagnosed instances of ZES.

ZES should be anticipated in patients with recurrent PUD in the absence of *H. pylori* infection or NSAID use, as well as in patients with multiple duodenal ulcers, ulcers in unusual locations (distal duodenum or jejunum), or severe or refractory diarrhea or gastroesophageal reflux disease. Although peptic ulcer occurs in more than 90% of patients with ZES, as many as 35% of individuals exhibit only diarrhea. The diagnosis of ZES is made when a fasting gastrin concentration of more than 1000 pg/mL exists in the setting of gastric acid hypersecretion. In equivocal cases (e.g., gastrin < 1000 pg/mL), a positive secretin provocative test will confirm the diagnosis. The secretin test is positive (≥ 200 pg/mL increase over the preinjection fasting gastrin level) in

about 90% of patients with ZES and moderately elevated gastrin levels. Basal acid output is elevated (>15 mmol per hour without previous gastric acid-reducing surgery and >5 mmol per hour with prior surgery) in more than 90% of patients with ZES. Because gastrinomas constitute a relatively uncommon cause of hypergastrinemia, other causes should be considered. The most common causes of hypergastrinemia are antrum-dominant *H. pylori* infection or achlorhydria related to either decreased intraluminal acid in the setting of atrophic gastritis or antisecretory therapy with PPIs. Hypergastrinemia may be related to other causes, including retained gastric antrum (after ulcer surgery), massive small bowel resection, chronic gastric outlet obstruction, and chronic renal failure. Therefore, acid hypersecretion, as documented by gastric acid analysis, is necessary for the diagnosis of ZES.

Once hypergastrinemia has been established and obvious causes have been excluded, efforts should focus on localizing and resecting the gastrin-secreting tumor. The single best imaging test for gastrinoma is somatostatin-receptor scintigraphy (SRS), which is more sensitive than any conventional imaging study, including CT, magnetic resonance imaging (MRI), and ultrasonography, although endoscopic ultrasonography (EUS) is equally sensitive for localizing primary tumors of the pancreas. If liver metastasis is present, a CT- or ultrasound-guided liver biopsy should be performed. In patients without liver metastasis, SRS will localize a possible primary tumor in 60% of cases. If the patient is a surgical candidate and SRS is positive for a primary tumor, no additional localization studies are required. If the SRS is negative for a possible primary tumor, the use of MRI, angiography, or EUS will detect a possible primary tumor in an additional 15% of patients. Multiple pancreatic or duodenal tumors are generally detected in patients with MEN-I syndrome, and although the precise role of surgery in these patients is less certain, some physicians recommend surgery if a lesion larger than 3 cm is identified with preoperative imaging techniques to decrease the possibility of hepatic metastasis. However, successful and long-lasting remission of MEN-I syndrome occurs rarely, if at all.

All patients with ZES, whether sporadic or familial, require antisecretory therapy after the diagnosis is established and during initial evaluation as attempts are made to localize the gastrinoma. Patients with ZES should be treated initially with a PPI using twice the dose normally employed to treat common gastroduodenal ulcers. Intravenous PPIs such as pantoprazole in daily doses ranging from 80 to 240 mg can be used in patients who are unable to take medications by mouth, including those undergoing surgery. The goal of therapy is a basal acid output of less than 10 mmol per hour in the hour preceding the next dose of the drug. Chronic therapy with PPIs uniformly results in continued inhibition of acid secretion, good symptom control, complete healing of any mucosal lesions, and few adverse effects.

Gastroparesis

Gastroparesis is a syndrome characterized by delayed gastric emptying, resulting in impaired transit of food from the stomach to the duodenum in the absence of mechanical obstruction. Symptoms of gastric stasis include early or easy

satiety, bloating, nausea, and vomiting. Because eating exacerbates symptoms, patients frequently exhibit anorexia, weight loss, and nutritional deficiencies. A wide range of clinical disorders is associated with impaired gastric emptying (Table 37-4). Diabetes mellitus is the most common cause of gastroparesis, and up to 60% of patients with diabetes complain of symptoms consistent with gastric stasis. Although gastroparesis is typically seen in individuals with long-standing (>10 years) type 1 diabetes who have other complications, such as peripheral and autonomic neuropathy, nephropathy, and retinopathy, GI complaints are also common within the first decade of diagnosis. Diabetic gastroparesis appears to occur as a result of permanent neuropathy of autonomic and enteric nerves, transitory variations in glycemic control, or a combination of both. Idiopathic gastroparesis is also common and comprises those instances with no clearly identifiable cause. Up to one third of these patients have virus-induced gastroparesis, with viral infiltration of the myenteric plexus in the stomach. Patients who have undergone gastric surgery, especially those having had preoperative gastric outlet obstruction as a complication of PUD, are also commonly affected by

Table 37-4 Causes of Delayed Gastric Emptying

Mechanical Causes

Peptic ulcer disease, scarred pylorus
 Malignancy: gastric cancer, gastric lymphoma, pancreatic cancer
 Gastric surgery: vagotomy, gastric resection, roux-en-Y anastomosis
 Crohn disease

Endocrine and Metabolic Causes

Diabetes mellitus
 Hypothyroidism
 Hypoadrenal states
 Electrolyte abnormalities
 Chronic renal failure
 Medications
 Anticholinergics
 Opiates
 Dopamine agonists
 Tricyclic antidepressants

Abnormalities of Gastric Smooth Muscle

Scleroderma
 Polymyositis, dermatomyositis
 Amyloidosis
 Pseudo-obstruction
 Myotonic dystrophy
 Neuropathy
 Scleroderma
 Amyloidosis
 Autonomic neuropathy

Central Nervous System or Psychiatric Disorders

Brainstem tumors
 Spinal cord injury
 Anorexia nervosa
 Stress

Miscellaneous

Idiopathic gastroparesis
 Gastroesophageal reflux disease
 Nonulcer (functional) dyspepsia
 Cancer cachexia or anorexia

gastroparesis. Finally, Parkinson disease, rheumatologic disorders, hypothyroidism or hyperthyroidism, chronic intestinal pseudo-obstruction, and a variety of paraneoplastic syndromes can also produce gastroparesis.

The diagnostic evaluation of delayed gastric emptying should focus on excluding structural and metabolic abnormalities. Endoscopy is the preferred initial test to rule out mechanical gastric outlet obstruction, and a small bowel follow-through radiograph may be useful to exclude small bowel lesions. Serum electrolytes, blood cell counts, and thyroid studies should also be performed. When these studies are negative, radionuclide scintigraphy (gastric-emptying scan) using a mixed solid-liquid meal can quantitate delayed gastric emptying. Assessment of solid emptying is more clinically relevant than liquid emptying. In especially difficult cases, GI manometry and electrogastrography may help in the diagnosis.

Managing gastroparesis begins with identifying and treating potentially correctable causes. Medications that reduce gastric emptying, such as narcotics, anticholinergics, and tricyclic antidepressants, should be avoided. Because liquids empty easier than solids, and because liquid emptying is often preserved in patients with gastroparesis, simple dietary modifications may be helpful in treatment. The diet should be modified to include blenderized foods and liquid supplements. High-fat and fiber-rich foods should be avoided because they inhibit gastric emptying under normal conditions and are less likely to empty. Medical options are limited and involve the use of prokinetic drugs, which are agents that improve transit in the GI tract.

Metoclopramide is a dopamine-2 receptor antagonist that also facilitates the release of acetylcholine from cholinergic nerve terminals in the gut, thereby accelerating gastric emptying. The efficacy of metoclopramide is inconsistent, and adverse effects and the development of tolerance complicate long-term therapy. Adverse effects occur in up to 20% of patients and include drowsiness, anxiety, fatigue, insomnia, restlessness, agitation, extrapyramidal effects, galactorrhea, and menstrual irregularities. The typical dosage is 10 mg, 20 to 30 minutes before meals and at bedtime, although doses as high as 80 mg or as low as 20 mg may be used daily. Doses should be reduced for patients with renal failure. Domperidone, another dopamine receptor antagonist with prokinetic properties, has similar efficacy to metoclopramide in the treatment of delayed gastric emptying but is currently not available in the United States.

Cisapride, an agent that increases gastric motor activity by facilitating the release of acetylcholine at the myenteric plexus, is no longer routinely available in the United States and other countries because of serious adverse effects, including ventricular tachycardia, ventricular fibrillation, torsades de pointes, and prolongation of the QT interval, which have been reported when cisapride is administered with other drugs that inhibit cytochrome P-450.

Erythromycin is a macrolide antibiotic that stimulates smooth muscle motilin receptors located at all levels of the GI tract. The prokinetic effects of erythromycin are related to its ability to mimic the effect of the GI peptide motilin to stimulate smooth muscle contraction, which accounts for the acceleration of solid and liquid gastric emptying. Erythromycin may dramatically improve gastric emptying in patients with severe diabetic gastroparesis when given acutely

at an intravenous dose of 1 to 3 mg/kg every 8 hours. Long-term use of the drug at a dose of 250 to 500 mg orally every 8 hours in patients with gastric stasis is of limited efficacy because of tachyphylaxis and side effects.

Endoscopic botulinum toxin A injection into the pyloric sphincter has also been reported in the treatment of delayed gastric emptying in small studies, but long-term benefit has not been proved.

In patients who are refractory to these measures, surgical placement of a jejunal tube, with or without a venting gastrostomy, may be necessary. Total parenteral nutrition is rarely indicated. Surgical gastrectomy should only be considered in patients with refractory postsurgical gastric stasis. Gastric pacemakers and other prokinetics, specifically new serotonin-receptor agonists, are under investigation and may be options in the future.

Rapid Gastric Emptying

Rapid gastric emptying is a far less common clinical problem than delayed gastric emptying. *Dumping syndrome* describes the alimentary and systemic manifestations of early delivery of large amounts of osmotically active food to the small intestine. Dumping syndrome is usually seen when the normal reservoir, grinding, and sieving properties of the stomach are disrupted, most commonly following surgery for obesity (Roux-en-Y gastric bypass) or PUD. The accelerated emptying of hypertonic boluses of nutrient material into the small intestine results in splanchnic vasodilation and release of vasoactive peptides. Early dumping symptoms, occurring about 30 minutes after a meal, include epigastric fullness and pain, nausea, vomiting, early satiety, and vasomotor features such as flushing, palpitations, and diaphoresis. Later symptoms, such as diaphoresis, tremulousness, and weakness, occur about 2 hours after a meal and may be caused by hypoglycemia from rebound hyperinsulinemia. Treatment of dumping syndrome involves dietary manipulation to decrease the volume and osmotic load emptied into the intestine. Frequent small feedings of meals low in carbohydrates, separation of liquid and solid intake, and avoidance of hypertonic fluids and lactose are usually helpful. When these measures fail, administration of octreotide at a dose of 25 to 50 mcg subcutaneously 30 minutes before meals may be helpful. Octreotide acts by slowing gastric emptying and intestinal transit as well as by inhibiting the release of insulin. Surgical procedures to slow gastric emptying have limited success.

Gastric Volvulus

Gastric volvulus occurs when the stomach twists on itself. This event may be transient, producing few if any symptoms, or may lead to obstruction or even ischemia and necrosis. *Primary gastric volvulus*, seen in one third of the patients, occurs below the diaphragm when the stabilizing ligaments are too lax as a result of congenital or acquired causes. *Secondary gastric volvulus* occurs above the diaphragm in association with paraesophageal hernias or other diaphragmatic defects. Acute gastric volvulus produces sudden, severe pain of the upper abdomen or chest, persistent retching

producing scant vomitus, and the inability to pass a nasogastric tube. This combination of symptoms, also known as Borchardt triad, should lead to a strong clinical suggestion of acute gastric volvulus. Chronic gastric volvulus may be associated with mild and nonspecific symptoms, such as epigastric discomfort, heartburn, abdominal fullness or bloating, and borborygmi, especially after meals. The diag-

nosis of gastric volvulus is made by upper GI series demonstrating an abrupt obstruction at the site of the volvulus. Acute gastric volvulus requires emergency surgical evaluation because of the substantial risk for mortality related to gastric ischemia or perforation. Treatment consists of surgical gastropexy and repair of any associated paraesophageal hernia.

Prospectus for the Future

Our understanding of a significant number of issues involving gastroduodenal pathologic mechanisms and therapeutics will continue to evolve in the next few years. Select goals include the following:

- Development of variations in the structure and delivery of antisecretory therapy, leading to formulations designed to provide increased rapid onset of action and to improve effectiveness in individuals who are unable to take medications by mouth or those with dysmotility or malabsorption
- Further clarification of the optimal *H. pylori* treatment regimen given increased antibiotic resistance profiles and the goal of improving patient compliance to treatment
- Procurement of evidence-based data to aid in managing stress-related mucosal ulcerations in critically ill patients
- Elucidation of the exact nature and strength of the association between COX-2-selective inhibitors and cardiovascular disease and future development of safer NSAIDs
- Further insight into the mechanism governing GI motility and the development of new agents for the treatment of motility disorders

Inflammatory Bowel Disease

Christopher S. Huang and Francis A. Farraye

Although a significant number of infectious organisms and noninfectious processes (e.g., medications, radiation, ischemia) can result in intestinal inflammation, the term *inflammatory bowel disease* (IBD) generally refers primarily to two idiopathic diseases: ulcerative colitis and Crohn disease. The diagnosis of IBD is made by incorporating clinical, endoscopic, radiologic, and histologic information. Ulcerative colitis is characterized by inflammatory changes that involve the colonic mucosa in a continuous superficial fashion, generally starting in the rectum and extending proximally. Depending on the extent of the disease, ulcerative colitis can be divided into proctitis (rectum only), proctosigmoiditis, left-sided colitis (extending to the splenic flexure), or pancolitis. This classification is important for both prognostic and therapeutic reasons. Unlike ulcerative colitis, Crohn disease can involve any segment of the gastrointestinal system, often in a discontinuous fashion. It is characterized by transmural inflammation, which results in significant complications such as abscesses, fistulas, and strictures. Despite the chronic nature of these two diseases, new and emerging targeted anti-inflammatory treatments hold great promise in helping to reduce morbidity and improve the quality of life of individuals with IBD.

Epidemiology

In the United States, about 1.4 million individuals have IBD, and the overall incidence of new cases of IBD is about 3 to 10 new cases per 100,000 people. During the past several decades, the incidence of ulcerative colitis has remained stable, whereas the incidence of Crohn disease has gradually increased. The prevalence of IBD is essentially 10-fold higher, between 30 and 100 per 100,000 people. A bimodal age of presentation exists, with an initial peak between the second and fourth decades of life followed by another peak at about the sixth decade of life. Both sexes are equally affected.

The incidence and prevalence of IBD reflect the genetic and environmental factors that contribute to these disorders.

For example, both diseases are common in northern climates, among whites, particularly in populations with Northern European ancestry, including North Americans, South Africans, and Australians. Individuals of Ashkenazi Jewish descent have also been found to have a twofold to eightfold increased risk for these disorders compared with non-Jews. Although the prevalence and incidence rates of IBD are lowest in Hispanics and Asians, IBD can occur in any ethnic or racial group from anywhere in the world.

Causes

Although the causes of IBD remain unknown, recent advances in the understanding of the genetic, immunologic, and environmental factors are beginning to decipher the etiologic factors of these complex disorders. Currently, it is believed that IBD results from an inappropriate, overactive mucosal immune response to commensal intestinal bacteria in genetically susceptible individuals.

GENETIC FACTORS

About 5% to 20% of patients with IBD have a first-degree relative with the disease, and first-degree relatives of IBD patients have about a 10- to 15-fold increased risk for developing IBD, predominantly with the same disease as the proband. A positive family history is generally more frequently observed in patients with Crohn disease than in patients with ulcerative colitis, suggesting that genetic factors contribute more significantly in the etiology of Crohn disease. Through advances in genome-wide association studies, several susceptibility loci on multiple chromosomes have been linked to IBD, supporting a polygenic cause to these disorders. Polymorphisms in the *NOD-2* gene (also known as *CARD-15*, located on chromosome 16) were the first definitive genetic risk factors identified for Crohn disease. Homozygous mutations of the *NOD-2* gene are associated with a greater than 20-fold increase in susceptibility for Crohn disease. Defects in the *NOD-2* protein appear

to result in abnormal intestinal immune responses to bacterial cell wall components. These gene mutations are estimated to account for about 15% to 25% of the cases of Crohn disease and are linked predominantly to fibrostenotic terminal ileal disease. Another gene of interest is the *IL-23R* gene on chromosome 1, which has also been shown to be strongly associated with IBD, particularly Crohn disease. Disease-associated *IL-23R* polymorphisms have also been reported in patients with ulcerative colitis, psoriasis, and ankylosing spondylitis. Many other genes have been uncovered by genome-wide association studies, such as *OCTN*, *DLG-5*, *ICAM-1*, and *TLR-4*, and are currently under investigation for their potential involvement in the pathogenesis of IBD.

IMMUNOLOGIC FACTORS

Profound alterations in mucosal immunology have been demonstrated in patients with IBD. In the normal immunologic state of the intestine, recently activated lymphoid tissue is abundant within the mucosal compartment. This state has been described as controlled, or *physiologic*, inflammation, which has likely developed in response to constant encounters with antigenic substances (derived from host microbial flora, or dietary and environmental sources) that have crossed the epithelial barrier from the luminal environment. Indeed, one of the main functions of the intestinal immune system is to discriminate noxious or harmful substances and organisms from nonharmful ones. As a result, a large and well-maintained network of many different mucosal immune cells exists, including cells involved in reducing immune responses (regulatory cells) and those involved in activating immune responses. In IBD, this homeostatic balance, or immune tolerance, is dysregulated, resulting in overactivation of the immune system. Crohn disease, for example, reflects an excessive and persistent CD4 helper T-cell subtype 1 (T_H1) immune response to components of commensal bacterial flora. The T_H1 cytokine profile, including interferon- γ , interleukin-2 (IL-2), IL-12, and tumor necrosis factor- α (TNF- α), is elevated in patients with Crohn disease. The cytokine profile of ulcerative colitis is atypical, with greater expression of IL-5 and IL-13 present, cytokines characteristically associated with a T_H2 response. More recently, non- T_H1 / T_H2 pathways have been identified as being potentially important in the pathogenesis of IBD. IL-23, for example, has been recognized as an inducer of a subset of proinflammatory T cells (T_H17) that secrete high levels of IL-17 and play an important role in mediating inflammation in murine models of colitis. IL-17 expression has been shown to be upregulated in active IBD, both Crohn disease and ulcerative colitis.

ENVIRONMENTAL FACTORS

Although believed to be important, the role of environmental factors in IBD pathogenesis remains poorly understood. Many infectious agents, including *Mycobacteria paratuberculosis* and measles virus, have been implicated in IBD, but none fulfills the criteria of true pathogens. Environmental factors are suspected because the disease is more common in industrialized countries, and the frequency has been increasing in countries that are becoming more industrial-

ized. It has been postulated that poor sanitation, food contamination, and crowded living conditions are associated with helminthic infection, which leads to regulatory T-cell conditioning and stimulation of IL-10 and transforming growth factor- β production by mononuclear cells, thereby preventing intestinal inflammation. However, to date, the only environmental factor clearly associated with IBD is tobacco smoking. Smoking seems to be protective against ulcerative colitis, whereas smokers with Crohn disease have more aggressive disease than do nonsmokers. No dietary triggers have been found to cause IBD, but elemental diets and diversion of the fecal stream can reduce recurrence of inflammation in Crohn disease.

Clinical Features of Ulcerative Colitis

Ulcerative colitis is characterized by chronic inflammation of the mucosal surface that involves the rectum (proctitis) and extends proximally through the colon in a continuous manner. The extent and severity of the colonic inflammation determine prognosis and presentation (insidious versus acute onset).

Most patients initially exhibit diarrhea, abdominal pain, urgency to defecate, rectal bleeding, and the passage of mucus per rectum. Patients occasionally have extraintestinal manifestations (see later discussion) before they develop intestinal symptoms. About 40% to 50% of patients have proctitis or proctosigmoiditis, 30% to 40% have left-sided colitis (disease extending to the splenic flexure), and the remaining 20% to 25% have pancolitis. Of the patients who initially show proctitis or proctosigmoiditis, about 15% develop more extensive disease over time.

The typical clinical course is of chronic intermittent exacerbations, followed by periods of remission. Signs of a worsening clinical course include the development of abdominal pain, dehydration, fever, and tachycardia. Clinical features, including bowel frequency, fever, increased heart rate, and blood in stools, as well as the presence of anemia and an elevated erythrocyte sedimentation rate (ESR) or C-reactive protein, have been used to assess severity of ulcerative colitis.

MAJOR COMPLICATIONS

Toxic Megacolon and Perforation

Toxic megacolon is characterized by gross dilation of the large bowel associated with fever, abdominal pain, dehydration, tachycardia, and bloody diarrhea, which may require urgent surgical intervention. Perforation can occur in the setting of toxic megacolon or in patients with active colitis, especially those taking corticosteroids.

Gastrointestinal Hemorrhage and Anemia

Although massive hemorrhage is uncommon, this complication is an indication for surgical intervention. Anemia commonly occurs and is caused by chronic blood loss from the involved colonic mucosa as well as bone marrow suppression from the inflammatory condition.

Colonic Adenocarcinoma

The risk for colon cancer is increased in patients with ulcerative colitis, the magnitude of which is related to the extent and duration of disease. Colon cancer risk is increased 10- to 20-fold (if disease extends proximal to the sigmoid colon) after 8 years of disease compared with that in unaffected individuals. Colonoscopy with surveillance biopsies are recommended every 2 years after 8 to 10 years of disease in patients with pancolitis and after 12 to 15 years in patients with left-sided colitis, followed by yearly examinations after 20 years of disease. Proctitis is not associated with an increased cancer risk. Patients with IBD and primary sclerosing cholangitis (PSC) appear to be at particularly increased risk, and yearly surveillance is recommended after the initial diagnosis of PSC. A minimum of 33 “random” mucosal biopsy samples are recommended during the colonoscopic examination, in addition to targeted samples of circumscribed lesions. The use of chromoendoscopy and other enhanced imaging techniques increases the detection of dysplastic lesions in patients with ulcerative colitis. Colectomy is indicated in patients with flat high-grade dysplasia, multifocal flat low-grade dysplasia, possibly unifocal flat low-grade dysplasia, or evidence of colorectal cancer. Polypoid dysplasia entirely removed by polypectomy without flat dysplasia elsewhere in the colon can be managed with continued surveillance colonoscopy.

Clinical Features of Crohn Disease

Crohn disease may involve any portion of the gastrointestinal tract, and it is the site of involvement, as well as the type of inflammation, that defines the clinical presentation. Unlike ulcerative colitis, the inflammation in Crohn disease is transmural, and the bowel wall can become thickened, fibrotic, and strictured. The mucosal surface may develop *cobblestoning* related to edema with linear ulcerations. Deep fissures can develop and result in microperforations and the formation of fistulous tracts. The disease may be continuous but often has *skip* lesions with intervening segments of normal intestine. The mesentery can become infiltrated with fat, known as *creeping fat*. The disease is often present for months or years before diagnosis, and, in children, growth retardation may be the sole presenting sign.

Distribution of Crohn disease is divided into three major patterns. The most common is ileocecal, which involves the distal portion of the small intestine (terminal ileum) and the proximal large bowel, and is observed in about 40% of patients. Ileocecal Crohn disease may mimic many other diseases, including acute appendicitis. Common symptoms include right lower quadrant abdominal pain, fever, weight loss, and sometimes a palpable inflammatory mass. Chronic inflammation, which leads to fibrosis and stricture formation, may result in partial or complete intestinal obstruction, as demonstrated by abdominal pain, distention, nausea, and vomiting. Because vitamin B₁₂ and bile salts are absorbed in the terminal ileum, ileal Crohn disease or surgical resection of the terminal ileum may lead to B₁₂ deficiency as well as deficiencies of the fat-soluble vitamins (A, D, E, and K) as a result of bile salt malabsorption.

The second major site of Crohn disease involves the small intestine, especially the terminal ileum, and is seen in about 30% of individuals at the time of presentation. Similar complications develop, including fistulas, which may form between different segments of bowel (e.g., enteroenteric, enterocolonic), bowel and skin (enterocutaneous), bowel and bladder (enterovesicular), and bowel and vagina (rectovaginal).

The third site of disease is confined to the colon and is observed in 25% of individuals at the time of presentation. Although the disease often spares the rectum, 30% to 40% of patients may develop disabling perianal involvement with fissures, fistulas, and abscesses. Diarrhea is the major consequence but usually with less bleeding than that seen in ulcerative colitis. Distinguishing Crohn colitis from ulcerative colitis can be difficult.

The remaining sites of Crohn disease are rare (5%) and include the esophagus, stomach, and duodenum.

MAJOR COMPLICATIONS

Stenosis (Stricture) of the Small Intestine or Colon

Stenosis may lead to bowel obstruction or stasis with subsequent small intestinal bacterial overgrowth.

Malabsorption

Extensive ileal mucosal disease may lead to malabsorption of vitamin B₁₂ (resulting in a megaloblastic anemia and neurologic side effects if not corrected) and malabsorption of bile salts (resulting in diarrhea induced by unabsorbed bile salts and potential fat-soluble vitamin deficiency). Depletion of the bile salt pool can lead to the formation of gallstones. Weight loss may result from generalized malabsorption caused by loss of absorptive surfaces.

Fistulas

Transmural inflammation may lead to spontaneous drainage into adjacent bowel loops (enteroenteric fistula), bladder (enterovesical fistula), skin (enterocutaneous fistula), and vagina (rectovaginal), or it may lead to abscess formation around bowel or in other surrounding tissues.

Nephrolithiasis

Chronic fat malabsorption leads to luminal binding of free fatty acids to calcium, allowing oxalate, which normally is poorly absorbed because it complexes to calcium in the gut lumen, to be absorbed. This increase in oxalate absorption increases the risk for urinary calcium oxalate stone formation. Patients with an ileostomy or chronic volume loss from diarrhea are also at increased risk for uric acid stones.

Malignancy

For colonic Crohn disease, the risk for colorectal cancer is equivalent to ulcerative colitis of similar extent and duration. Therefore, screening and surveillance recommendations are similar to those for ulcerative colitis (see previous discussion). Patients with only small intestinal Crohn disease without colonic involvement are not thought to be at increased risk for colorectal cancer. The rates of small bowel carcinoma and lymphoma are increased in patients with Crohn disease.

Diagnosis

The diagnosis of IBD is based on a constellation of clinical features, laboratory tests, and endoscopic, radiographic, and histologic findings. Laboratory tests are not specific and usually reflect inflammation (leukocytosis) or anemia. Perinuclear antineutrophil cytoplasmic antibody (p-ANCA) is positive in up to 70% of patients with ulcerative colitis but rarely positive in patients with Crohn disease, whereas anti-*Saccharomyces cerevisiae* antibodies (ASCA) are common in Crohn disease and are rarely found in ulcerative colitis. Additional markers including anti-CBir-1 and anti-Omp-C may improve the sensitivity and specificity of serologic testing. Stool examination for ova and parasite identification and testing for *Clostridium difficile* toxin and enteric bacterial pathogens should be performed to exclude infections that can mimic IBD.

Colonoscopy in patients with ulcerative colitis reveals a granular mucosa, decreased vascular markings, decreased mucosal reflection, and superficial ulcerations (Fig. 38-1). In more severe cases, the mucosa is friable, with deeper ulcerations and exudate. Patients with long-standing disease have *pseudopolyps*, which represent islands of normal tissue in regions of previous ulceration. On endoscopic examination in Crohn disease (Fig. 38-2), the involved mucosa may show aphthoid ulcerations, deep linear or stellate ulcers, edema, erythema, exudate, and friability with intervening areas of normal mucosa (skip lesions).

In Crohn disease, small bowel radiography (i.e., small bowel follow-through) has traditionally been the best study with which to investigate the jejunum and ileum, although video capsule endoscopy has recently become increasingly used in this setting. Using this technology, small ulcerations and strictures that are undetectable on small bowel radiography can be visualized (**Web Fig. 38-1**), although patients

with known or suspected strictures or fistulas should not undergo capsule endoscopy given the risk for capsule retention. On small bowel radiography, involved areas have edema and thickening of the bowel wall that lead to bowel loop separation and can also show ulcerations of the mucosa, fistulas, or strictures. A tight, long stricture in the small bowel is commonly called the *string sign* (Fig. 38-3). Linear ulcers with segments of edematous or uninvolved mucosa lead to the characteristic pattern referred to as *cobblestoning*. Computed tomographic (CT) scanning can often identify bowel wall thickening with surrounding inflammation as well as intra-abdominal abscesses and fistulas. The recent development of CT enterography and magnetic resonance enterography represent advances in small bowel imaging technology and will likely become primary imaging studies in patients with known or suspected Crohn disease.

Mucosal biopsies in ulcerative colitis reveal crypt architectural distortion, with crypt abscesses and infiltration by plasma cells, neutrophils, lymphocytes, and eosinophils (Fig. 38-4). In Crohn disease, the inflammation is transmural and more commonly focal. Granulomas are found in 25% to 30% of histologic specimens in Crohn disease, but not in ulcerative colitis, and can assist in the diagnosis of Crohn disease in the right clinical setting (Fig. 38-5).

Differential Diagnosis

The differential diagnosis of IBD includes infectious colitis, ischemic colitis, radiation enteritis, enterocolitis induced by nonsteroidal anti-inflammatory drugs, diverticulitis, appendicitis, gastrointestinal malignancies, and irritable bowel syndrome. In patients with acute onset of bloody diarrhea, infectious causes that must be excluded include *Salmonella enteritidis*, *Shigella* species, *Campylobacter jejuni*, *Escherichia*

Figure 38-1 Endoscopic image in ulcerative colitis demonstrating diffuse inflammation characterized by erythema, edema, friability, and hemorrhage.

coli O157, and *C. difficile*. Among the infectious causes, *Yersinia enterocolitica* can mimic Crohn disease because the pathogen causes ileitis, mesenteric adenitis, fever, diarrhea, and right lower quadrant abdominal pain. *Mycobacterium tuberculosis*, strongyloidiasis, and amebiasis must be excluded in high-risk populations because these infections can mimic IBD, and treatment with corticosteroids can lead to disseminated infection and death.

Extraintestinal Manifestations

Although both ulcerative colitis and Crohn disease primarily involve the bowel, they are associated with inflammatory manifestations in other organ systems, reflecting the systemic nature of these disorders (Table 38-1). Most of these manifestations occur frequently when the bowel is involved, and, in some cases, they may become more difficult to treat than the bowel disease itself.

The most common extraintestinal manifestation is arthritis, of which two major types have been identified. The first is a peripheral, large joint, asymmetrical, seronegative, oligoarticular, nondeforming arthritis (about 20% of patients) that may involve the knees, hips, wrists, elbows, and ankles. This *peripheral arthropathy* usually parallels the course of the large bowel disease (*colitic arthritis*) and usually lasts for only

Figure 38-4 Mucosal biopsy demonstrating crypt branching and a crypt abscess characteristic of ulcerative colitis (hematoxylin and eosin stain). (Courtesy of Niall Swan, MD.)

a few weeks. A second arthritis is axial in location, and its activity does not mirror that of the bowel disease. It consists of sacroiliitis or ankylosing spondylitis. Ankylosing spondylitis (about 5% to 10% of IBD patients) presents with low back pain and stiffness, usually worse during the night, in the morning, or after inactivity. Sacroiliitis alone (without ankylosing spondylitis) is common in IBD (up to about 80% of patients), but many of these patients are asymptomatic.

Liver complications of IBD include both intrahepatic and biliary tract diseases. Intrahepatic diseases include fatty liver, pericholangitis, chronic active hepatitis, and cirrhosis. Pericholangitis, also known as small-duct sclerosing cholangitis, is the most common of these diseases and usually is asymptomatic, identified only by abnormalities in alkaline phosphatase and γ -glutamyl transpeptidase on laboratory tests and histologically by portal tract inflammation and bile ductule degeneration. Small-duct sclerosing cholangitis may progress to cirrhosis.

Ankylosing spondylitis
Sacroiliitis
Ocular
Uveitis
Episcleritis
Miscellaneous
Hypercoagulable state
Autoimmune hemolytic anemia
Amyloidosis

Biliary tract disease includes an increased incidence of gallstones and primary sclerosing cholangitis (PSC). PSC is a chronic cholestatic liver disease marked by fibrosis of the intrahepatic and extrahepatic bile ducts, occurring in 1% to 4% of patients with ulcerative colitis and less often in Crohn disease. Overall, about 70% of patients with PSC have ulcerative colitis. Fibrosis leads to strictures of the bile ducts, which, in turn, may lead to recurrent cholangitis (fever, right upper quadrant pain, and jaundice) and progression to cirrhosis. In addition, about 10% of patients develop cholangiocarcinoma. Medical or surgical therapy for the IBD does not modify the course of PSC, and most patients will progress to cirrhosis and liver failure over 5 to 10 years unless a liver transplantation is performed.

The two classic dermatologic manifestations of IBD are pyoderma gangrenosum and erythema nodosum. Pyoderma gangrenosum (about 5% of patients) exhibits as a discrete ulcer with a necrotic base, usually on the legs. The ulcer may spread and become large and deep, destroying soft tissues. Pyoderma parallels the activity of the IBD in 50% of cases. Treatment is usually with systemic or intralesional steroids, or both. Other treatment options include dapsone, cyclosporine, and infliximab. Erythema nodosum (10% of patients, usually with peripheral arthropathy) exhibits raised, tender nodules, usually over the anterior surface of the tibia. It heals without scarring and responds to treatment for the underlying bowel disease. A less common dermatologic manifestation of IBD is Sweet syndrome, or acute febrile neutrophilic dermatosis. This is a condition characterized by the sudden onset of fever, leukocytosis, and tender, erythematous, well-demarcated papules and plaques that show dense neutrophilic infiltrates on histologic examination.

Ocular manifestations of IBD include uveitis and episcleritis (5%). Uveitis (or iritis) is an inflammatory lesion of the anterior chamber and produces blurred vision, photophobia, headache, and conjunctival injection. Local therapy includes steroids and atropine. Episcleritis is less serious

Table 38-2 Differentiating Features

	Ulcerative Colitis	Crohn Disease
Site of involvement	Only involves colon Rectum almost always involved	Any area of the gastrointestinal tract Rectum usually spared
Pattern of involvement	Continuous	Skip lesions
Diarrhea	Bloody	Usually nonbloody
Severe abdominal pain	Rare	Frequent
Perianal disease	No	In 30% of patients
Fistula	No	Yes
Endoscopic findings	Erythematous and friable Superficial ulceration	Aphthoid and deep ulcers Cobblestoning
Radiologic findings	Tubular appearance resulting from loss of haustral folds	String sign of terminal ileum RLQ mass, fistulas, abscesses
Histologic features	Mucosa only Crypt abscesses	Transmural Crypt abscesses, granulomas (about 30%)
Smoking	Protective	Worsens course

ASCA, anti-*Saccharomyces cerevisiae* antibodies; p-ANCA, perinuclear antineutrophil cytoplasmic antibody; RLQ, right lower quadrant.

than uveitis, producing burning eyes and scleral injection, and is treated with topical steroids.

Other complications of IBD include chronic anemia (common), digital clubbing and hypertrophic osteoarthropathy (uncommon in adults), an increased incidence of thromboembolic disease (uncommon), and amyloidosis (rare).

Differentiation between Ulcerative Colitis and Crohn Disease

Generally, the diagnoses of ulcerative colitis and Crohn disease can be made based on the findings as described in their respective sections presented earlier and those outlined in Table 38-2. As noted, most Crohn patients have small bowel involvement, skip lesions, and pain, whereas most ulcerative colitis patients have bloody diarrhea with involvement of the rectum and a continuous, superficial spread of the disease. The endoscopic, radiologic, and histologic criteria aid in the phenotypic differentiation of these disease entities. However, occasionally, a diagnosis of *indeterminate* colitis is made as a result of an overlap of findings. For example, colonic Crohn disease may produce superficial continuous rectal involvement similar to ulcerative proctitis. Similarly, chronic ulcerative colitis can infrequently result in

inflammation of the terminal ileum, called *backwash ileitis*. In many indeterminate cases, repeated examination is necessary, or complications develop that help identify the form of the disease.

Treatment (Induction and Maintenance of Remission)

As part of the initial management of patients with IBD, the clinician must determine the extent and assess the severity of the disease. Patients with mild or moderate disease can be managed as outpatients with close monitoring in association with a gastroenterologist. Patients with severe or fulminant disease, as indicated by abdominal pain, fever, tachycardia, anemia, and leukocytosis, require hospital admission and multidisciplinary team management. Because IBD is a chronic recurrent illness, treatment is centered on controlling the acute attack with induction of remission followed by maintenance of remission. Treatment options for ulcerative colitis and Crohn disease are reviewed in Table 38-3.

5-AMINOSALICYLIC ACID

The aminosalicylates are given either orally or topically (suppository and enema) and are safe and effective in the treatment of mild to moderate disease as well as in maintenance of remission of ulcerative colitis. The efficacy of most of these agents in the induction or maintenance of remission of Crohn disease is questionable. This category includes sulfasalazine (Azulfidine) at a dose of 4 to 6 g/day in divided doses, which consists of 5-aminosalicylic acid (5-ASA) linked to a sulfapyridine moiety and which is activated following the release of the 5-ASA after bacterial lysis in the colon. Side effects, including headache, nausea, and skin

reactions, may require discontinuation of sulfasalazine in about 30% of patients. Reversible oligospermia may occur with sulfasalazine, and rare serious side effects include pleuropericarditis, pancreatitis, agranulocytosis, interstitial nephritis, and hemolytic anemia. Patients who take sulfasalazine need folic acid supplementation. Newer derivatives of oral 5-ASA compounds, such as mesalamine (Pentasa, 4 g per day in divided doses; Asacol, 2.4 g per day in divided doses; Lialda, 2.4 to 4.8 g once daily), olsalazine (Dipentum, 1 to 2 g per day in divided doses), and balsalazide (Colazal, 6.75 g per day in divided doses), as well as topical forms of mesalamine (Canasa suppositories, 1000 mg once daily; or Rowasa enemas, 4 g once nightly), are being commonly used because of a favorable side-effect profile. In addition to their use in the primary treatment of IBD, several studies suggest that long-term use of 5-ASA medications may reduce the risk for colorectal cancer in patients with ulcerative colitis.

CORTICOSTEROIDS

Corticosteroids may be used topically, orally, or intravenously and are effective for controlling active disease but are not useful for maintaining remission. They are indicated for moderate or severe disease and in patients in whom treatment with 5-ASA fails. The most commonly used agent is prednisone, started in doses between 40 and 60 mg per day. Patients typically improve rapidly, and the medication is usually tapered down slowly, that is, 5 to 10 mg per week until discontinuation. Patients who do not improve after 1 week of oral treatment and those with more severe disease are best treated in the hospital with intravenous corticosteroids, such as intravenous hydrocortisone, 300 mg per day, or methylprednisolone, which can be given either by continuous infusion or in three divided doses. Corticosteroids have numerous side effects with long-term use. Budesonide (Entocort, 9 mg given once daily), a corticosteroid that undergoes extensive first-pass hepatic metabolism, is now available for inducing and maintaining remission of ileocolonic Crohn disease and may offer long-term benefits with decreased corticosteroid side effects. Controlled trials have shown that budesonide is more effective than placebo and oral 5-ASA, and has similar efficacy to prednisolone for the induction of remission in Crohn disease.

ANTIBIOTICS

Antibiotics are primarily used in patients with Crohn disease who have colonic, perianal, or fistulizing disease. Intravenous antibiotics are also part of the initial treatment in patients with severe, toxic, or fulminant colitis. The two commonly used antibiotics are metronidazole (Flagyl) and ciprofloxacin (Cipro). Ciprofloxacin is prescribed at a dosage of 500 mg twice a day. Metronidazole is prescribed at a dosage of 20 mg/kg per day in three divided doses. Patients should be warned of potential side effects, such as a disulfiram (Antabuse) effect and peripheral neuropathy.

IMMUNOMODULATORS

Included in this category are azathioprine (Imuran, 2 to 2.5 mg/kg per day) and its active metabolite 6-

Table 38-3 Treatment Options

Disease Severity	Ulcerative Colitis	Crohn Disease
Mild	Oral and topical 5-ASA compounds	5-ASA compounds Antibiotics Elemental diet
Moderate	Oral and topical 5-ASA compounds Oral steroids Azathioprine, 6-MP Infliximab	5-ASA compounds Antibiotics Budesonide or oral steroids Azathioprine, 6-MP Methotrexate Infliximab, adalimumab, certolizumab, natalizumab
Severe	Intravenous steroids Cyclosporine Infliximab Surgery	Intravenous steroids Azathioprine, 6-MP Methotrexate Infliximab, adalimumab, certolizumab, natalizumab Surgery

5-ASA, 5-aminosalicylic acid; 6-MP, 6-mercaptopurine.

mercaptopurine (6-MP) (Purinethol, 1 to 1.5 mg/kg per day) as well as methotrexate and cyclosporine. Azathioprine and 6-MP are effective therapies for maintaining remission in both Crohn disease and ulcerative colitis and are used primarily as steroid-sparing agents. They have a slow onset of action (months) but are generally safe and well tolerated. Other regimens include subcutaneous or intramuscular methotrexate for induction (25 mg weekly) and maintenance of remission (15 to 25 mg weekly) in active Crohn disease and intravenous cyclosporine (2 to 4 mg/kg per day given over 24 hours) as *bridge* treatment for severe steroid-refractory ulcerative colitis. Given the potential for both short-term and long-term side effects, as well as the need for close follow-up, patients needing these medications are best managed by gastroenterologists.

BIOLOGIC THERAPY

Advances in our knowledge of the immunopathogenesis of IBD have led to a new class of therapies that target specific aspects of the immune system, collectively known as the *biologic agents*. The first such agent to be used in IBD was infliximab, a chimeric monoclonal antibody to TNF- α , which has been shown to be effective in the treatment of moderate to severe Crohn disease, including fistulizing disease. More recently, infliximab has also been shown to be beneficial in the treatment of ulcerative colitis that is refractory to conventional medical therapy. Because infliximab is a chimeric antibody, its toxicities include infusion reactions, delayed-type hypersensitivity reactions, and formation of autoantibodies (which can reduce its efficacy). Two newer anti-TNF agents, adalimumab (a fully human monoclonal antibody), and certolizumab pegol (a humanized anti-TNF antibody Fab fragment), have also proved efficacious in patients with moderate to severe Crohn disease who have not responded well to conventional treatments. These two agents are administered subcutaneously, and may have a lower toxicity profile. Natalizumab, a humanized anti- α_4 -integrin antibody, blocks inflammatory cell migration and adhesion and has recently been approved for the treatment of moderate to severe Crohn disease in patients who have had an inadequate response to, or are unable to tolerate, conventional Crohn disease therapies including inhibitors of TNF- α .

Because of the potent effects these biologic agents have on the immune system, careful patient selection and monitoring for complications are necessary. Reactivation of latent tuberculosis and other serious infections have been reported with the anti-TNF agents, and there may be an increased risk for non-Hodgkin lymphoma and possibly solid tumors as well. Natalizumab has been linked to rare cases of progressive multifocal leukoencephalopathy caused by the human polyoma JC virus.

PROBIOTICS

Probiotics are viable nonpathogenic organisms that, after ingestion, may prevent or treat intestinal diseases. Probiotics are being explored in treatment of IBD and may help prevent recurrence after surgery for Crohn disease and to treat pouchitis after ileal pouch-anal anastomosis.

NUTRITIONAL SUPPORT

Nutritional support is an important adjunctive aspect in the management of patients with IBD. However, the role of nutrition as a primary treatment has been limited to patients with small bowel Crohn disease. These patients may achieve and maintain remission with total parenteral nutrition or elemental diets after prolonged periods (at least 4 weeks). Many patients with Crohn disease and ulcerative colitis experience weight loss during exacerbations of their illness and need caloric supplements. Vitamins and minerals can be given orally as a multivitamin with folic acid. Vitamin B₁₂ should be supplemented parenterally in patients who have extensive ileal disease or an ileal resection. Patients taking corticosteroids require supplemental calcium and vitamin D, and individuals with extensive small bowel involvement can also develop malabsorption of fat-soluble vitamins (A, D, E, and K), iron deficiency, and rarely trace minerals. Lactose-free diets, as well as low-fiber diets, may be necessary in patients with active disease or strictures.

ANTIDIARRHEALS AND BILE SALT RESIN BINDERS

Antidiarrheal agents and bile salt resin binders are adjuncts used to manage diarrhea in patients with IBD. Antidiarrheal agents should be used cautiously during exacerbations of colitis because they can precipitate toxic megacolon. The main role of these medications involves controlling diarrhea in patients who have undergone previous resections. Generally, when less than 100 cm of terminal ileum has been resected, patients can develop a bile salt malabsorptive state during which bile salts enter the colon and result in a secretory diarrhea. Bile salt resin binders such as cholestyramine are an effective treatment in these cases. When patients have undergone one or more extensive resections, the bile salt pool is depleted, and fat malabsorption develops. These patients may require a low-fat diet supplemented with medium-chain triglycerides and antidiarrheal agents, but bile salt resin binders should not be used.

SURGICAL MANAGEMENT

Surgical intervention is indicated for patients with severe complications such as obstruction, perforation, massive gastrointestinal hemorrhage, and toxic megacolon not responsive to medical treatment. The other main indication for surgical treatment is the presence of dysplasia or cancer. For patients with ulcerative colitis, regardless of the extent of disease, the entire colon must be removed, and the operation is essentially curative. About 20% to 25% of patients have pancolitis, and one third to one half will require colectomy within 2 to 5 years of diagnosis, depending on the severity of their colitis. In contrast, less than 10% of individuals with mild disease or proctitis will undergo colectomy by 10 years after diagnosis. Historically, the initial operation for ulcerative colitis was a total proctocolectomy and Brooke ileostomy. More recently, the ileal pouch-anal anastomosis has become the operation of choice in most patients. In this operation, the colon is removed, and the small bowel is constructed into a reservoir (ileal pouch) that

is anastomosed to the anus, allowing defecation through the anus. Complications of this operation include the development of pouchitis, fecal incontinence, reduced fertility, and need for reoperation.

Surgery is not curative in Crohn disease and is generally avoided, if possible. Nonetheless, 10 years after a diagnosis of Crohn disease, more than 60% of patients will require

surgery. Many surgical procedures in patients with Crohn disease are performed to manage complications of the disease, including segmental resection, stricturoplasty, fistulectomy, and abscess drainage. Unfortunately, the recurrence rate is high, with 70% of patients having an endoscopic recurrence within 1 year of surgery and 50% having a symptomatic recurrence within 4 years.

Prospectus for the Future

As our understanding of the etiologic and pathophysiologic aspects of inflammatory bowel disease increases, major advancements in diagnosis and treatment are anticipated. These advancements include the following:

- The use of molecular, genetic, and serologic tests to differentiate between subtypes of disease as well as identify individuals at high risk for developing complications of inflammatory bowel disease

- The increased, and earlier, use of biologic agents to specifically target aspects of the immune system and inflammatory pathways known to be involved in IBD pathophysiology
- Improvements in the detection of dysplasia and prevention of colorectal cancer (including chemoprevention) in patients with chronic colitis

Neoplasms of the Gastrointestinal Tract

Paul C. Schroy III

Esophageal Carcinoma

Carcinoma of the esophagus is one of the most lethal of all cancers. The lack of early symptoms and serosal barrier, as well as the rich, bidirectional esophageal lymphatic flow, often results in advanced disease by the time of diagnosis. The American Cancer Society estimates that about 16,500 new cases of esophageal cancer and 14,530 esophageal cancer deaths will occur in the United States in 2009. Historically, squamous cell carcinoma (SCC) constituted 95% of all esophageal carcinomas. Since 1980, however, the incidence of adenocarcinoma of the esophagus has rapidly increased and now accounts for about 50% of newly diagnosed cases of esophageal carcinoma. The epidemiology of SCC differs from that of adenocarcinoma of the esophagus, but the symptoms, treatments, and prognoses are similar.

INCIDENCE AND EPIDEMIOLOGY

The incidence of SCC varies dramatically throughout the world. The highest rates are found in developing countries such as northern China, Iran, India, and parts of southern Africa. SCC is relatively uncommon in the United States, with an annual incidence of less than 5 cases per 100,000 population. Esophageal cancer is rare among individuals younger than 40 years, but thereafter increases in incidence with each subsequent decade. Men are affected more often than women, and African Americans have a fivefold increase in incidence compared with other racial and ethnic groups. The cause of SCC is unknown, but environmental, dietary, and local esophageal factors have been implicated. Heavy alcohol consumption and smoking are the predominant risk factors for SCC in the United States. In developing countries, nutritional deficiencies (e.g., selenium), betel nut chewing, human papillomavirus infection, and consumption of extremely hot drinks (e.g., tea), nitrates, and pickled vegetables, are also important risk factors. Predisposing conditions include lye strictures, radiation injury, Plummer-Vinson syndrome, achalasia, tylosis, and celiac disease.

Adenocarcinoma of the esophagus is primarily a disease of white men. The primary risk factor for adenocarcinoma is Barrett esophagus, a condition in which specialized intestinal-type columnar mucosa replaces the normal squamous mucosa in response to chronic gastroesophageal reflux disease. It is presumed that intestinal metaplasia progresses to low-grade dysplasia and then high-grade dysplasia and finally adenocarcinoma. The risk for developing adenocarcinoma in the setting of Barrett esophagus is about 0.5% per year. Long-standing gastroesophageal disease, obesity, and cigarette smoking have also been implicated as potential causative factors. Endoscopic surveillance with biopsy is recommended for Barrett esophagus but not chronic gastroesophageal reflux disease.

Clinical Presentation

Early and curable esophageal carcinoma is frequently asymptomatic and detected serendipitously. The presence of symptoms heralds an advanced and most often incurable stage of disease. Under careful questioning, most patients will have had symptoms for a few months before seeking medical attention. Dysphagia is the most common symptom of esophageal carcinoma. It occurs when the esophageal lumen has been compromised by about 75% of its normal diameter. Difficulty swallowing solid foods precedes dysphagia to liquids. With complete obstruction, regurgitation, aspiration, and cough or pneumonia may occur. Pulmonary symptoms may also occur if a tracheoesophageal fistula is present. Patients uniformly have weight loss and anorexia. Chest pain, hiccups, or hoarseness indicates involvement of adjacent structures such as the mediastinum, diaphragm, and recurrent laryngeal nerve, respectively. If gastrointestinal bleeding occurs, it is often occult or associated with iron deficiency anemia. Life-threatening gastrointestinal hemorrhage can occur if the tumor has invaded major vessels. Clubbing of the nails and paraneoplastic syndromes, such as hypercalcemia and Cushing syndrome, are rarely seen.

DIAGNOSIS

Patients with dysphagia or other suggestive symptoms should be evaluated by upper endoscopy or an esophageal barium study. The advantage of endoscopy includes the opportunity to obtain tissue of the cancer, either by biopsy or brush cytologic study. Esophageal carcinoma may appear as a plaque, an ulcer, a stricture, or a mass. Nearly 90% of adenocarcinomas develop in the distal esophagus, whereas 50% of SCCs occur in the middle third of the esophagus, and the other 50% are evenly distributed in the proximal and distal esophagus. Computed tomography (CT) scanning of the chest and abdomen is performed to detect invasion of local structures and metastases to the lung and liver. Endoscopic ultrasonography (EUS), with its ability to image the esophageal wall as a five-layer structure that correlates with histologic layers, is more accurate than CT for staging tumor depth, local invasion, and regional node involvement. EUS also permits targeted fine-needle aspiration of suspicious findings.

THERAPY

Stage is the most important prognostic factor for the survival of patients with esophageal cancer and influences the treatment options. Staging is based on the tumor-node-metastasis (TNM) classification system. Only localized tumors confined to the wall of the esophagus are potentially curable by surgery. Overall 5-year survival rates for patients undergoing curative resection, however, are just 5% to 20%. Preoperative chemotherapy with multidrug regimens combined with radiation therapy may reduce local recurrence rates and improve survival. Chemotherapy plus radiation therapy is also recommended for patients with locally unresectable disease, medical conditions that preclude surgery, and those who refuse surgery. Patients with metastatic disease should be considered for palliative treatment of dysphagia. Local treatment with endoscopic methods (such as malignant stricture dilation), placement of an endoprosthesis (stent), and tumor ablation by laser or photodynamic therapy are often the methods of choice for rapid palliation. More sustained palliation can be achieved using combined chemotherapy and radiation therapy.

Gastric Carcinoma

Gastric carcinoma is one of the leading causes of cancer-related deaths worldwide. For unknown reasons, the incidence of gastric cancer has declined dramatically in the United States since the 1930s. Despite its declining incidence, the American Cancer Society estimates that about 21,100 new cases and 10,620 gastric cancer deaths will occur in 2009. Unfortunately, gastric cancer is often advanced at the time of diagnosis; the 5-year survival rate is about 24%.

INCIDENCE AND EPIDEMIOLOGY

More than 90% of gastric cancers are adenocarcinomas. The incidence of gastric cancer varies widely throughout the world. The disease is more common in developing countries than industrialized nations and shows a predilection for

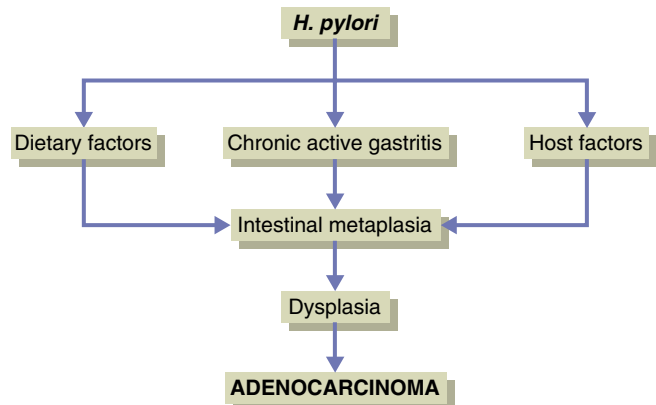

Figure 39-1 Model for the development of gastric adenocarcinoma.

urban and lower socioeconomic groups. Japan, China, the Andean regions of South America, and Eastern Europe exhibit the highest rates. The United States has among the lowest incidence rates at less than 10 cases per 100,000 population. Gastric cancer rarely occurs before age 40 years; thereafter, the incidence rises steadily, peaking in the seventh decade. Men are afflicted at a rate nearly twice that of women. African Americans, Hispanic Americans, and Native Americans are 1.5 to 2.5 times more likely to develop gastric cancer than whites. Migrants typically acquire the risk of their host countries, suggesting an important role for environmental factors. Low socioeconomic status, improper food storage, and other dietary and local gastric factors are associated with the disease. Dietary factors include deficiencies in fats, protein, and vitamins A and C and excesses in salted meat and fish, smoked foods, pickled vegetables, and nitrates. Predisposing conditions including atrophic gastritis, post-gastrectomy states, achlorhydria, pernicious anemia, adenomatous polyps, and Ménétrier disease are also associated with an increased incidence. The World Health Organization has classified *Helicobacter pylori* as a carcinogen and epidemiologically linked to gastric adenocarcinoma (Fig. 39-1). However, only a small proportion of patients infected with *H. pylori* develop gastric adenocarcinoma.

Gastric lymphomas account for fewer than 5% of primary gastric malignancies. The stomach is the most common site of extranodal non-Hodgkin lymphoma, but Hodgkin lymphoma of the stomach is rare. Gastric mucosa-associated lymphoid tissue (MALT) lymphomas are associated with *H. pylori* infection in 90% of cases and are reported to regress in 60% to 70% of cases after eradication of *H. pylori*. MALT lymphomas can also occur in association with various autoimmune and immunodeficiency syndromes. Most develop in individuals older than 50 years, and there is a slight male predominance.

CLINICAL PRESENTATION

The location, size, and growth pattern of gastric malignancies may influence the presenting symptoms. Abdominal discomfort is the most frequent symptom; however, early satiety, nausea, and vomiting may occur, especially with gastric outlet obstruction. Gastrointestinal bleeding may manifest as iron deficiency anemia, occult bleeding, or

frank upper gastrointestinal hemorrhage. Anorexia and weight loss often accompany other symptoms. The signs of metastatic disease, which may be found on physical examination and signify incurability, include a Virchow (left supraclavicular) node, a Blumer shelf (mass in the perirectal pouch, found on digital rectal examination), and a Krukenberg tumor (metastasis to the ovaries). A variety of paraneoplastic syndromes have been associated with gastric adenocarcinoma and warrant an investigation for a gastrointestinal malignancy. They include Trousseau syndrome (thrombosis), acanthosis nigricans (pigmented dermal lesions), membranous nephropathy, microangiopathic hemolytic anemia, Leser-Trélat sign (seborrheic keratoses), and dermatomyositis.

DIAGNOSIS

The diagnostic tests for gastric malignancies include double contrast (barium) upper gastrointestinal radiography or endoscopy. Lesions detected on barium study require endoscopic biopsy and cytologic study for histologic evaluation. Gastric carcinomas may appear as ulcers, masses, enlarged gastric folds, or an infiltrative process with a nondistensible stomach wall (linitis plastica). The accuracy of endoscopic ultrasonography is in the range of 77% to 93% for determining the depth of invasion and 65% to 90% for predicting regional node involvement. CT scanning of the chest and abdomen may detect metastases in the lung and liver but is otherwise poor for staging. Laparoscopy is increasingly being used for staging and determination of resectability with high accuracy.

THERAPY

The standard treatment of gastric cancer is complete surgical resection with removal of all gross and microscopic disease. The postoperative local-regional recurrence rate remains 80%. A postoperative combination of chemotherapy plus radiation therapy reduces local recurrence rates and improves survival in patients undergoing curative resection. In the United States, nearly two thirds of patients present with advanced disease (stages III to IV), with a survival rate of less than 20%. Chemotherapy is the mainstay of treatment for such patients, but long-term survival is rare. Palliative resection may be performed to prevent obstruction or treat bleeding; radiation therapy and endoscopy may also be of palliative benefit in select patients. Treatment options for gastric lymphomas include some combination of chemotherapy, radiation therapy, and surgery, depending on stage of disease.

Colorectal Polyps and Carcinoma

Carcinoma of the colon and rectum is the third most common cancer and the second most common cause of cancer deaths in American men and women. More than 146,970 new cases and 49,920 colorectal cancer-related deaths will occur in 2009. Screening has been shown to be an effective strategy for reducing both colorectal cancer mortality, through early detection, and incidence, through the identification and removal of premalignant adenomas.

INCIDENCE AND EPIDEMIOLOGY

Worldwide incidence and mortality of colorectal cancer varies considerably. With the notable exception of Japan, industrialized countries are at greatest risk. In the United States, incidence rates have declined slightly during the past decade but remain in excess of 40 cases per 100,000 persons. About 6% of Americans will develop colorectal cancer during their lifetime. Age is an important determinant of risk. Although extremely uncommon in individuals younger than 35 years (except those with rare predisposing genetic syndromes), the incidence of colorectal cancer increases steadily with age, beginning at about 40 years of age, with an approximate doubling with each successive decade thereafter to about 80 years of age. Cancer of the colon affects men and women at similar rates, whereas cancer of the rectum is more common in men. Colorectal cancer does not appear to have a racial predilection; however, African Americans are more likely to present with advanced-stage disease. Epidemiologic studies have identified a number of modifiable risk factors related to colorectal cancer. Factors associated with an increased risk for the disease include obesity, red meat, alcohol, and tobacco; conversely, factors associated with a decreased risk include physical activity, nonsteroidal anti-inflammatory agents, and multivitamins.

Most colorectal cancers are believed to arise from benign adenomatous polyps (adenomas). The epidemiology of colorectal adenomas is similar to that of colorectal cancer. In general, the prevalence of colorectal adenomas in a given country parallels the prevalence of colorectal cancer. Age is an important determinant of prevalence in high-risk countries. In the United States, autopsy studies suggest an overall prevalence of 50%, ranging from about 30% at age 50 years to 55% at age 80 years. Fortunately, only a minority of adenomas progress to colorectal cancer. It is unknown how long an adenoma takes to develop into an invasive cancer, but data from multiple observational studies suggest at least 10 years. Insight into the molecular mechanisms responsible for the adenoma-carcinoma sequence suggests that colorectal carcinogenesis is a multistage process (Fig. 39-2) resulting from the accumulation of genetic alterations involving various oncogenes (e.g., *K-ras*), tumor suppressor genes (e.g., *APC* or β -*catenin*, *DCC*, *SMAD-4*, *SMAD-2*, and *p53*), or DNA mismatch repair genes (e.g., *hMLH-1*).

High-risk groups have been identified and include those with a personal or family history of colorectal cancer or adenomas, various genetic polyposis and nonpolyposis syndromes, and inflammatory bowel disease (Table 39-1). Hereditary nonpolyposis colorectal cancer (HNPCC) and familial adenomatous polyposis (FAP) are well-defined genetic syndromes associated with the highest risk for colorectal cancer. HNPCC (Lynch syndromes) is characterized by inherited mutations in one of the DNA mismatch repair genes (e.g., *hMLH-1* or *hMSH-2*), early-onset colorectal cancer (average age, 44 years) in the absence of polyposis, a predominance (60% to 70%) of tumors proximal to the splenic flexure, an excess of both colorectal and extracolonic (e.g., endometrial) cancers, and an estimated lifetime risk for colorectal cancer of 80% to 90%. In contrast, FAP is characterized by inherited mutations in the *APC* gene, the appearance of hundreds of colorectal adenomas during the second or third decade of life, and a risk for colorectal cancer

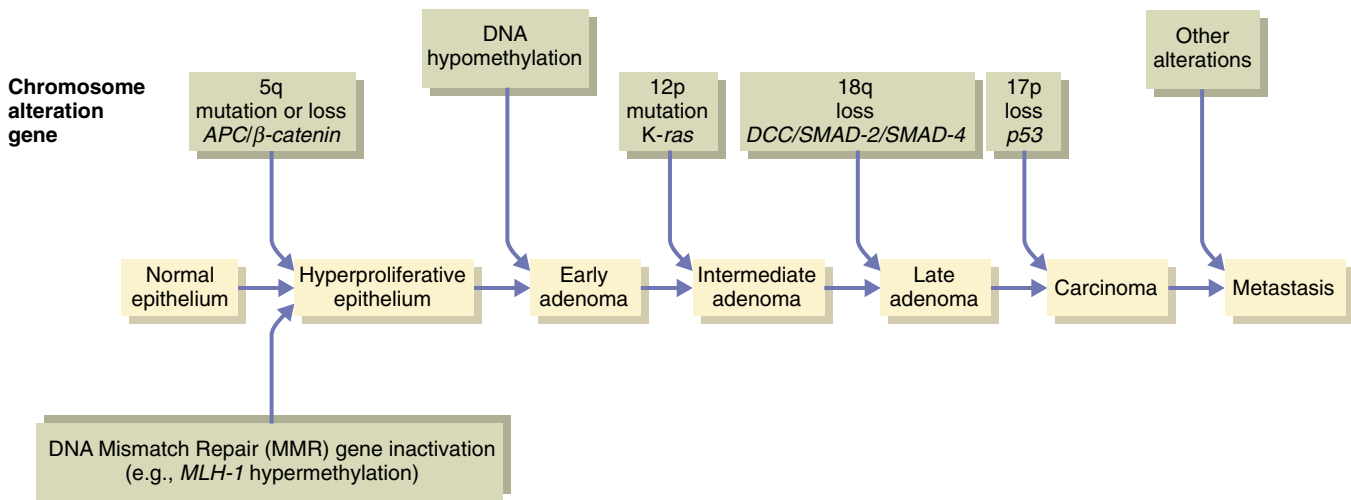

Figure 39-2 A genetic model for colorectal tumorigenesis.

Table 39-1 Risk Factors for Colorectal Cancer

Age \geq 50 yr
Personal history of adenomatous polyps or colorectal cancer
Familial adenomatous polyposis or Gardner syndrome
<i>MYH</i> -associated adenomatous polyposis
Hereditary nonpolyposis colon cancer
Ulcerative colitis or Crohn colitis
First-degree relative with colon cancer or adenomatous polyps diagnosed before age 60 yr
Hamartomatous polyposis syndrome (Peutz-Jeghers syndrome, juvenile polyposis)

that approaches 100% by the fifth decade if left untreated. FAP is also associated with benign fundic gland polyps in the stomach and duodenal adenomas and adenocarcinomas that have a predilection for the periampullary region. Gardner syndrome is a variant of FAP in which affected probands also exhibit a variety of extraintestinal manifestations such as osteomas, desmoids, and other soft tissue tumors. Congenital hypertrophy of the retinal pigment epithelium is an early benign manifestation of both FAP and Gardner syndrome. *MYH*-associated adenomatous polyposis syndrome is indistinguishable from FAP clinically but caused by mutations of the base excision repair gene, mutY homologue (*MYH*) rather than *APC*.

Peutz-Jeghers syndrome is an autosomal dominant condition characterized by hamartomatous polyposis of both the small and large bowel and mucocutaneous pigmentation. Affected individuals are at increased risk for both gastrointestinal (stomach, small bowel, and colon) and extraintestinal (e.g., genital tract, pancreas, and breast) malignancies occurring at a young age. Generalized juvenile polyposis is another inherited hamartomatous polyposis syndrome associated with a small, albeit increased, risk for colorectal cancer.

CLINICAL PRESENTATION

Most colorectal neoplasms are asymptomatic until advanced. Gastrointestinal blood loss is the most common symptom

and may present as occult bleeding, hematochezia, or unexplained iron deficiency anemia. Other symptoms include abdominal pain from obstruction or invasion, change in bowel habits, or unexplained anorexia or weight loss. A palpable mass may be present in patients with advanced cancers of the cecum.

DIAGNOSIS

All patients with symptoms suggestive of colorectal neoplasia should undergo an evaluation of the colon by colonoscopy, flexible sigmoidoscopy, or double contrast barium enema. About 50% of colorectal adenomas and cancers are located between the rectum and splenic flexure; however, the prevalence of cancers proximal to the splenic flexure increases with increasing age, especially among women. Colorectal cancers may arise in sessile (flat) or pedunculated (on a stalk) polyps, or they may appear as a stricture, a fungating mass, or an ulcerated mass. Colonoscopy has greater accuracy than a barium enema study in the detection of small polyps and early cancers as well as the ability to remove neoplasms or biopsy lesions at the time of the examination. Lesions detected on barium enema study necessitate colonoscopic evaluation. CT scanning and of the abdomen and pelvis is used preoperatively to assess the extent of metastatic disease. Magnetic resonance scanning and positron emission tomography may also be useful in detecting metastatic disease in select patients. EUS is used for the preoperative staging of rectal cancer. Carcinoembryonic antigen level is measured preoperatively for a baseline value and, if elevated, monitored to detect tumor recurrence postoperatively.

Periodic screening by colonoscopy, CT colonography (virtual colonoscopy), flexible sigmoidoscopy, or double-contrast enema is recommended for asymptomatic, average-risk patients beginning at age 50 years. Stool blood testing and stool DNA testing are alternative screening methods for patients who refuse one of the preferred methods (Table 39-2). Screening recommendations for high-risk patients vary depending on the risk factor (see Table 39-2) but in general rely on colonoscopy performed at a younger age and at more frequent intervals than for those at average risk.

Table 39-2 Colorectal Cancer (CRC) Screening and Surveillance Recommendations*

Indication	Recommendations
Average risk	Beginning at age 50 yr: Colonoscopy every 10 yr Computed tomographic colonography every 5 yr Flexible sigmoidoscopy every 5 yr Double-contrast barium enema every 5 yr (Stool blood testing annually or stool DNA testing acceptable but not preferred)
One or two first-degree relatives with CRC at any age or adenoma at age < 60 yr	Colonoscopy every 5 yr beginning at age 40 yr, or 10 yr younger than earliest diagnosis, whichever comes first
Hereditary nonpolyposis colorectal cancer	Genetic counseling and screening [†] Colonoscopy every 1 to 2 years beginning at age 25 yr and then yearly after age 40 yr [‡]
Familial adenomatous polyposis and variants	Genetic counseling and testing [†] Flexible sigmoidoscopy yearly beginning at puberty [‡]
Personal history of CRC	Colonoscopy within 1 yr of curative resection; repeat at 3 yr and then every 5 yr if normal
Personal history of colorectal adenoma	Colonoscopy every 3 to 5 yr after removal of all index polyps
Inflammatory bowel disease	Colonoscopy every 1 to 2 yr beginning after 8 yr of pancolitis or after 15 yr if only left-sided disease

*Recommendations proposed by the American Cancer Society and U.S. Multi-Society Task Force on Colorectal Cancer; recommendations for average-risk patients also endorsed by the American College of Radiology.

[†]Whenever possible, affected relatives should be tested first because of potential false-negative results.

[‡]Screening recommendation for individuals with positive or indeterminate tests as well as for those who refuse genetic testing.

Colonoscopic surveillance is recommended for patients with a history of colorectal cancer or adenomas and inflammatory bowel disease.

THERAPY

The rate of survival of patients with colorectal carcinoma is based on the stage of disease (Table 39-3). Unfortunately, 45% of patients first come to medical attention with stage III or IV disease. Surgery alone is curative for early-stage colorectal cancers. Surgery and adjuvant chemotherapy with 5-fluorouracil and leucovorin ± oxaliplatin or capecitabine alone are recommended for stage III colon cancer. For patients with stage II and III rectal cancer, the combination of postoperative radiation and 5-fluorouracil (± leucovorin) has been found to significantly reduce the recurrence rate, cancer-related deaths, and overall mortality. Independent of nodal status, preoperative chemoradiotherapy followed by adjuvant chemotherapy is recommended for patients with locally advanced rectal cancers. For patients with stage IV disease, palliative surgery, chemotherapy, and radiation therapy are the mainstays of therapy.

Carcinoid Tumors

The overall incidence of gastrointestinal carcinoid tumors in the United States is estimated at 1 to 2 cases per 100,000 people. The most common sites, in descending order of frequency, are the small intestine (ileum), rectum, appendix, colon, and stomach.

Carcinoid tumors arise from neuroendocrine cells and contain a variety of secretory granules containing various hormones and biogenic amines. Serotonin is synthesized

Table 39-3 Survival and Comparison of Dukes and TNM Staging in Colorectal Carcinoma

Dukes	TNM Stage	5-Year Survival Rate (%)
A	I	93
B	II	72-85
C	III	44-83
D	IV	8

from 5-hydroxytryptophan and metabolized in the liver to 5-hydroxyindoleacetic acid, which is biologically inert and secreted in the urine. The release of serotonin (hindgut tumors) and other vasoactive substances into the systemic circulation is thought to cause the carcinoid syndrome. Therefore, carcinoid metastases in the liver or other sites that drain into systemic veins may be associated with the carcinoid syndrome, as may primary carcinoids in the ovary or bronchus. The symptoms include episodic flushing, wheezing, diarrhea, right-sided valvular heart disease, and, potentially, vasomotor collapse. Localized tumors may present with gross or occult bleeding, obstructive symptoms, or abdominal pain depending on their location.

Most carcinoids are indolent; however, the malignant potential is variable and appears to be related to the site and, often, the size of the primary tumor. Carcinoids arising in the ileum and those 2 cm or larger have the greatest malignant potential. Surgical resection is the only curative treatment for carcinoid tumors. Somatostatin analogues are highly effective in the management of the symptoms of carcinoid syndrome.

Prospectus for the Future

Further elucidation of the clinical and molecular epidemiologic mechanisms of gastrointestinal neoplasms will improve risk stratification and enable clinicians to tailor their use of screening and surveillance strategies, chemopreventive agents, and therapeutic options.

Progress in our understanding of the cellular and molecular pathways that underlie neoplastic transformation and tumor

progression will provide additional targets for selective pharmacologic or immunologic therapies.

Technologic advances will facilitate the endoscopic diagnosis and treatment of premalignant and malignant diseases of the gastrointestinal tract.

Diseases of the Pancreas

David R. Lichtenstein

Anatomy and Physiology

The pancreas is an organ located in the retroperitoneum (Fig. 40-1) that weighs between 70 and 120 g and is about 12 to 20 cm in length. The head of the pancreas is nestled in the C loop of the duodenum, and the tail extends obliquely posterior to the stomach toward the hilum of the spleen. The pancreas consists of the pancreatic acinus and islet cells. The acinar cells compose more than 95%, and the islets about 1% to 2%, of the pancreatic mass. Hormones that the islets produce include insulin, glucagon, somatostatin, and pancreatic polypeptide. The functional exocrine unit of the pancreas is the pancreatic acinus, which is composed of both acinar and ductal epithelial cells. Acinar cells synthesize proteolytic digestive enzymes, which are packaged separately in the Golgi region into condensing vacuoles and transported in an inactive form referred to as *zymogens* to the apical portions of the cell, where they are discharged into the central ductule of the acinus by exocytosis. The ductules coalesce to form larger ducts, which empty into the duodenum at the ampulla of Vater. Inactive enzymes secreted into the duodenum are converted to an active form by enterokinase secreted from small bowel enterocytes. Trypsinogen, converted to active trypsin in the duodenum by enterokinase, is the trigger enzyme that subsequently converts the other zymogens to active enzymes (Fig. 40-2). Enzymes secreted in an active form include lipase, amylase, and ribonuclease. The ductal cells secrete primarily water and electrolytes, which decrease the viscosity of the protein-rich acinar secretions and alkalize gastric contents emptied into the duodenum to levels at which the pancreatic enzymes become catalytically active (pH ranges from >3.5 to 4).

Normal Pancreas Development

At about 4 weeks of gestation, the dorsal pancreas forms as an evagination from the duodenum, and shortly thereafter, the ventral pancreas forms from the hepatic diverticulum. Rotation of the duodenum places the two pancreatic buds in close proximity at 7 to 8 weeks of gestation, at which time

their main ducts begin to fuse. If fusion is incomplete, the duct of Wirsung drains only the ventral pancreas through the major ampulla, and the duct of Santorini drains the bulk of the pancreas (dorsal pancreas) through the relatively small accessory ampulla. This common anomaly, termed *pancreas divisum*, is present in 5% to 10% of the general population and may be associated with acute and chronic pancreatitis. Theories suggest that pancreatitis may result from relative outflow obstruction of the main dorsal duct through the small accessory ampulla. Endoscopic papillotomy or surgical sphincteroplasty are two therapeutic maneuvers that may reduce the incidence of recurrent pancreatitis by increasing drainage through the accessory papilla.

Acute Pancreatitis

Acute pancreatitis is best defined as an acute inflammatory process of the pancreas that may also involve peripancreatic tissues and remote organ systems. The overall incidence is 1 in 4000 for the general population. Most patients with acute pancreatitis have a mild course and recover with restoration of normal pancreatic function and gland architecture. However, in 10% to 20%, the various pathways that contribute to increased intrapancreatic and extrapancreatic inflammation result in what is generally termed *systemic inflammatory response syndrome* (SIRS). In some instances, SIRS predisposes to multiple organ dysfunction or pancreatic necrosis. Early steps in the management of patients with acute pancreatitis can decrease severity, morbidity, and mortality. Prevention of the septic and nonseptic complications in patients with severe acute pancreatitis depends largely on monitoring, vigorous hydration, and early recognition of pancreatic necrosis and cholelithiasis.

CAUSES AND PATHOGENESIS

The pathogenesis of acute pancreatitis remains incompletely understood. Based on experimental models, the initiating event in acute pancreatitis is intra-acinar activation of trypsin from trypsinogen, resulting in acute intracellular injury, pancreatic autodigestion, and the potential for

Figure 40-1 Normal anatomy of the pancreas.

Figure 40-2 Mechanism of proenzyme activation in the intestinal lumen. (Adapted from Solomon TE: Exocrine pancreas: Pancreatitis. In The Undergraduate Teaching Project in Gastroenterology and Liver Disease, Unit 24. Bethesda, Md, American Gastroenterological Association, 1984.)

profound systemic complications once activated enzymes are leaked into the bloodstream. Initiating events may include obstruction of the pancreatic duct (e.g., gallstones, pancreatic tumor), overdistention of the pancreatic duct (e.g., from endoscopic retrograde cholangiopancreatography [ERCP]), reflux of biliary or duodenal juices into the pancreatic duct, changes in permeability of the pancreatic duct, ischemia of the organ, and toxin-induced cholinergic hyperstimulation.

During the initial hospitalization for acute pancreatitis, reasonable attempts to determine etiology is appropriate, particularly those causes that may affect acute management. The cause of acute pancreatitis is readily identified in 70% to 90% of patients after an initial evaluation consisting

Table 40-1 Causes of Acute Pancreatitis

Obstructive Causes

Gallstones
Tumors: ampullary or pancreatic tumors
Parasites: *Ascaris* or *Clonorchis* species
Developmental anomalies: pancreas divisum, choledochoceles, annular pancreas
Periampullary duodenal diverticula
Hypertensive sphincter of Oddi
Afferent duodenal loop obstruction

Toxins

Ethyl alcohol
Methyl alcohol
Scorpion venom: excessive cholinergic stimulation causes salivation, sweating, dyspnea, and cardiac arrhythmias; seen mostly in the West Indies
Organophosphorus insecticides

Drugs

Definite association (documented with rechallenges): azathioprine/6-mercaptopurine, valproic acid, estrogens, tetracycline, metronidazole, nitrofurantoin, pentamidine, furosemide, sulfonamides, methyl dopa, cytarabine, cimetidine, ranitidine, sulindac, dideoxycytidine
Probable association: thiazides, ethacrynic acid, phenformin, procainamide, chlorthalidone, L-asparaginase

Metabolic Causes

Hypertriglyceridemia, hypercalcemia, end-stage renal disease

Trauma

Accidental: blunt trauma to the abdomen (car accident, bicycle)
Iatrogenic: postoperative, endoscopic retrograde cholangiopancreatography, endoscopic sphincterotomy, sphincter of Oddi manometry

Infectious

Parasitic: ascariasis, clonorchiasis
Viral: mumps, rubella, hepatitis A, hepatitis B, non-A and non-B hepatitis, coxsackievirus B, echovirus, adenovirus, cytomegalovirus, varicella virus, Epstein-Barr virus, human immunodeficiency virus
Bacterial: *Mycoplasma*, *Campylobacter jejuni*, tuberculosis, *Legionella* species, leptospirosis

Vascular

Ischemia: hypoperfusion (such as postcardiac surgery) or atherosclerotic emboli
Vasculitis: systemic lupus erythematosus, polyarteritis nodosa, malignant hypertension

Idiopathic

Ten to 30% of patients with pancreatitis; up to 60% of these patients have occult gallstone disease (biliary microlithiasis or gallbladder sludge). Other less common causes include sphincter of Oddi dysfunction and mutations in the cystic fibrosis transmembrane regulator.

Miscellaneous

Penetrating peptic ulcer
Crohn disease of the duodenum
Pregnancy associated
Pediatric association: Reye syndrome, cystic fibrosis

of history, physical examination, focused laboratory testing, and routine radiologic evaluation. Gallstones account for 45%, alcohol 35%, miscellaneous causes 10%, and idiopathic causes 10% to 20% of acute pancreatitis cases (Table 40-1).

CLINICAL MANIFESTATIONS

Abdominal pain is virtually always present and may be severe and refractory to analgesics. Pain often radiates to the back and is usually worse when supine. The onset may be swift with pain reaching maximal intensity within 30 minutes, is frequently unbearable, and characteristically persists for more than 24 hours without relief. Physical examination usually reveals severe upper abdominal tenderness at times associated with guarding. Ileus occurs when the inflammatory process extends into the small intestinal and colonic mesentery or when a chemical peritonitis occurs. Other manifestations include nausea, vomiting, and fever caused by the significant inflammatory process and release of cytokines (Fig. 40-3).

In acute pancreatitis, a wide variety of toxic materials, including pancreatic enzymes, vasoactive materials (e.g., kinins), and other toxic substances (e.g., elastase, phospholipase A₂), are liberated by the pancreas and extravasate along fascial planes in the retroperitoneal space, lesser sac, and the peritoneal cavity. These materials cause chemical

irritation and contribute to third-space losses of protein-rich fluid, hypovolemia, and hypotension. These toxic materials may also reach the systemic circulation by lymphatic and venous pathways and contribute to subcutaneous fat necrosis and end-organ damage, including shock, renal failure, and respiratory insufficiency (atelectasis, effusions, and acute respiratory distress syndrome [ARDS]). Grey Turner sign (ecchymosis of the flank) or Cullen sign (ecchymosis in the periumbilical region) may be seen in association with hemorrhagic pancreatitis.

Metabolic problems are common in severe disease and include hypocalcemia, hyperglycemia, and acidosis. Hypocalcemia is most commonly caused by concomitant hypoalbuminemia. Other mechanisms may include complexing of calcium to released free fatty acids, protease-induced degradation of circulating parathyroid hormone (PTH), and failure of PTH to release calcium from bone. Local spread of inflammation leads to effects on contiguous organs that include gastritis and duodenitis, splenic vein thrombosis, colonic necrosis, and external compression of the common bile duct, leading to biliary obstruction. Trypsin can activate

Figure 40-3 The pathophysiology of acute pancreatitis is not fully understood, but, as this schematic illustration implies, a cascade of events seems likely, beginning with the release of toxic substances into the parenchyma and ending with shock and death. Damage to the ductal epithelium or acinar cell injury may result from bile reflux, increased intraductal pressure, alcohol, or trauma. (Adapted from Grendell JH: The pancreas. In Smith LH Jr, Thier SO [eds]: Pathophysiology: The Biological Principles of Disease, 2nd ed. Philadelphia, WB Saunders, 1985, p 1228.)

plasminogen to plasmin and induce clot lysis. On the other hand, trypsin can activate prothrombin and thrombin and produce thrombosis, leading to disseminated intravascular coagulation. Extrapancreatic fluid collections occur when fluid extravasates from the pancreas or surrounding leaky tissues. They are located in or near the pancreas and lack a wall of granulation or fibrous tissue. Acute fluid collections occur more commonly with severe pancreatitis. Most of these lesions regress spontaneously, and almost all remain sterile. The older term *phlegmon* was used in the past to describe inflammatory collections, but it is too ambiguous and imprecise for current use, given that it does not differentiate acute fluid collections from areas of pancreatic necrosis nor infected from noninfected collections.

Pancreatic pseudocysts are defined as encapsulated non-epithelial lined collections of pancreatic juice, either pure or containing debris, single or multiple, small or large, and they can be located in or adjacent to the pancreas. Fluid collections must be present for a minimum of 4 weeks from the onset of pancreatitis to be termed a pseudocyst. Although most pseudocysts remain asymptomatic, presenting symptoms may include abdominal pain, early satiety, nausea, and vomiting due to compression of the stomach or gastric outlet. Rapidly enlarging pseudocysts may rupture, hemorrhage, obstruct the extrahepatic biliary tree, erode into surrounding structures, extend into the mediastinum, and become infected. Most pseudocysts less than 6 cm in diameter will resolve over time, and one third of lesions less than 10 cm in diameter remain asymptomatic or resolve. Indications for pseudocyst drainage include suspicion of infection or progressive enlargement with associated symptoms described previously. Asymptomatic pseudocysts should be followed. Pseudocysts can be drained surgically, percutaneously or endoscopically. The choice of treatment for symptomatic pseudocysts is frequently determined by the locally available expertise and by clinician preference because no method has been shown to be superior to the others. Pancreatic fistula occurs as a result of duct disruption and is treated with total parenteral nutrition, endoscopic stenting, and octreotide. Surgical intervention may be needed if the conservative approach is unsuccessful.

DIAGNOSIS

The diagnosis of acute pancreatitis is based on a combination of clinical, biochemical, and radiologic factors. There is general acceptance that a diagnosis of acute pancreatitis requires two of the following three features: (1) abdominal pain characteristic of acute pancreatitis, (2) serum amylase or lipase more than 3 times the upper limit of normal, and (3) characteristic findings of acute pancreatitis on computed tomography (CT) scan. Elevated serum pancreatic enzymes may occur in a wide variety of other conditions, including bowel perforation, intestinal obstruction, mesenteric ischemia, tubo-ovarian disease, and renal failure. Serum lipase is slightly more specific and remains normal in some conditions associated with an elevation of serum amylase, including macroamylasemia, parotitis, and tubo-ovarian disease. The serum amylase level usually rises rapidly, as does the serum lipase level, and may remain elevated for 3 to 5 days. Serum lipase remains elevated longer than amylase and thus may be helpful if patients seek medical attention several days

after symptom onset. Repeated measurements of pancreatic enzymes have little value in assessing clinical progress, and the magnitude of serum amylase or lipase elevation does not correlate with the severity of pancreatitis. Macroamylase and macrolipase can occasionally cause isolated nonpathologic elevations of these enzymes, a situation in which the measurement of urinary clearance is useful.

Pancreatic imaging with CT scanning can be used to confirm a diagnosis of pancreatitis (pancreatic enlargement, peripancreatic inflammatory changes, and extrapancreatic fluid collections). Selective CT scanning may also be useful in evaluating complications and assessing severity of disease (see later discussion), although a normal CT scan is present in 15% to 30% of mild cases. Acute gallstone pancreatitis should be suspected in patients with gallstones on ultrasonography or elevated liver tests, in particular an aspartate aminotransferase level elevated greater than threefold. Magnetic resonance imaging (MRI) is similar to CT with respect to imaging the inflamed pancreas and may be preferred in individuals at risk for contrast-induced injury (e.g., contrast allergy or renal insufficiency). However, recent studies also indicate the potential for gadolinium-induced nephrotoxicity with MRI examinations. MRI is also sensitive for the detection of necrosis, small neoplasms of the pancreas, and stones in the pancreaticobiliary tree.

SEVERITY OF DISEASE

Supportive therapy alone is effective in treating 75% of all patients with acute pancreatitis. Twenty-five percent of patients, however, will suffer a complication, with one third succumbing to complications, yielding an overall mortality rate of 5% to 10%. Early deaths within the first 2 weeks are the result of multisystem organ failure caused by the release of inflammatory mediators and cytokines. Late deaths result from local or systemic infection. The risks for infection and death correlate with disease severity and the presence and extent of pancreatic necrosis. Therefore, a combination of clinical scoring and CT grade provides the most precise prognostic information.

Patients should be stratified into mild or severe levels of illness based on well-established clinical criteria such as Ranson criteria (Table 40-2) or Acute Physiologic and Chronic Health Evaluation (APACHE II) scores. With increasing scores, the likelihood of a complicated, prolonged, and fatal outcome increases. The mortality rate is about 1% when fewer than three Ranson signs exist, 10% to 20% when three to five signs exist, and more than 50% when six Ranson signs exist. Similarly, an APACHE II score greater than 8 has been shown to predict severe pancreatitis. Conversely, a fatal outcome is unlikely with an APACHE II score less than 8. The distinction between interstitial and necrotizing acute pancreatitis has important prognostic implications (Fig. 40-4). Interstitial pancreatitis is characterized by an intact microcirculation and uniform enhancement of the gland on contrast-enhanced CT scanning. About 20% to 30% of patients with acute pancreatitis have necrotizing pancreatitis. Necrotizing pancreatitis is characterized by disruption of the pancreatic microcirculation so that large areas do not enhance on CT (Fig. 40-5). The presence of pancreatic necrosis predicts a worse severity of pancreatitis, particularly infection in the necrotic pancreatic tissue, also termed

Table 40-2 Signs Used to Assess Severity of Acute Pancreatitis

At Time of Admission or Diagnosis

- Age > 55 yr
- White blood cell count > 16,000/mm³
- Blood glucose > 200 mg/dL
- LDH > 2 × normal
- ALT > 6 × normal

During Initial 48 Hours

- Decrease in hematocrit > 10%
- Serum calcium < 8 mg/dL
- Increase in blood urea nitrogen > 5 mg/dL
- Arterial PO₂ < 60 mm Hg
- Base deficit > 4 mEq/L
- Estimated fluid sequestration > 600 mL

ALT, alanine aminotransferase; LDH, lactate dehydrogenase; PO₂, partial pressure of oxygen.

Data from Ranson JH, Rifkind KM, Turner JW: Prognostic signs and nonoperative peritoneal lavage in acute pancreatitis. *Surg Gynecol Obstet* 43:209-219, 1976. By permission of *Surgery, Gynecology and Obstetrics*.

infected necrosis. Infected necrosis develops in 30% to 50% of patients with acute necrotizing pancreatitis but rarely in those with interstitial disease (<1%). The mortality rate for infected necrosis approaches 30%, accounting for more than 80% of deaths from acute pancreatitis. In those individuals with necrotizing pancreatitis and suspected infection (fever, leukocytosis, organ failure), antibiotics should be administered while appropriate cultures (including culture of CT-guided percutaneous aspiration of the pancreas) are obtained. Antibiotics can be discontinued if no source of infection is found because the success of prophylactic antibiotics in patients with severe pancreatitis in reducing infectious complications (central line sepsis, pulmonary infection, urinary tract infection, and infected pancreatic necrosis) has not been demonstrated. Moreover, broad-spectrum antibiotic use in these individuals may lead to the emergence of resistant organisms and fungal infections in the necrotic pancreas. Because clinical and laboratory findings are often similar in patients with either sterile or infected necrosis, the diagnosis of infected necrosis is made by percutaneous

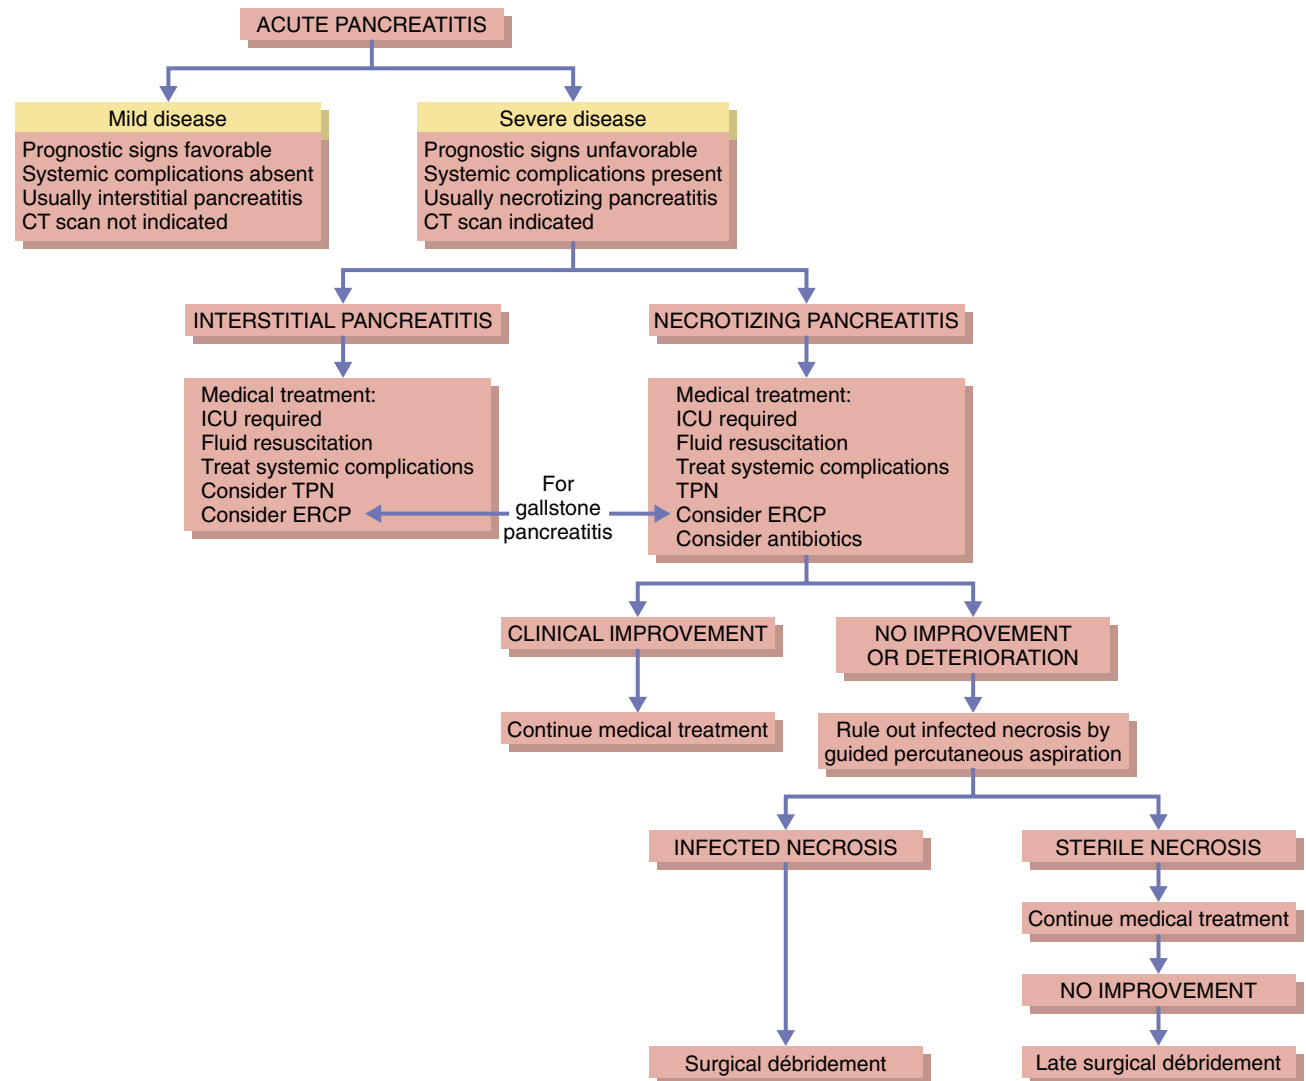

Figure 40-4 Therapeutic algorithm for evaluating acute pancreatitis. CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; ICU, intensive care unit; TPN, total parenteral nutrition. (From Banks PA: Acute and chronic pancreatitis. Philadelphia, WB Saunders, 1998, p 833.)

Figure 40-5 Contrast computed tomography scans demonstrating interstitial pancreatitis (A) and necrotizing pancreatitis (B).

CT-guided needle aspiration (Gram stain and culture), which is safe and accurate. Patients with infected necrosis require surgical débridement, whereas patients with sterile necrosis can be followed with supportive therapy, reserving surgical débridement for persistent end-organ failure.

TREATMENT

In addition to supportive care, the goals of medical therapy include limiting systemic complications and preventing pancreatic infection once necrosis takes place. No specific treatments have proved effective in lowering morbidity and mortality, including agents that put the pancreas to rest (e.g., somatostatin, calcitonin, glucagon, nasogastric suction, histamine-2 receptor blockers) and enzyme inhibitors (e.g., aprotinin, gabexate mesilate). All patients should receive close supportive care, including effective analgesia, fluid resuscitation, and nutritional support if oral nutrition is anticipated to be withheld for more than 7 to 10 days. To meet metabolic demands and rest the pancreas, nutrition can be provided by total parenteral nutrition through central venous access or preferably as enteral feeding through a jejunal nasoenteric feeding tube. Systemic complications are best managed in an intensive care unit with aggressive fluid administration and hemodynamic monitoring. Emergency ERCP (**Web Video 40-1**) for removing impacted gallstones or establishing biliary drainage is indicated for patients with evidence of biliary sepsis. This procedure should be followed by elective cholecystectomy.

Chronic Pancreatitis

Chronic pancreatitis is defined as an inflammatory disease of the pancreas characterized by irreversible morphologic changes that typically cause pain and permanent loss of function. Chronic pancreatitis can be classified into nonobstructive and obstructive types (Table 40-3). The most common nonobstructive cause is chronic alcoholism (70%). Alcohol can cause episodes of acute pancreatitis, but at the

Table 40-3 Causes of Chronic Pancreatitis

Nonobstructive

Alcohol
 Idiopathic: 10%-20% of total cases
 Tropical, nutritional
 Inherited: cystic fibrosis, hereditary
 Traumatic
 Metabolic: hypertriglyceridemia, hypercalcemia

Obstructive

Benign obstruction: sphincter of Oddi dysfunction or papillary stenosis, pancreas divisum with obstruction of accessory ampulla
 Neoplastic obstruction: tumors of the ampulla or ductal system

time of the initial attack, structural and functional abnormalities often exist indicative of underlying chronic pancreatitis. Because most alcoholics do not develop pancreatitis, the presumption is that other unidentified genetic, dietary, or environmental influences exist. If alcoholism is excluded, most patients with chronic pancreatitis in the United States have no demonstrable cause, termed idiopathic (20%). Gallstone pancreatitis, the major cause of acute pancreatitis, almost never leads to chronic pancreatitis. Calcific pancreatitis of the tropics is a major cause of chronic pancreatitis worldwide. Other miscellaneous causes (10%) include trauma, pancreas divisum, cystic fibrosis, hereditary pancreatitis, and metabolic disturbances such as hypercalcemia and hypertriglyceridemia.

PATHOGENESIS

Alcoholic pancreatitis is the result of abnormal secretion and necrosis fibrosis of the gland. The *abnormal secretion theory* notes that chronic alcohol ingestion induces hypersecretion of protein from the acinar cell, increased secretion of ionized calcium, concomitant defects in ductal bicarbonate (HCO_3^-) secretion decreasing the solubility of secretory proteins

(GP2), and reduced secretion of lithostathine (formerly called *pancreatic stone protein*), a low-molecular-weight, nonenzymatic protein that inhibits lattice formation by binding to growth sites of calcium carbonate crystals. These secretory defects favor the formation of calcium-protein complexes and ultimately lead to intraductal protein precipitates that obstruct ductules. Progressive blockage of both small ducts and the main pancreatic duct leads to further structural deterioration of ducts, acinar tissue, and eventually islets of Langerhans. The *necrosis fibrosis theory* suggests that alcohol may also have specific cytotoxic effects on acinar cells that act independently to cause tissue damage, possibly even acute pancreatitis. The acute attacks of pancreatitis lead to necrosis of the parenchyma and disruption of the ductal system. After the necrosis subsides and healing occurs, fibrosis of the main duct occurs, which obstructs the gland and leads to large duct disease.

Hereditary pancreatitis results from a mutation of a gene on chromosome 7q that encodes for an abnormal cationic trypsinogen, which cannot be inactivated by intracellular protective proteins. Normally active trypsin is degraded by cleavage of Arg at position 117. In hereditary pancreatitis, Arg is mutated to His, preventing cleavage and resulting in accumulation of active trypsin.

CLINICAL MANIFESTATIONS

Although several different clinical patterns can be seen, most patients with chronic pancreatitis experience pain that can be episodic or continuous. Pain may be accompanied by steatorrhea with symptoms of diarrhea and weight loss. On occasion, patients exhibit exocrine or endocrine insufficiency in the absence of pain. Other patients are asymptomatic and found to have chronic pancreatitis incidentally on imaging.

The pain of chronic pancreatitis is poorly understood. Possible causes include inflammation of the pancreas, increased intrapancreatic pressure, neural inflammation, or extrapancreatic causes, such as stenosis of the common bile duct and duodenum. Evidence in favor of pressure as a cause of pancreatic pain includes reports of pain relief following endoscopic or surgical decompression of a dilated main pancreatic duct. Steatorrhea does not occur until the output of lipase is decreased to less than 10% of normal. Diabetes mellitus is a late complication of chronic pancreatitis, becoming apparent only after 80% to 90% of the gland is severely damaged. The complications of chronic pancreatitis include the development of pseudocysts, pancreatic fistulas, biliary obstruction, pancreatic cancer, small bowel bacterial overgrowth, and gastric varices secondary to splenic vein thrombosis.

DIAGNOSIS

Because direct biopsy of the pancreas is considered too risky, the diagnosis of chronic pancreatitis is typically based on tests of pancreatic structure and function. Marked structural changes usually, but not always, correlate with severe functional impairment, as determined by pancreatic function tests. In early chronic pancreatitis, however, mild abnormalities of pancreatic function can precede any morphologic changes seen on imaging. Moreover, tests of pancreatic

structure may remain normal even with advanced deterioration of pancreatic function and with severe structural deterioration. Laboratory evaluation, such as amylase and lipase, are frequently normal in the setting of well-established chronic pancreatitis, and serum pancreatic enzymes thus neither confirm nor exclude the diagnosis.

TESTS OF FUNCTION

The secretin stimulation test is considered the gold standard functional test for diagnosing chronic pancreatitis. The observation that HCO_3^- production is impaired early in chronic pancreatitis has led to the rationale for use of this test to diagnose chronic pancreatitis in the early stages of disease (sensitivity of 95%). This test involves the oral placement of a catheter into the duodenum for aspiration of pancreatic juice before and after stimulation with intravenous secretin. This quantitative measure of pancreatic secretion and enzyme activity is primarily performed in patients with chronic abdominal pain in whom the diagnosis of chronic pancreatitis is suspected and in whom results of imaging studies are negative or equivocal. The secretin test is not widely given because the study is labor intensive and is uncomfortable for patients.

Several less invasive tests have been developed, but they are all less accurate than the secretin test, especially in the diagnosis of early chronic pancreatitis. The 72-hour fecal fat determination is often regarded as the gold standard to document steatorrhea (fecal fat > 7 g per 24 hours); however, the test is not specific for pancreatic exocrine insufficiency. The test also lacks sensitivity because steatorrhea will not occur in chronic pancreatitis until pancreatic lipase output falls to less than 5% to 10% of normal. The serum trypsinogen level correlates with functioning acinar parenchyma. A low level (<10 ng/mL) is highly specific for exocrine pancreatic insufficiency. The sensitivity is 80% to 90% in patients with advanced chronic pancreatitis with steatorrhea but only 10% to 20% in those without steatorrhea. Fecal chymotrypsin or elastase levels may be used as a simple stool test of pancreatic function, but neither is commonly employed in the United States.

TESTS OF STRUCTURE

Findings that suggest chronic pancreatitis include ductal abnormalities (dilation, stones, duct irregularity), parenchymal abnormalities (calcification, inhomogeneity, atrophy), gland contour changes, and pseudocysts. Imaging studies may be normal in the early stages of disease. Plain film radiography of the abdomen for detecting pancreatic calcifications can be seen in 20% to 50% of individuals with alcohol-induced chronic pancreatitis. The test should be the first diagnostic test performed when pancreatitis is suspected because it is both simple and inexpensive. Calcifications not detected on plain films can be detected more readily by CT scanning (Fig. 40-6).

ERCP (**Web Video 40-2**) and endoscopic ultrasonography (EUS) are the most sensitive imaging studies to evaluate for structural abnormalities of the pancreatic parenchyma and ductular system. The major limitation of ERCP is the development of procedure-related acute pancreatitis in up to 5% of patients. As a result, ERCP should be reserved for

Figure 40-6 Computed tomography scan of a patient with calcifications and small pseudocysts in the pancreas consistent with chronic pancreatitis.

patients in whom the diagnosis cannot be established or for evaluating symptomatic complications (stones, strictures) associated with chronic pancreatitis. EUS appears to be promising, with early findings that may be more sensitive compared with other tests of structure or function. Magnetic resonance cholangiopancreatography (MRCP) is a noninvasive diagnostic imaging modality that provides visualization of the pancreatic and biliary systems with images similar to those seen by ERCP but without the risk for precipitating acute pancreatitis.

TREATMENT

Pancreatic enzyme preparations are effective at treating malabsorption and are clinically indicated if patients suffering from chronic pancreatitis lose more than 10% of their body weight, excrete more than 15 g per day of fat with their stool, or suffer from dyspepsia. Four types of pancreatic enzyme preparations are available. Most commercial preparations consist of pancreatin, which is the shock-frozen powdered extract of porcine pancreas containing lipase, amylase, trypsin, and chymotrypsin. Enzyme supplements are not absorbed from the gastrointestinal tract but rather are inactivated by enteral bacterial flora or digestive secretions and fecally eliminated. Administration of acid-stable, encapsulated microspheres or microtablets filled with pancreatic enzymes has greatly increased the efficacy of enzyme supplementation in chronic pancreatitis. Patients with documented exocrine insufficiency should eat three main meals a day and three snacks in between. In general, 25,000 to 50,000 IU of lipase should be ingested simultaneously along with a main meal and 25,000 IU of lipase with snacks; it should not be taken either before or after the meals. When gastric hyperacidity is present, proton pump inhibitors or histamine-2 receptor antagonists should be used to delay enzyme inacti-

vation. In cases of progressive maldigestion and steatorrhea, supplementing lipid-soluble vitamins parenterally may be necessary. In cases of severe exocrine insufficiency, one third of the daily caloric intake can be met by administering medium-chain triglycerides (MCTs), which do not require lipolysis by lipase for absorption. Although clinically effective, patients usually do not like MCT fat because of poor palatability. Symptom improvement, not laboratory tests, demonstrates the efficacy of enzyme supplementation. If these methods do not provide improvement, the next step is to decrease dietary fat intake to less than 50 g per day and to substitute MCTs, which do not require hydrolysis before absorption, for some dietary fat. Other factors may accentuate steatorrhea, including concomitant small bowel bacterial overgrowth, which can occur in up to 25% of patients with chronic pancreatitis. Bacterial overgrowth may be caused by hypomotility of the gut secondary to inflammatory diseases of the head of the pancreas or to chronic use of narcotic analgesics.

The greatest challenge in treating chronic pancreatitis is controlling abdominal pain. Pain is said to improve over time but may take years and is not uniform. Methods of pain relief initially include abstinence from alcohol, analgesics, and pancreatic enzyme supplements. Supplemental pancreatic enzymes are given to decrease cholecystokinin-mediated pancreatic secretion, an approach that alleviates pain in some patients with chronic pancreatitis. Therapy is initiated with large doses of pancrelipases (non-enteric-coated) pancreatic enzyme preparations because, in theory, the enteric-coated preparations release their enzymes further down the intestine away from the stimulatory cholecystokinin (CCK) enterocytes. Nerve blocks (celiac plexus block and splanchnicectomy) yield equivocal results. Endoscopic decompression of pancreatic duct obstruction secondary to strictures or stones may result in pain relief. Surgical ductal drainage, usually with lateral pancreaticojejunostomy (Puestow procedure), may effectively decrease pain in about 80% of patients. This procedure is safe and has an operative mortality rate of less than 5%; however, only 50% of patients are free of pain at 5-year follow-up. Patients with nonobstructed, nondilated ductal systems may require pancreatic resection.

Carcinoma of the Pancreas

Carcinoma of the pancreas is the fourth leading cause of cancer in adults, with about 28,000 new cases and 25,000 deaths annually. The prognosis is grim; less than 20% of all patients are alive beyond the first year of disease, and only 1% to 3% are alive beyond the fifth year. Carcinoma of the pancreas accounts for about 5% of cancer deaths in the United States. More than 90% of these tumors are adenocarcinomas and arise from the ductal cells.

CAUSES AND PATHOGENESIS

Contributing factors include age, gender (male risk ratio 1.4:1), carcinogens, cigarette smoking, hereditary pancreatitis, chronic pancreatitis, and possibly a high-fat diet. Occu-

Diagnosis and Staging of Pancreatic Cancer

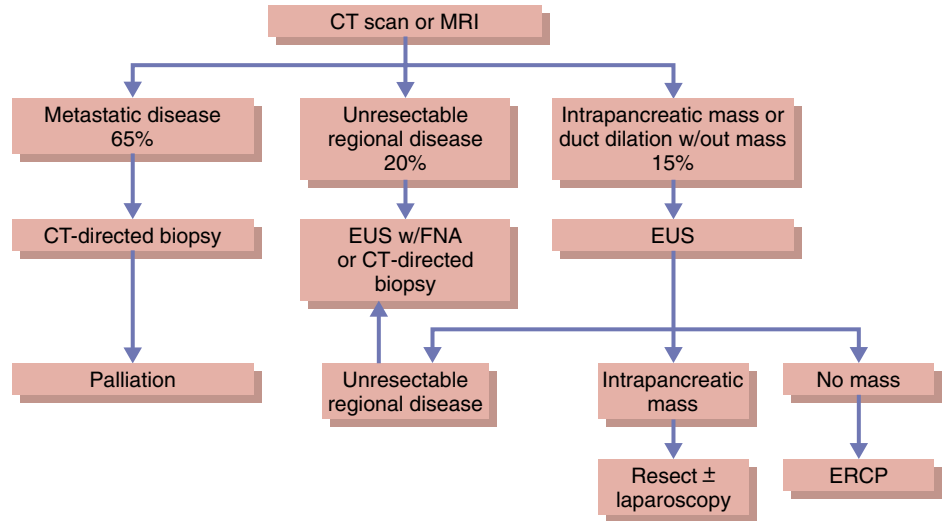

Figure 40-7 Diagnostic algorithm for evaluating a patient with suspected pancreatic carcinoma. CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography. (From Cello JP: Pancreatic cancer. In Feldman M, Scharschmidt BF, Sleisenger MH [eds]: *Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management*, 6th ed. Philadelphia, WB Saunders, 1998, p 865.)

pational exposure to β -naphthylamine and benzidine are clear risk factors; however, these substances are not thought to be causative agents in most patients. Patients with long-standing diabetes may also be at a slightly increased risk. Neither alcohol nor coffee consumption appears to be a risk factor.

CLINICAL MANIFESTATIONS

The clinical manifestations of pancreatic carcinoma may be nonspecific and are often insidious. The tumor has usually reached an advanced stage by the time of diagnosis. Common presenting signs and symptoms of pancreatic cancer include jaundice, weight loss, and abdominal pain. The pain is usually constant, with radiation to the back. Because most cancers begin in the pancreatic head, patients may exhibit obstructive jaundice or a large, palpable gallbladder (Courvoisier sign). Painless jaundice is the most common presentation in patients with a potentially resectable and curable lesion. Anorexia, nausea, and vomiting may also occur, along with emotional disturbances, such as depression. Other, less common presenting symptoms include signs of migratory thrombophlebitis (Trousseau sign), acute pancreatitis, diabetes, paraneoplastic syndromes (Cushing syndrome), hypercalcemia, gastrointestinal bleeding, splenic vein thrombosis, and a palpable abdominal mass.

DIAGNOSIS AND STAGING

Diagnosis of pancreatic cancer is frequently suggested by the presence of a pancreatic mass on imaging studies. Evidence of a dilated pancreatic duct, hepatic metastases, invasion of vessels, or a dilated common bile duct in the setting of biliary obstruction may also be found. The appearance on imaging may be impossible to distinguish from benign causes of pancreatic masses such as focal pancreatitis. CT and MRI are the best initial studies to define a mass and assess for liver metastasis or vascular invasion. ERCP should be considered if

pancreatic cancer is suspected but a mass is not found on other imaging studies. ERCP will show a main pancreatic duct stricture in at least 97% of such cases (Fig. 40-7).

The use of tumor markers to diagnose carcinoma of the pancreas has yielded disappointing results. The tumor marker CA 19-9 has a sensitivity of 80% to 90% and a specificity of 85% to 95% in diagnosing pancreatic cancer in patients exhibiting signs and symptoms suggestive of pancreatic cancer. EUS, when compared with other imaging studies (spiral CT, MRI, and angiography), is the most accurate diagnostic and staging technique, providing information of tumor location, vascular invasion, and lymph node involvement. The major determinant of both operative resectability and long-term survival is the presence of vascular invasion (superior mesenteric artery or vein, portal vein) or metastatic disease. Unfortunately, only 10% to 20% of carcinomas in the head of the pancreas and essentially no cancers of the body and tail are resectable for cure. If evaluation is conclusive that a pancreatic tumor is not resectable, the first objective is to confirm the cell type, which can be done accurately by CT- or EUS-guided biopsy. When non-operative staging suggests a resectable tumor, some centers prefer a staging laparoscopy before attempted curative resection.

TREATMENT

Surgery for resectable carcinoma of the head of the pancreas usually involves a Whipple operation. If resection cannot be done at the time of laparotomy, biliary diversion should be done to relieve jaundice, and gastrojejunostomy is performed if duodenal invasion is present to relieve duodenal obstruction. Surgery offers the only chance for cure. The rate of operative mortality is less than 5%. Attempts at radiation and chemotherapy have met with little success and only modest improvements in patient survival. For patients with inoperable lesions, palliative interventions to alleviate jaundice, pain, and intestinal obstruction often become the focus of therapy.

Prospectus for the Future

Our understanding of the pathophysiologic mechanisms responsible for pancreatitis and pancreatic malignancy will continue to evolve. This improved understanding will lead to early diagnosis and improved treatment options.

- Improvements in our understanding of the genetic predisposition for developing pancreatitis will lead to the identification of at-risk individuals and ultimately treatment options to prevent pancreatic injury.
- Elucidation of inciting factors and subsequent inflammatory mediators responsible for the local and systemic injuries seen in acute pancreatitis will offer early treatment options to reduce tissue injury and thereby reduce the severity of the disease process.

- Technologic advances in the endoscopic and minimally invasive surgical treatment of pancreatic necrosis will facilitate care and reduce morbidity and mortality.
- New modalities to evaluate tissue characteristics in early chronic pancreatitis will provide a gold standard for diagnosis and thereby allow for early detection and more appropriate treatment when pain is the presenting symptom.
- Further characterization of the early biologic changes that precede the development of symptomatic pancreatic malignancy will result in prevention, early detection, and new nonsurgical modalities for treatment.

Laboratory Tests in Liver Disease

Rajan Kochar and Michael B. Fallon

The liver, the largest internal organ in the body, plays a central role in many essential physiologic processes, including glucose homeostasis, plasma protein synthesis, lipid and lipoprotein synthesis, bile acid synthesis and secretion, and vitamin storage (B₁₂, A, D, E, and K). In addition, the liver is vital in biotransformation, detoxification, and excretion of a vast array of endogenous and exogenous compounds. The clinical manifestations of liver disease are varied and can be quite subtle. Clues to the existence, severity, and origin of liver disease may be obtained from a thorough history and physical examination as well as by routine laboratory screening tests.

Laboratory Tests of Liver Function and Disease

Understanding the utility of different types of laboratory tests of the liver is extremely important in characterizing the underlying liver disease. Unlike tests used to assess function of other organ systems (e.g., arterial blood gas, creatinine clearance), many so-called liver function tests do not directly measure hepatic function and may not accurately reflect the cause or severity of the liver disease process. Specific diagnostic tests such as serologic tests for viral, autoimmune, and inherited liver disease are covered in other chapters.

Tests of Hepatic Function

The great variety of functions that the liver performs has made it difficult to devise a simple, inexpensive, reproducible, and noninvasive test that accurately reflects hepatic capacity for all functions. Instead, currently available tests of liver function are indirect, static measurements of serum levels of compounds that are synthesized, metabolized, or excreted by the liver. The liver has a large reserve capacity, and therefore results of *function* tests may remain relatively normal until liver dysfunction is severe.

The most widely available and useful liver function tests are outlined in Table 41-1. The serum albumin level and

prothrombin time both reflect the hepatic capacity for protein synthesis. The prothrombin time is dependent on coagulation factors II, V, VII and X and responds rapidly to altered hepatic function because of the short serum half-lives of factors II and VII (about 6 hours). This makes the prothrombin time a useful marker of hepatic synthetic function that can be followed as frequently as daily. However, because serum levels of factors II, VII, IX, and X are dependent on vitamin K, coexistent vitamin K deficiency must be excluded or treated before using the prothrombin time as a measure of hepatic function. In contrast, the serum half-life of albumin is 14 to 20 days, and serum levels fall with prolonged liver dysfunction or in acute liver impairment. Malnutrition and renal or gastrointestinal losses merit consideration in the setting of significant hypoalbuminemia, especially if the prothrombin time is relatively well preserved. Serum globulins may be increased in some patients with chronic liver disease such as hepatitis C and cirrhosis. Elevations of individual gamma-globulins can be indicative of specific disease processes such as autoimmune hepatitis (total immunoglobulin G [IgG]), primary biliary cirrhosis (IgM), and alcoholic liver disease (IgA).

Serum ammonia may be elevated in liver disease. Although it is a poor marker of hepatic function, it is used frequently in the diagnosis of portosystemic encephalopathy.

Quantitative tests of liver function, including indocyanine green clearance, galactose elimination capacity, aminopyrine breath test, antipyrine clearance, monoethylglycineylidide, and caffeine clearance may be superior to conventional biochemical tests in predicting prognosis. However, the clinical utility of these tests has not been established, and they are limited primarily to research centers.

Screening Tests of Hepatobiliary Disease

Screening tests of hepatobiliary disease (see Table 41-1) may be divided into two categories: (1) tests of biliary obstruction

Table 41-1 Laboratory Tests of Hepatic Function

	Property Examined	Causes of Abnormal Results
Tests of Hepatic Function (Normal Values)		
Serum albumin (3.5-5.5 mg/dL)	Protein synthetic capacity (over days to weeks)	Decreased synthetic capacity Protein malnutrition Increased protein loss (nephrotic syndrome, protein-losing enteropathy) Increased extracellular fluid volume
Prothrombin time (10.5-13 sec)	Protein synthetic capacity (hours to days)	Decreased synthetic capacity (especially factors II and VII) Vitamin-K deficiency Consumptive coagulopathy
Screening Tests of Hepatobiliary Disease		
Tests of Biliary Obstruction or Impaired Bile Flow		
Serum bilirubin (0.2-1 mg/dL) (3.4-17.1 mmol/L)	Extraction of bilirubin from blood; conjugation and excretion into bile	Hemolysis Diffuse liver disease Cholestasis Extrahepatic bile duct obstruction Congenital disorders of bilirubin metabolism
Serum alkaline phosphatase (also 5'-nucleotidase and γ -glutamyl transpeptidase) (56-176 U/L)	Increased enzyme synthesis and release	Bile duct obstruction Cholestasis Infiltrative liver disease (neoplasms, granulomas) Bone destruction, remodeling Pregnancy
Tests of Hepatocellular Damage		
Aspartate aminotransferase (AST) (10-30 U/L)	Release of intracellular enzyme	Hepatocellular necrosis Cardiac or skeletal muscle necrosis
Alanine aminotransferase (ALT) (5-30 U/L)	Release of intracellular enzyme	Same as AST; however, more specific for liver cell damage

and cholestasis, and (2) tests of hepatocellular damage, based on the mechanisms responsible for the abnormal test. However, none of the tests is specific for either category, and the overall pattern and the relative magnitude of abnormalities in these two categories of tests often provide diagnostic clues to the type of liver disease present.

Bilirubin is present in the serum in two forms: unconjugated (indirect) and conjugated (direct). Normal serum bilirubin level is less than 1 mg/dL, with the conjugated fraction representing up to 30% of the total. The *serum bilirubin* level reflects a balance between bilirubin production and its conjugation and excretion into bile by the liver. The differential diagnosis for hyperbilirubinemia (see Chapter 42) requires consideration of an extensive list of disorders in which bilirubin production (hematologic disorders with predominantly unconjugated hyperbilirubinemia), hepatic metabolism (congenital abnormalities of bilirubin conjugation, liver disease), or excretion (congenital abnormalities of bilirubin excretion or biliary obstruction with predominantly conjugated hyperbilirubinemia) is altered. Hence, an elevated serum bilirubin determination is not specific for any cause of liver disease. However, such an abnormality, especially in association with predominant elevations in other tests of biliary obstruction, should prompt an evaluation for potentially treatable biliary abnormalities. Recognizing that serum bilirubin levels may not return promptly to normal after relief of biliary obstruction or improvement in liver disease is important because some bilirubin binds covalently to albumin and is removed from the circulation only as albumin is catabolized.

Serum alkaline phosphatase activity reflects a group of isoenzymes derived from liver, bone, intestine, and placenta.

Serum levels are elevated in association with a variety of conditions, including cholestasis, partial or complete bile duct obstruction, bone regeneration, pregnancy, and neoplastic, infiltrative, and granulomatous liver diseases. An isolated elevated alkaline phosphatase level may be the only clue to partial obstruction of the common bile duct, to obstruction of ducts in a single lobe or segment of liver, or to neoplastic or granulomatous hepatic disease. In cholestasis, serum alkaline phosphatase levels rise as a result of retention of bile acids in the liver, which solubilize alkaline phosphatase off the hepatocyte plasma membrane, as well as stimulate its synthesis. 5'-Nucleotidase and γ -glutamyl transpeptidase, other hepatocyte plasma membrane enzymes, are similarly released into the circulation during bile duct obstruction or cholestasis and are used to confirm that an elevated alkaline phosphatase level is caused by hepatobiliary disease. An isolated elevated serum alkaline phosphatase with normal 5'-nucleotidase and γ -glutamyl transpeptidase enzymes suggests a nonhepatic cause, and electrophoretic fractionation of alkaline phosphatase isoenzymes may be useful to confirm alternate sources.

Aspartate (aspartate aminotransferase [AST] or serum glutamic-oxaloacetic transaminase [SGOT]) and *alanine* (alanine aminotransferase [ALT] or serum glutamic-pyruvic transaminase [SGPT]) *aminotransferases* are intracellular amino-transferring enzymes present in large quantities in hepatocytes. After injury or death of liver cells, these enzymes are released into the circulation. In general, the serum aminotransferases are sensitive (albeit nonspecific) tests of liver damage, and the height of the serum aminotransferase activity level reflects the severity of hepatic necrosis, with important exceptions. For instance, both enzymes require pyridoxal

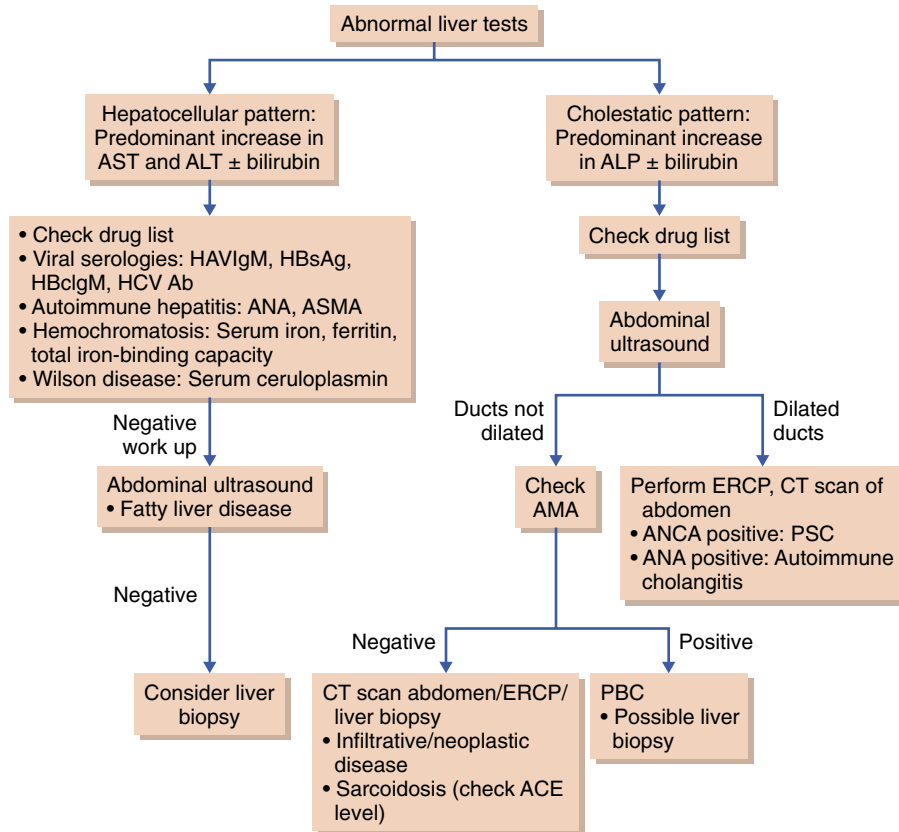

Figure 41-1 Abnormal liver function test patterns and diagnostic approach. ACE, angiotensin-converting enzyme; ALT, alanine aminotransferase; AST, aspartate aminotransferase; ALP, alkaline phosphatase; ANCA, antineutrophil cytoplasmic antibody; ANA, antinuclear antibody; AMA, antimicrobial antibody; ASMA, anti-smooth muscle antibody; ERCP, endoscopic retrograde cholangiopancreatography; CT, computed tomography; HAVIgM, hepatitis A immunoglobulin M; HBsAg, hepatitis B surface antigen; HBcIgM, hepatitis B core immunoglobulin M; HCVAb, hepatitis C virus antibody; PBC, primary biliary cirrhosis; PSC, primary sclerosing cholangitis.

5'-phosphate as a cofactor, and the relatively low serum aminotransferase values seen in patients with severe alcoholic hepatitis (usually 300 U/L) may reflect deficiency of this cofactor. ALT is found primarily in hepatocytes and an elevation in ALT is more specific than AST for liver disease. In most hepatocellular disorders, ALT is higher than or equal to the AST, with the exception of alcoholic liver disease, in which the ratio is reversed, and an AST/ALT ratio of more than 3 is highly suggestive of alcohol as the underlying cause. Lower ALT levels are due to a deficiency of pyridoxal 5'-phosphate. Although aminotransferase levels are increased in a wide array of liver diseases, extremely high levels (15 times the upper limit of normal) generally indicate acute hepatocellular necrosis from viral or toxic causes (such as acetaminophen toxicity) or, less frequently, indicate acute bile duct obstruction or hepatic ischemia (*shock liver*). Patients who have isolated asymptomatic elevations of AST and ALT may have nonalcoholic fatty liver disease (caused by obesity, insulin resistance and diabetes, or hyperlipidemia), alcohol-induced liver disease, or hepatocellular disease, such as hemochromatosis or chronic viral hepatitis. These patients should be screened for treatable diseases. Some patients may require liver biopsy.

Individual liver function tests frequently do not indicate the nature of the underlying liver disease. However, the overall *pattern* of liver test abnormalities and the relative

magnitude of abnormalities in individual tests often provide significant insight into whether the nature of the liver disease is primarily hepatocellular or cholestatic. Figure 41-1 outlines common patterns of liver test abnormalities and a diagnostic evaluation. Isolated elevation in indirect bilirubin and, rarely, total bilirubin levels greater than 5 mg/dL will occur in hemolysis or Gilbert syndrome. Bile duct obstruction rarely increases AST and ALT above 500 U/L or alkaline phosphatase above 4 to 5 times higher than the upper limits of normal. Ischemic hepatitis often produces ALT and AST levels above 1000 mg/dL, with rapid resolution after fluid resuscitation, excluding other causes of acute hepatocellular necrosis.

Common liver function test patterns in patients with cirrhosis include mildly elevated enzymes (AST and ALT) and elevated bilirubin (primarily conjugated) and alkaline phosphatase associated with thrombocytopenia and prolonged prothrombin time. Specific causes of cirrhosis influence the liver function abnormalities observed (see Chapter 45).

Liver Biopsy

Biopsy and histologic examination of liver tissue are frequently valuable in the differential diagnosis, staging, and consideration of treatment of diffuse or localized parenchy-

mal diseases (e.g., cirrhosis, hepatitis, hemochromatosis, tumors) or hepatomegaly. Liver biopsies can be performed either by a percutaneous or by a transjugular approach. Tissue from a biopsy represents 1/50,000 of total liver tissue, and sampling variability has been noted. Although generally safe, serious complications such as bleeding (1 per 1000) and death (1 per 10,000) may occur. Absolute contraindications

include uncooperative patient, prothrombin time greater than 3 to 5 seconds, platelets under 50,000/mm³, nonsteroidal anti-inflammatory drug use in previous 7 to 10 days, and suspected echinococcal cysts in the liver. Recently, noninvasive serum markers and ultrasound and magnetic resonance elastography have been increasingly studied as alternatives to liver biopsy to assess hepatic fibrosis.

Prospectus for the Future

In a significant number of liver disorders that exhibit abnormal liver tests (e.g., hepatitis C, nonalcoholic fatty liver disease), an important diagnostic consideration is the degree of hepatic fibrosis. In general, liver biopsy has been the gold standard for staging disease based on the amount of fibrosis found. Recently, transient elastography and a large number of panels of serum markers have been used to predict the degree of hepatic fibrosis noninvasively, particularly in hepatitis C infection. *Transient elastography* is a sonographic technique based on the theory that a “shear wave” moves faster in a less elastic liver (more fibrosis and scarring) than a normal or less fibrotic liver. A low-frequency shear wave is emitted from a probe, and the amount of time it takes to progress through a set “window” of tissue is measured and used as an index of tissue elasticity and fibrosis. This technique has shown accurate results in advanced fibrosis (stages 3 and 4). Several serum markers of fibrosis have

also been evaluated and found to be good for ruling out advanced fibrosis but not for confirming mild or intermediate fibrosis. Using transient elastography and serum markers together has shown increased accuracy in assessing hepatic fibrosis. The use of such tests to predict hepatic fibrosis is likely to increase both in viral and in nonviral liver disease in the near future and may eventually replace liver biopsy as the primary means of assessing degree of hepatic fibrosis.

Another area of active investigation in liver disease is the use of genetic testing to predict susceptibility to drug-induced hepatotoxicity and to predict therapeutic response to specific therapies for liver disease. These pharmacogenomic techniques have the potential to detect genetic markers that may guide the use of drug therapies for liver disease and prevent drug-induced liver disease.

Jaundice

Klaus Mönkemüller, Helmut Neumann, and Michael B. Fallon

Jaundice, also known as *icterus* (Greek for yellow), connotes the yellow pigmentation of skin, sclerae, and mucous membranes that is caused by elevated serum bilirubin levels (hyperbilirubinemia). The word jaundice derives from the French *jaune*, meaning yellow. Jaundice per se is not a pathologic condition but rather a sign of various illnesses such as liver diseases and various hematologic disorders. There is one exception for which bilirubin can be pathologic: in newborns, hyperbilirubinemia can cause severe cerebral damage in neonates due to deposition of unconjugated bilirubin in the cerebral basal ganglia or nuclei. This completely preventable and treatable disease is known as kernicterus (from the German *Kern*, meaning nucleus). Normal serum bilirubin levels range from 0.5 to 1 mg/dL, and jaundice becomes clinically evident at levels higher than 2.5 to 3 mg/dL. Typically, plasma bilirubin concentration must exceed 1.5 mg/dL for the discoloration to be easily visible.

Bilirubin Metabolism

Hyperbilirubinemia can be classified based on the three phases of hepatic bilirubin metabolism: (1) uptake, (2) conjugation, and (3) excretion into the bile, the last step being rate limiting. However, a more practical way to categorize jaundice is into prehepatic, hepatic, and posthepatic causes (Table 42-1). This latter classification is useful for the practicing clinician.

Most of the bilirubin (80%) is derived from the breakdown of senescent red blood cells, whereas the remainder derives from ineffective erythropoiesis and catabolism of myoglobin and hepatic hemoproteins such as cytochrome P-450. The normal rate of bilirubin production is about 4 mg/kg body weight daily (Fig. 42-1). After erythrocytes have completed their normal life span of 120 days, or sooner in cases of hematologic disorders, they are destroyed within the reticuloendothelial system and release their contents into the bloodstream, where it is ingested by macrophages, which in turn split the hemoglobin into heme and globin. The heme ring is cleaved by the enzyme microsomal heme oxygenase to form biliverdin (from the Latin *viridis*, meaning green, i.e., green color pigment), which is then converted to

the tetrapyrrole pigment bilirubin by the cytosolic enzyme biliverdin reductase. This unconjugated (or “indirect,” see later discussion of the *van der Bergh reaction*) bilirubin is released into the plasma, where it is tightly bound to albumin and then transported to the liver. Because unconjugated bilirubin is insoluble in water, it cannot be excreted in urine or bile. However, it will dissolve in lipid-rich environments and thus traverses the blood-brain barrier and placenta.

After dissociating from albumin in the space of Disse, unconjugated bilirubin is transported across the liver cell plasma membrane and attaches to intracellular binding proteins (ligandin). It is then conjugated with glucuronic acid by the enzyme uridine diphosphate (UDP) glucuronyl transferase to form bilirubin monoglucuronide and diglucuronide, which are water soluble. Conjugated bilirubin is excreted into bile by active transport across the canalicular membrane by a multispecific canalicular transporter. When biliary excretion of conjugated bilirubin is impaired, the pigment regurgitates from hepatocytes into plasma, causing an increase in the plasma level. Because conjugated bilirubin is water soluble and less tightly bound to albumin than is unconjugated bilirubin, it is readily filtered by the glomerulus and appears in the urine, giving it a dark color (choloria). Once in bile, bilirubin enters the intestine, where bacteria convert it to colorless tetrapyrroles (urobilinogens) that are excreted in feces. Up to 20% of urobilinogen is reabsorbed and undergoes enterohepatic circulation or excretion in urine.

Laboratory Measurement of Bilirubin

The *van den Bergh reaction*, which is the most commonly used test for detecting bilirubin in biologic fluids, combines bilirubin with diazotized sulfanilic acid to form a colored compound. The direct-reacting fraction is roughly equivalent to conjugated bilirubin and the indirect-reacting fraction (total minus direct fraction) to unconjugated bilirubin. This characteristic provides a means for classifying jaundice into two categories: unconjugated hyperbilirubinemia and conjugated hyperbilirubinemia.

Table 42-1 Classification of Jaundice

Prehepatic (Predominantly Unconjugated Hyperbilirubinemia)**Overproduction**

Hemolysis (e.g., spherocytosis, sickle cell disease, hemolysis of the newborn, autoimmune disorders)
 Ineffective erythropoiesis (e.g., megaloblastic anemias)
 Hematomas
 Pulmonary emboli

Hepatic (Unconjugated Hyperbilirubinemia)**Decreased Hepatic Uptake**

Gilbert syndrome
 Drugs (e.g., rifampin, radiographic contrast agents)
 Neonatal jaundice
 Posthepatitis
 Decreased cystolic binding proteins (e.g., newborn or premature infants)
 Portocaval shunt
 Prolonged fasting

Decreased Conjugation Due to Limited Glucuronyl Transferase Activity

Gilbert syndrome
 Crigler-Najjar syndrome types I and II
 Neonatal jaundice
 Breast-milk jaundice
 Chronic persistent hepatitis
 Wilson disease
 Noncirrhotic portal fibrosis
 Drug inhibition (e.g., chloramphenicol)

Predominantly Conjugated Hyperbilirubinemia**Impaired Hepatic Excretion**

Familial disorders (Dubin-Johnson syndrome, Rotor syndrome, benign recurrent cholestasis, cholestasis of pregnancy)
 Hepatocellular infiltrative disorders
 Liver metastasis
 Liver cirrhosis
 Hepatitis (viral, bacterial, parasitic, autoimmune, ethanol and drug induced)
 Drug-induced cholestasis (especially chlorpromazine, erythromycin estolate, isoniazid, halothane)
 Primary biliary cirrhosis
 Primary sclerosing cholangitis
 Pericholangitis
 Congestive heart failure
 Shock
 Toxemia of pregnancy
 Sarcoidosis
 Hepatic trauma
 Amyloidosis
 Autoimmune cholangiopathy
 Vanishing bile duct syndrome
 Sepsis
 Postoperative complications

Extrahepatic**Extrahepatic Biliary Obstruction**

Gallstones, choledocholithiasis
 Cholecystitis
 Tumors of the head of the pancreas (adenocarcinoma, mucinous duct ectasia, neuroendocrine tumors, metastasis)
 Tumors of bile ducts (cholangiocarcinoma, Klatskin tumor: cholangiocarcinoma at the bifurcation)
 Gallbladder cancer
 Tumors of the ampulla of Vater (adenoma, adenocarcinoma)
 Tumors of the duodenum (adenocarcinoma, lymphoma)
 Hemobilia (blood in the biliary tree)
 Biliary strictures (postcholecystectomy, post-liver transplantation, primary sclerosing cholangitis)
 Congenital disorders (biliary atresia, idiopathic dilation of common bile duct, cystic fibrosis)
 Metastasis to the hepatic hilum
 Primary bile duct lymphoma
 Cholangiopathy of acquired immunodeficiency syndrome
 Choledochal cysts
 Infectious cholangiopathy (*Clonorchis sinensis*, *Ascaris lumbricoides*, *Fasciola hepatica*)
 Chronic pancreatitis (fibrosis of the head of the pancreas)

Figure 42-1 Bilirubin production, metabolism, and excretion (see text for detailed description). UDP, uridine diphosphate; UDPGA, uridine diphosphate glucuronic acid.

Unconjugated Hyperbilirubinemia

Mechanisms that cause unconjugated hyperbilirubinemia are (1) overproduction, (2) impaired hepatic uptake, and (3) decreased conjugation of bilirubin. These disorders are not usually associated with significant hepatic disease.

ETIOLOGY OF HYPERBILIRUBINEMIA

Prehepatic

Prehepatic jaundice can be caused by any condition resulting in excessive bilirubin production or hepatic uptake. These conditions include an increased production of bilirubin that may result from hemolysis (intravascular or extravascular), hematomas, or pulmonary emboli. Furthermore, certain genetic diseases can lead to an increased red cell lysis and therefore hemolytic jaundice. Examples are glucose 6-phosphate dehydrogenase deficiency, sickle cell anemia, and spherocytosis. Infectious diseases like malaria can also cause jaundice by breakdown of red blood cells. Jaundice resulting from hemolysis is characteristically mild, and serum bilirubin levels rarely exceed 5 mg/dL in the absence of coexisting hepatic diseases. Ineffective erythropoiesis, which may be significantly increased in megaloblastic anemias, also leads to mild jaundice. Hemolysis can be

investigated by examining the peripheral blood smear (and in some cases the bone marrow smear) and measuring the reticulocyte count, haptoglobin, lactate dehydrogenase (LDH), erythrocyte fragility, and Coombs test.

Hepatic

Every condition resulting in hepatic injury can cause hepatic jaundice. These conditions include any causes of hepatitis, such as infectious diseases (viral, bacterial), toxic metabolites (alcohol, carbon tetrachloride, amanita), drugs (rifampin, flavaspidic acid, iodinated contrast agents), autoimmune disorders (autoimmune hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis), and liver tumors (mostly metastasis). Other, less common causes included Gilbert syndrome, Crigler-Najjar syndrome, and Niemann-Pick disease type C (a metabolic disorder in which cholesterol and glycolipids are stored in the body rather than sphingomyelin, resulting in progressive neurologic damage).

IMPAIRED HEPATIC UPTAKE

Impaired hepatic uptake causes jaundice that occurs after administering certain drugs, such as rifampin (competition for bilirubin uptake) and those involved in treating Gilbert syndrome. Gilbert syndrome is a benign disorder that affects up to 7% of the population, with male predominance. It commonly exhibits during the second or third decade of life as mild unconjugated hyperbilirubinemia that is exacerbated

by fasting or is noted on routine laboratory testing. Most patients have a bilirubin level that is less than 3 mg/dL. The genetic defect is usually a homozygous abnormality in the TATAA element of the promoter region of the UDP glucuronyl transferase gene. The diagnosis is strongly suggested by unconjugated hyperbilirubinemia in which normal hepatic enzymes exist and overt hemolysis is absent. Liver biopsy is generally not indicated. Therapy is not usually given, but the bilirubin level does decrease significantly with phenobarbital administration.

IMPAIRED CONJUGATION

Crigler-Najjar syndrome occurs as a result of impaired conjugation of bilirubin that is caused by genetically determined decrease or absence of UDP glucuronyl transferase activity. Conjugation may also be impaired by mild, acquired defects of UDP glucuronyl transferase induced by drugs such as chloramphenicol.

Neonatal Jaundice

In neonates, jaundice develops for two main reasons. First, the relative immature hepatic metabolic pathways are unable to conjugate bilirubin as efficiently and quickly as in adults. Second, bilirubin production is increased. Of those two mechanisms, the major defect is in bilirubin conjugation, which may cause mild to moderate unconjugated hyperbilirubinemia between the 2nd and 5th days of life, lasting until the 8th day in normal births or to about the 14th day in premature births. This neonatal jaundice is usually harmless and does not require any kind of therapy. Severe pathologic unconjugated hyperbilirubinemia in the neonate is usually caused by a combination of hemolysis secondary to blood group incompatibility and defective conjugation. This neonatal jaundice is a serious condition that requires immediate attention because severe hyperbilirubinemia is associated with a risk for permanent neurologic damage (*kernicterus*). Phototherapy is the treatment of choice. If jaundice does not improve using phototherapy, other etiologies of neonatal jaundice should be sought (Table 42-2).

Conjugated Hyperbilirubinemia

Conjugated hyperbilirubinemia is generally associated with impaired formation or excretion of *all* components of bile, a situation termed *cholestasis*. The two major mechanisms of conjugated hyperbilirubinemia are (1) a defect in the excretion of bilirubin from hepatocytes into bile (intrahepatic cholestasis) or (2) a mechanical obstruction to the flow of bile through the bile ducts.

IMPAIRED HEPATIC EXCRETION (INTRAHEPATIC CHOLESTASIS)

Intrahepatic cholestasis can result from a wide range of conditions, including those that impair canalicular transport (e.g., drugs) and those that cause destruction of the small

Alagille syndrome

intrahepatic bile ducts (e.g., primary biliary cirrhosis, tumors).

Primary biliary cirrhosis is a chronic, progressive liver disease that occurs primarily in women and is characterized by the destruction and subsequent disappearance of small lobular bile ducts. The gradual decrease in the number of bile ducts leads to progressive cholestasis, portal inflammation, fibrosis, and eventually cirrhosis.

Drug-induced cholestasis may be caused by a wide array of drugs. Culprits include but are not limited to nitrofurantoin, oral contraceptives, anabolic steroids, erythromycin, cimetidine, gold salts, chlorpromazine, prochlorperazine, imipramine, sulindac, tolbutamide, ampicillin, and other penicillin-based antibiotics.

Postoperative jaundice typically occurs 1 to 10 days after surgery and has an incidence of 15% after heart surgery and 1% after elective abdominal surgery. It is multifactorial in origin. In hepatocellular disease, all three steps of hepatic bilirubin metabolism are impaired. Excretion, the rate-limiting step, is usually the most affected, leading to predominantly conjugated hyperbilirubinemia. Jaundice may be profound in acute hepatitis (see Chapter 43) without adverse prognostic implications. In contrast, in chronic liver disease, persistent jaundice usually implies irreversible decrease in hepatic function and a poor prognosis.

POSTHEPATIC

Posthepatic jaundice is also called *obstructive jaundice* and results from a complete or partial obstruction of the intrahepatic or extrahepatic bile ducts. The most common causes are gallstones in the common bile duct or pancreatic head tumors. Not infrequently, the first sign of pancreatic cancer is jaundice. Other causes include strictures of the common bile duct, biliary atresia, ductal carcinoma, pancreatitis, pancreatic pseudocysts, or parasites named *liver flukes* (e.g., *Clonorchis sinensis*, *Dicrocoelium dendriticum*, or *Opisthorchis viverrini*). *Mirizzi syndrome* is a rare cause of posthepatic jaundice affecting up to 0.7% to 1.4% of all cholecystectomies in which the common bile duct obstruction is caused

by an extrinsic compression from an impacted stone in the cystic duct (see Table 42-1).

Clinical Approach to Jaundice

Because the differential diagnosis of jaundice is broad, a thorough history and physical examination and a judicious use of laboratory and imaging studies are needed to define its cause. Jaundice appears as yellowing of the skin and sclera. Other conditions may cause yellowing or darkening of the skin (e.g., carotinemia, Addison disease, quinacrine ingestion), but scleral and mucosal discolorations are absent in these conditions. The most important initial step is to define whether the jaundice is predominantly caused by an elevation of unconjugated or of conjugated bilirubin. If jaundice is primarily the result of unconjugated bilirubin, evaluation for hemolysis is appropriate. In patients with elevated conjugated bilirubin, the clinical challenge lies in distinguishing whether biliary obstruction or impaired hepatic excretion is the cause (see Chapter 41).

In cholestatic jaundice caused by biliary obstruction or impaired hepatic excretion, the alkaline phosphatase level is typically increased more than 3 times normal, whereas serum transaminases are usually elevated less than 5-fold to 10-fold (see Chapter 40). Patients with cholestasis also may develop pruritus and malabsorption of fat and fat-soluble vitamins (A, D, E, and K). Recurrent abdominal pain and nausea (gallstones) and epigastric pain radiating to the back with weight loss and gallbladder distention (carcinoma of the pancreatic head) suggest the presence of specific causes of biliary obstruction. In complete biliary obstruction, conjugated hyperbilirubinemia is prominent and usually peaks at about 30 mg/dL in the absence of renal failure. Eosinophilia may accompany drug-induced jaundice. Inquiry about the use of drugs known to cause cholestasis, serologic testing for anti-mitochondrial antibody for primary biliary cirrhosis, and endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography to evaluate primary sclerosing cholangitis may be helpful.

In jaundice produced by hepatocellular disease resulting from a variety of causes (see Chapters 43 and 45), serum transaminases are characteristically elevated more than 10-fold, and alkaline phosphatase levels are less than 3 times normal. Evidence of hepatocellular damage and disease is also frequently present and includes a prolonged pro-

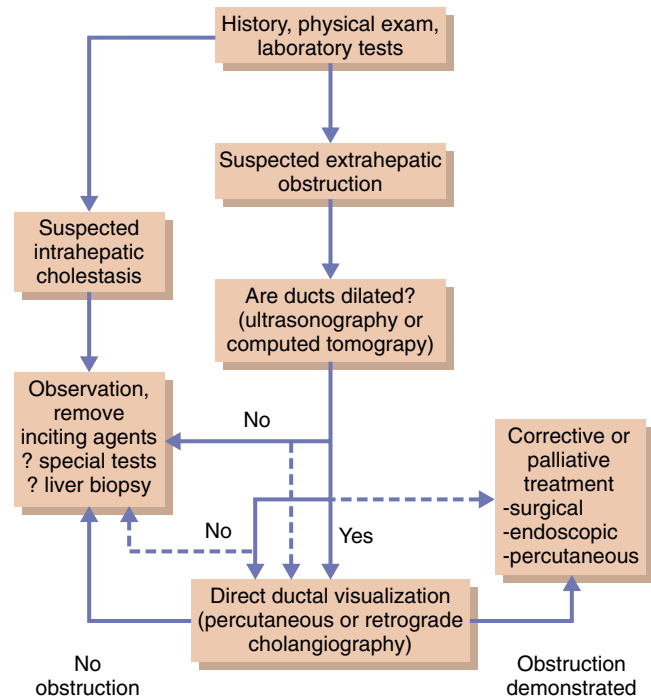

Figure 42-2 Approach to the patient with cholestatic jaundice. The algorithm demonstrates the systematic consideration of the available diagnostic options.

thrombin time, hypoalbuminemia, and clinical features of hepatic dysfunction (i.e., palmar erythema, spider angiomas, gynecomastia, and ascites). An inquiry about the use of drugs known to cause hepatocellular injury, alcohol, risk factors for viral hepatitis, and preexisting liver disease, along with serologic testing for hepatitis (see Chapter 43), may be useful.

A diagnostic approach to jaundice is outlined in Figure 42-2. If extrahepatic obstruction is suspected, noninvasive studies such as ultrasound or computed tomography should be used to determine whether bile ducts are dilated. If dilated ducts are found on noninvasive imaging, direct cholangiography (either endoscopic or radiologic) will provide the most reliable approach to management and potential treatment of cholestatic jaundice. If intrahepatic cholestasis is suggested clinically and extrahepatic obstruction is excluded by noninvasive means or by direct cholangiography, liver biopsy will sometimes be useful in determining the cause of cholestasis.

Prospectus for the Future

Important issues regarding both the diagnosis of and therapy for jaundice remain. A fundamental diagnostic issue is distinguishing obstructive jaundice from intrahepatic diseases. During the past 5 to 10 years, both magnetic resonance cholangiopancreatography and endoscopic ultrasound (EUS) technology have greatly improved. Increasing experience with these modalities and continuing technical advances have reduced dramatically ERCP as a common diagnostic modality. Furthermore, the use of EUS-based techniques to enhance capabilities in therapeutic ERCP is likely to expand.

Another rapidly advancing area involves understanding the molecular mechanisms and regulation of bile secretion both under normal conditions and in the setting of specific causes of jaundice. These insights, as well as new information regarding the genetic predisposition to drug-induced cholestasis, will likely lead to novel therapeutic options to diminish the adverse effects of jaundice as well as provide a means to decrease the incidence of drug-induced cholestatic liver disease.

Acute and Chronic Hepatitis

Rajan Kochar, Aasim M. Sheikh, and Michael B. Fallon

The term *hepatitis* denotes inflammation of the liver. It is applied to a broad category of clinicopathologic conditions that result from the damage produced by viral, toxic, metabolic, pharmacologic, or immune-mediated attack on the liver. The common pathologic features of hepatitis are hepatocellular necrosis, which may be focal or extensive, and inflammatory cell infiltration of the liver, which may predominate in the portal areas or may extend into the parenchyma.

Acute hepatitis implies a condition lasting less than 6 months, culminating either in complete resolution of the liver damage with return to normal liver function and structure or a rapid progression of the acute injury toward extensive necrosis and a fatal outcome. Physical examination is usually unremarkable but may show enlarged, tender liver and icteric mucous membranes. Laboratory evidence of hepatocellular damage in the form of elevated aminotransferase (aspartate aminotransferase [AST] and alanine aminotransferase [ALT]) levels are the hallmark and may show elevations 20- to 100-fold normal values. Independent of the cause of hepatitis and the level of biochemical abnormality, the clinical course may range from subclinical to severe hepatocellular dysfunction, with evidence of impairment of coagulation, marked jaundice, and disturbance of neurologic function (see Chapter 44).

Chronic hepatitis is defined as a sustained inflammatory process in the liver reflected by liver function test abnormalities lasting longer than 6 months and is often difficult to differentiate from acute hepatitis on clinical or histologic criteria alone. Patients are typically asymptomatic and generally have lower aminotransferase abnormalities compared with those with acute hepatitis. Histologically, a diagnosis of chronic hepatitis requires the presence of inflammatory cells in the biopsy but also typically has evidence of significant fibrous deposition, disruption of hepatic lobular architecture, and possibly progression toward cirrhosis.

Acute Hepatitis

The causes of acute hepatitis include viral hepatitis (hepatitis A through E), drugs (prescription, nonprescription, and illicit), alcohol, toxins, autoimmune hepatitis, and Wilson disease. The mechanisms whereby these agents produce hepatic damage include direct toxin-induced necrosis (e.g., acetaminophen, *Amanita phalloides* toxin) and host immune-mediated damage (e.g., viral hepatitis). Massive hepatic necrosis is the dominant process in cases of *Amanita* poisoning, and the clinical course is more aptly described as fulminant hepatic failure (see Chapter 44) than as acute hepatitis. Such a course is less common but well recognized with all other causative agents. **Web Figure 43-1** is an algorithm detailing diagnostic approach to acute hepatitis. 

Acute Viral Hepatitis

ETIOLOGY

Five hepatotropic viruses cause acute viral hepatitis (Table 43-1). Hepatitis viruses A (HAV), B (HBV), C (HCV), D (HDV), and E (HEV) have all been characterized at the molecular level. All are RNA viruses except HBV, which is an enveloped DNA virus. HAV is the most common cause of acute viral hepatitis in the United States, followed by HBV. HBV has been extensively characterized. The complete HBV virion (Dane particle) consists of several components that elicit distinct antibody responses from the host (Fig. 43-1). Clinically relevant is the surface envelope (hepatitis B surface antigen [HBsAg]), a core of partially double-stranded circular DNA (HBV DNA) to which is attached a DNA polymerase, and a nucleocapsid (hepatitis B core antigen [HBcAg] and hepatitis B early antigen [HBeAg]) that encloses the DNA and the polymerase. HCV is the most

Table 43-1 Characteristics of Common Causative Agents of Acute Viral Hepatitis

	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Causative agent	28-nm RNA virus	42-nm DNA virus; core and surface components	30-nm enveloped/ RNA virus	36-nm hybrid particle with HBsAg coat	30- to 32-nm nonenveloped RNA virus
Transmission	Fecal-oral; water-borne or food-borne; sexual transmission	Parenteral inoculation, sexual and vertical; direct contact	Similar to HBV but vertical transmission; poor sexual transmission	Similar to HBV	Similar to HAV
Incubation period	2-6 wk	4 wk-6 mo	5-10 wk	Similar to HBV	2-9 wk
Period of infectivity	2-3 wk in late incubation and early clinical phase	During HBsAg positivity (occasionally only with anti-HBc positivity)	During HCV RNA positivity	During HDV RNA or anti-HDV positivity	Similar to HAV
Onset	Acute	Acute, insidious	Insidious	Acute, insidious	Acute
Massive hepatic necrosis	Rare	Uncommon	Rare	Yes	Yes
Carrier state	No	Yes	No	Yes	No
Chronic hepatitis	No	1% to 10% (90% in neonates)	Common (85%)	Common	No
Cancer	No	Yes	Yes	Yes/No	No
Treatment	Supportive	Supportive Lamivudine in select cases	Interferon- α \pm ribavirin	Treat hepatitis B	Supportive
Prophylaxis	Hygiene, immune serum globulin, vaccine	Hygiene, hepatitis B immune globulin, vaccine	Hygiene	Hygiene, HBV vaccine	Hygiene, sanitation, vaccine

HAV, hepatitis A virus; HBc, hepatitis B core; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus.

Figure 43-1 Schematic diagram of hepatitis B virus (HBV)-related particles in serum and the associated antigens (*in parentheses*). The spheres and filaments consist of only hepatitis B surface glycoproteins (HBsAg). They are 20 nm in diameter and are 10,000-fold greater in concentration than the complete virion (Dane particle: 40 nm diameter).

prevalent hepatitis virus worldwide but is an infrequent cause of symptomatic acute hepatitis. It accounts for most cases of acute hepatitis previously designated non-A, non-B. Cytomegalovirus and Epstein-Barr virus only occasionally cause acute hepatitis. HDV is an incomplete RNA virus that requires HBsAg for transmission from cell to cell; thus it causes hepatitis only in patients with hepatitis B, both acute (HDV co-infection) and chronic (HDV superinfection). Seven to 10% of presumed acute viral hepatitis cases have as yet unidentified cause or causes.

TRANSMISSION

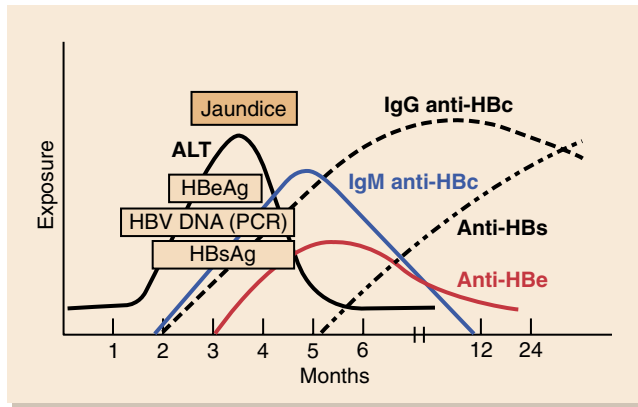

The modes of transmission of the hepatitis viruses are noted in Table 43-1.

HAV and HEV are both excreted in the feces before onset of symptoms and are transmitted by the fecal-oral route (Fig. 43-2). They are thus implicated in most instances of water-borne and food-transmitted infection and in epidemics of viral hepatitis. HEV is linked to outbreaks in East Asia, Central Africa, the Middle East, and Mexico. It has a high rate of attack in young adults in these endemic areas and can lead to fulminant hepatitis, particularly in pregnant women.

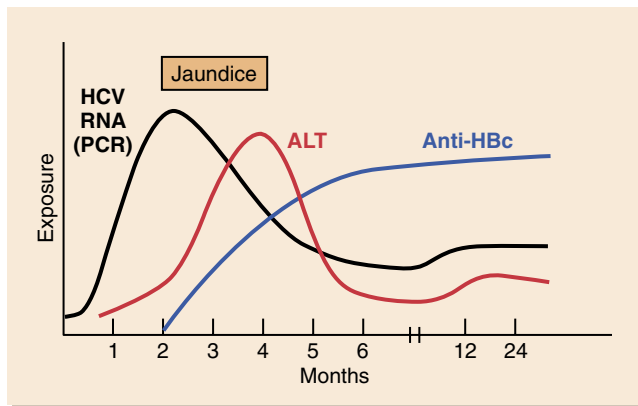

HBV and HCV are both transmitted parenterally. HBV is present in virtually all body fluids and excreta of carriers. Transmission occurs most commonly through blood and blood products, contaminated needles, and sexual contact. High-risk transmission groups include the following: sexual partners of acutely and chronically infected persons, with male homosexuals being at particularly high

risk, intravenous drug abusers, infants of infected mothers (*vertical transmission*), and health professionals. Patients with increased exposure to blood or blood products or with impaired immunity (e.g., patients undergoing dialysis and patients with leukemia, hemophilia, or trisomy 21 syndrome) are also highly susceptible to HBV.

HCV was the main cause of post-transfusion hepatitis before 1992. It is presently the most common cause of hepatitis in intravenous drug users, and it accounts for a substan-

tial number of cases of sporadic, community-acquired hepatitis. The risk for vertical and sexual transmission of hepatitis C is much lower than with hepatitis B.

CLINICAL AND LABORATORY MANIFESTATIONS

Acute viral hepatitis typically begins with a prodromal phase lasting several days and characterized by constitutional and gastrointestinal symptoms including malaise, fatigue, anorexia, nausea, vomiting, myalgia, and headache. A mild fever may be present. Symptoms suggestive of influenza may be prominent. Arthritis and urticaria resembling serum sickness, attributed to immune complex deposition, may be present in 5% to 10% of cases of acute hepatitis B and C. Taste and smell alteration may occur. Jaundice soon appears with bilirubinuria and acholic (pale) stools, often accompanied by an improvement in the patient's sense of well-being. The liver is usually tender and enlarged; splenomegaly is found in about one fifth of patients. Notably, large proportions of all patients with acute viral hepatitis are asymptomatic or have symptoms without jaundice (*anicteric hepatitis*). In such instances, medical attention is often not sought.

Aminotransferases (ALT and AST) are released from the acutely damaged hepatocytes, and serum levels rise often to greater than 20-fold normal and as high as 100-fold normal. An elevated serum bilirubin (>2.5 to 3 mg/dL) results in jaundice and defines *icteric hepatitis*. Values higher than 20 mg/dL are uncommon and approximately correlate with the severity of disease. Elevations in serum alkaline phosphatase are usually limited to 3 times normal levels, except in cases of cholestatic hepatitis. A complete blood cell count most commonly shows mild leukopenia with atypical lymphocytes. Anemia and thrombocytopenia may also be present. The icteric phase of acute viral hepatitis may last days to weeks, followed by gradual resolution of symptoms and laboratory values.

SERODIAGNOSIS

The ability to detect the presence of viral nucleic acids in hepatitis B, C, and D and antigen or antibodies to components of hepatitis A through E has fostered progress in the epidemiology of viral hepatitis. These viral markers are used in the diagnosis of acute viral hepatitis (see Fig. 43-2; Tables 43-2 and 43-3). An etiologic diagnosis is of great importance in planning preventive and public health measures pertinent to the close contacts of infected patients and in evaluating prognosis. Epstein-Barr virus and cytomegalovirus hepatitis may also be diagnosed by the appearance of specific antibodies of the immunoglobulin M (IgM) class. In acute hepatitis B, HBsAg and HBeAg are present in serum. Both are usually cleared within 3 months, but HBsAg may persist in some patients with uncomplicated cases for 6 months to 1 year. Clearance of HBsAg is followed after a variable "window" period by emergence of anti-HBs, which confers long-term immunity. Anti-HBc and anti-HBe appear in the acute phase of the illness, but neither provides immunity. Uncommonly, during the serologic window period, anti-HBc IgM, a marker of active viral replication suggesting recent infection, may be the only evidence of HBV infection. HDV infec-

Table 43-2 Serologic Markers of Viral Hepatitis

Agent	Marker	Definition	Significance
Hepatitis A virus (HAV)	Anti-HAV	Antibody to HAV	—
	IgM type	—	Current or recent infection or convalescence
	IgG type	—	Current or previous infection; conferring immunity
Hepatitis B virus (HBV)	HBsAg	HBV surface antigen	Positive in most cases of acute or chronic infection
	HBeAg	HBe antigen; a component of the HBV core	Transiently positive in acute hepatitis B May persist in chronic infection
	HBV DNA	Infectious viral genomic material	Reflection of presence of viral replication, whole Dane particles in serum, high infectivity
	Anti-HBe	Antibody to HBe antigen	Serum level reflects degree of viral replication; predicts response to therapy Transiently positive in convalescence Persistently present in some chronic cases
	Anti-HBc (IgM or IgG)	Antibody to HBV core antigen	Usually a reflection of low infectivity Positive in all acute and chronic cases
	Anti-HBs	Positive in late convalescence in most acute cases	Antibody to HBV surface antigen and after vaccination
Hepatitis C virus (HCV)	Anti-HCV	Antibodies to a group of recombinant HCV peptides	Positive on average 12 wk after exposure; not protective Persistent in acute, chronic, or past infection
	HCV RNA	Infectious viral genomic material	Reflects ongoing infection, level inversely linked to treatment response
Hepatitis D virus (HDV)	Anti-HDV (IgM or IgG)	Antibody to HDV antigen	Acute or chronic infection seen with positive HBsAg; not protective
	HDV antigen	Viral peptide	IgM and IgG clear in resolving infection
	HDV RNA	Infectious viral genomic material	IgG persists in chronic infection Persists in chronic infection Most reliable test for acute or chronic infection
Hepatitis E virus (HEV)	Anti-HEV (IgM or IgG)	Antibody to HEV antigen	Acute or chronic infection IgM may persist up to 6 months

IgG, immunoglobulin G; IgM, immunoglobulin M.

tion superimposed on HBV infection is most reliably detected by polymerase chain reaction (PCR) testing for HDV RNA. Other possible tests include HDV antigen and anti-HDV (IgM and IgG antibodies). Acute hepatitis C can be detected using a sensitive PCR assay for HCV RNA within 2 weeks of exposure. Serum antibodies to HCV develop within 12 weeks of exposure or within 4 to 5 weeks after biochemical abnormalities are discovered. At onset of symptoms, 30% of patients will be missed if checked by serum enzyme immunoassay (EIA) for HCV antibody alone. Commercial EIAs for hepatitis E to detect both IgM and IgG class antibodies are also available but may lack general sensitivity and specificity. The HEV IgM antibody is present for up to 6 months after exposure.

COMPLICATIONS

Cholestatic Hepatitis

In some patients, most commonly during HAV infection, a self-limited period of cholestatic jaundice may supervene that is characterized by marked conjugated hyperbilirubinemia, elevation of alkaline phosphatase, and pruritus. Investigation may be required to differentiate this condition from mechanical obstruction of the biliary tree (see Chapter 45).

Fulminant Hepatitis

Massive hepatic necrosis occurs in less than 1% of patients with acute viral hepatitis and leads to a devastating and often

fatal condition called *fulminant hepatic failure*. This condition is discussed in detail in Chapter 44.

Chronic Hepatitis

Hepatitis A does not progress to chronic liver disease, although occasionally it has a relapsing course. Persistence of aminotransferase elevation and viral antigens or nucleic acids beyond 6 months in patients with hepatitis B and C suggests evolution to chronic hepatitis, although slowly resolving acute hepatitis may occasionally lead to such test abnormalities for up to 12 months, with eventual complete resolution. Chronic hepatitis is considered in detail later in this chapter.

Rare Complications

Acute viral hepatitis may be followed by *aplastic anemia*, which affects mostly male patients and results in a mortality rate of greater than 80%. Pancreatitis, myocarditis, pericarditis, pleural effusion, and neurologic complications, including Guillain-Barré syndrome, aseptic meningitis, and encephalitis, have also been reported. Cryoglobulinemia and glomerulonephritis are associated with hepatitis B and C, and polyarteritis nodosa with hepatitis B.

MANAGEMENT

All cases of acute hepatitis A, B, and E, unless complicated by fulminant hepatitis, are self-limited (see Table 43-2). Treatment of acute hepatitis C is important, and recent data support that early treatment within 12 weeks of diagnosis with pegylated interferon- α induces high sustained virologic response rates. Studies of antiviral therapy in acute hepatitis B have not shown clear benefit, although many experts advocate use of nucleoside or nucleotide analogues, specifically in the setting of acute liver failure due to hepatitis B. The treatment in all other cases is largely supportive and includes rest, maintenance of hydration, and adequate dietary intake. Most patients show a preference for a low-fat, high-carbohydrate diet. Alcohol should be avoided. Vitamin supplementation is of no proven value, although vitamin K may be indicated if prolonged cholestasis occurs. Nausea can be treated with small doses of metoclopramide and hydroxyzine. Hospitalization is indicated for patients with severe nausea and vomiting and for those with evidence of deteriorating liver function, such as hepatic encephalopathy or pro-

longation of the prothrombin time. In general, hepatitis A and E may be regarded as noninfectious after 3 weeks, whereas hepatitis B is potentially infectious to sexual contacts throughout its course, although the risk is low once HBsAg has cleared.

PREVENTION

Both feces and blood from patients with hepatitis A and E contain virus during the prodromal and early icteric phases of the disease (see Fig. 43-2). Raw shellfish concentrate the HAV from sewage pollution and may serve as vector of the disease. General hygienic measures should include hand washing by contacts and careful handling, disposal, and sterilization of excreta and contaminated clothing and utensils. Close contacts of patients with hepatitis A should receive anti-HAV serum immunoglobulin as soon as possible after exposure. HAV vaccination is appropriate for children and travelers to endemic areas, individuals with immunodeficiency or chronic liver disease, and those with high-risk behaviors or occupations. Recently, a recombinant vaccine for HEV has been shown to be safe and effective in a high-risk population (healthy adults in an endemic area) in a randomized controlled trial, but formal guidelines for its use have not been established. Hepatitis B is rarely transmitted by body fluids other than blood. However, it is highly infectious, and strict adherence to universal precautions is mandatory. Efforts at preventing hepatitis B have involved the use of immunoglobulin-enriched anti-HBs (HBIG) and recombinant HBV vaccines. Postexposure prophylaxis with HBIG after blood or mucosal exposure (e.g., needlestick, eye splash, sexual contacts of patients with acute hepatitis B, neonates born to mothers with acute or chronic infection) should be given within 7 days along with HBV vaccine. Preventive vaccination is currently recommended for high-risk groups and individuals (health care professionals, patients undergoing dialysis, patients with advanced liver disease or hemophilia, residents and staff of custodial care institutions, sexually active homosexual men) and is advocated universally for children.

No accepted prevention strategies are available for HCV. Serum immunoglobulin is not useful for postexposure prophylaxis. The advent of widespread blood product screening for anti-HCV has made post-transfusion hepatitis a rarity.

Alcoholic Fatty Liver and Hepatitis

Alcohol abuse is a major cause of liver disease in the Western world. Three major pathologic lesions resulting from alcohol abuse are (1) fatty liver, (2) alcoholic hepatitis, and (3) cirrhosis. These lesions are not mutually exclusive, and there may be features of all three lesions in the same patient. The first two lesions are potentially reversible and may sometimes be confused clinically with viral hepatitis or gallbladder or biliary tract disease. Alcoholic cirrhosis is discussed in Chapter 45.

MECHANISM OF INJURY

Mechanisms of liver injury caused by alcohol are complex. Ethanol and its metabolites, acetaldehyde and nicotinamide adenine dinucleotide phosphate (NADP), are directly hepatotoxic and cause a large number of metabolic derangements. Induction of cytochrome P-450 (CYP2E1) and cytokine pathways, particularly tumor necrosis factor- α (TNF- α), is also critical in initiating and perpetuating hepatic injury and producing the lesions of alcoholic hepatitis.

Hepatotoxic effects from alcohol vary considerably among individuals. Nevertheless, consumption by men of 40 to 80 g of ethanol per day (one beer or one mixed drink = 10 g of ethanol) for 10 to 15 years carries a substantial risk for the development of alcoholic liver disease, whereas women appear to have a lower threshold of injury. Malnutrition and presence of other forms of chronic liver disease may potentiate the toxic effects of alcohol on the liver, and genetic factors may contribute to individual susceptibility.

CLINICAL AND PATHOLOGIC FEATURES

Alcoholic fatty liver may exhibit as incidentally discovered tender hepatomegaly. Some patients consult a physician because of pain in their right upper quadrant. Jaundice is rare. Aminotransferases are mildly elevated (<5 times normal). Liver biopsy shows diffuse or centrilobular fat occupying most of the hepatocyte.

Alcoholic hepatitis, a severe and prognostically ominous lesion, is characterized by the following histologic triad: (1) Mallory bodies (intracellular eosinophilic aggregates of cytokeratins), usually seen near or around the cell nuclei of hepatocytes; (2) infiltration by polymorphonuclear leukocytes; and (3) a network of interlobular connective tissue surrounding hepatocytes and central veins (*pericellular, perivenular, and perisinusoidal fibrosis*). Patients with this histologic lesion may be asymptomatic or extremely ill with hepatic failure. Anorexia, nausea, vomiting, weight loss, and abdominal pain are common symptoms. Hepatomegaly is present in 80% of patients with alcoholic hepatitis, and splenomegaly is often present. Fever is common, but bacterial infection should always be excluded because patients with alcoholic liver disease are prone to develop pneumonia, as well as infection of the urinary tract and the peritoneal cavity, when ascites is present. Jaundice is commonly present and may be pronounced, with cholestatic features that require differentiation from biliary tract disease

(see Chapter 42). Cutaneous signs of chronic liver disease may be found, including spider angiomas, palmar erythema, and gynecomastia. Parotid enlargement, testicular atrophy, and loss of body hair may be prominent (see Chapter 45). Ascites and encephalopathy may be present and indicate severe disease. The white blood cell count may be strikingly elevated, whereas aminotransferase levels are only modestly increased (range, 200 to 400 U/L), which is an important differentiating feature from other forms of acute hepatitis in which aminotransferases are significantly increased (invariably in the thousands). The ratio of AST to ALT nearly always exceeds 2:1, in contrast to viral hepatitis, in which the aminotransferase levels are usually increased in parallel. Prolonged prothrombin time, hypoalbuminemia, and hyperglobulinemia may be found.

DIAGNOSIS

A history of excessive prolonged alcohol intake is often difficult to obtain from patients with alcoholic liver disease. However, historical, clinical, and biochemical features of alcoholic hepatitis are often sufficient to establish the diagnosis. Many patients suspected or found to imbibe alcohol excessively may have causes other than alcohol for their liver disease (e.g., chronic viral hepatitis). Thus, when other causes of liver disease are suggested and the patient's alcohol intake is uncertain, appropriate serologic testing and a liver biopsy may be needed to establish a diagnosis.

COMPLICATIONS AND PROGNOSIS

Alcoholic fatty liver disease completely resolves with cessation of alcohol intake. Alcoholic hepatitis can also resolve, but more commonly it progresses either to cirrhosis, which may already be present at the time of initial presentation, or to hepatic failure and death. The development of encephalopathy, ascites, deteriorating renal function (*hepatorenal syndrome*), and gastrointestinal bleeding from varices often complicates alcoholic hepatitis (see Chapter 45). Patients with a hepatic discriminant function (DF) higher than 32 ($DF = 4.6 \times [\text{prothrombin time (in seconds)} - \text{control (in seconds)}] + \text{total bilirubin [mg/dL]}$) have high risk for mortality.

TREATMENT

Fatty liver and early stages of alcoholic hepatitis (without extensive fibrosis) are reversible conditions, and therefore complete abstinence from alcohol is the most important step. The cornerstone of treatment of acute alcoholic hepatitis is meticulous supportive care. A high-calorie diet with vitamin (particularly thiamine) and protein supplementation is instituted and may require administration by nasogastric tube in patients with severe anorexia. In the absence of infection, gastrointestinal bleeding, or renal failure, specific patients with alcoholic hepatitis with DF greater than 32 and hepatic encephalopathy may benefit from corticosteroids. Because TNF- α plays a role in the pathogenesis of alcohol induced liver injury, several strategies for TNF- α inhibition have been evaluated as treatment options. Pentoxifylline (an oral TNF- α antagonist) has in a single randomized trial shown benefit in severe alcoholic

hepatitis by diminishing the risk for renal failure. Recent studies using infliximab (monoclonal antibody) and etanercept (TNF- α receptor blocker) in alcoholic hepatitis have shown an increased frequency of severe infections and higher mortality, and these agents are not recommended for therapy.

Drug-Induced and Toxin-Induced Hepatitis

A broad spectrum of hepatic disease may result from a variety of therapeutic drugs or toxins (Table 43-4). The pathophysiologic mechanisms whereby these hepatic lesions are produced are complex. At one end of the spectrum is a predictable, dose-dependent, direct toxic effect on hepatocytes that leads to frank centrilobular hepatocellular necrosis, typical of acetaminophen and carbon tetrachloride toxicity. Other reactions are generally not predictable and usually occur for unknown reasons in susceptible persons (*idiosyncratic drug reaction*). In some instances, genetically determined differences in pathways of hepatic drug metabolism may result in metabolites with greater toxic potential. Classic examples include viral hepatitis–like reactions (halothane and isoniazid), cholestatic hepatitis (chlorpromazine),

granulomatous hepatitis (allopurinol), chronic hepatitis (methyldopa), and pure cholestasis without inflammation or hepatocellular necrosis (estrogens and androgens). Immune-mediated hepatic damage may contribute in some cases, possibly when the drugs or their metabolites act as a hapten on the surface of hepatocytes. A few important classes of drugs that cause hepatitis are discussed here.

ANALGESICS

Acetaminophen overdose is the leading cause of acute liver failure in the United States, accounting for 40% to 50% of all cases, and carries a mortality rate close to 30%. Acetaminophen is metabolized by the hepatic cytochrome P-450 system to a potentially toxic metabolite that is subsequently rendered harmless through conjugation with glutathione. When massive doses are taken (>10 to 15 g), the formation of excess toxic metabolites depletes the available glutathione and produces necrosis. Acetaminophen overdose, commonly taken in a suicide attempt, leads to nausea and vomiting within a few hours. These symptoms subside and are followed in 24 to 48 hours by clinical and laboratory evidence of hepatocellular necrosis (raised aminotransferase levels) and hepatic dysfunction (prolonged prothrombin time and hepatic encephalopathy). Similar findings may occur with therapeutic doses of acetaminophen in patients with chronic alcoholism or malnutrition. Extensive liver necrosis may lead to fulminant hepatic failure and death. In a patient with nonstaggered overdose, a serum acetaminophen level should be drawn 4 to 24 hours after ingestion. If plotted on a treatment nomogram of plasma drug concentration against time, it can predict the severity of outcome and need for therapy. Treatment with *N*-acetylcysteine given orally (140-mg/kg bolus followed by 70 mg/kg \times 17 doses) or intravenously, thought to promote hepatic glutathione synthesis, may be life saving.

Nonsteroidal anti-inflammatory drugs (NSAIDs) as a class are an important cause of drug-induced liver disease. *Salicylates* cause dose-dependent hepatocellular injury that is usually clinically mild and easily reversible. *Diclofenac*, one of the most commonly prescribed NSAIDs worldwide, has been linked to asymptomatic elevation of aminotransferases, acute hepatitis, and fulminant hepatic failure. *Sulindac* is considered the most likely NSAID to produce hepatic injury and causes a damage spectrum ranging from hepatocellular to mixed to pure cholestatic injury. Whether the newer cyclo-oxygenase-2–selective NSAIDs have a lower risk for hepatotoxicity is uncertain.

ANTIBIOTICS AND ANTIVIRALS

Antimicrobials as a class are the most frequently incriminated agents causing drug-induced liver injury. Amoxicillin–clavulanic acid is the leading cause of antibiotic-related liver injury and results in a cholestatic hepatitis. Men appear to be more susceptible than women. Other common agents include nitrofurantoin, isoniazid, trimethoprim-sulfamethoxazole, and fluoroquinolones. Isoniazid, as a single-drug prophylaxis against tuberculosis, commonly produces raised serum aminotransferase levels in 20% of patients. This effect appears to be transient and self-limited in most patients. However, a 1% incidence exists of clinical hepatitis,

Table 43-4 Classification of Drug-Induced Liver Disease

Category	Examples
Predictable hepatotoxins with zonal necrosis	Acetaminophen
Nonspecific hepatitis	Carbon tetrachloride
	Aspirin
	Oxacillin
Viral hepatitis-like reactions	Herbs (chaparral, germander)
	Halothane
	Isoniazid
Cholestasis	Phenytoin
	Estrogens
	Erythromycin
Noninflammatory	Amoxicillin, clavulanic acid
Inflammatory	17 α -substituted steroids
	Chlorpromazine
Fatty liver: large droplet	Antithyroid agents
	Ethanol
Fatty liver: small droplet	Corticosteroids
	Amiodarone
Chronic hepatitis	Allopurinol
	Methyldopa
Tumors	Nitrofurantoin
	Estrogens
Vascular lesions	Vinyl chloride
	6-Thioguanine
	Anabolic steroids
Fibrosis	Herbs (senna, comfrey)
	Methotrexate
Granulomas	Allopurinol
	Sulfonamides

which progresses to fatal hepatic necrosis in 10% of affected patients. Individual and age-related differences in hepatic acetylation of potentially toxic isoniazid metabolites may be important in this injury. Thus, the incidence of severe hepatic damage increases with age such that significant elevation of aminotransferase levels in persons who are older than 35 years is an indication for discontinuing the drug. Erythromycin is an established agent causing cholestatic injury. Trimethoprim-sulfamethoxazole characteristically causes cholestatic or mixed injury. A large number of agents used to treat HIV infection have been linked with hepatic injury of various forms. Important among these agents are nevirapine, ritonavir, and indinavir.

CENTRAL NERVOUS SYSTEM AGENTS

Central nervous system agents are second only to antimicrobials as a frequent cause of drug-induced liver injury. Important categories are anticonvulsants and anesthetics. Other common agents include duloxetine, bupropion, and fluoxetine. Among anticonvulsants, sodium valproate, phenytoin, carbamazepine, and lamotrigine are the most common drugs causing liver injury. Phenytoin and carbamazepine have been implicated in an *antiepileptic hypersensitivity syndrome*, characterized by a triad of rash, fever, and hepatocellular injury that may lead to fulminant hepatic failure. Lymphadenopathy and a mononucleosis-like picture with atypical lymphocytes may be present. Renal and pulmonary involvement may also occur. Historically, the anesthetic agent halothane caused an uncommon acute viral hepatitis-like reaction several days after exposure in susceptible persons. Hepatic injury was caused in part by an allergic response to hepatic neoantigens produced by halothane metabolism, and the severity of this reaction increased with repeated exposure. Newer, commonly used halogenated anesthetic agents (e.g., isoflurane, enflurane) are hepatotoxic in a much smaller number of patients, though cross-sensitivity does exist.

HERBS

Herbal supplements are taken throughout the world, and about \$5 billion per year is spent in the United States alone on herbal agents. Incorrectly considered to be safe because they are *natural*, many herbs are hepatotoxic. *Senecio*, *Heliotropium*, *Crotalaria*, and comfrey contain pyrrolizidine alkaloids that cause hepatic veno-occlusive disease. Hepatotoxicity ranging from mild hepatitis to massive necrosis and fulminant hepatic failure has been associated with the use of chaparral, germander, pennyroyal oil, mistletoe, valerian root, comfrey, and Ma huang. Milk thistle, often taken by patients with chronic hepatitis and cirrhosis, has not been associated with hepatotoxicity, but its benefit is undefined because of a lack of controlled studies.

Chronic Hepatitis

Chronic hepatitis is defined as a hepatic inflammatory process that fails to resolve after 6 months and, in those with acute viral hepatitis, by persistence of serum viral antigens and nucleic acids beyond a similar period.

ETIOLOGY

Acute viral hepatitis can ultimately lead to chronic hepatitis, with the notable exceptions of HAV and HEV. Nonalcoholic steatohepatitis (NASH) is now considered the most frequent cause of chronic hepatitis in the United States and Western Europe. Several drugs may produce chronic hepatitis, the best recognized being methyl dopa. In contrast to acute hepatitis, an etiologic agent is sometimes difficult to identify in cases of chronic hepatitis. The pathogenesis of these idiopathic forms may represent quiescent autoimmune disease, undetected past drug-induced injury or NASH, antibody-negative viral infections, or misdiagnosed cholestatic liver injury (e.g., primary biliary cirrhosis, primary sclerosing cholangitis).

CLASSIFICATION

Current classification of chronic hepatitis is based on the *etiologic agent* responsible for disease, the *grade* of injury (determined by the numbers and location of inflammatory cells), and the *stage* of disease on liver biopsy (determined by the degree, location, and distortion of normal architecture by fibrosis). This classification allows integration of knowledge of the natural history of specific causes with histologic features of hepatic damage to assess the severity and prognosis of the process. Thus, in general, biochemical and serologic studies along with liver biopsy are used in the diagnosis and management of chronic hepatitis.

Chronic Viral Hepatitis

Chronic hepatitis B follows acute hepatitis B in 5% to 10% of adults in the United States. HBV infection without evidence of any liver damage may persist, resulting in asymptomatic or *healthy* hepatitis B carriers. In Asia and Africa, many such carriers appear to have acquired the virus from infected mothers during infancy (vertical transmission). Patients who are HBsAg and HBeAg positive and have high serum HBV DNA (>20,000 IU/mL or >100,000 copies/mL), coupled with increased serum aminotransferases (ALT, 2 times normal) are in a high replicative phase (see Table 43-3). In contrast, patients in a low replicative phase are HBsAg and anti-HBe positive, have low serum HBV DNA (<20,000 IU/mL or <100,000 copies/mL), and near-normal or normal aminotransferases. Such patients can go into high replicative phase and exhibit acute or chronic hepatitis B. A subgroup of patients with chronic hepatitis B may be HBeAg negative but still be in a high replicative phase, as evidenced by high HBV DNA levels in serum. These patients have a precore or core mutant form of hepatitis B. Patients infected with HBV in high replicative phase are at highest risk for developing cirrhosis and hepatocellular carcinoma. Such patients and those who have already progressed to early cirrhosis are the primary targets of anti-HBV therapy. Currently, seven drugs are approved as single agents for treating hepatitis B in the United States, including injectable interferon- α (pegylated and nonpegylated) and oral nucleoside or nucleotide analogues (e.g., lamivudine, telbivudine, adefovir, tenofovir, entecavir). All these drugs lead to suppression of serum viral DNA to a

variable amount as well as seroconversion from HBeAg to anti-HBe in 10% to 30% of patients. Resistance to the oral agents with prolonged use is a major concern and is highest for lamivudine among the current agents. Interferon, on the other hand, has numerous side effects and may not be well tolerated. In general, patients without cirrhosis with active replication may be treated with interferon- α or more commonly with nucleoside and nucleotide analogues. In patients with cirrhosis, interferon- α is not an appropriate therapy, and long-term nucleoside or nucleotide analogue therapy is recommended in patients even with lower levels of viral replication.

Chronic hepatitis C develops in up to 75% of individuals acutely exposed to HCV and is estimated to affect 1.8% of the U.S. population. More than 20% of these patients may develop cirrhosis in about 30 years. Hepatitis C has six major genotypes, of which, in the United States, genotype 1 is the most common, followed by genotypes 2 and 3. Genotype has no impact on course of illness but is the most important determinant of successful outcome of treatment. Chronic hepatitis C is currently treated with a combination of pegylated interferon- α injections and oral ribavirin. Durable suppression of viral activity (sustained virologic response [SVR], defined as undetectable HCV RNA 6 months after therapy) occurs in as many as 80% of all patients infected with genotype 2 or 3 when treated for 24 weeks and in 50% of those infected with genotype 1 when treated for 48 weeks. Recent studies indicate that patients with a rapid virologic response (RVR, defined as undetectable HCV RNA at 4 weeks, particularly genotypes 2 or 3, may be treated with a shorter duration of therapy. Both interferon and ribavirin have numerous side effects, which contraindicates their use in 50% or more of patients currently infected with HCV. Of the remaining 50%, therapy is usually advised for patients with favorable genotypes or those who demonstrate moderate to high fibrosis on liver biopsies. Newer agents in development for hepatitis C include protease inhibitors as part of a new class of agents called *specifically targeted antiviral therapy for hepatitis C* (STAT-C). Successful treatment of chronic hepatitis B and C may lead to a decrease in hepatic inflammation and fibrosis and to a reduced risk for progression to cirrhosis and the development of hepatocellular carcinoma.

Autoimmune Hepatitis

Autoimmune liver disease has several forms; however, the typical disease occurs in young women and is characterized by significant hepatic inflammation with a preponderance of plasma cells and fibrosis. The presence of hypergammaglobulinemia, as well as antinuclear antibody (ANA) or anti-smooth muscle antibody (anti-SMA), represents the most common classic or type 1 variant. Type 2 autoimmune hepatitis is characterized by the presence of anti-liver-kidney microsomal antibodies (anti-LKM) and the absence of ANA and anti-SMA. Type 2 autoimmune hepatitis occurs most commonly in girls and young women. A third type of autoimmune hepatitis with antibodies to soluble liver antigen or liver-pancreas antigen (anti-SLA/LP) is no longer considered a unique entity because these antibodies can be found in type 1 and type 2 autoimmune hepatitis as well. There are

no pathognomonic features of autoimmune hepatitis, and the diagnosis is made by a combination of factors. Recently, a simplified diagnostic algorithm that includes the presence of autoantibodies, hypergammaglobulinemia, typical liver histology, and absence of viral hepatitis has proved useful in identifying patients with autoimmune hepatitis. Extrahepatic manifestations that include amenorrhea, rashes, acne, vasculitis, thyroiditis, and Sjögren syndrome are common. Evidence of hepatic failure and the presence of chronic disease on biopsy at the time of diagnosis are frequent. Indications for treatment include abnormal liver function tests and significant hepatic inflammation on biopsy. Corticosteroids are the mainstay of treatment, typically in combination with azathioprine to minimize long-term use of high-dose steroids. This regimen is efficacious in most patients (>80%) and, in many instances, prolongs survival.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD), a term that encompasses steatosis (fatty liver), nonalcoholic steatohepatitis (NASH), and cirrhosis secondary to NASH, has become increasingly recognized as the most common reason for abnormal liver function tests among adults in the United States and Western Europe. Although NAFLD most commonly occurs in persons who are overweight, have diabetes, and have hyperlipidemia, it can also occur in persons of normal weight. Estimates indicate that about 30 million Americans have NAFLD, and of these, 8.6 million have NASH, with nearly 20% having signs of advanced disease (i.e., bridging fibrosis, cirrhosis) on histologic examination. Noninvasive modalities for diagnosis of NAFLD include radiologic imaging and serum markers of hepatic fibrosis. However, liver biopsy with histologic examination is the most accurate test for determining presence of NASH and defining the degree of fibrosis. Histologic criteria for NASH include macrovesicular fatty infiltration (mainly triglyceride); inflammation, including polymorphonuclear leukocytes; and hepatocyte injury (ballooning degeneration or necrotic hepatocytes), with or without fibrosis. The pathogenesis is still under investigation, but insulin resistance plays an essential role leading to lipolysis and hyperinsulinemia, upregulation of cytochrome P-450 pathways, and impaired mitochondrial and peroxisomal fatty acid oxidation. This state leads to excessive oxidative stress, cytokine induction, and inflammation. Weight reduction and exercise are established to improve liver histology in NASH. Clinical trials assessing lipid-lowering agents and drugs that improve insulin resistance (e.g., thiazolidinediones and metformin) are ongoing, but efficacy and safety are not yet established.

Genetic and Metabolic Hepatitis

Wilson disease and α_1 -antitrypsin deficiency generally occur before the age of 35 years, and a family history of liver disease

may be present. Wilson disease is caused by mutation in the *WD* gene and is autosomal recessive. A resultant accumulation of copper in various tissues occurs, including liver, brain, and the corneas, with neuropsychiatric signs and symptoms and liver disease ranging from steatosis to chronic hepatitis to fulminant liver failure. Diagnostic evaluation for Wilson disease includes low serum ceruloplasmin and high urinary and hepatic copper levels. Therapy is indefinite and includes copper chelation, typically with trientine, followed by diminishing copper absorption with zinc supplementation. α_1 -antitrypsin deficiency is also inherited as an autosomal recessive disorder. The normal gene product is

designated as PiM, and the deficiency variants are PiS (50% to 60% α_1 -antitrypsin expression) and PiZ (10% to 20% α_1 -antitrypsin expression). The most common carrier phenotypes are PiMS and PiMZ, and the disease phenotypes are PiZZ, PiSS, and PiSZ. A low serum α_1 -antitrypsin level and diastase-positive staining of hepatocellular inclusions on liver biopsy suggest α_1 -antitrypsin deficiency. Phenotypic testing has been considered the gold standard for the diagnosis. However, genotypic testing is now available. Intravenous pooled human plasma α_1 -antitrypsin and recombinant gene therapy are options for patients with emphysema but are not useful for patients with liver disease.

Prospectus for the Future

A better understanding of the molecular genetics and replication cycles of hepatitis B and C, as well as the role of cell-mediated and humoral immunity (or lack thereof) in various forms of chronic viral and nonviral hepatitis, has led to an expansion of therapeutic options for patients with these diseases. Therapeutic vaccines designed to boost humoral immunity against specific HCV and HBV epitopes are currently in clinical trials. Several STAT-C agents that target specific enzymes involved in hepatitis C replication, including protease inhibitors such as telaprevir and boceprevir and other non-nucleoside inhibitors, are in various stages of development, including ongoing clinical trials. At least five new drugs targeting hepa-

titis B replication are on the horizon. The next step is to assess, in combination, the numerous anti-HBV drugs, both old and new, to enhance their efficacy while diminishing the risk for viral resistance. Increasing experience with the use of newer immunosuppressive agents with novel mechanisms of action such as mycophenolate mofetil, tacrolimus, and cyclosporine opens avenues for studying these agents in patients with autoimmune hepatitis. Finally, recognition of the central role of TNF- α in the pathogenesis of alcoholic hepatitis has led to investigation of a significant number of TNF- α antagonists, currently in use for rheumatologic and autoimmune diseases, in this disorder.

Fulminant Hepatic Failure

Brendan M. McGuire and Michael B. Fallon

Fulminant hepatic failure (FHF) is defined as the onset of encephalopathy occurring within 8 weeks of the onset of jaundice in a patient with hepatic injury and no prior history of liver disease. *Late-onset hepatic failure* is recognized as the development of encephalopathy in patients between 8 and 24 weeks after the onset of jaundice. The pathogenesis of FHF involves severe widespread hepatic necrosis, commonly resulting from acute viral infection with hepatitis A, B, C, D, or E viruses (see Chapter 43). It may also result from exposure to hepatotoxins such as acetaminophen, isoniazid, halothane, valproic acid, or mushroom toxins (e.g., those of *Amanita phalloides*). Reye syndrome (a disease predominantly of children) and acute fatty liver of pregnancy, both of which are characterized by microvesicular fatty infiltration and little hepatocellular necrosis, often resemble FHF. Other rare causes of FHF include Wilson disease, hepatic ischemia, autoimmune hepatitis, and malignancy. In a significant number of patients with FHF, no cause is found, although a viral infection is usually presumed to be responsible (**Web Figs. 44-1 and 44-2**).

Diagnosis

The diagnosis of FHF is based on the combination of hepatic encephalopathy and liver failure. It is characterized biochemically by significantly elevated serum bilirubin and transaminase levels and marked prolongation of the prothrombin time.

Treatment

Treatment of FHF remains supportive because the underlying cause of liver failure is rarely treatable. However, most processes that result in widespread liver cell necrosis and FHF are transient events, and liver cell regeneration with recovery of liver function often occurs if patients do not die from the complications of liver failure in the interim. Meticulous supportive treatment in an intensive care unit setting has been shown to improve survival. Patients with FHF should be treated in centers with experience with this disease and with a liver transplantation program. Numerous com-

plications result from FHF, and thorough identification and treatment of each are essential (Table 44-1).

Hepatic encephalopathy is often the first and most dramatic sign of liver failure. The pathogenesis of hepatic encephalopathy remains unclear. Hepatic encephalopathy that accompanies FHF differs from that associated with chronic liver disease in two important aspects: (1) it often responds to therapy only when liver function improves, and (2) it is frequently associated with two other potentially treatable causes of coma: hypoglycemia and cerebral edema. Therapy for hepatic encephalopathy in FHF differs slightly from the principles outlined in Chapter 45. Lactulose may be given orally, per nasogastric tube, or rectally, but the oral route should not be used if the patient is at risk for aspiration. Lactulose should be discontinued if no improvement is noted after several doses are administered. Intubation is often necessary to protect the airway from aspiration and to allow ventilation in patients with advanced encephalopathy.

Cerebral edema, the pathogenesis of which is unknown, is a common complication and the leading cause of death in FHF. Clinically, differentiating FHF from hepatic encephalopathy is difficult, and computed tomography of the head is often unreliable. Therefore, measuring intracranial pressure is important. The goal is to maintain an intracranial pressure of less than 20 mm Hg. Management includes control of agitation, head elevation of 20 to 30 degrees, hyperventilation, administration of mannitol, barbiturate-induced coma, and urgent liver transplantation.

Hypoglycemia is a common complication of liver failure resulting from impaired hepatic gluconeogenesis and insulin degradation. All patients should receive 10% glucose intravenous infusions with frequent monitoring of blood glucose levels. Other metabolic abnormalities commonly occur, including hyponatremia, hypokalemia, respiratory alkalosis, and metabolic acidosis. Thus, frequent monitoring of blood electrolytes and pH is indicated.

Bleeding occurs frequently and is commonly caused by gastric erosions and impaired synthesis of clotting factors. All patients should receive vitamin K and prophylactic gastric acid suppression. Fresh-frozen plasma should be used if clinically significant bleeding occurs or if major pro-

Table 44-1 Management of Selected Problems in Fulminant Hepatic Failure

Complications	Pathogenesis	Management
Hepatic encephalopathy	Liver failure	Search for treatable causes (e.g., hypoglycemia, drugs used for sedation, sepsis, gastrointestinal bleeding, electrolyte imbalance, decreased PO_2 , increased PCO_2); lactulose
Cerebral edema	Unknown	Elevate head of bed 20-30 degrees; hyperventilate (PCO_2 , 25-30 mm Hg); mannitol, 0.5-1 g/kg intravenous bolus over 5 min; pentobarbital infusion; urgent liver transplantation
Coagulopathy and gastrointestinal hemorrhage	Decreased synthesis of clotting factors Gastric erosions	Vitamin K; fresh-frozen plasma if actively bleeding and for prevention of bleeding; gastric acid suppression
Hypoglycemia	Decreased gluconeogenesis Decreased insulin degradation	Intravenous 10% dextrose, monitor every 2 hr; 30%-50% dextrose may be needed
Agitation	May be caused by: Encephalopathy Intracranial pressure Hypoxemia	Search for treatable causes (e.g., PO_2 , skin ulcers, lacerations, abscesses); soft restraints; if severely agitated and a concern for injury, consider sedation along with mechanical ventilation to protect airway
Infection	Liver failure and invasive monitoring	Surveillance cultures and low threshold for empiric antibiotics

PCO_2 , partial pressure of carbon dioxide; PO_2 , partial pressure of oxygen.

cedures, including intracranial pressure monitoring and central line placement, are performed.

Infection is one of the leading causes of death in FHF. As many as 80% of patients with FHF develop infection (80% bacterial, 20% fungal). Patients are at higher risk for infection as a result of impaired immunity resulting from liver failure and of the need for invasive monitoring. Severe infection may occur without fever or leukocytosis. Therefore, frequent cultures and a low threshold for beginning antibiotics are required.

Hepatic Transplantation

Hepatic transplantation (see Chapter 45) has been performed with success in patients with FHF and is the treatment of choice for patients who appear unlikely to recover spontaneously. Because of the urgent need for transplantation, potential candidates should be transferred to trans-

plantation centers before significant complications develop (e.g., coma, cerebral edema, hemorrhage, infection). Transplantation is usually indicated in patients with severe encephalopathy or coagulopathy.

Prognosis

The cause of FHF and the degree of hepatic encephalopathy are important in determining prognosis. Patients with FHF from acetaminophen overdose or viral hepatitis A or B have a better survival rate than do patients with Wilson disease or without a known cause. The short-term survival rate for patients with FHF in coma is 20% without liver transplantation. The 1-year survival rate of patients with FHF after liver transplantation is 80% to 90%. Patients who survive without a transplant also have an excellent prognosis because liver tissue usually regenerates normally, regardless of the cause of FHF.

Prospectus for the Future

The development of effective therapy for FHF has been an ongoing focus of clinical and basic investigators for many years. Recently, a significant number of advances suggest the potential for improved treatments. Specifically, basic insights into the mechanisms of hepatocyte cell death and regeneration have defined specific pathways that may be manipulated to decrease hepatocyte loss and improve hepatocyte regeneration in

response to acute injury. Such therapies are effective in animal models and are likely to be explored in humans. In addition, ongoing clinical trials with the use of hypothermia in FHF suggest that cooling may decrease cerebral injury and improve overall survival. Multicenter trials will be needed to confirm the efficacy of such an approach.

Cirrhosis of the Liver and Its Complications

Rajan Kochar, Miguel R. Arguedas, and Michael B. Fallon

Definition and Etiopathogenesis

Cirrhosis is the irreversible end result of a variety of inflammatory, toxic, metabolic, and congestive insults to the liver. These insults lead to the formation of interconnecting bands of fibrous tissue that surround *nodules* consisting of foci of regenerating hepatocytes. These regenerative nodules may be small (<3 mm; *micronodular cirrhosis*), a typical feature of alcoholic cirrhosis, or large (>3 mm; *macronodular cirrhosis*), more commonly seen as a sequela to chronic active hepatitis. The disruption of the normal hepatic lobular architecture distorts the vascular bed and contributes to portal hypertension and intrahepatic shunting. Normal hepatocyte function is disturbed by the resulting inadequacy of blood flow and ongoing inflammatory, toxic, or metabolic damage to hepatocytes. In addition, disturbances in cellular regulation and differentiation during hepatocyte regeneration may lead to the development of hepatocellular carcinoma. Therefore, the clinical features of cirrhosis and its complications arise from portal hypertension, hepatocellular dysfunction, and altered cellular differentiation (Table 45-1). These disturbances are associated with significant morbidity and mortality, with more than 25,000 deaths occurring annually in the United States as a result of chronic liver disease. Alcohol consumption, hepatitis C virus infection, and nonalcoholic fatty liver disease are the most common causes of cirrhosis in Western industrialized nations, whereas hepatitis B is a major cause in Asia and in developing countries. Other important causes include biliary cirrhosis (primary and secondary), autoimmune hepatitis, cardiac cirrhosis, inherited diseases, and metabolic disorders. Cryptogenic cirrhosis remains a diagnosis of exclusion. Chronic active hepatitis, nonalcoholic fatty liver disease, and α_1 -antitrypsin deficiency are discussed in Chapter 43. Hemochromatosis and Wilson disease are covered in Chapter 63. Common and

uncommon conditions that may lead to cirrhosis are listed in Table 45-2.

Diagnosis

Patients with cirrhosis are often asymptomatic, and the diagnosis is incidentally established at the time of physical examination, laboratory testing, or radiologic testing for unrelated purposes. Alternatively, patients may present with specific complications of cirrhosis such as variceal bleeding, ascites, spontaneous bacterial peritonitis, and hepatic encephalopathy.

Liver biopsy is considered the gold standard for the diagnosis of cirrhosis. In most cases, however, the diagnosis can be made reliably by a combination of clinical, laboratory, and radiologic findings, and liver biopsy is done more often to assess the stage and severity of disease, prognosis, and response to treatment.

CLINICAL FEATURES

Symptoms are often nonspecific and include fatigue, malaise, weakness, weight gain or weight loss, anorexia, nausea, increased abdominal girth, and abdominal discomfort. Physical findings include jaundice, abnormal liver span or consistency, splenomegaly, ascites, lower extremity edema, spider angiomas, palmar erythema, nail changes (Terry nails—proximal nail plate discoloration; and Muehrcke lines—white horizontal lines), gynecomastia, caput medusae, asterix, and testicular atrophy. Table 45-1 highlights the pathogenetic mechanisms underlying these signs and symptoms.

LABORATORY FINDINGS

Hepatocellular dysfunction leads to impaired protein synthesis (hypoalbuminemia and prolongation of prothrombin

Table 45-1 Clinical Features and Pathogenesis of Cirrhosis

Signs and Symptoms	Pathogenesis
Constitutional	
Fatigue, anorexia, malaise, weakness, weight loss	Liver dysfunction
Cutaneous	
Spider angiomas, palmar erythema	Altered estrogen and androgen metabolism
Jaundice	Decreased bilirubin excretion
Caput medusae	Portosystemic shunting due to PH
Endocrine	
Gynecomastia, testicular atrophy, decreased body hair in men; decreased libido virilization and menstrual irregularities in women	Altered estrogen and androgen metabolism
Gastrointestinal	
Abdominal pain	Hepatomegaly, hepatocellular carcinoma
Abdominal swelling	Ascites due to PH
Gastrointestinal bleeding	Variceal hemorrhage due to PH
Hematologic	
Anemia, leukopenia, thrombocytopenia	Hypersplenism secondary to PH
Ecchymosis	Decreased synthesis of coagulation factors
Neurologic	
Altered sleep pattern, somnolence, confusion, asterixis	Hepatocellular dysfunction and portosystemic shunting
PH, portal hypertension.	

time), hyperbilirubinemia, low blood urea nitrogen levels, and elevated serum ammonia levels. *Portal hypertension* is responsible for thrombocytopenia and leukopenia resulting from splenic sequestration (hypersplenism). Anemia may result from hypersplenism or gastrointestinal blood loss. Patients with ascites may have dilutional hyponatremia. The levels of liver enzymes may vary with the etiology and stage of cirrhosis.

RADIOLOGIC FEATURES

Current radiologic modalities include ultrasound (with and without Doppler of the portal and hepatic venous vasculature), computed tomography, and magnetic resonance imaging. Imaging findings supportive of the diagnosis of cirrhosis include relative enlargement of the left hepatic and caudate lobes as a result of right lobe atrophy, surface nodularity, and features of portal hypertension such as ascites, intra-abdominal varices, and splenomegaly. These findings in the presence of clinical and laboratory features of cirrhosis preclude the need for a diagnostic liver biopsy, and it is considered only when the cause of liver disease is in doubt.

Major Complications of Cirrhosis

The major sequelae of cirrhosis are as follows:

- As a consequence, predominantly of *hepatocellular dysfunction*:
 - Jaundice
 - Coagulopathy
 - Hypoalbuminemia
- As a consequence, predominantly of *portal hypertension*:
 - Variceal hemorrhage
 - Ascites
 - Spontaneous bacterial peritonitis
 - Hepatorenal syndrome
 - Hepatic encephalopathy
 - Hepatopulmonary syndrome
- Hepatocellular carcinoma

The pathophysiologic interrelationships among these complications are shown diagrammatically in Figure 45-1.

HEPATOCELLULAR DYSFUNCTION

Cirrhosis results in impaired synthesis of proteins by hepatocytes, which leads to disturbances in the conjugation and excretion of bilirubin, hypoalbuminemia, deficient production of coagulation factors, and diminished capacity for hepatic detoxification (see Chapters 41 and 44).

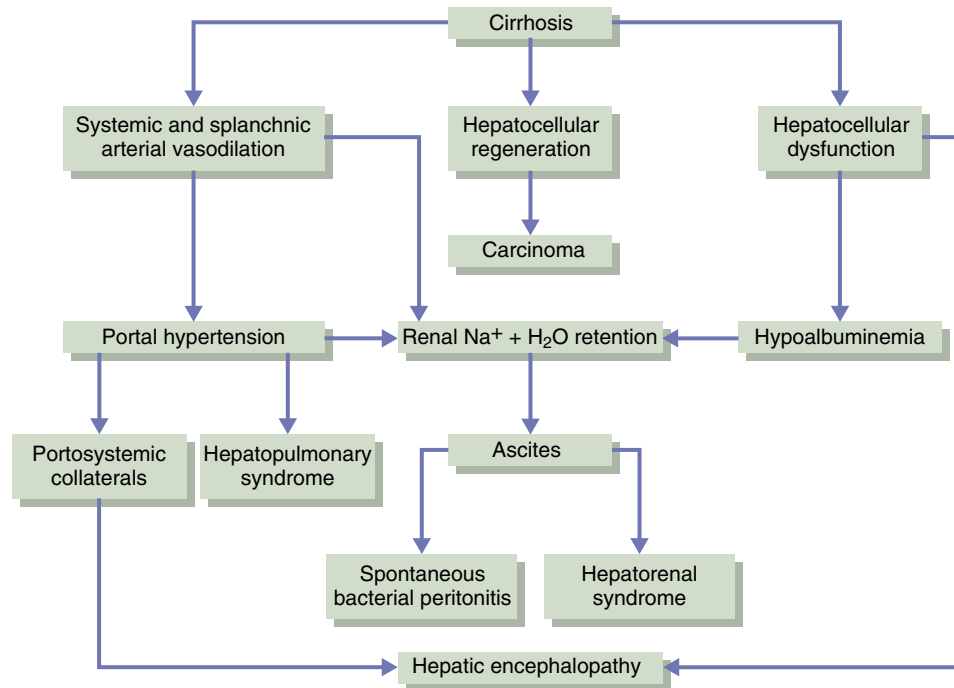

Figure 45-1 Inter-relationships among the complications of cirrhosis.

PORTAL HYPERTENSION

The normal portal venous pressure is low (5 to 10 mm Hg), and the hepatic venous pressure gradient (HVPG), which reflects sinusoidal pressure, is less than 5 mm Hg. In cirrhosis, the distortion of hepatic architecture by fibrous tissue and regenerative nodules, as well as a dynamic component caused by an increase in intrahepatic vascular tone, leads to increased resistance to portal venous flow, resulting in increased portal venous pressure (>10 mm Hg). The HVPG is measured using a transvenous approach by subtracting free hepatic venous pressure from the wedged hepatic venous pressure.

Although cirrhosis is the most important cause of portal hypertension, any process leading to increased resistance to portal blood flow into (presinusoidal) or through (sinusoidal) the liver or to hepatic venous outflow from the liver (postsinusoidal) may result in portal hypertension (Table 45-3). In addition, cirrhosis is associated with increased cardiac output, which leads to greater splanchnic blood flow, further aggravating portal hypertension. It is important to recognize that the HVPG is reliably increased only in sinusoidal portal hypertension.

In an attempt to decompress the portal system, venous collaterals form between the portal and systemic circulations. Major sites of collateral vessel formation include the gastroesophageal junction, retroperitoneum, rectum, and falciform ligament of the liver (abdominal and periumbilical collaterals). Clinically, the most important collaterals are those connecting the portal vein to the azygos vein through dilated, tortuous veins (varices) in the submucosa of the gastric fundus and esophagus.

Table 45-3 Causes of Portal Hypertension

Increased Resistance to Flow

Presinusoidal

Extrahepatic

- Portal or splenic vein occlusion (thrombosis, sclerosis, tumor)

Intrahepatic

- Schistosomiasis
- Congenital hepatic fibrosis
- Sarcoidosis

Sinusoidal

- Cirrhosis (many causes)
- Alcoholic hepatitis

Postsinusoidal

Intrahepatic

- Veno-occlusive disease

Extrahepatic

- Budd-Chiari syndrome
- Cardiac causes: constrictive pericarditis

Increased Portal Blood Flow

- Splenomegaly not caused by liver disease
- Arteriportal fistula

Variceal Hemorrhage

Gastroesophageal varices may develop when the portal pressure gradient exceeds 10 mm Hg, and the risk for variceal rupture leading to hemorrhage occurs when the gradient is greater than 12 mm Hg. Hemorrhage develops in 10% to 30% of patients every year, and each episode of variceal hemorrhage is associated with a mortality rate as high as

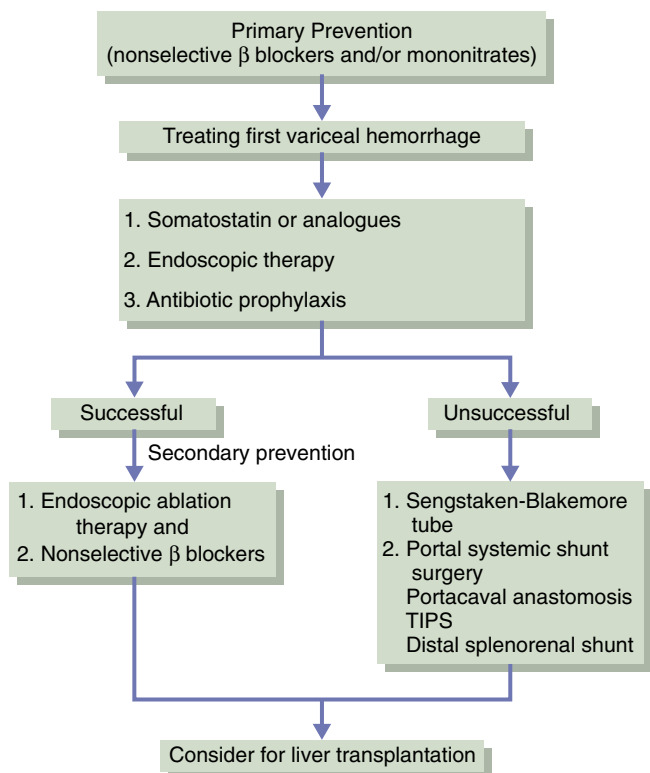

Figure 45-2 Prevention and treatment of variceal bleeding. TIPS, transjugular intrahepatic portosystemic shunt.

15% to 30%. Bleeding occurs most commonly from large varices in the esophagus when high tension in the walls of these vessels leads to rupture. Among gastric varices, fundal varices have the highest rate of bleeding and may bleed with portal pressure gradients of less than 12 mm Hg. Variceal bleeding usually causes painless hematemesis, melena, or hematochezia, which typically leads to hemodynamic compromise (see Chapter 34), further aggravated by impaired hepatic synthesis of coagulation factors (from hepatocellular dysfunction) and thrombocytopenia (from hypersplenism).

The management of gastroesophageal varices includes the treatment of acute variceal hemorrhage, the prevention of rebleeding (secondary prophylaxis), and the prevention of the initial episode of bleeding (primary prophylaxis) (Fig. 45-2). In the setting of acute variceal hemorrhage, the initial intervention consists of hemodynamic resuscitation with colloids such as blood or fresh-frozen plasma and airway protection and ventilatory support, if necessary. Combined pharmacologic and endoscopic therapy is superior to either therapy alone, especially if pharmacologic therapy is instituted immediately. In addition, prophylactic intravenous antibiotics should be administered early because they reduce the risk for infection, rebleeding, and death. Current pharmacologic therapy consists of somatostatin or its synthetic analogues (i.e., octreotide, vapreotide). These agents are best instituted before endoscopic examination. Endoscopic therapy includes band ligation and/or sclerotherapy (**Web Video 45-1**). Prospective studies have demonstrated that band ligation is the preferred modality given the lower inci-

dence of adverse effects and complications. In patients with gastric variceal hemorrhage, endoscopic variceal ablation with cyanoacrylate glue is superior to band ligation, although this therapy is not approved in the United States. Balloon tamponade (Sengstaken-Blakemore tube, Linton tube, or Minnesota tube) is a temporary measure reserved for patients in whom endoscopic therapy fails in the setting of massive hemorrhage. These patients may need to undergo portal decompression through a surgical shunt or transjugular intrahepatic portosystemic shunt (TIPS) placement. After an initial episode of variceal bleeding, recommendations for secondary prophylaxis include a combination of nonselective β blockers (propranolol and nadolol) and variceal obliteration through repeated courses of endoscopic band ligation. However, individual patient characteristics may dictate whether nonselective β blockers can be used. There are no formal recommendations on frequency and duration of follow-up endoscopy, although it is generally done at 1- to 6-month intervals after obliteration of varices. Endoscopic screening has been recommended to identify patients at high risk for variceal bleeding (i.e., those with large varices) so that primary prophylaxis can be instituted. Several studies suggest that certain clinical features (e.g., thrombocytopenia, ascites, telangiectasias) may help predict patients who are likely to have large varices, but given the poor predictive values of these features, endoscopic screening should be performed in all patients newly diagnosed with cirrhosis. Capsule endoscopy has been evaluated as a less invasive screening alternative to upper endoscopy but is currently less sensitive in diagnosing varices. Primary prophylaxis should be instituted for all patients with large varices and in those with advanced liver disease (Child class B and C) with small varices. Nonselective β blockers are the agents of choice for primary prophylaxis because they reduce portal blood flow and vascular resistance and hence portal pressure. In patients with contraindications or intolerance to β blockers, variceal obliteration through endoscopic band ligation is the best alternative.

Ascites

Ascites is the accumulation of excess fluid in the peritoneal cavity. Although cirrhosis is the most common cause of ascites, this condition may have numerous other causes (Table 45-4). The serum ascites-albumin gradient has replaced the exudative-transudative classification of ascites. An elevated serum ascites-albumin gradient (>1.1 g/dL, serum albumin concentration–ascites albumin concentration) signifies the presence of portal hypertension. Ascites becomes clinically detectable with fluid accumulation greater than 500 mL. Shifting dullness to percussion is the most sensitive clinical sign of ascites, but ultrasonography can readily detect smaller fluid volumes (250 mL).

The precise sequence of events leading to the development of cirrhotic ascites remains debated. However, both excess renal sodium and water retention resulting from portal hypertension and splanchnic vasodilation resulting in overflow of fluid into the peritoneum (*overflow theory*) and decreased effective circulating blood volume resulting from systemic arterial vasodilation leading to activation of

neurohumoral systems and sodium and water retention (*underflow theory*) play a role.

Management of cirrhotic ascites consists initially of sodium restriction, preferably to less than 2 g per day. Restricted fluid intake may be necessary if hyponatremia (<125 mEq/L) is present. The administration of spironolactone, an aldosterone antagonist, supplemented with a loop diuretic (e.g., furosemide), is effective in about 90% of patients. Diuresis should be monitored closely because aggressive diuretic therapy may result in electrolyte disturbances (i.e., hyponatremia, hypokalemia) and hypovolemia, leading to impaired renal function and potentially precipitating hepatic encephalopathy. *Refractory ascites* occurs in about 10% of patients with cirrhosis and is defined as persistent tense ascites despite maximal diuretic therapy (spironolactone, 400 mg per day, and furosemide, 160 mg per day) or the development of azotemia or electrolyte disturbances at submaximal doses of diuretics. Treatment in these patients includes repeated large-volume paracentesis and colloid volume expansion with albumin, TIPS placement, and liver transplantation (Fig. 45-3). In recent years, vaso-

pressin receptor antagonists called *aquaretics* (they promote electrolyte-free water excretion) are increasingly being studied for use in hyponatremia and may have a role in refractory ascites. These agents downregulate *aquaporin-2* channels in the collecting ducts and reduce water reabsorption. *Conivaptan* is an aquaretic recently approved by the U.S. Food and Drug Administration.

Spontaneous Bacterial Peritonitis

Cirrhotic patients may develop infection of ascitic fluid leading to acute spontaneous bacterial peritonitis (SBP) without an obvious source of contamination. The most common organisms include *Escherichia coli* and other Enterobacteriaceae such as *Klebsiella* species. Gram-positive organisms such as *Streptococcus*, *Enterococcus*, and *Pneumococcus* species may also be found. The microbiology of SBP is distinct from secondary peritonitis. Anaerobes are rarely found, and typically a single organism is isolated. Clinical features include fever, abdominal pain, and signs of peritoneal irritation. Often, the infection may be clinically silent or may be demonstrated by the development of hepatic encephalopathy or renal insufficiency. Therefore, diagnostic paracentesis should be considered in any patient with cirrhotic ascites who deteriorates clinically. The diagnosis is strongly suggested if the ascitic fluid polymorphonuclear leukocyte count is greater than 250 cells/mL and is confirmed by culture, preferably inoculated into blood culture bottles at the time of paracentesis. The use of rapid bedside diagnostic methods such as leukocyte esterase reagent strips is not routinely recommended in view of low sensitivity. Treatment is directed at the offending organism, and empiric therapy can be initiated with a third-generation cephalosporin to cover gram-negative bacilli and gram-positive cocci, and should be narrowed to the specific pathogen. Response to treatment is usually seen within 72 hours, and duration

Table 45-4 Causes of Ascites

Serum Ascites-Albumin Gradient	
High: >1.1 g/dL	Low: <1.1 g/dL

of therapy can be limited to 5 days unless bacteremia is present, in which case a 2-week course is recommended. The administration of intravenous albumin has been shown to decrease the incidence of renal dysfunction and to improve short-term survival. Given the high rates of recurrence (up to 70% within 1 year), long-term antibiotic prophylaxis is indicated in patients with a prior episode of spontaneous bacterial peritonitis (recurrence rate reduction to <20%) and also in patients without a previous episode but with advanced liver failure and low ascitic protein levels (<1 g/dL), whereas short-term prophylaxis should be considered in patients with cirrhosis and ascites who are hospitalized with upper gastrointestinal bleeding. Common prophylactic regimens for SBP include fluoroquinolones (ciprofloxacin, 750 mg per week; norfloxacin, 400 mg per day) and trimethoprim-sulfamethoxazole (1 double-strength tablet daily). Long-term antibiotic prophylaxis can increase susceptibility to severe gram-positive bacterial infections.

Hepatorenal Syndrome

Serious liver disease from any cause may be complicated by a form of functional renal failure, termed the *hepatorenal syndrome*, which almost invariably occurs in the presence of significant hepatic synthetic dysfunction and ascites. This syndrome occurs in about 4% of patients with decompensated cirrhosis, and some prospective series have determined that the probability of developing this syndrome in patients admitted to the hospital for the treatment of ascites may be as high as 30% to 40% at 2 years. Typically, the kidneys are histologically normal, with the capacity of regaining normal function in the event of recovery of liver function such as after liver transplantation. Severe cortical vasoconstriction has been demonstrated angiographically, and it reverses when these kidneys have been transplanted into patients who do not have cirrhosis. The renal dysfunction is characterized by a declining glomerular filtration rate, oliguria, low urine sodium (<10 mEq/L), normal urinary sediment, and azotemia, often with a disproportionately high ratio of blood urea nitrogen to creatinine. Two types of hepatorenal syndrome have been described. Type I is characterized by rapidly progressive renal failure that occurs within 2 weeks and is associated with a dismal prognosis. In type II, renal dysfunction occurs more slowly and is associated with a better prognosis. The decline in renal function often follows one of three events in a patient with cirrhosis and ascites: infection, overdiuresis, or large-volume paracentesis.

Hepatorenal syndrome should be diagnosed only after plasma volume depletion (a common cause of reversible, prerenal azotemia in patients with cirrhosis, particularly in patients receiving diuretics) and other forms of acute renal injury have been excluded. Mortality is high in hepatorenal syndrome; therefore, in all patients with cirrhosis, precipitating factors should be avoided (overdiuresis, dehydration from lactulose, nephrotoxic agents such as nonsteroidal anti-inflammatory drugs [NSAIDs]) and treated (diagnosis and treatment of spontaneous bacterial peritonitis and alcoholic hepatitis) as rapidly as possible.

Recently, several medical therapies have been studied and may have some benefit, including octreotide in combination with midodrine (α -adrenergic agonist), vasopressin ana-

logues (terlipressin), and intravenous albumin. TIPS has also been reported to stabilize or even improve renal function, but liver transplantation has become the accepted treatment for hepatorenal syndrome.

Hepatic Encephalopathy

Hepatic encephalopathy is a complex neuropsychiatric syndrome that may complicate severe or advanced liver disease or extensive portosystemic collateral formation (*shunting*). Two major forms of hepatic encephalopathy are recognized: acute and chronic.

Acute hepatic encephalopathy usually occurs in the setting of fulminant hepatic failure. Cerebral edema plays an important role in this setting, progression to coma is common, and mortality is extremely high (see Chapter 44). *Chronic hepatic encephalopathy* usually occurs in the setting of cirrhosis and is often reversible. It commonly produces disturbances in the sleep-wake cycle, subtle neurologic dysfunction, and behavioral changes.

The pathogenesis of hepatic encephalopathy in the setting of cirrhosis is thought to involve the inadequate hepatic removal of predominantly nitrogenous compounds or other toxins ingested or formed in the gastrointestinal tract. Ammonia, derived from both amino acid deamination and bacterial hydrolysis of nitrogenous compounds in the gut, has been implicated in the pathogenesis of hepatic encephalopathy, but venous ammonia blood levels correlate poorly with the presence or degree of encephalopathy. Other potential contributors to hepatic encephalopathy have been investigated, including γ -aminobutyric acid, mercaptans, short-chain fatty acids, benzodiazepine-like compounds, imbalance between plasma branched-chain and aromatic amino acids, altered cerebral metabolism (disturbed sodium-potassium adenosine triphosphatase [Na^+ , K^+ -ATPase] activity), zinc deficiency, and deposition of manganese in the basal ganglia.

The clinical features of hepatic encephalopathy include disturbances of higher neurologic function (e.g., intellectual and personality disorders, dementia, inability to copy simple diagrams [*constructional apraxia*], disturbance of consciousness), disturbances of neuromuscular function (e.g., asterixis, hyperreflexia, myoclonus), and rarely a Parkinson-like syndrome and progressive paraplegia. One of the earliest manifestations is the alteration of the normal sleep-wake cycle. Hepatic encephalopathy is usually divided into stages according to its severity (Table 45-5). Hypoglycemia, subdural hematoma, meningitis, and drug overdose should be considered in the differential diagnosis of hepatic encephalopathy.

Treatment of hepatic encephalopathy is based on identifying and addressing precipitating factors (Table 45-6), short-term restricting of dietary protein, reducing and eliminating substrates for the generation of nitrogenous compounds, and preventing ammonia absorption from the bowel. Gastrointestinal bleeding and increased protein intake may provide increased substrate for the bacterial or metabolic formation of nitrogenous compounds that induce encephalopathy. Patients prone to develop hepatic encephalopathy have increased sensitivity to drugs that depress the central nervous system, and the use of these drugs should be avoided

Table 45-5 Stages of Hepatic Encephalopathy

Stage*	Clinical Manifestations
I	Apathy Restlessness Reversal of sleep rhythm Slowed intellect Impaired computational ability Impaired handwriting
II	Lethargy Drowsiness Disorientation Asterixis
III	Stupor (arousable) Hyperactive reflexes, extensor plantar responses
IV	Coma (response to painful stimuli only)

*Stage 0 encephalopathy is used to describe subclinical impairment of intellectual function.

in these patients. Protein restriction may be considered in patients with severe encephalopathy, but long-term restriction is associated with worsening malnutrition. Treatment with formulas rich in branched-chain amino acids has shown no benefit in improving encephalopathy or mortality. Reduction and elimination of nitrogenous compound substrates can be achieved by administering enemas and using antibiotics that reduce colonic bacteria (i.e., neomycin, metronidazole, rifaximin). Nonabsorbable disaccharides (i.e., lactulose) are fermented to organic acids by colonic bacteria, lowering stool pH and trapping ammonia in the colon, and thereby preventing absorption. In addition, the cathartic effect of lactulose eliminates ammonia and other nitrogenous compounds, and patients are usually directed to achieve two to three soft stools per day as the goal of lactulose therapy.

Hepatopulmonary Syndrome

Hepatopulmonary syndrome occurs in 10% to 30% of patients with cirrhosis and is characterized by gas exchange abnormalities (increased alveolar-arterial gradient and hypoxemia) as a result of intrapulmonary vascular dilation. The vascular dilation leads to impaired oxygen transfer from alveoli to the central stream of red blood cells within capillaries, resulting in a *functional* intrapulmonary right-to-left shunt that improves with 100% oxygen. Intrapulmonary shunting can be demonstrated through contrast echocardiography. In this modality, agitated saline, which creates microbubbles, is injected into a peripheral vein while performing two-dimensional echocardiography. Delayed visualization (after the third heartbeat following injection) of microbubbles in the left cardiac chambers indicates intrapulmonary vasodilation, whereas early visualization occurs with intracardiac shunting. Clinical features range from subclinical abnormalities in gas exchange to profound

Table 45-6 Hepatic Encephalopathy: Precipitating Factors

Alkalosis: most often induced by diuretics
Hypovolemia: most often induced by diuretics

hypoxemia causing significant dyspnea. The presence of hepatopulmonary syndrome significantly increases mortality and worsens functional status and quality of life. No proven medical therapy exists, but supplemental oxygen improves arterial oxygen levels. The treatment of choice is liver transplantation, which often leads to complete reversal of the syndrome.

HEPATOCELLULAR CARCINOMA

Hepatocellular carcinoma (HCC) accounts for less than 2.5% of all malignancies in the United States. Recent epidemiologic studies, though, have demonstrated a 71% relative increase in the age-adjusted incidence rate of this malignancy over the past 20 years. In other areas of the world, including sub-Saharan Africa, China, Japan, and Southeast Asia, HCC is one of the most frequent malignancies and is an important cause of mortality, particularly in middle-aged men. HCC often arises in a cirrhotic liver and is closely associated with chronic viral hepatitis. Hepatitis B virus DNA has been shown to integrate in the host cell genome, where it may disrupt tumor suppressor genes and activate oncogenes. In areas of high prevalence, vaccination to prevent infection with hepatitis B virus has reduced the incidence of this disease. The exact pathophysiologic mechanisms leading to tumorigenesis in patients with other causes of cirrhosis (e.g., hemochromatosis, alcohol, hepatitis C viral infection) remain poorly understood. Risk factors for development of HCC, as well as its clinical manifestations, are listed in Table 45-7. Currently used imaging techniques for detecting HCC and the most common appearance of the tumor are listed in Table 45-8. A tissue specimen may be necessary to confirm the diagnosis of HCC in some cases but may not be needed if characteristic clinical and radiologic features are present, especially when accompanied by a rise in serum α -fetoprotein levels. Diagnosis of small, treatable tumors is possible with intensive screening programs that employ imaging studies and serum α -fetoprotein levels, although the long-term outcomes and cost-effectiveness of these strategies remain unclear. Patients with well-compensated cirrhosis may undergo surgical resection or liver transplantation, whereas, in patients with advanced cirrhosis, liver transplantation should be considered. Nonsurgical options include percutaneous ethanol injection, arterial

Table 45-7 Hepatocellular Carcinoma**Incidence**

From 1 to 7 per 100,000 to >100 per 100,000 in high-risk areas

Serum α -fetoprotein > 400 ng/mL

chemoembolization, and radiofrequency ablation. In patients with widespread, multifocal disease and in those with vascular invasion, the prognosis is poor, with median survival from the time of diagnosis of less than 6 months. However, recently, sorafenib (angiogenesis inhibitor) has been approved for use in unresectable HCC and has been shown to prolong survival in such patients.

HEPATIC TRANSPLANTATION

Liver transplantation is a highly successful procedure in patients with progressive, advanced, and otherwise untreatable liver disease. Advances in surgical techniques and supportive care, the use of cyclosporine and tacrolimus for immunosuppression, and careful selection of patients have all contributed to the excellent results of liver transplantation. From 70% to 80% of patients undergoing liver transplantation survive at least 3 years, usually with good quality of life. The most common indication for liver transplantation in the United States is chronic liver disease resulting from hepatitis C virus infection. Other liver diseases for which transplantation is commonly performed include cirrhosis from alcoholic liver disease, nonalcoholic fatty liver disease, autoimmune hepatitis, primary biliary cirrhosis, and

After gadolinium administration, the tumor increases in intensity

primary sclerosing cholangitis. Patients with hepatitis B are candidates for liver transplantation if they can be given hepatitis B immunoglobulin or nucleoside analogues (i.e., lamivudine) to help prevent recurrence. Excellent results have also been obtained in selected patients with fulminant hepatic failure (see Chapter 44). Liver transplantation for malignant hepatobiliary disease has been less successful because of recurrent disease in the transplanted liver.

The timing of liver transplantation presents a particular challenge given the insufficient availability of donor organs. Liver-assist devices for temporary support until an organ becomes available are being evaluated. Recently, the United Network for Organ Sharing has accepted the Model for End-Stage Liver Disease (MELD) system for determining organ allocation. The MELD system consists of a prognostic model that predicts mortality according to selected clinical and laboratory variables, therefore prioritizing organ availability to patients with more advanced disease in whom predicted mortality is high.

VASCULAR DISEASE OF THE LIVER

Disorders of the hepatic vasculature are uncommon and include portal vein thrombosis, hepatic vein thrombosis (Budd-Chiari syndrome), and veno-occlusive disease. Affected patients usually have portal hypertension with or without associated liver dysfunction, which may mimic the presentation of cirrhosis.

Portal Vein Thrombosis

Thrombosis of the portal vein may develop after abdominal trauma, umbilical vein infection and neonatal sepsis, intra-abdominal inflammatory diseases (e.g., pancreatitis), hypercoagulable states, or in association with cirrhosis. In most cases, however, particularly in children, the cause is unknown. The disease produces the manifestations of portal hypertension; however, liver histology is usually normal. The diagnosis is established by angiography, but noninvasive imaging modalities such as Doppler ultrasonography, com-

puted tomography, and magnetic resonance imaging may reveal thrombus, collateral circulation near the porta hepatis, and splenomegaly. In long-standing portal vein thrombosis, tortuous venous channels develop within the organized clot, leading to *cavernous transformation*.

In acute portal vein thrombosis, thrombolysis may be attempted, but anticoagulation with warfarin remains the mainstay of therapy. In most patients, recanalization of the thrombus occurs within 6 months of initiating anticoagulation. Recommendations for duration of anticoagulation following an acute event vary and are usually 3 to 6 months. Long-term anticoagulation may be used in chronic thrombosis, especially when associated with hypercoagulable states. Concern exists that anticoagulation may precipitate hemorrhage from varices that arise as a consequence of portal hypertension, although studies have not shown an increased risk for variceal bleeding in anticoagulated patients with chronic portal vein thrombosis. If variceal hemorrhage occurs, it is best managed with endoscopic obliteration. Prophylaxis with β blockers to prevent variceal bleeding may decrease portal pressure and potentially propagate thrombus and is generally not recommended. If endoscopic treatment fails, surgical management with portosystemic shunting may be attempted, but this approach is often difficult because of the absence of suitable patent vessels.

Budd-Chiari Syndrome

The occlusion of the major hepatic veins or the inferior vena cava, especially in the intrahepatic and suprahepatic segments, causes Budd-Chiari syndrome. Most cases are caused by hematologic disease (e.g., polycythemia vera, paroxysmal nocturnal hemoglobinuria, essential thrombocytosis, and other myeloproliferative disorders), pregnancy, oral contraceptive use, tumors (especially hepatocellular carcinoma), hypercoagulable states (e.g., factor V Leiden mutation, protein C and S deficiency), abdominal trauma, and congenital webs of the vena cava. About 20% of cases are idiopathic, but many of these patients may have early, subclinical myeloproliferative disease or genetic mutations associated with a hypercoagulable state.

The presentation of Budd-Chiari syndrome can be acute, which may be associated with fulminant liver failure, or it may exhibit as a subacute or chronic illness. Acute disease produces right upper quadrant abdominal pain, hepatomegaly, ascites, and jaundice, whereas the subacute or chronic form produces primarily portal hypertension. Elevation of serum bilirubin and transaminase levels may be mild, but liver function is often poor, with profound hypoalbuminemia and coagulopathy. The diagnosis can be established noninvasively with Doppler ultrasonography, which may show decreased or absent hepatic vein blood flow, and computed tomography, which shows delayed or absent contrast filling of the hepatic veins and hypertrophy of the caudate lobe. Magnetic resonance angiography may also demonstrate the previously mentioned findings. Hepatic venography is especially useful in cases in which the results of the noninvasive modalities are inconclusive. Venography often shows an inability to catheterize and visualize the hepatic veins; the characteristic *spider web pattern*

of collateral vessels may also be demonstrated, and the inferior vena cava may appear compressed, owing to hepatomegaly or an enlarged caudate lobe. On liver biopsy, centrilobular congestion, hemorrhage, and necrosis (*nutmeg liver*) are seen, with cirrhosis developing in patients with chronic obstruction.

Treatment should be individualized and is dependent on the mode and severity of presentation and the potential cause of the disease. Supportive therapy to relieve ascites and edema (e.g., dietary sodium restriction, diuretics) and chronic anticoagulation may be considered in patients with chronic Budd-Chiari syndrome in whom methods to decompress congestion are not feasible. Thrombolysis followed by anticoagulation is most useful in patients with acute forms. In selected patients (e.g., those with venous webs or strictures or single-vessel thrombosis), angioplasty with or without stent placement may be used. Decompressive modalities are most useful before the development of cirrhosis and include transjugular intrahepatic portacaval and side-to-side portacaval shunts. In patients with cirrhosis, liver transplantation followed by continued anticoagulation is often considered the best option.

Veno-occlusive Disease

Veno-occlusive disease, also called *sinusoidal obstruction syndrome*, is characterized by jaundice, painful hepatomegaly, and fluid retention that most often occurs after cytoreductive therapy and before bone marrow transplantation but may also follow exposure to other drugs and herbal preparations (e.g., azathioprine, pyrrolizidine alkaloids). Endothelial cell injury leads to obstruction at the level of the hepatic venules and the sinusoids.

The diagnosis is clinically suspected when weight gain, epigastric–right upper quadrant abdominal pain, and jaundice develop within the first 3 to 4 weeks after bone marrow transplantation. Laboratory abnormalities include hyperbilirubinemia, elevated transaminases, and in severe cases, profound synthetic dysfunction. Clinical manifestations may be rapidly progressive and may lead to multiorgan dysfunction and death in 20% to 25% of patients. Doppler abdominal ultrasonography may reveal ascites, reversal of portal vein flow, and an elevated hepatic artery resistance index. Liver biopsy is diagnostic and is usually obtained using the transjugular approach. The advantages of this approach compared with the percutaneous route include measurement of the hepatic venous pressure gradient (typically elevated in veno-occlusive disease) and a lower incidence of bleeding.

Mild forms of the disease may favorably respond only to supportive therapy. In moderate to severe disease, treatment has been attempted with tissue plasminogen activator and heparin, antithrombin III, prostaglandin E₁, and glutamine plus vitamin E, although their efficacy has not been clearly established. Recently, defibrotide (a mixture of porcine-derived single-stranded phosphodiester oligonucleotides) has been evaluated as a potential treatment option for severe veno-occlusive disease. It is an attractive option because of lack of severe adverse effects, but convincing evidence for its efficacy has not been established.

Prospectus for the Future

For many years, cirrhosis has been viewed as an irreversible fibrotic reaction to chronic liver injury. However, as the mechanisms of hepatic fibrosis have been explored and treatments for chronic liver disease have been implemented, cirrhosis has been increasingly seen as an imbalance of multiple factors that regulate the generation and degradation of collagen. Among the consequences of the increased understanding of hepatic fibrogenesis is the potential for development of specific agents that influence collagen production and those that may prevent and even diminish hepatic fibrosis. A significant number of antifibrotic agents have been successfully used in animal models of liver injury, and these agents are likely to enter clinical use in the near future.

Another key issue in the therapy of complications of cirrhosis is defining the effectiveness of medical treatment of esophageal varices. Noncardioselective β -adrenergic blockers decrease the risk for variceal bleeding. This effect is established to occur in the subgroup of patients who have a significant reduction in portal pressure measured by hepatic venous pressure recordings. Currently, direct measurement of hepatic venous pressures is not routinely used to assess efficacy of noncardioselective

β -adrenergic blockers in lowering portal pressure. The development of noninvasive means to measure portal pressures or targeted measurement of hepatic venous pressure recordings in patients treated with noncardioselective β -adrenergic blockers are likely to help guide treatment of esophageal varices.

During the past few years, several artificial liver support systems have been proposed and studied in acute liver failure (ALF) and acute on chronic liver failure (ACLF). The system currently being evaluated extensively in the United States and Europe is the molecular adsorbents recirculating system (MARS), which is based on the principles of extracorporeal albumin dialysis (ECAD). Because a large number of toxins that accumulate in liver failure are bound to albumin, using an albumin-rich dialysate across an albumin-enriched polymer membrane has shown significant biochemical and clinical improvement in patients with ALF or ACLF. Patients receiving ECAD have reduced serum bilirubin levels, bile acid levels, and improvement in encephalopathy and synthetic function (increased serum albumin). These findings are promising, but a survival benefit has not been assessed, and these systems are not standard of care yet.

Disorders of the Gallbladder and Biliary Tract

Shyam Varadarajulu, Rudolf Garcia-Gallont, and Michael B. Fallon

The main role of the biliary tract and gallbladder is to transport bile into the intestines, which, in turn, is essential for digesting fat. Diseases of the gallbladder and the biliary tract are among the most common afflictions of humankind. This chapter examines the most common gallbladder and biliary tract disorders, focusing on cholelithiasis. The reader is referred to Chapter 42 for a detailed discussion of bilirubin metabolism and the diagnostic approach to jaundice and to Chapter 35 for a review of the various imaging techniques used to study the biliary tract.

Normal Biliary Anatomy and Physiology

Figure 46-1 outlines the normal anatomy of the liver and biliary tract. The liver produces 500 to 1500 mL of bile per day. Bile passes through the canaliculi to the hepatic bile ducts and then into the common hepatic duct. Tonic contraction of the sphincter of Oddi, located in the region of the ampulla of Vater, during fasting diverts about one half of the bile through the cystic duct into the gallbladder, where it is stored and concentrated. Cholecystokinin, released after food is ingested, causes the sphincter of Oddi to contract and then to relax, allowing delivery of a timed bolus of bile, rich in bile acids, into the intestine. Bile acids, detergent molecules possessing both fat-soluble and water-soluble moieties, convey phospholipids and cholesterol from the liver to the intestine where cholesterol undergoes fecal excretion (see Chapter 42, Fig. 42-1). In the intestinal lumen, bile acids solubilize dietary fat and promote its digestion and absorption. Bile acids are, for the most part, efficiently reabsorbed by the small intestinal mucosa, particularly in the terminal ileum, and are recycled to the liver for re-excretion, a process termed *enterohepatic circulation*.

Gallstones (Cholelithiasis)

In studies performed in the United States, Europe, and South America, about 10% to 15% of adults have gallstones. In the United States, gallstone disease leads to more than 500,000 cholecystectomies annually, with estimated costs of \$4.5 billion per year. Gallstones are of two types: (1) cholesterol (75%) and (2) pigmented (black or brown) (25%), the latter being composed of calcium bilirubinate and other calcium salts. The risk factors for cholelithiasis are shown in Table 46-1.

PATHOGENESIS OF CHOLELITHIASIS

The three main factors that lead to cholesterol gallstone formation are (1) cholesterol supersaturation of bile, (2) nucleation, and (3) gallbladder hypomotility. The liver is the most important organ in regulating total-body cholesterol stores. Once secreted, cholesterol, which is insoluble in water, is solubilized in bile by forming mixed micelles with bile acids and phospholipids. In most individuals, many of whom do not develop stones, more cholesterol is in bile than can be maintained in stable solution (supersaturated bile). As bile becomes more supersaturated, aggregation of microscopic cholesterol molecules into coalescent vesicles that crystallize (nucleation) takes place. Gradual deposition of additional layers of cholesterol leads to the appearance of macroscopic stones. Factors that influence nucleation include bile transit time, gallbladder contraction, bile composition (concentration of cholesterol, phospholipids, and bile salts), and presence of bacteria, mucin, and glycoproteins, which act as a nidus to initiate cholesterol crystal formation. The interplay between *pronucleating* and *antinucleating* factors in the gallbladder may determine whether cholesterol gallstones will form from supersaturated bile.

Figure 46-1 Normal anatomy and histology of the liver and biliary tract. Materials destined for metabolism or excretion by the liver (such as unconjugated bilirubin) enter the sinusoidal bed and cross the endothelial barrier and the space of Disse. Unconjugated bilirubin is taken up by the hepatocyte, conjugated with glucuronide to become water soluble, and excreted into bile across the canalicular membrane of the hepatocyte. The canaliculi empty into bile ductules (BD), which, in turn, lead to the interlobular (small), septal (medium), and large intrahepatic bile ducts and finally to the main branches of the common bile duct. The portal areas, or portal triads, are composed mainly of portal vein (PV), hepatic artery (HA), and BD branches (*left side, magnification*). Tonic contraction of the sphincter of Oddi, located in the region of the ampulla of Vater, during fasting diverts about one half of the bile through the cystic duct into the gallbladder, where it is stored and concentrated to be released later during meal times. Diseases at any level of the biliary tree can lead to cholestasis and obstructive jaundice; for example, primary sclerosing cholangitis is caused by inflammatory obstruction of the interlobular bile ducts, whereas stones, cancer of the ampulla of Vater, or pancreatitis can cause distal obstruction of the common bile duct. Investigation of the bile duct is best accomplished using a side-viewing endoscope to insert a catheter into the ampulla of Vater, with injection of contrast to obtain an endoscopic retrograde cholangiogram (*right side, inset*). If pathology is detected (e.g., cholangitis, stricture, stone), therapeutic maneuvers such as stone removal, stenting, or sphincterotomy to enlarge the distal opening of the common bile duct can be performed.

Gallbladder sludge is a superconcentrated mixture of bile acids, bilirubin, cholesterol, mucus, and proteins that exhibits various degrees of fluidity and is prone to precipitate into semisolid or solid form.

The pathophysiologic factors of pigment stones is less well understood compared with gallstone formation; however, increased production of bilirubin conjugates (hemolytic states), increased biliary calcium (Ca^{2+}) and bicarbonate (HCO_3^-), cirrhosis, and bacterial deconjugation of bilirubin to a less soluble form are all associated with pigment stone formation.

Table 46-1 Risk Factors for Cholelithiasis

Primary

Age
Obesity
Female sex
Rapid weight loss
Race (e.g., Native American)

Secondary

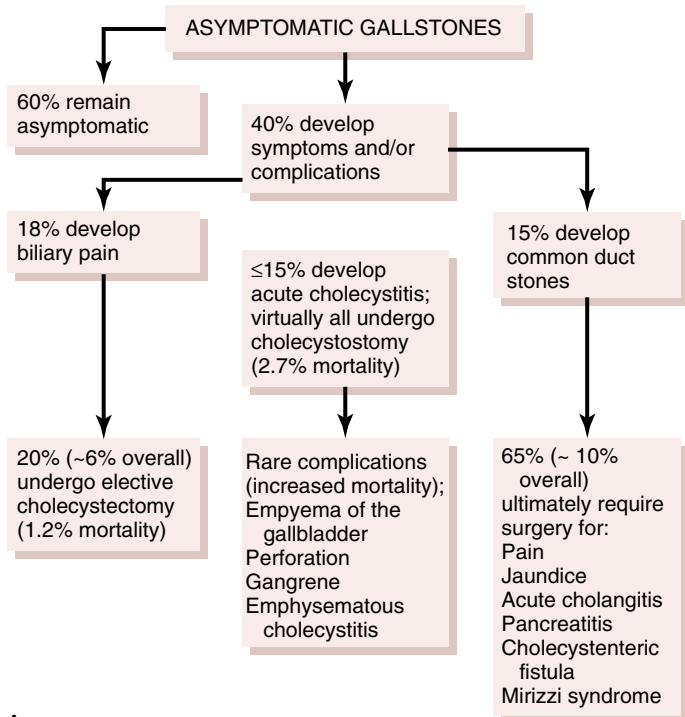

Use of oral contraceptives
Pregnancy
Diabetes mellitus
Use of insulin
Low socioeconomic status
Sedentary lifestyle
Total parenteral nutrition
Hemolysis
Biliary parasites (e.g., *Clonorchis sinensis*)

Many of the recognized predisposing factors for cholelithiasis and gallbladder sludge can be understood in terms of the pathophysiologic scheme outlined previously:

1. Biliary cholesterol saturation is increased by estrogens, multiparity, oral contraceptives, obesity, rapid weight loss, and terminal ileal disease, which decreases the bile acid pool.
2. Nucleation is enhanced by biliary parasites, recurrent bacterial infection of the biliary tract, and antibiotics such as ceftriaxone, which has a proclivity to concentrate and crystallize with calcium in the biliary tree. Total parenteral nutrition and blood transfusions also promote bile pigment accumulation and *gelfaction* of sludge.
3. Bile stasis is caused by gallbladder hypomotility (resulting from pregnancy, somatostatin, or fasting), bile duct strictures, choledochal cysts, biliary parasites, and total parenteral nutrition.

CLINICAL MANIFESTATIONS OF GALLSTONES

Most individuals with gallstones remain asymptomatic (50% to 60%), about one third develop biliary colic or chronic cholecystitis, and 15% develop acute complications. The natural history of gallstone disease is outlined in Figure 46-2. Obstruction of the biliary tract at any level by stones or sludge is the underlying cause of all manifestations of gallstone disease. Obstruction by gallstones can occur at the level of the cystic duct, common hepatic duct, common bile duct, and ampulla of Vater.

A

Figure 46-2 Natural history of asymptomatic gallstones. **A**, The clinical syndromes associated with gallstones are shown here, and the numbers represent the approximate percentage of adults who develop one or more of these symptoms or complications over a 15- to 20-year period. Over this period, about 30% of individuals with gallstones undergo surgery. (The risk for developing complications of gallstones varies considerably among series. The figures shown here represent those derived from more recent studies). **B**, Clinical manifestations of symptomatic gallstones.

Appendicitis

duct, and ampulla of Vater (see Fig. 46-1). Symptoms arise from contraction of the gallbladder during transient obstruction of the cystic duct by gallstones, whereas persistent obstruction of the cystic duct leads to superimposed inflammation or infection of the gallbladder (i.e., acute cholecystitis). Obstruction of the distal common bile duct may result in abdominal pain, cholangitis (infection of the biliary tract), or pancreatitis (resulting from pancreatic duct obstruction). The presence of a large stone in the cystic duct can cause common bile duct obstruction and is referred to as *Mirizzi syndrome*. Common conditions to consider in the differential diagnosis of gallstone disease are listed in Table 46-2.

Asymptomatic Gallstones

Asymptomatic patients should be followed expectantly. Prophylactic cholecystectomy is considered in groups at increased risk for developing complications: (1) patients with diabetes who have a greater morbidity and mortality from acute cholecystitis; (2) persons with a calcified (porcelain) gallbladder or large gallbladder polyps, which are associated with an increased risk for carcinoma of the gallbladder; (3) persons with sickle cell anemia, in whom hepatic crises may be difficult to differentiate from acute cholecystitis; (4) children with gallstones because they frequently develop symptomatic disease; and (5) Native Americans, who are predisposed to developing gallbladder cancer in the setting of gallstones.

Biliary Colic

The term *chronic cholecystitis* has been used to denote recurrent and *nonacute* symptoms caused by the presence of gallstones over a period of days to several years. A better term for this condition is *biliary colic* because the presence of symptoms correlates poorly with pathologic findings in the gallbladder wall. Biliary colic is typically a steady ache in the epigastrium or right upper quadrant, of sudden onset, reaching a plateau of intensity over a few minutes, which subsides gradually over 30 minutes to several hours. Referred

pain may be felt at the tip of the scapula or right shoulder. Nausea and vomiting may occur, whereas fever and a palpable mass (signs of acute cholecystitis) are not evident. Other symptoms such as dyspepsia, fatty food intolerance, bloating and flatulence, heartburn, and belching may occur in patients with gallstones; however, these symptoms are nonspecific and frequently occur in individuals with normal gallbladders.

Gallstones can be best demonstrated by transabdominal ultrasonography (sensitivity and specificity, >95%), which has become the initial test to evaluate cholelithiasis. Ultrasound accuracy drops to 20% for visualization of stones within the common bile duct. This limitation of transabdominal ultrasound has been overcome by endoscopic ultrasonography (Web Video 46-1 shows gallstones on endoscopic ultrasonography) and magnetic resonance cholangiopancreatography (MRCP), both of which have an accuracy of 90% to 95% for detecting cholelithiasis and common bile duct stones. Oral cholecystography is no longer used for the routine evaluation of gallstones.

Laparoscopic cholecystectomy has replaced open cholecystectomy as the treatment of choice for recurrent biliary pain. Open cholecystectomy is generally reserved for selected high-risk patients (e.g., those with prior abdominal surgery with adhesions, obesity, or cirrhosis). Laparoscopic cholecystectomy may be accompanied by intraoperative endoscopic retrograde cholangiopancreatography (ERCP) (see Chapter 35 and Fig. 46-1) or transoperative radiologic examination of the common bile duct if concomitant choledocholithiasis is suspected. Factors that may predict the presence of choledocholithiasis include jaundice, pancreatitis, abnormal liver tests, and bile duct dilation.

Cholecystectomy relieves symptoms of biliary pain in virtually all patients with gallstone disease and prevents development of future complications. Dissolution of cholesterol gallstones by orally administered chenodeoxycholic acid or ursodeoxycholic acid is successful in highly selected patients but is slow and costly and requires lifelong administration. Alternative methods to eliminate gallstones, including contact dissolution and fragmentation of stones, are used rarely.

Acute Cholecystitis

Acute cholecystitis refers to distention, edema, ischemia, inflammation, and secondary infection of the gallbladder, generally resulting from obstruction of the cystic duct by gallstones or less commonly by cancer or sludge. The clinical hallmark of acute cholecystitis is the acute onset of upper abdominal pain that lasts for several hours. The pain gradually increases in severity and typically localizes to the epigastrium or right hypochondrium with radiation to the right lumbar, scapular, and shoulder area. Nausea and vomiting, anorexia, and low-grade fever are common. Unlike biliary pain, the pain of acute cholecystitis does not subside spontaneously. The findings on physical examination in patients with acute cholecystitis may include inspiratory arrest on palpation of the right upper quadrant (Murphy sign), fever, and less commonly mild jaundice or a palpable gallbladder.

Complications of acute cholecystitis include emphysematous cholecystitis (in people with diabetes, older adults, and individuals who are immunosuppressed), empyema,

gangrene, and perforation of the gallbladder. Gallbladder perforation may be free into the peritoneum or through a cholecystenteric fistula with gallstone migration and bowel obstruction (gallstone ileus). Mirizzi syndrome is the occurrence of profound jaundice resulting from extrinsic compression of the common hepatic duct by an impacted stone in the cystic duct at the gallbladder neck.

The diagnostic modalities employed for acute cholecystitis are similar to those for biliary pain. An ultrasound examination that shows the presence of gallstones, along with pericholecystic fluid, gallbladder wall thickening, and localized tenderness over the gallbladder (ultrasonographic Murphy sign), provides strong supportive evidence for acute cholecystitis. Radionuclide scanning after intravenous administration of technetium-99m (^{99m}Tc)-diisopropyl iminodiacetic acid or hepatobiliary iminodiacetic acid (HIDA) scan is the most accurate test to confirm the clinical impression of acute cholecystitis. If the gallbladder fills with the isotope, acute cholecystitis is highly unlikely, whereas if contrast enters the bile duct and duodenum, but the gallbladder is not visualized, the clinical diagnosis of acute cholecystitis is strongly supported.

Because of the high risk for recurrent acute cholecystitis, most patients need to undergo cholecystectomy, often performed within the first 24 to 48 hours after presentation or, less often, 4 to 8 weeks after an acute episode (Fig. 46-3). Cholecystostomy may be performed on patients with a high operative risk. Antibiotics are generally used when fever or leukocytosis are present. Expectant management is reserved for patients with uncomplicated disease who are not good operative candidates or those in whom the diagnosis is not clear.

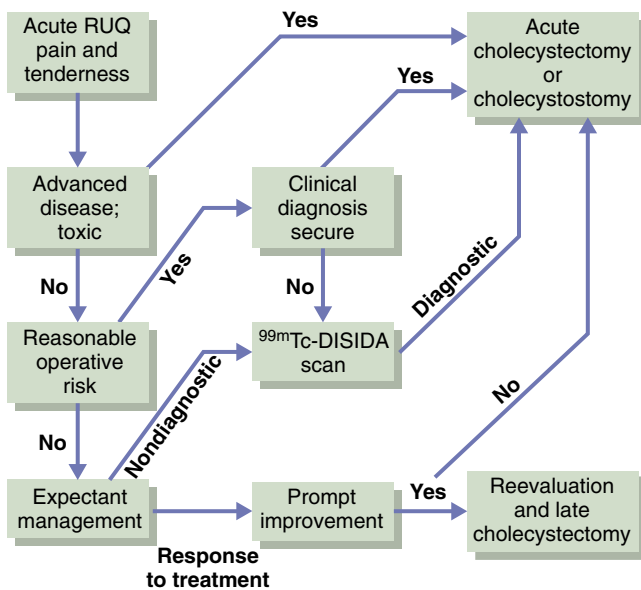

Figure 46-3 Scheme for managing patients with right upper quadrant (RUQ) pain and tenderness who are thought to have acute cholecystitis. This scheme is based on a policy of early operation (conventional or laparoscopic) for appropriate patients and use of cholecystostomy (operative or percutaneous) for patients who are poor operative risks.

Acalculous Cholecystitis

Acalculous cholecystitis accounts for 5% of cases of acute cholecystitis and carries higher morbidity and mortality rates than acute calculous cholecystitis. It is classically associated with the triad of prolonged fasting, immobility, and hemodynamic instability such as occurs in critically ill patients, especially if they have required total parenteral nutrition or blood transfusions. Gallbladder ischemia and sludge may be important in the pathogenesis. Acalculous cholecystitis is also seen in patients with AIDS, in whom it is usually caused by infectious agents such as cytomegalovirus or *Cryptosporidia*. Ultrasonographic features include absence of gallstones, thickened gallbladder wall, and a positive Murphy sign. As in acute cholecystitis, the gallbladder is not visualized on HIDA scan. Management includes antibiotics and cholecystectomy. If the patient is seriously ill, the gallbladder can be drained percutaneously to relieve the obstruction (cholecystostomy).

Choledocholithiasis and Acute Cholangitis

In the United States, most stones in the common bile duct (choledocholithiasis) originate from the gallbladder, occurring in up to 15% of persons with cholelithiasis (see Fig 46-4). Less commonly, stones may form de novo in the biliary tree. Common bile duct stones may be asymptomatic (30% to 40%), or they may produce biliary colic, jaundice, cholangitis, or pancreatitis.

Acute (suppurative) cholangitis is defined as life-threatening infection and inflammation of the biliary tract as the result of choledocholithiasis. The classic clinical manifestations of acute cholangitis are abdominal pain, jaundice, and fever (Charcot triad). Clinical findings may be absent in elderly or immunosuppressed patients. Cholangitis is a medical-surgical emergency that can lead rapidly to sepsis,

Figure 46-4 Cholangiogram at ERCP demonstrating a common bile duct stone.

shock, and death. Diagnosis is based on a compatible clinical and laboratory picture (abnormal liver function tests and leukocytosis) and radiologic or endoscopic evidence of common bile duct stones.

Treatment of acute cholangitis includes administration of broad-spectrum antibiotics and prompt removal of stones, typically with ERCP (see Fig. 46-1) and endoscopic sphincterotomy (**Web Video 46-2**). Cholecystectomy is subsequently performed when the patient has stabilized.

Gallstone Pancreatitis

Considering that gallstone pancreatitis recurs in 25% of patients, a cholecystectomy should be performed once the patient has recovered clinically from an attack of pancreatitis. If the patient remains jaundiced during an attack of presumed gallstone pancreatitis, suggestive of a stone in the bile duct, an ERCP is performed so that stones can be extracted by sphincterotomy.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis is an idiopathic condition of nonmalignant, nonbacterial, chronic inflammatory fibrosis and obliteration of the intrahepatic and extrahepatic bile ducts. It most commonly occurs in young men (two thirds are younger than 45 years), often in association with ulcerative colitis (70% of patients with primary sclerosing cholangitis have ulcerative colitis). The clinical spectrum of primary sclerosing cholangitis is broad, ranging from asymptomatic patients with abnormal liver enzymes (typically an elevated alkaline phosphatase) to recurring episodes of fever, chills, abdominal pain, and jaundice. The diagnosis of primary sclerosing cholangitis is made by ERCP or MRCP, which shows characteristic changes (beading) of the intra-

Figure 46-5 Cholangiogram at ERCP demonstrating the characteristic beading of the intra- and extra-hepatic bile ducts in a patient with PSC.

hepatic or extrahepatic bile duct, or both (see Fig 46-5). No proven therapy exists for primary sclerosing cholangitis, although ursodeoxycholic acid and methotrexate are being used in some centers. Other forms of therapy include prophylactic antibiotics for prevention of recurrent bacterial cholangitis, treatment of pruritus, and repletion of fat-soluble vitamins. Endoscopic dilation of a *dominant* biliary stricture during ERCP is an effective treatment of cholestasis in selected patients. Most patients with advanced primary sclerosing cholangitis eventually progress to end-stage liver disease, and evaluation for liver transplantation is appropriate in advanced disease. One third of patients with primary sclerosing cholangitis will develop cholangiocarcinoma; therefore, thorough clinical, laboratory (liver function tests and cancer markers such as CA 19-9), and radiologic follow-up are warranted.

Other Disorders of the Biliary Tree

BILIARY STRICTURES

Benign biliary strictures usually result from surgical injury or chronic pancreatitis. Biliary strictures resulting from surgical injury may cause symptoms days to years later. Early diagnosis is important because strictures that partially obstruct are clinically asymptomatic and may cause secondary biliary cirrhosis. Biliary stricture should be suspected in any patient with a history of surgery of the right upper quadrant or chronic pancreatitis (typically caused by alcohol) with a persistently elevated serum alkaline phosphatase and γ -glutamyl transpeptidase. Endoscopic balloon catheter dilation with or without stenting or surgical repair is useful in selected patients.

OTHER NONMALIGNANT CAUSES OF BILIARY OBSTRUCTION

Structural abnormalities such as choledochal cysts, Caroli disease (congenital saccular intrahepatic bile duct dilation), and duodenal diverticula may also cause bile duct obstruction, often with secondary choledocholithiasis resulting from bile stasis. Hemobilia, with intermittent bile duct obstruction by blood clots, may be caused by hepatic injury, neoplasms, or hepatic artery aneurysms. Biliary parasites should always be considered as a cause of biliary strictures in the appropriate epidemiologic setting. *Ascaris lumbricoides* is a common cause of cholangitis and jaundice in South America, Africa, and the Indian subcontinent. *Clonorchis sinensis* is the etiologic agent of oriental cholangiohepatitis in Korea and Southeast Asia and in immigrants to the United States. The liver fluke *Fasciola hepatica* is a leading cause of biliary strictures and cholangitis worldwide, most commonly in the Bolivian Andes.

BILIARY NEOPLASMS

Biliary neoplasms such as gallbladder cancer, cancer of the ampulla of Vater, and cholangiocarcinoma are uncommon in the United States, but gallbladder cancer is common in other parts of the world, such as Chile and Southeast Asia.

Risk factors for developing these cancers include primary sclerosing cholangitis, chronic ulcerative colitis, choledochal cysts, gallstones, *C. sinensis* infection, hepatolithiasis, and α_1 -antitrypsin deficiency. Cholangiocarcinoma and cancer of the ampulla of Vater usually exhibit as unremitting painless jaundice, although necrosis and sloughing of the tumor may cause intermittent biliary obstruction and the appearance of occult fecal blood. If cholangiocarcinoma is present at the bifurcation of the extrahepatic bile duct (50% of cases), the condition is known as *Klatskin tumor* (see Fig 46-6). Carcinoma of the gallbladder often produces advanced disseminated disease with weight loss, jaundice, pruritus, and a large right upper quadrant mass. Symptoms of gallbladder cancer also may resemble those of acute or chronic cholecystitis, particularly when the tumor is small. Although early-stage tumors can be treated surgically, most cases are diagnosed at an advanced stage and are hence incurable.

GALLBLADDER POLYPS

Gallbladder polyps are outgrowths of the gallbladder mucosal wall. Most of these lesions are not neoplastic but are hyperplastic or represent lipid deposits (cholesterolosis). Patients who have gallbladder polyps and concomitant gallstones should undergo cholecystectomy regardless of the polyp size or the presence of symptoms because gallstones are a risk factor for gallbladder cancer in patients with gallbladder polyps. Cholecystectomy should also be recommended for patients who have biliary colic or pancreatitis. Patients with gallbladder polyps larger than 1 cm should undergo cholecystectomy because of their malignant potential. Polyps smaller than 1 cm should be monitored with periodic imaging.

Figure 46-6 Cholangiogram at ERCP demonstrating Klatskin tumor at the bile duct bifurcation.

SPHINCTER OF ODDI DYSFUNCTION

Sphincter of Oddi dysfunction is a benign motility disorder leading to noncalculous obstruction to the flow of bile or pancreatic juice at the level of the pancreatobiliary junction. Patients typically have unexplained abdominal pain (biliary-type pain), with or without elevations of the liver tests. In a selected group of patients, endoscopic or surgical sphincterotomy is of value.

Prospectus for the Future

Imaging of the biliary tract is a critical component of the diagnosis and treatment of biliary disorders. MRCP and endoscopic ultrasound are increasingly used to define which patients require more invasive evaluation and treatment by ERCP. These modalities may also provide important additional information not obtainable by ERCP. As technology improves, these alternate techniques are likely to become the mainstay of diagnosis for biliary disorders, allowing ERCP to be targeted to patients who require specific diagnostic and therapeutic interventions.

A second area of focus in biliary tract disorders is the accurate diagnosis of cholangiocarcinoma, particularly in the setting of primary sclerosing cholangitis. A significant number of novel genetic and immunologic approaches for analysis of bile and biliary epithelium have recently been exploited. These markers may provide a means for significantly enhancing the sensitivity and specificity of detecting cholangiocarcinoma.

Hematopoiesis and Hematopoietic Failure

Eunice S. Wang and Nancy Berliner

Hematopoiesis

Hematopoiesis is the process that determines the formation and development of the wide variety of cellular elements of the blood. The constituents of peripheral blood arise by a complex and carefully regulated process of ontogeny. The pluripotent hematopoietic stem cell both maintains itself by self-renewal and undergoes multilineage differentiation to generate the appropriate numbers and types of cells within the circulating blood compartment (Table 47-1). The hematopoietic system is unique in that it is constantly undergoing this full cycle of maturation by which a primitive cell develops into a variety of highly specialized end-stage cells, all of which have different life spans and are present in different quantities. The bone marrow must have the capacity to produce cells to compensate for the normal rapid turnover of hematopoietic cells resulting from senescence, utilization, and migration into tissue spaces. Furthermore, it must have a reserve capacity to produce additional cells in response to unusual demands that arise from bleeding, infection, or other stresses. Understanding the repeated cycle of cellular ontogeny and self-renewal that meets these challenges provides important insights into normal and pathologic mechanisms in hematology.

HEMATOPOIETIC TISSUES

Hematopoiesis commences in the embryonic yolk sac, in which early erythroblasts in blood islands form the first hemoglobinized cells. After 6 weeks of gestation, the fetal liver begins producing primitive lymphocytoid cells, megakaryocytes, and erythroblasts, and the spleen becomes a secondary site of erythropoiesis. Hematopoiesis then shifts to its definitive long-term site in the bone marrow, the principal site for lifelong hematopoiesis in the normal host. Early in life, all fetal bones contain this regenerative bone marrow, but the marrow becomes progressively replaced by fat with age. In adults, active marrow resides only in the axial skeleton (sternum, vertebrae, pelvis, and ribs) and in the proximal ends of the femur and humerus. Consequently, bone

marrow samples, needed for many hematologic diagnoses, are usually obtained from the iliac crest or sternum. Under pathologic conditions that stress the capacity of the marrow space, as seen in diseases associated with marrow fibrosis (myeloproliferative diseases) or in severe inherited hemolytic anemia (thalassemia major), extramedullary hematopoiesis may be reestablished in sites of fetal hematopoiesis, especially the spleen.

STEM CELL THEORY OF HEMATOPOIESIS

All mature hematopoietic cells are hypothesized to originate from a small population of pluripotent stem cells. Comprising less than 1% of all cells in the bone marrow, these cells bear no distinctive morphologic markings and are best defined by their unique functional properties. Stem cells have two distinctive characteristics. First, they are highly resilient and productive, capable of continuously replenishing huge numbers of granulocytes, lymphocytes, and erythrocytes throughout life. The demand for a continuous fluctuating supply of blood cells requires a hematopoietic system capable of producing large numbers of selected cells in a short time. For example, overwhelming infection by invading microorganisms triggers the release of neutrophils, whereas hypoxia or acute blood loss leads to increased red blood cell production. Second, hematopoietic stem cells (HSCs) represent a self-renewing cell population that is able to maintain its numbers while also providing a continued supply of progenitor cells of multiple different lineages.

Despite their vast proliferative potential, under normal conditions, most HSCs are quiescent, and few cells undergo expansion or differentiation at any one time. However, their ability to proliferate is striking. Studies with lethally irradiated mice have demonstrated the ability of a few transplanted cells (termed *colony-forming unit-spleen cells* [CFU-S]) to regenerate multilineage hematopoiesis.

The signals regulating the differentiation of pluripotent stem cells into committed progenitors are unknown. Data suggest that the first step toward lineage commitment is a *stochastic* (chance) event; subsequent stages of maturation

are hypothesized to occur under the influence of growth factors, or cytokines (Table 47-2). Cytokines act on different cells through specific cytokine receptors. Activation of these receptors induces signal-transduction pathways that lead to changes in gene transcription and eventual cell proliferation and differentiation. These growth factors have also been shown to act as survival factors for the developing hematopoietic cells by preventing *apoptosis* (programmed cell death). This process occurs in the cellular milieu of the bone

marrow, and the well-recognized fact is that hematopoiesis also depends in part on the nonhematopoietic cells (fibroblasts, endothelial cells, osteoblasts, and fat cells) that make up the bone marrow microenvironment. Recent research in HSC biology has focused on how these cells are regulated by growth factors in the marrow local microenvironment and by unique cell surface ligand interactions between stem cells and the surrounding stromal cells in well-defined sites termed *stem cell niches*.

HEMATOPOIETIC DIFFERENTIATION PATHWAY

Traditionally, hematopoiesis has been hypothesized to proceed along a tightly regulated hierarchy (Fig. 47-1) governed by effects of intrinsic transcription factors and cytokines in the bone marrow microenvironment. As more primitive cells mature under the influence of specific regulatory cytokines, they undergo several cell divisions and become *progenitor cells* committed to one lineage. They also lose their self-renewal capacity. Morphologically, these cells are transformed from nonspecific blastlike cells into cells that can be identified by their color, shape, and granular and nuclear content. Functionally, they acquire distinguishing cell surface receptors and responses to specific signals. Maturing *granulocytes* and *erythroid cells* undergo several more cell divisions in the bone marrow, whereas *lymphocytes* travel to the thymus and lymph nodes for further development. *Megakaryocytes* cease cellular division but continue with nuclear replication. Eventually, these cells are released from the marrow as fully functional *erythrocytes*, *mast cells*, *granulocytes*, *monocytes*, *eosinophils*, *macrophages*, and *platelets*.

Table 47-1 Normal Values for Peripheral Blood Cells

Cell Type and Size	Mean	Range
Hemoglobin	Women: 14 g/dL Men: 15.5 g/dL	Women: 12-16 g/dL Men: 13.5-17.5 g/dL
Hematocrit	Women: 41% Men: 47%	Women: 36%-46% Men: 41%-53%
Reticulocyte Count	1%	0.5%-1.5%
Mean corpuscular volume	80-100	
Platelet count	250,000/mcL	150,000-400,000/mcL
Total white count	7400/mcL	4500-11,000/mcL
Neutrophils	4400/mcL (40%-60%)	1800-7700/mcL
Lymphocytes	2500/mcL (20%-40%)	1000-4800/mcL
Monocytes	300/mcL (<5%)	

Table 47-2 Cytokines and Their Activities

Abbreviation	Name	Effects on Hematopoiesis
EPO	Erythropoietin	Stimulation of proliferation and maturation of erythroid progenitors; produced by the kidney in response to anemia and hypoxia; important clinically for treatment of anemia associated with low EPO levels (renal failure, anemia of chronic disease)
G-CSF	Granulocyte colony-stimulating factor	Stimulation of proliferation and maturation of granulocytes; more broad-based effect because also increases release of <i>stem cells</i> in peripheral blood; clinically important for treatment of neutropenia and mobilization of stem cells for transplantation
GM-CSF	Granulocyte-monocyte colony-stimulating factor	Proliferation of granulocyte and monocyte precursors; role unclear in steady-state hematopoiesis because knockout has no hematopoietic phenotype
TPO	Thrombopoietin	Proliferation of megakaryocytes; results disappointing in clinical studies
M-CSF	Monocyte colony-stimulating factor	Proliferation of monocytes
IL-2	Interleukin-2	Proliferation of T cells
IL-3	Interleukin-3 (multi-CSF)	Proliferation of granulocytes, monocytes; broad-based effects, appearing to increase the proliferation of <i>stem cells</i> ; not in use clinically
IL-4	Interleukin-4	Proliferation of B cells
IL-5	Interleukin-5	Proliferation of T cells, B cells; proliferation and differentiation of eosinophils
IL-11	Interleukin-11	Proliferation of megakaryocytes; undergoing clinical testing
LIF	Leukemia inhibitory factor	Proliferation of stem cells and megakaryocytes
SCF	Stem cell factor (kit ligand)	Proliferation of progenitor cells; broad-based effects on multiple lineages

CSF, colony-stimulating factor.

Figure 47-1 Schema of the development of the cells of the bone marrow. Ba, basophil; BFU, blast-forming unit; CFU, colony-forming unit; E, erythroid; Eo, eosinophil; G, granulocyte; GEMM, granulocyte-erythrocyte-macrophage-megakaryocyte; GM, granulocyte-macrophage; Meg, megakaryocyte; NK, natural killer.

Pluripotent Stem Cells

The pluripotent HSC is morphologically indistinguishable and is best identified by its expression of the cell differentiation antigen, CD34, and by its ability to form pluripotent colonies in vitro. Under the influence of interleukin-1 (IL-1), IL-3, IL-6, fms-like tyrosine kinase 3 (*flt-3*), and a specific stem cell factor (*c-kit* ligand, or steel factor), this cell matures into either a myeloid-lineage stem cell (CFU-granulocyte-erythrocyte-macrophage-megakaryocyte [CFU-GEMM]) or a lymphoid-lineage stem cell. In the presence of granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-3, the myeloid stem cell will further differentiate into daughter cells of its named lineages (see Fig. 47-1). The lymphopoietic stem cell, in contrast, will become either a pre-B cell or a prothymocyte (pre-T cell) and will leave the marrow for further maturation.

Erythroid Lineage

Primitive erythroid precursors arising from the myeloid stem cell are called burst-forming unit-erythroid cells. These cells then differentiate into CFU-erythroid (CFU-E) cells, which are the committed progenitor cells of erythrocytes. CFU-E cells express receptors for erythropoietin (EPO), an 18-kD molecule produced by renal interstitial cells in response to low oxygenation states or anemia. EPO upregulates proliferation of CFU-E cells and promotes their maturation into proerythroblasts and reticulocytes, which begin to synthesize hemoglobin (see Table 47-2).

Granulocyte and Monocyte Lineages

Human GM-CSF acts early in the hematopoietic pathway to regulate maturation of the CFU-GEMM stem cell. Differen-

tiation of this myeloid precursor into specific committed progenitors occurs under the direction of granulocyte-CSF (G-CSF) and monocyte-CSF (see Table 47-2). CFU-granulocyte cells undergo sequential transformation into easily recognizable myeloblasts, myelocytes, and eventually early polymorphonuclear neutrophils with their characteristic polysegmented nuclei. CFU-monocyte cells, in contrast, retain a single nucleus as they mature from monoblasts to promonocytes to monocytes and sometimes macrophages.

Other Lineages

Eosinophils and basophils develop from CFU-GEMM cells under the influence of IL-5 and IL-3-IL-4, respectively. The acquisition of their specific granular contents helps in distinguishing their precursors from those of early monocytes. The development of platelets is morphologically distinct from the other lineages. CFU-GEMM cells differentiate into CFU-megakaryocyte cells, so named because these cells cease cell division early but not nuclear replication. Megakaryocytes are the only cells in the body with the capacity to double their DNA content (termed *endomitosis*). Over the course of several cell cycles, the maturing megakaryocyte eventually acquires several times the nuclear content of other cells in preparation for its eventual dissolution into platelets with a fraction of the cytoplasm of other hematopoietic cells. Two growth factors, thrombopoietin (TPO) and IL-11, have been shown to increase platelet counts by promoting megakaryocyte development (see Table 47-2).

Stem Cell Plasticity

Provocative recent data have challenged the conventional paradigm of hierarchical hematopoietic stem differentiation. Experts have proposed that hematopoietic stem cells can not only differentiate back into more immature progenitors, but can also cross lineages and transdifferentiate into nonlymphohematopoietic cells such as myocytes, hepatocytes, gastrointestinal epithelial cells, and neurons. Whether this *plasticity* of hematopoietic stem cells is truly an intrinsic property of adult stem cells or is caused by contaminating cells of other populations, fusion of hematopoietic cells with other tissue cells, or artifacts introduced by *ex vivo* stem cell isolation techniques remains controversial. Nevertheless, the suggestion that adult hematopoietic stem cells may be a dynamic renewable resource for tissue repair and regeneration holds great future promise.

Primary Hematopoietic Failure Syndromes

Diseases of the hematopoietic stem cell that disrupt the normal regulated pattern of stem cell development can result in underproduction of mature progeny (*aplastic anemia*), overproduction of mature progeny (*myeloproliferative disease*), or failed differentiation with the production of excess immature forms (*myelodysplasia* and *acute leukemia*). *Hematopoietic failure*, defined as the inability of hematopoietic stem cells to produce normal numbers of mature blood cells, manifests clinically as peripheral pancytopenia (decreased production of all blood cell lineages). Although marrow dysfunction causing pancytopenia can arise from a

 Hairy cell leukemia

II. Systemic Diseases with Secondary Bone Marrow Effects

Metastatic solid tumor to marrow
 Autoimmune disorders (systemic lupus, Sjögren syndrome)
 Nutritional deficiencies (vitamin B₁₂, folate, alcoholism)
 Infections (overwhelming sepsis from any cause, viruses, brucellosis, ehrlichiosis [mycobacteria])
 Storage diseases (Gaucher disease, Niemann-Pick disease)
 Anatomic (hypersplenism)

number of causes, both hematologic and nonhematologic (Table 47-3), primary bone marrow failure disorders are characterized by a profound impairment of the ability of the HSC to replenish the stem cell pool. Rarely, marrow failure syndromes are found to be due to intrinsic HSC defects. In most cases, these disorders are the result of extrinsic damage to inherently normal HSC. The most common treatment modalities for primary hematopoietic failure disorders consist of exogenous growth factor administration and stem cell transplantation.

GROWTH FACTORS IN CLINICAL USE

The discovery of the factors that influence normal hematopoiesis has led to important applications to the treatment of patients with defects in hematopoietic cell production. The discovery that committed hematopoietic cells of each lineage can be stimulated to proliferate and differentiate in the presence of specific cytokines (see Table 47-2) has been of great clinical utility. Advances in DNA technology have led to the synthesis and purification of recombinant human (rh) proteins with similar biologic activity *in vivo*. The administration of these products to patients has allowed the successful manipulation of the numbers of mature cells in the peripheral blood. For example, exogenous erythropoietin is now considered a mainstay in the management of anemia caused by renal failure, chemotherapy, and marrow failure syndromes. The use of G-CSF or GM-CSF in patients with febrile neutropenia and documented infection or sepsis after chemotherapy or radiation therapy has been demonstrated to reduce hospital stays and to shorten the period of high infection risk. Administration of GM-CSF has also been hypothesized to improve host immune responses to fungal infections. High-dose G-CSF also is routinely used to mobilize CD34⁺ marrow stem cells into the peripheral blood for collection before and after stem cell transplantation in patients with delayed stem cell engraftment (see later). Early trials of TPO growth factors to stimulate platelet production

were halted owing to development of antihuman platelet antibodies in some patients. Second-generation thrombopoietic agents bearing no structural resemblance to TPO but designed to bind and activate the TPO receptor are in clinical trials. Treatment with romiplostim, a recombinant protein defined as a peptibody and given as a weekly subcutaneous injection, was recently approved for patients with chronic immune-mediated thrombocytopenia based on studies showing a doubling of platelet counts and decreased platelet transfusion requirements in treated patients. Eltrombopag, an orally available small organic TPO agonist, was given daily to similar patients and also induced platelet elevations with little reported toxicity. The potential application of TPO agonists for management of thrombocytopenia in marrow failure syndromes awaits the results of ongoing phase III clinical trials.

HEMATOPOIETIC STEM CELL TRANSPLANTATION**Types of Transplantations**

Our understanding of HSC biology has fostered the development of techniques to manipulate these cells for therapeutic purposes. The fact that the antitumor effects of most chemotherapeutic drugs and radiation therapy are dose dependent and that both cause a major dose-limiting toxicity of myelosuppression has long been known. Hematopoietic stem cell transplantation permits the administration of intense myeloablative doses of chemotherapy and total-body radiation intended to eradicate malignant cells followed by the infusion of stem cells (either from a donor or from the same patient) to replete the ablated marrow. Although historically used in the treatment of primary stem cell disorders such as leukemia, the therapeutic potential of transplantation is now being employed for patients with nonmalignant hematologic malignancies (e.g., aplastic anemia, sickle cell anemia, congenital immunodeficiencies), solid tumors (e.g., renal cell carcinoma, melanoma), and nonmalignant autoimmune diseases (e.g., amyloidosis, systemic lupus). In general, younger patients (<50 years of age) are considered the best candidates for this intensive therapy, although this too is changing in the setting of newer supportive modalities. Several modes of stem cell transplantation have been developed. In *autologous transplantation*, the patient's bone marrow or peripheral blood stem cells are collected during remission following high-dose chemotherapy or rhG-CSF administration. These cells are cryopreserved, thawed, and reinfused. Such an approach incurs a higher risk for relapse as a result of reinfusion of a stem cell product that may remain contaminated with tumor. *Allogeneic stem cell transplantation* is a procedure whereby abnormally functioning hematopoietic bone marrow is eradicated and is replaced with normal bone marrow or stem cells from a compatible source, either a related or an unrelated donor. High-dose chemotherapy with or without total-body radiation is administered to destroy the patient's bone marrow, followed by the infusion of new stem cells that engraft and restore normal hematopoiesis. Treatment-related morbidity is significant, with a procedure-related mortality of 10% to 30%; however, improvements in supportive care and immunomodulatory therapy designed to suppress *graft-versus-host*

disease (GVHD), an autoimmune phenomenon in which intact lymphocytes in the transplanted marrow attack the host tissues, are continuing to improve outcome. Donor and patient are tested for compatibility of human leukocyte antigen (HLA) and major histocompatibility complex (MHC) proteins expressed on all cells. Three major HLA class I antigens (A, B, and C) and three MHC class II antigens (DP, DQ, and DR) have been developed. The six HLA gene loci are tightly linked on chromosome 6 and are almost always inherited on a single cluster of genes, or *haplotype*. Therefore, all children are a *half-match* (*haploidentical*) to each of their parents, and full siblings have a 25% probability of being HLA identical to one another. HLA-matched non-related transplants have higher rates of GVHD than transplants from HLA-matched related donors as a result of other minor HLA incompatibilities. Patients who receive *HLA-mismatched* stem cell transplantation risk acute GVHD, marrow rejection, and fatal marrow aplasia. Morbidity and mortality associated with non-HLA-compatible transplants can be prohibitive.

Increasing evidence indicates that the excellent response of some patients to HSC transplantation is partly related to the active suppression of the patient's original or residual or relapsing disease by cells from the newly transplanted donor graft, referred to as the *graft-versus-leukemia* (GVL) effect. Studies have documented the compelling observation that infusion of donor lymphocytes can restore remission in patients with evidence of relapse after allogeneic transplantation for chronic myelogenous leukemia (CML). Conversely, procedures that minimize the reactivity between donor and host increase disease relapse. For example, the rate of relapse in patients who receive *syngeneic* (identical twin) *stem cell transplantation* and in patients who receive T-cell-depleted marrow in an attempt to reduce GVHD is increased.

The observation of the effectiveness of donor lymphocyte infusions in controlling CML has led to the conclusion that the immunologic effects of transplanted allogeneic cells may be as important as (or more important than) cytoreduction for the cure of some hematologic malignancies. To further exploit these effects, *nonmyeloablative stem cell transplantations* are now performed, whereby patients receive conditioning and immunosuppressive regimens in doses sufficient to permit donor stem cell engraftment without aggressive cytoreduction. These *mini-transplants* result in chimeric marrows (part patient, part donor) without significant periods of cytopenias or hematopoietic compromise, although most responding patients convert to a fully donor-derived marrow over time. Although still experimental, these procedures are increasingly being used in patients who are otherwise ineligible for traditional myeloablative transplantation regimens (age >50 to 55 years or other comorbidities) or in individuals with nonmalignant autoimmune or congenital disorders.

Hematopoietic Stem Cell Sources for Transplantation

Historically, stem cell transplantations have employed allogeneic *bone marrow* (BM) *stem cells* aspirated from the posterior iliac crest of the donor and intravenously infused into the patient following myeloablation and immunosuppressive therapy. The process of engraftment or reconstitution

of normal hematopoietic function takes several weeks. Patients often require almost daily platelet and red blood cell transfusions and are hospitalized during this period of prolonged neutropenia to minimize life-threatening bacterial, viral, and fungal infections. Other complications include severe mucositis, hemorrhagic cystitis, GVHD, relapsed disease, and graft failure. The discovery that high-dose rhG-CSF treatment results in the mobilization of large numbers of CD34⁺ hematopoietic progenitor and stem cells from bone marrow sites into circulating blood (up to 10- to 15-fold increase over baseline levels) has led to the use of *peripheral blood stem cells* (PBSC) collected by apheresis procedures in place of bone marrow stem cells for allogeneic transplantation. When compared with marrow-derived stem cells, PBSC engraft more rapidly after myeloablation. Patients receiving allogeneic PBSC transplants have decreased neutrophil recovery time, lower transfusion requirements, and fewer inpatient hospital days with similar rates of acute GVHD and long-term survival outcomes as traditional marrow transplanted patients. Because PBSC collections often contain threefold to fourfold more CD34⁺ stem cells and 10-fold more lymphoid cells than do harvested marrow grafts, higher rates of chronic GVHD may occur. *Umbilical cord blood* (UCB) *stem cells* have also been found to be a rich source of immature CD34⁺ HSCs. The less stringent HLA compatibility requirements of UCB-HSC matches have led to the increasing use of these transplants as a therapy for patients lacking full compatible HLA-matched PBSC or BM donors. Although still considered experimental, some transplantation centers have reported similar long-term outcomes following UCB transplants as conventional marrow or peripheral blood stem cell transplants for primary hematologic diseases. However, the relatively fewer (and limited) numbers of CD34⁺ stem cells found in harvested umbilical cord units accounts for a much slower hematopoietic recovery following UCB and a statistically higher risk for nonengraftment compared with other stem cell sources. For this reason, UCB transplantation procedures have been limited to pediatric patients and smaller adults or to adult patients for whom there is more than one HLA-compatible UCB unit.

APLASTIC ANEMIA

Etiology and Pathogenesis

Aplastic anemia (AA) is a rare disorder characterized by pancytopenia with a markedly hypocellular bone marrow. This disease was first described by Paul Ehrlich in 1888, who noted that autopsy bone marrow specimens from a young woman who died of severe anemia and neutropenia were extremely hypoplastic. More recent studies demonstrate that patients with severe AA possess only a fraction of normal pluripotent stem cell numbers despite normal functional marrow stromal cells and normal or even elevated levels of stimulatory cytokines. AA is an uncommon disease. The incidence ranges from 1 to 5 cases per million in the general population, found predominantly in young adults (20 to 25 years of age) and older adults (60 to 65 years of age). Interestingly, the incidence is threefold higher in developing countries (Thailand and China) compared with industrialized Western nations (Europe and Israel), a fact that is not

Table 47-4 Causes of Acquired Aplastic Anemia

Drugs (dose related): chemotherapeutic agents, antibiotics (chloramphenicol, trimethoprim-sulfamethoxazole)
Idiosyncratic (many unproven): chloramphenicol, quinacrine, nonsteroidal anti-inflammatory drugs, anticonvulsants, gold, sulfonamides, cimetidine, penicillamine
Toxins: benzene and other hydrocarbons, insecticides
Viral infection: hepatitis, Epstein-Barr virus, human immunodeficiency virus
Immune disease: graft-versus-host disease in immunodeficiency, hypogammaglobulinemia
Paroxysmal nocturnal hemoglobinuria (PNH)
Radiation
Pregnancy

explained by differences in drug or radiation exposure. A small proportion of AA cases occur in the context of a congenital bone marrow failure disorder, such as Fanconi anemia, Shwachman-Diamond syndrome, and dyskeratosis congenita. The most common congenital AA, Fanconi anemia, is an autosomal recessive disorder arising from mutations in genes encoding DNA repair proteins.

The known causes of acquired AA are numerous (Table 47-4) and range from myeloablative radiation exposure to common viruses and medications. Prior bone marrow toxicity from drugs, chemicals (benzene, cyclic hydrocarbons found in petroleum products, rubber glue, insecticides, chemical dyes), or radiation predisposes to AA because these agents directly injure proliferating and differentiating HSC by inducing DNA damage. In contrast, therapies such as cytotoxic chemotherapy (especially with alkylating agents) and radiation target all rapidly cycling cells and often induce reversible bone marrow aplasia. Despite these many causes of acquired AA, most AA cases are idiopathic.

Acquired and congenital AA appear to be linked etiologically through abnormal telomere maintenance. Telomeres are repeated nucleotide sequences, which cap and protect chromosome ends from degradation. Cell division leads to normal telomere erosion; when telomeres reach a critically short length, cells cease to proliferate, senesce, and undergo apoptosis, often with accompanying DNA damage and genomic instability. The presence of the telomerase enzyme in normal HSC preserves long telomeres and promotes quiescence and prolonged cellular life span. Patients with autosomal dominant dyskeratosis congenita have mutations in genes for telomerase complexes, predisposing to premature aging and enhanced marrow failure in the setting of accelerated telomere shortening. One third of patients with acquired AA also have short telomeres likely due to a combination of genetic, environmental, and epigenetic factors.

Autoreactive host lymphocytes also function as culprits in destroying normal hematopoiesis in AA. Bone marrow stromal cells and cytokine levels in patients with AA are normal. The fact that AA also occurs in diseases of immune dysregulation and after viral infections further suggests an immune-mediated mechanism for the disease. One hypothesis is that antigens presented to the immune system by viruses or drugs trigger cytotoxic T-cell responses that then persist to destroy normal stem cells. In rare instances, 1 in 100,000 patients will develop a severe AA as an idiosyncratic

drug reaction. Whether these individuals unknowingly possess a certain genetic predisposition to sensitivity to exposures (such as nonsteroidal anti-inflammatory drugs, sulfonamides, or the Epstein-Barr virus) commonly found in the general population is unknown.

Clinical Features

The clinical onset of AA can be insidious or abrupt. Patients often complain of symptoms related to their cytopenias: weakness, fatigue, dyspnea, or palpitations resulting from anemia; gingival bleeding, epistaxis, petechiae, or purpura caused by low platelet counts; or recurrent bacterial infections caused by low or nonfunctioning neutrophils. Physical examination is often normal except in patients with congenital AA who may have various abnormalities.

Laboratory Studies

Diagnostic confirmation of AA requires bone marrow biopsy to confirm hypocellularity and to rule out other marrow processes. Normal bone marrow cellularity ranges from 30% to 50% up to age 70 years and is under 20% after age 70 years (Web Fig. 47-1A). In contrast, bone marrow cellularity in patients with AA usually ranges from 5% to 15% cellularity with increased fat accumulation and few, if any, hematopoietic cells (primarily plasma cells and lymphocytes) (Web Fig. 47-1B). In AA, hematopoietic progenitor and precursor cells are morphologically normal but number less than 1% of normal levels and have been shown to be markedly dysfunctional with a decreased ability to form differentiated progenitor cell colonies in vitro. Evidence of increased blasts, dysplastic hematopoietic cells (such as pseudo-Pelger-Huët abnormalities or micromegakaryocytes) (Web Fig. 47-2), or clonal cytogenetically abnormal cells in the peripheral blood or marrow are diagnostic of acute leukemia or myelodysplasia and not AA, even in the setting of a hypocellular marrow. In young patients, a diagnosis of Fanconi anemia is made by demonstrating enhanced sensitivity of cultured cells to mitomycin or diepoxybutane-induced chromosomal damage. Although patients with AA typically have a low reticulocyte count from low red blood cell production with a paucity of blood cells (Web Fig. 47-3A) and macrocytic red cells (Web Fig. 47-3B) on the peripheral smear, patients with other primary marrow disorders may also exhibit similar findings.

Treatment

Treatment of AA is based on the severity of disease. Patients with mild cytopenias can be monitored expectantly. However, patients with severe AA based on peripheral blood cells counts (defined as a neutrophil count <500/ μ L, platelet count <20,000/ μ L, anemia with corrected reticulocyte count <1%, and marrow cellularity 5% to 10%) have a poor median survival rate of 2 to 6 months without treatment. Because most of these patients die from overwhelming infections, supportive care with broad-spectrum antibiotics, antifungal agents, and antiviral agents is warranted in patients with advanced neutropenia. Red blood cell and platelet transfusions are helpful in patients who are profoundly symptomatic (with care given to patients eligible for transplantation).

Current therapeutic approaches to AA are focused on either replacing the defective HSC by stem cell transplanta-

tion or controlling an overactive immune response. All young patients with severe AA and an HLA-compatible bone marrow donor should be considered for allogeneic bone marrow transplantation, which offers the best chance for definitive cure. Although long-term survival is excellent in patients younger than 30 years transplanted from a sibling donor (75% to 90%), morbidity from the transplant itself and the management of long-term transplant-related complications are continuing problems. Outcome in patients older than 40 years or in patients without an HLA-matched related donor are poor.

The presumed immune mechanisms for drug-induced aplasia have provided the impetus for immunosuppressive approaches to the treatment of AA in older patients, in patients who are unable to find a compatible stem cell donor, and in those who are otherwise ineligible for stem cell transplantation. Treatment with a combination of antithymocyte globulin (ATG) and cyclosporine (a specific T-cell inhibitor) allows for restoration of marrow function (i.e., independence from red blood cell or platelet transfusions) in 70% to 80% of patients, with a 5-year survival rate in responders of 90%. Side effects of ATG include anaphylaxis and serum sickness as a result of foreign antigens in the antisera, which are generally self-limited. Patients often relapse and recur with this disease and may warrant retreatment with repeat ATG, newer immunosuppressive agents (such as mycophenolate mofetil), androgens, and experimental agents. Treatment with traditional chemotherapies such as cyclophosphamide has usually proved too toxic. Because endogenous cytokine production is usually high in patients with AA, the routine use of growth factors such as rhG-CSF, EPO, or stem cell factor is generally ineffective; however, in patients with refractory disease, long-term administration of combination cytokines appears to have some effects in sustaining blood cell counts. Patients who survive the initial treatment of aplasia, however, remain at increased risk for the emergence of other primary hematologic disorders, such as myelodysplasia, leukemia, and paroxysmal nocturnal hemoglobinuria (PNH). The relationship of such clonal disorders to the pathogenesis of the original aplastic anemia is controversial.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Etiology and Pathogenesis

PNH is an uncommon disease characterized by intravascular hemolysis and venous thrombosis in association with bone marrow failure. The disease arises from expansion of pluripotent hematopoietic stem cells containing a somatic mutation in the phosphatidylinositol glycan complementation class A (*PIG-A*) gene. Loss of *PIG-A*, which codes for a membrane lipid moiety (glycosyl phosphatidylinositol [GPI]), leads to abnormal hematopoietic cells deficient in dozens of proteins that are normally attached to the cell surface by the GPI anchor. Disease manifestations of PNH result from lack of the GPI-linked proteins (CD55 and CD59) that usually protect red blood cells and platelets from complement-mediated attack. Loss of CD55 or CD59 leads to increased immune destruction of blood cells. Blood cells arising from abnormal PNH clones can have complete (type

III cells) or partial (type II cells) GPI deficiency. The degree of GPI deficiency is associated with the severity of the clinical symptoms. Of note, GPI-deficient cells almost always coexist in the marrow with varying populations of normal GPI-expressing cells (type I cells). The presence of small numbers of abnormal PNH clones in patients with AA or myelodysplastic syndrome (MDS, discussed later) suggest significant overlap in the etiologies of all three of these diseases. This has led to the reclassification of PNH into “classic PNH disease” and “PNH in the setting of another specified bone marrow disorder.” Mechanistically, it is postulated that suppression of normal hematopoiesis by the host immune system, directly or indirectly by a preceding or coexistent disorder, provides a marrow environment favoring selective expansion of PNH stem cell clones and their deficient blood cell progeny over normal hematopoiesis.

Clinical Features and Laboratory Studies

Patients are typically younger individuals who present with chronic complaints of abdominal pain, dysphagia, erectile dysfunction, and intense lethargy due to smooth muscle dystonia resulting from depletion of circulating nitric oxide levels by free hemoglobin. Acute exacerbations often occur on an intermittent to frequent basis and are difficult to manage. The diagnosis of PNH is made by identification of complete or partial GPI protein deficiency on red cells and granulocytes, usually identified by loss of CD59, CD55, CD16, or CD24 expression in a clonal population. Laboratory tests reveal ongoing low-grade intravascular hemolysis with increased LDH levels correlating with severity of hemolysis and symptoms. Cytopenias, particularly anemia, often render patients transfusion dependent with ongoing hemoglobinuria due to the release of free plasma hemoglobin from intracellular compartments. Median survival from diagnosis is usually 10 to 15 years. Venous thrombosis involving the cerebral and intra-abdominal veins occurs in about half of patients and is the cause of death in up to one third, although the etiology of the increased thrombotic risk is not entirely understood. Other causes of morbidity and mortality are side effects of progressive aplastic anemia (see AA, discussed earlier) and a 5% long-term risk for leukemic transformation. About 15% of PNH patients have spontaneous resolution of disease without long-term sequelae, suggesting that *PIG-A* mutations may appear transiently and disappear spontaneously in normal hematopoietic cell populations for unknown reasons.

Treatment

Treatment of PNH ranges from supportive care with transfusions and iron and folic acid supplementation to allogeneic stem cell transplantation in select patients for curative intent. Documented venous thrombosis is treated with life-long full anticoagulation. *Eculizumab* is a humanized antibody that binds with high affinity to the complement protein C5, preventing terminal complement-mediated intravascular hemolysis in patients with PNH. Results from multiple clinical trials have shown that eculizumab therapy decreases hemolysis and hemoglobinuria, reduces requirements for red blood cell transfusions, and is associated with significant improvement in quality of life for PNH patients. Therapy is generally well tolerated with a theoretical increased risk for

meningococcal infections due to complement-mediated blockade. Eculizumab therapy may also result in decreased risk for life-threatening thrombosis, which would ultimately improve long-term survival in this disease.

MYELODYSPLASTIC SYNDROME

Etiology and Pathogenesis

Myelodysplastic syndrome (MDS) is a heterogeneous group of blood disorders characterized by ineffective and disordered hematopoiesis in one or more of the major myeloid cell lines: erythroid cells, neutrophils and their precursors, and megakaryocytes. Patients have one or more cytopenias despite the presence of normal or increased numbers of hematopoietic cells in the bone marrow. Disordered maturation is accompanied by increased intramedullary *apoptosis* (programmed cell death), which contributes to the decreased release of mature cells into the periphery.

Primary MDS is predominantly a disease of elderly persons and occurs in about 1 in 500 patients between the ages of 60 and 75 years. Most cases are idiopathic. Although often considered “preleukemic” disease, the overall risk for MDS transformation to acute myeloid leukemia (AML) is only 25% to 30%. However, the identification of characteristic gene deletions (5q-) and translocations diagnostic of both MDS and AML subtypes (see Chapter 48) underline the likelihood of similar mechanisms of clonal myeloid stem cell injury in both disorders.

Persons with prior exposure to radiation, chemotherapy, and organic chemicals (benzene) are at increased risk for developing secondary MDS. This disorder may occur at any age and comprises 10% to 15% of all diagnosed MDS cases. MDS arising months to years after prior chemotherapy (involving any cytotoxic agent but particularly after alkylating agents and anthracyclines), ionizing radiation, radio-labeled antibody therapy, or stem cell transplantation for cancer is termed therapy-related MDS (t-MDS). Because t-MDS typically swiftly evolves to more aggressive disease, these cases have recently been reclassified with therapy-related acute myeloid leukemia (t-AML) and treated accordingly (see Chapter 48).

Clinical Features

Most patients with MDS are referred for evaluation of an incidental finding of peripheral cytopenias. Symptomatic patients usually exhibit findings related to the secondary effects of cytopenias: bleeding and bruising caused by thrombocytopenia, infection caused by leukopenia, or fatigue and dyspnea related to anemia. Physical examination is usually unremarkable, although 25% or more of patients may have splenomegaly. In some patients with MDS, development of skin lesions with fever (acute febrile neutrophilic dermatosis, or Sweet syndrome) may herald the transformation of MDS into acute leukemia. The disease course of MDS varies widely. Some patients may live normal life spans, but most die prematurely of cytopenia-related complications, marrow failure, or evolution to AML. Median survival is usually less than 2 years.

Laboratory Studies

Dysplasia of myeloid hematopoietic cells is evident in the blood and marrow of MDS patients. Review of the periph-

eral blood smear may show characteristic morphologic abnormalities in addition to cytopenias. Erythroid cells are usually macrocytic, often with basophilic stippling. Neutrophils are often hypogranular and hypolobulated, with a characteristic bilobed nuclear morphology termed *pseudo-Pelger-Huët abnormality*. Pelger-Huët anomaly should be anticipated when automated differential cell counts report unusually large numbers of bands. The bone marrow in MDS is usually normocellular or hypercellular, although 10% of patients may have a hypocellular marrow. Dysplastic changes usually occur in all three cell lines. Erythroid cells appear megaloblastic, with multinucleated cells or asynchronous nuclear-cytoplasmic development. Extremely small *micromegakaryocytes* and agranular megakaryocytes may also be present. The myeloid series shows poor maturation with a *left shift* to earlier hypogranulated myeloid forms. Although elevated numbers of myeloid blasts are common, increasing blasts are indicative of progression toward acute leukemia. Electron microscopy of the marrow shows cellular changes (prominent nuclear chromatin, cytoplasmic vacuoles, and blebs) characteristic of increased apoptosis (**Web Fig. 47-3**).

The natural history (and treatment of) some MDS subtypes is correlated with specific cytogenetic abnormalities, and hence careful molecular studies of the marrow should be performed at initial evaluation. For example, MDS associated with deletion of the short arm of chromosome 7 (7p-) or complex cytogenetic abnormalities such as monosomy 7 or trisomy 8 often have poor clinical outcomes. Presence of an isolated deletion in the long arm of chromosome 5 may have a well-characterized clinical course (termed the *5q-syndrome*). Patients are predominantly older women with a refractory macrocytic anemia, normal or elevated platelet counts, and an overall better clinical prognosis. These patients often live for several years with intermittent red blood cell transfusions and have a low risk for eventual leukemic transformation. The presence of multiple or complex cytogenetic aberrations carries a worse prognosis.

Although one third to one half of patients presenting with cytopenia and myeloid dysplasia will have diagnostic clonal cytogenetic abnormalities in marrow cells, in many cases, the marrow karyotype is normal. For these patients, the diagnosis of MDS should be one of exclusion with other potential causes of marrow failure and pancytopenia evaluated (see Table 47-3). MDS should never be diagnosed in acute disease states, during chronic hospitalization, or within 6 months of known myelotoxic therapy (radiation, chemotherapy). Causes such as vitamin B₁₂ or folate deficiency, alcohol use, and HIV infection should be considered. A patient with possible MDS and a hypocellular bone marrow must be evaluated for aplastic anemia. In general, the presence of (1) consistent cytopenia in one of more myeloid lineages, (2) no other obvious etiologies, and (3) dysplasia of at least 10% myeloid marrow cells or 5% to 19% blast cells should be considered MDS.

In the past, MDS was classified based on dysplastic marrow morphology and percentage of blasts into five subtypes: refractory anemia, refractory anemia with ringed sideroblasts, refractory anemia with excess blasts, refractory anemia with excess blasts in transformation, and chronic myelomonocytic leukemia (CMML). More recently, these five subtypes were expanded to eight subtypes, with recognition of

Table 47-5 World Health Organization Classification of Myelodysplastic Syndromes

Refractory Anemia (RA)

Blood: anemia, no or rare blasts
BM: erythroid dysplasia only, <5% blasts, and <15% ringed sideroblasts

Refractory Anemia with Ringed Sideroblasts (RARS)

Blood: anemia, no blasts
BM: ≥15% ringed sideroblasts, erythroid dysplasia only, <5% blasts

Refractory Cytopenia with Multilineage Dysplasia (RCMD)

Blood: cytopenias (bicytopenia or pancytopenia), no or rare blasts, $<1 \times 10^9/L$ monocytes
BM: dysplasia in ≥10% of the cells of two or more myeloid cell lines, <5% blasts, no Auer rods, <15% ringed sideroblasts

Refractory Cytopenia with Multilineage Dysplasia and Ringed Sideroblasts (RCMD-RS)

Blood: cytopenias (two or more), no or rare blasts, no Auer rods, and $<1 \times 10^9/L$ monocytes
BM: dysplasia in ≥10% of the cells of two or more myeloid cell lines, <5% blasts, ≥15% ringed sideroblasts, no Auer rods

Refractory Anemia with Excess Blasts—1 (RAEB-1)

Blood: cytopenias, <5% blasts, no Auer rods, and $<1 \times 10^9/L$ monocytes
BM: unilineage or multilineage dysplasia, 5%-9% blasts, and no Auer rods

Refractory Anemia with Excess Blasts—2 (RAEB-2)

Blood: cytopenias, 5%-19% blasts, Auer rods $\pm <1 \times 10^9/L$ monocytes
BM: unilineage or multilineage dysplasia, 10%-19% blasts, \pm Auer rods

Myelodysplastic Syndrome—Unclassified (MDS-U)

Blood: cytopenias, no or rare blasts, no Auer rods
BM: unilineage dysplasia in one myeloid line, <5% blasts, and no Auer rods

MDS Associated with Isolated del(5q)

Blood: anemia, usually normal or increased platelet count, and <5% blasts
BM: normal to increased megakaryocytes with hypolobulated nuclei, <5% blasts, isolated cytogenetic abnormality of deletion 5q, and no Auer rods

BM, bone marrow.

multilineage dysplasia as an important feature (i.e., refractory cytopenia with multilineage dysplasia, refractory cytopenia with multilineage dysplasia and ringed sideroblasts) and the reclassification of CMML as myeloproliferative-myelodysplastic syndrome (Table 47-5). The presence of an isolated 5q- cytogenetic abnormality in MDS was established as a distinct clinical syndrome. Evidence of marrow dysplasia following prior chemotherapy, radiation, or other myeloablative therapy is now considered therapy-related AML (t-AML). Although in general, MDS patients with refractory anemia and excess blasts or refractory cytopenias with multilineage dysplasia fare poorly, morphologic classification of MDS correlates only approximately with overall survival.

Classification of MDS into clinical prognostic categories remains a work in evolution. In 1998, the International Prognostic Scoring System (IPSS) was developed by an inter-

national working group to better predict clinical outcomes in MDS. The IPSS divides patients with MDS into three prognostic categories based on cytogenetic abnormalities, cytopenias, advanced age, and percentage of bone marrow blasts and provides median survival and time to leukemia transformation for each IPSS stage (Table 47-6). Based on criticism that the IPSS relies only on characteristics of patients at disease onset and includes cases now considered to be AML by the World Health Organization (WHO) criteria, a new WHO classification-based prognostic scoring system (WPSS) was devised emphasizing WHO morphology, karyotype, and transfusion dependence at any time during MDS disease course. Division of MDS patients into five new risk categories was validated to predict for overall survival and leukemic evolution for MDS at any follow up time (Table 47-7).

Treatment

New insights into the pathophysiology of ineffective hematopoiesis characterizing MDS has led to a number of therapeutic options for this disease, allowing for individualized therapy based on patient preference, performance status, disease biology, and prognostic risk category.

Supportive Therapy

Most patients with MDS are elderly individuals who may not tolerate or desire aggressive intervention without hope of cure. Many who are considered low risk for disease transformation are either transfusion independent or are managed supportively with chronic red blood cell and platelet transfusions to maintain quality of life. One complication of chronic transfusion therapy is iron overload caused by the delivery of between 200 and 250 mg of iron with each unit of transfused red blood cells. Excess iron is stored in macrophages and eventually accumulates in the hepatic parenchyma, myocardium, skin, and the pancreas, leading to secondary hemochromatosis or transfusional iron overload. Clinical symptoms include liver dysfunction, heart failure, hyperpigmentation, or diabetes mellitus. To prevent these, patients who develop marked elevations in transferrin saturation or serum ferritin levels should undergo iron chelation therapy with deferoxamine or an oral agent (deferiprone). Chronic administration of recombinant EPO has also been shown to reduce transfusion needs in some MDS patients, particularly those with low endogenous serum EPO levels and few transfusion requirements. Individuals with recurrent or refractory neutropenic infections also often receive G-CSF and GM-CSF treatment alone or in addition to EPO and antibiotic regimens. All these treatments are supportive in nature and do not affect overall survival.

Intensive Therapy

Patients with high-risk MDS (defined as MDS with cytogenetic abnormalities predisposing to leukemia transformation or high levels of circulating blasts with IPSS scores of Int-2 or higher, see Table 47-7) are candidates for aggressive AML-based chemotherapy (see Chapter 48). These standard regimens are designed to eradicate rapidly proliferating blast cells, not dysfunctional MDS cells, and therefore unsurprisingly are associated with a high relapse rate (within 12 to 18 months) and no significant prolongation of overall survival, even in patients who achieve remission. As in other

Table 47-6 International Prognostic Scoring System (IPSS) for Myelodysplastic Disorders

Score	Blasts	Karyotype	Cytopenias*	Overall Score	Median Survival (yr)
0	<5%	Normal, Y-, 5q-, 20q-	0-1 cytopenias	0	5.7
0.5	5%-10%	All other abnormalities	2-3 cytopenias	0.5-1.0	3.5
1.0		Abnormal 7, >3 abnormalities		1.5-2.0	1.2
1.5	11%-20%			2.5 or higher	0.4
2.0	21%-30%				

*Cytopenias are defined as hemoglobin < 10q/dL; neutrophils < 1500/ μ L; platelets < 100,000/ μ L.

Table 47-7 World Health Organization (WHO) Classification-Based Prognostic Scoring System (WPSS) for Myelodysplastic Disorders

Variable	0	1	2	3
WHO category	RA, RARS, 5q-	RCMD, RCMD-RS	RAEB-1	RAEB-2
Karyotype*	Good	Intermediate	Poor	—
Transfusion requirement†	No	Regular	—	—

Note: Risk groups were as follows: very low (score = 0), low (score = 1), intermediate (score = 2), high (score = 3 to 4), and very high (score = 5 to 6).

MDS, myelodysplastic syndrome; RA, refractory anemia; RARS, refractory anemia with ringed sideroblasts; RCMD, refractory cytopenia with multilineage dysplasia; RCMD-RS, refractory cytopenia with multilineage dysplasia and ringed sideroblasts; RAEB-1, refractory anemia with excess of blasts—1; RAEB-2, refractory anemia with excess of blasts—2; 5q-, myelodysplastic syndrome with isolated del(5q) and marrow blasts less than 5%.

*Karyotype was as follows: good: normal, -Y, del (5q), del (20q); poor: complex (≥ 3 abnormalities), chromosome 7 anomalies; and intermediate: other abnormalities.

†Red blood cell (RBC) transfusion dependency was defined as having at least one RBC transfusion every 8 weeks over a period of 4 months.

hematologic stem cell disorders, the only curative therapy is allogeneic stem cell transplantation, ideally performed at complete remission. AML-based chemotherapy may be offered to such patients before transplantation. All patients younger than 40 years with MDS and a HLA-matched sibling donor should be offered transplantation at diagnosis. Long-term disease-free survival rates for such patients with low-risk disease are more than 50%. The high transplant-related mortality, morbidity, and relapse rates associated with mismatched or unrelated donor transplants or with transplantation in older MDS patients have led these types of transplantation to be held in reserve until development of high-risk disease.

Targeted Therapeutic Agents

Although not curative, a panoply of novel therapeutic agents targeting the unique biologic features of MDS have been shown to improve outcomes for many MDS patients ineligible for or unwilling to pursue stem cell transplantation or supportive care. These agents, administered largely in the outpatient setting, have induced disease remissions, retarded leukemia evolution, and for the first time, prolonged overall survival of MDS patients.

The recognition that epigenetic modifications of the abnormal HSC clones in MDS affect cell growth and apoptosis and are central to disease pathogenesis led to the clinical application of two DNA methyltransferase inhibitors (5-azacytidine and decitabine) to the treatment of the disease. These agents are hypothesized to reverse the abnormal hypermethylation and gene silencing in abnormal HSC. 5-Azacytidine has been shown to delay time to leukemia transformation in two thirds of patients with transfusion-dependent MDS, decrease transfusion requirements, and improve quality of life compared with transfusion support

alone. A phase III clinical trial comparing 5-azacytidine with conventional care regimens for higher-risk MDS patients showed a superior overall survival advantage favoring 5-azacytidine treatment. These results are the first to demonstrate that any therapy can alter the natural history of this disease and renders 5-azacytidine the new standard of care for transfusion-dependent MDS patients. Decitabine is a related compound to 5-azacytidine and represents an alternative treatment option for patients with high-risk MDS. Decitabine therapy has been shown to induce remission and reduce transfusion needs in MDS patients compared with supportive care and historical controls; however, the survival benefit of decitabine use in MDS has yet to be demonstrated. One unique feature of DNA methyltransferase inhibitor therapy with either hypomethylating agent is the observation that most therapeutic responses occur 4 to 6 months after treatment initiation. Moreover, MDS patients treated with 5-azacytidine who did not achieve a defined complete remission in the marrow nevertheless still survived significantly longer than patients treated with supportive care alone. These data suggest that, in contrast to AML, the best treatment for MDS is not cytotoxic-mediated eradication of abnormal HSC clones but chronic (epigenetic) modification of cells resulting in restoration of normal hematopoiesis. It remains to be seen whether achievement of remission after hypomethylation modulation in MDS equates with long-term disease control.

Certain MDS disease subgroups appear to have hematopoietic failure mediated at least in part by autoimmune cells selectively targeting the destruction of normal HSC. These disease subsets exhibit significant overlap with AA and PNH (described earlier in this chapter). For instance, a proportion of young patients with low-risk MDS disease and a HLA-DR15 haplotype have demonstrated a 30% to 50%

improvement in counts after T-cell immunosuppressive therapy with ATG or cyclosporine. MDS patients with isolated trisomy 8 or the demonstrated presence of PNH clones, or both, have also been reported to respond to treatment with immunosuppressive agents.

Some patients with MDS characterized by deletions in the long arm of chromosome 5 (5q⁻ aberration) have a disease that is extraordinarily sensitive to therapy with lenalidomide, an immunomodulatory agent shown to exert antigrowth effects on MDS cells and the MDS marrow microenvironment. Complete and durable responses occur in up to 66% of 5q⁻ syndrome MDS patients after lenalidomide therapy and are accompanied by disappearance of the abnormal cytogenetic clone in the marrow in some patients.

Defects in ribosomal protein function, specifically the ribosomal subunit protein RPS-14, have been identified as the etiology of 5q⁻ syndrome MDS, paralleling findings implicating a different ribosomal subunit (RPS-19) in the congenital bone marrow syndrome Diamond-Blackfan anemia. This suggests a common link between these diseases. How lenalidomide works to correct hematologic abnormalities in 5q⁻ MDS patients remains an area of active investigation. Lenalidomide also induces responses in up to one third of non-5q⁻ MDS patients demonstrating a specific defect in erythroid differentiation on gene expression profiling. Whether unique gene signatures or other biologic markers in MDS patients can be used to further tailor therapy for MDS patients remains to be seen.

Prospectus for the Future

The field of stem cell biology is rapidly changing. The study of hematopoietic stem cell function in marrow failure syndromes provides hints of specific molecular pathways disturbed in many diseases of hematopoietic and nonhematopoietic stem cells. These observations are also furthering our understanding of the complex interplay among AA, PNH, and MDS. Understanding of stem cell plasticity and the stem cell niche in regulating disease may open promising new avenues for therapies of a wide array of disease. Umbilical cord blood stem cells represent a potential source of donor cells for allogeneic stem cell transplantation in patients with primary hematologic diseases lacking other HLA-matched marrow donors. Non-myeloablative stem cell transplantations (mini-transplants) employing low-dose conditioning and immunosuppressive regimens represent another emerging treatment option for

older patients with primary marrow failure syndromes. Thrombopoietin agonists that effectively stimulate platelet production in chronic immune thrombocytopenic states are likely to play an increasing role in the treatment of primary marrow failure syndromes. Novel agents targeting the unique biologic features of ineffective hematopoiesis in marrow failure syndromes have improved outcomes for many patients over the past few years: eculizumab in PNH; 5-azacytidine in transfusion-dependent MDS; immunosuppressive drugs in AA and MDS subsets; lenalidomide in 5q⁻ MDS. The finding that therapeutic responses to lenalidomide in patients with MDS lacking 5q⁻ can be predicted by the presence of a specific erythroid differentiation gene signature strongly suggests that future research may result in delineation of additional unique biologic pathways to further tailor therapeutic options for this disease.

Clonal Disorders of the Hematopoietic Stem Cell

Eunice S. Wang and Nancy Berliner

Malignant transformation involves combined defects in cellular maturation and differentiation. The multistep theory of oncogenesis suggests that these defects are often separable and may contribute to a stepwise progression from a normal to a fully transformed cell. The continuous cycling of hematopoietic cells provides a milieu for the development of clonal genetic abnormalities that support this model. Clonal defects of the hematopoietic stem cell give rise to an array of preleukemic and leukemic disorders. Primary defects of maturation give rise to the *myelodysplastic disorders* (discussed in Chapter 47), whereas loss of normal control of proliferation results in *myeloproliferative disease*. All of these disorders are preleukemic, with a variable but definite rate of transformation to acute leukemia.

Myeloproliferative Neoplasms

ETIOLOGY AND PATHOGENESIS

Myeloproliferative neoplasms (MPNs), also known as chronic myeloproliferative diseases (MPDs), are clonal stem cell disorders characterized by leukocytosis, thrombocytosis, erythrocytosis, splenomegaly, and bone marrow hypercellularity. The hallmark of MPN is the failure of a transformed multipotent stem cell to respond to normal feedback mechanisms regulating hematopoietic cell mass. Stem cells from patients with MPN demonstrate clonal colony growth *in vitro* when these cells are grown in the presence of serum without the addition of exogenous cytokines, and this technique has been used as a diagnostic test for MPN. MPNs have traditionally been divided into four classic disorders based on the predominant hyperproliferative cell type: polycythemia vera (PV), essential thrombocytosis (ET), primary myelofibrosis (PMF; also known as idiopathic myelofibrosis or agnogenic myeloid metaplasia), and chronic myelogenous leukemia (CML). Hypereosinophilic syndrome (HES),

mast cell disease, and other less common diseases are also included (Table 48-1).

Complications of MPN arise from the overproduction of one or more lineages in the blood. All can be associated with clonal evolution and blastic transformation to acute leukemia (**Web Fig. 48-1**), although, with the exception of CML, this is an infrequent and late complication. In most patients with MPN, the pathogenesis of disease is now attributed to dysfunctional kinases. In CML, a reciprocal translocation between chromosomes 9 and 22 (termed the *Philadelphia chromosome*) results in a breakpoint cluster region—the Abelson leukemia (*bcr-abl*) fusion protein with constitutive kinase activity. In PV, PMF, and ET, a mutation involving the substitution of a valine for phenylalanine at position 617 (V617F) in the Janus kinase 2 (JAK2) has been identified in most patients and may account for the abnormal growth properties that characterize these stem cell disorders. Identification of somatic JAK2 mutations in all MPNs has led to the clinical development and testing of orally bioavailable small molecule inhibitors that selectively target JAK2 for treatment of MPN. Results from these trials are eagerly awaited.

Polycythemia Vera

ETIOLOGY AND PATHOGENESIS

PV, literally meaning *increased red blood cells in the blood*, is a syndrome of increased red blood cell mass in the peripheral blood resulting from a clonal multipotent hematopoietic stem cell defect. When patients are first diagnosed with an elevated hemoglobin per unit volume (*erythrocytosis*), initial evaluation should focus on whether this increase reflects an enhanced red cell mass (i.e., *absolute erythrocytosis* or *polycythemia*) or a normal red cell mass in the presence of a decreased plasma volume (i.e., *relative erythrocytosis* caused by dehydration or other causes). The latter condition is not true polycythemia (Table 48-2). Polycythemia or absolute erythrocytosis is defined as *an absolute increase in red cell*

Table 48-1 World Health Organization 2008 Classification Scheme for Myeloid Neoplasms

1. Acute myeloid leukemia
2. Myelodysplastic syndrome (MDS)
3. Myeloproliferative neoplasms (MPNs)
 - a. Chronic myelogenous leukemia
 - b. Polycythemia vera
 - c. Essential thrombocythemia
 - d. Primary myelofibrosis
 - e. Chronic neutrophilic leukemia
 - f. Chronic eosinophilic leukemia, not otherwise categorized
 - g. Hypereosinophilic syndrome
 - h. Mast cell disease
 - i. MPNs, unclassifiable
4. MDS, MPD
5. Myeloid neoplasms associated with eosinophilia and abnormalities of PDGF-RA, PDGF-RB, or FGF-R1

FGF-R1, fibroblast growth factor receptor-1; PDGF-RA, platelet-derived growth factor receptor alpha polypeptide; PDGF-RB, platelet-derived growth factor receptor beta polypeptide.

mass caused by increased red blood cell production. Under normal conditions, the body's ability to increase red blood cell production in states of hypoxemia, anemia, hemolysis, and acute blood loss ensures continuous oxygen delivery to tissues. In response to physiologic stimuli, pluripotent stem cell precursors are activated by erythropoietin (EPO) to differentiate into erythroid progenitor cells and eventually hemoglobin-carrying erythrocytes. When numbers of mature red blood cells are adequate, a negative feedback mechanism suppresses further EPO production, and the serum hemoglobin level remains normal.

PV is a primary clonal stem cell disorder of unknown origin that is characterized by predominant erythrocytosis associated with other hematopoietic abnormalities. Although one half of all patients have concurrent leukocytosis or thrombocytosis, erythrocytosis is the hallmark and the cause of the most serious clinical complications of this disease. Diagnosis of PV was formerly one of *exclusion* based on an elevated red cell mass, splenomegaly, thrombocytosis, leukocytosis, lack of hypoxemia and other secondary causes of polycythemia, and elevated levels of leukocyte alkaline phosphatase and serum vitamin B₁₂-binding protein levels. More recent information on the disease pathophysiology has led to new diagnostic criteria (Table 48-3) based on the discovery of JAK2 mutations in virtually all patients with PV. Identification of low serum EPO levels and EPO-independent erythroid colony growth are now regarded as the only secondary criteria helpful in establishing a primary PV diagnosis.

CLINICAL FEATURES AND LABORATORY STUDIES

PV occurs in 1 to 3 of 100,000 people, with a median age at onset of 65 years. Early recognition and treatment of PV are important because untreated patients with PV suffer significant morbidity and mortality from thromboembolic disease in the cerebral, coronary, and mesenteric circulations.

Table 48-2 Causes of Erythrocytosis

- I. Relative or spurious erythrocytosis (normal red cell mass)
 - A. Hemoconcentration secondary to dehydration (diarrhea, diaphoresis, diuretics, water deprivation, emesis, ethanol, hypertension, preeclampsia, pheochromocytoma, carbon monoxide intoxication)
- II. True or absolute erythrocytosis
 - A. Polycythemia vera
 - B. Primary congenital polycythemia
 - C. Secondary erythrocytosis caused by:
 1. Congenital causes (e.g., activating mutation of erythropoietin receptor)
 2. Hypoxia caused by carbon monoxide poisoning, high oxygen affinity hemoglobin, high-altitude residence, chronic pulmonary disease, hypoventilation syndromes such as sleep apnea, right to left cardiac shunt, neurologic defects involving the respiratory center
 3. Nonhypoxic causes with pathologic erythropoietin production
 - a. Renal disease (cysts, hydronephrosis, renal artery stenosis, focal glomerulonephritis, renal transplantation)
 - b. Tumors (renal cell cancer, hepatocellular carcinoma, cerebellar hemangioblastoma, uterine fibromyoma, adrenal tumors, meningioma, pheochromocytoma)
 4. Drug-associated causes
 - a. Androgen therapy
 - b. Exogenous erythropoietin growth factor therapy

Adapted from Hoffman R, Benz EJ, Shattil SJ, et al (eds): Hematology: Basic Principles and Practice, 2nd ed. New York, Churchill Livingstone, 1995.

Table 48-3 World Health Organization 2008 Diagnostic Criteria for Polycythemia Vera

Major Criteria

1. Hemoglobin (Hgb) >18.5 g/dL (men), >16.5 (women); or Hgb or hematocrit (Hct) >99% reference range for age, sex, or altitude of residence; or Hgb >17 g/dL (men), >15 g/dL (women) if associated with a sustained increase of ≥ 2 g/dL from baseline that cannot be attributed to correction of iron deficiency; or elevated red cell mass (>25% above mean normal predicted value)
2. Presence of JAK2 V617F or similar mutation

Minor Criteria

1. Bone marrow trilineage myeloproliferation
2. Subnormal serum erythropoietin level
3. Endogenous erythroid colony formation in vitro

Either both major criteria and one minor criterion or the first major criterion and two minor criteria must be met for diagnosis of polycythemia vera.

Twenty percent of patients show symptoms of arterial and venous thrombosis, and thrombosis remains the most common cause of death. Typically, patients complain of headache, visual problems, mental clouding, and pruritus after bathing. Occlusive vascular events such as stroke, transient ischemic attacks, myocardial ischemia, and digital pain, paresthesias, or gangrene are common. In addition, pulmonary, deep vein, hepatic, and portal vein thromboses may

occur. Paradoxically, patients are also predisposed to hemorrhagic events, which are presumably caused by abnormal platelet function, and such patients may exhibit gastrointestinal bleeding. Physical examination often shows retinal vein occlusion, ruddy cyanosis, and splenomegaly.

Peripheral blood often appears microcytic, with or without iron deficiency. Bone marrow examination shows a hypercellular marrow with pronounced hyperplasia of erythroid lineage cells (see **Web Fig. 48-2E**). Cytogenetic features at the time of diagnosis are usually normal; the development of clonal cytogenetic abnormalities heralds transformation in the later stages of disease. The incidence of the JAK2 V617F mutation in patients with PV ranges up to 97% in various studies.

TREATMENT

Without treatment, one half of all patients with PV die of thrombotic complications within 18 months of diagnosis. With therapy, PV is a chronic, progressive disease. The risk for transformation to myelofibrosis and myeloid leukemia is 5% to 20% over 20 years. Patients with advanced age, prior history of thrombosis, and high hematocrit values are at high risk for subsequent vascular events. Therefore, intermittent phlebotomy is the mainstay of treatment and usually results in iron deficiency anemia, which further reduces the rate of red blood cell production. Cyto-reductive therapy is indicated for patients with intolerant or failing phlebotomy, with a prior history of or risk factors for thrombosis, or with symptomatic splenomegaly. Low-dose chemotherapeutic agents (such as chlorambucil, busulfan) and radioactive phosphorus (^{32}P) used in the past to treat leukocytosis and thrombocytosis have been associated with increased toxicity and risk for secondary AML. Current therapies include hydroxyurea (a low-dose cytotoxic agent that does not appear to increase leukemic risk), interferon- α (used in young patients and women during pregnancy), and anagrelide (a megakaryotoxic agent used for treating refractory thrombocytosis). Goals of therapy are hematocrit values less than 45% in men and less than 42% in women. As with all myeloproliferative disorders, initiation of cyto-reductive therapy may precipitate hyperuricemia (resulting in secondary gout and uric acid stones), warranting treatment with allopurinol. Low-dose aspirin and treatment of asymptomatic thrombocytosis has been demonstrated to decrease thromboembolic events in patients with PV and is especially important in older patients with significant cardiac risk factors. In younger patients, nonsteroidal anti-inflammatory drugs and antiplatelet agents should be used judiciously because of the risk for gastrointestinal hemorrhage. With effective therapy, the long-term survival of these patients is excellent.

Essential Thrombocythemia

ETIOLOGY, PATHOGENESIS, AND LABORATORY STUDIES

ET (also known as *primary thrombocythemia*) is a pluripotent stem cell disorder resulting in elevated levels of platelets

Table 48-4 World Health Organization (2008) Diagnostic Criteria for Essential Thrombocythemia

Major Criteria

1. Platelet count $\geq 450 \times 10^9/\text{L}$
2. Megakaryocyte proliferation with large and mature morphology. No or little granulocytic or erythroid proliferation
3. Not meeting WHO criteria for CML, PV, PMF, MDS or other myeloid neoplasm
4. Demonstration of JAK2 V617F or other clonal marker or no evidence of reactive thrombocytosis

Diagnosis of essential thrombocytopenia requires meeting all four major criteria.

CML, chronic myelogenous leukemia; MDS, myelodysplastic syndrome; PMF, primary myelofibrosis; PV, polycythemia vera; WHO, World Health Organization.

and white blood cells. Platelet function and length of survival remain normal. Because elevated platelet counts (termed *thrombocytosis*) can occur secondary to other underlying causes (including bacterial infections, sepsis, iron deficiency, autoimmune diseases, and other malignant diseases), these other causes must be excluded before a diagnosis of ET is considered. In general, diagnosis requires a platelet count exceeding $450,000 \times 10^9/\text{L}$ with JAK2 mutation or no evidence of reactive thrombocytosis. In addition, bone marrow histology displays predominant proliferation involving the megakaryocytic lineage with increased mature megakaryocytes and little, if any, granulocytic or erythroid proliferation. Marrow immunohistochemical and cytogenetic studies to exclude diagnoses of myelodysplasia, myelofibrosis, or the Philadelphia chromosome diagnostic of CML are essential (Table 48-4). Although no genetic or biologic marker that is 100% specific for ET has been found, the presence of the JAK2 V617F mutation is found in more than one half of samples of patients with ET. Unlike other MPNs, bone marrow cells from patients with ET frequently do not show factor-independent colony growth, and the precise cause of this disease (and relationship with JAK2 mutational status) is under intense investigation.

CLINICAL FEATURES

ET is an uncommon disorder with an increasing number of cases found in patients who are asymptomatic on routine laboratory testing. Although the median age at onset is 60 to 65 years, 10% to 25% of patients are younger than 40 years of age. Up to two thirds of patients are symptomatic. Vasomotor symptoms include headache, dizziness, visual changes, and *erythromelalgia* (burning pain and erythema of feet and hands). Serious arterial thrombotic complications such as transient ischemic attacks, strokes, seizures, angina, and myocardial infarcts may occur. Patients may rarely have purpuric skin lesions or hematomas. The risk for gastrointestinal bleeding is less than 5%.

TREATMENT

In general, patients with this disorder have long-term survival rates similar to those of age-matched control patients.

The risk for leukemic transformation is extremely low (3% to 4%) in comparison with other MPNs. However, morbidity from recurrent hemorrhagic and thrombotic complications is high and cannot be reliably predicted from the platelet count or platelet function abnormalities. Because treatment requires lifelong administration for disease control, assessment of risk factors and prior history of clinical signs and symptoms dictate therapeutic choices. All patients benefit from aggressive management of cardiovascular risk factors (such as smoking, hypertension, obesity, and hypercholesterolemia). Low-dose enteric aspirin may be used in all patients to relieve neurologic symptoms and carries a minimal risk for bleeding. Although young and pregnant patients are often not treated until they become symptomatic, older patients (>60 years) and those with a prior history of thrombosis or long disease duration may benefit from the addition of platelet-lowering agents. Hydroxyurea, a nonspecific myelosuppressive agent, is the most common first-line agent and is generally well tolerated with low long-term leukemogenic risks. Anagrelide (an oral antiplatelet agent that inhibits platelet aggregation and megakaryocyte maturation) is also used, primarily as a second-line agent after hydroxyurea failure resulting from associated acute side effects (fluid retention, palpitations), hemorrhage (with concomitant aspirin use), and risk for myelofibrosis transformation. Both of these agents are known teratogens and therefore cannot be used in the significant fraction of patients with ET who are young women of childbearing age. Because patients with ET have a high incidence of fetal wastage, interferon- α (a cytokine that alters the biologic mechanisms of the malignant clone but does not cross the placenta), in addition to heparin or aspirin, has been recommended to improve pregnancy outcomes in these patients.

Primary Myelofibrosis

ETIOLOGY, PATHOGENESIS, AND LABORATORY STUDIES

PMF (also known as *idiopathic myelofibrosis* or *agnogenic myeloid metaplasia*) is a clonal stem cell disorder characterized by abnormal excessive marrow fibrosis leading to marrow failure. An abnormal myeloid precursor is believed to give rise to dysplastic megakaryocytes that produce increased levels of fibroblast growth factors. These cytokines act on normal fibroblasts and other stromal cells, a process that stimulates excessive proliferation and collagen deposition. Over time, increasing fibrosis of the bone marrow leads to premature release of multipotent hematopoietic precursors into the periphery. These cells then migrate and reestablish themselves in other sites, thereby shifting hematopoiesis out of the bone marrow and into other tissues, especially the spleen and liver. This process is termed *extramedullary hematopoiesis*.

Early in the disease, patients may be asymptomatic with incidental findings of abnormal blood counts on routine laboratory tests. Although low blood counts may be present, overall platelet and red blood cell numbers at onset may be increased or normal depending on the degree of compensatory extramedullary hematopoiesis. Review of the peripheral

FAB-M₇, French-American-British acute myeloid leukemia classification subtype 7.

Table 48-6 World Health Organization 2008 Diagnostic Criteria for Primary Myelofibrosis

Major Criteria

1. Megakaryocyte proliferation and atypia accompanied by reticulin and/or collagen fibrosis; or in the absence of reticulin fibrosis, the megakaryocytic changes must be accompanied by increased marrow cellularity, granulocytic proliferation, and often decreased erythropoiesis (i.e., prefibrotic primary myelofibrosis)
2. Not meeting World Health Organization criteria for chronic myelogenous leukemia, polycythemia vera, myelodysplastic syndrome, or other myeloid neoplasm
3. Demonstration of JAK2 V617F or other clonal marker or no evidence of reactive marrow fibrosis

Minor Criteria

1. Leukoerythroblastosis
2. Increased serum lactate dehydrogenase level
3. Anemia
4. Palpable splenomegaly

Diagnosis of primary myelofibrosis requires meeting all three major criteria and two minor criterion.

blood will commonly reveal leukoerythroblastic changes characterized by teardrop-shape erythrocytes, giant platelets, and nonleukemic immature myeloid, erythroid, and leukocyte cells. Diagnosis of PMF is made by demonstration of bone marrow fibrosis with markedly increased reticulin or collagen fibers (see **Web Fig. 48-1**) or increased marrow cellularity. Other underlying causes of bone marrow fibrosis, both neoplastic and non-neoplastic (Table 48-5), should be ruled out. Testing for JAK2 or other clonal markers should also be performed (Table 48-6).

CLINICAL FEATURES

PMF is a rare chronic disease, usually seen in elderly persons, with an annual incidence of 0.5 cases per 100,000. Although

many patients are asymptomatic at diagnosis, most will complain over time of progressive fatigue and dyspnea related to anemia or early satiety and left upper quadrant pain associated with splenomegaly and splenic infarction. More than one half of these patients develop massive hepatosplenomegaly. In more advanced disease, patients may have constitutional symptoms such as fever, weight loss, and night sweats. As bone marrow failure evolves, complications of neutropenia and thrombocytopenia develop. Bleeding from occult disseminated intravascular coagulation is a risk. Extramedullary hematopoiesis in the peritoneal and pleural cavities, as well as in the central nervous system (CNS) and spinal cord, may also cause symptoms.

TREATMENT

Median survival in PMF is poor, ranging from 2 to 5 years. The most commonly accepted adverse prognostic factors at onset include hemoglobin less than 10g/dL, leukocyte count less than 4000/mcL or more than 30,000/mcL, a high percentage of circulating blasts, and the presence of constitutional symptoms. Other clinical factors of note are age greater than 60 years, thrombocytopenia, massive hepatosplenomegaly, and cytogenetic abnormalities. Over time, the disease may progress from a chronic phase to an accelerated phase, with acute leukemic transformation in 8% to 10% of patients. Treatment of PMF-related AML is usually ineffective. Other causes of nonleukemic death include heart failure, infection, intracranial hemorrhage, and pulmonary embolism.

At present, no medical therapy has been shown to prolong overall survival or retard disease progression significantly in PMF. Young patients with HLA-matched sibling donors may be considered for potentially curative experimental allogeneic stem cell transplantation (SCT) at academic medical centers. All patients with symptomatic anemia benefit from palliative transfusions and administration of recombinant erythropoietin, androgens (danazol), or low-dose thalidomide to maintain red blood cell levels. Symptoms caused by excess thrombocytosis and leukocytosis or progressive extramedullary hematopoiesis may be managed with hydroxyurea (as a first-line agent), interferon- α (in younger patients), or low-dose chemotherapeutic agents such as busulfan, interferon- α , or melphalan (with long-term leukemogenic potential). Splenectomy is offered to patients with symptomatic splenomegaly, refractory thrombocytopenia, hypermetabolic symptoms, and portal hypertension but may be associated with significant operative morbidity and mortality. Patients who are not surgical candidates may benefit from palliative splenic irradiation or from new biologic agents under development that target the abnormal marrow microenvironment.

Chronic Myelogenous Leukemia

ETIOLOGY AND PATHOGENESIS

CML is characterized by a predominant increase in the granulocytic cell line associated with concurrent erythroid and

platelet hyperplasia. It is unique among the MPN in its characteristic natural history, including an inevitable transformation to acute leukemia. CML was the first hematologic malignant disease shown to be associated with a specific chromosomal abnormality. More than 95% of patients with CML have a clonal expansion of a stem cell that has acquired the Philadelphia chromosome, a balanced translocation between chromosomes 9 and 22 designated t(9;22)(q34;q11). This translocation fuses the *abl* virus gene on chromosome 9 to the *bcr* gene on chromosome 22 and generates a novel *bcr-abl* oncogene. The gene product, the *bcr-abl* protein, is a constitutively active cytoplasmic tyrosine kinase that has been found to induce leukemia in hematopoietic stem cells. The expression of the *bcr-abl* fusion protein activates multiple downstream signal transduction pathways to permit proliferation independent of cytokine and stromal regulation and render cells resistant to chemotherapy and normal programmed cell death (*apoptosis*). A subset of patients with CML but lacking a detectable Philadelphia chromosome have subsequently been found to possess detectable *bcr-abl* fusion products by reverse transcriptase-polymerase chain reaction (RT-PCR), indicating a subchromosomal translocation resulting in the same pathologic gene product. The diagnosis of CML is made by detection of the Philadelphia chromosome using karyotype, PCR, or fluorescent in situ hybridization (FISH) analysis. Identification of the Philadelphia chromosome has allowed for easier diagnosis and monitoring of disease. Exquisitely sensitive and quantitative RT-PCR procedures not only allow for detection of up to a single *bcr-abl*-positive cell in 10^5 to 10^6 peripheral cells but also permit measurement of disease status in both peripheral blood and marrow samples. Responses to treatment regimes in CML are now defined as hematologic (restoration of normal peripheral blood cell counts), cytogenetic (loss of the Philadelphia chromosome by normal karyotypic or FISH analysis), and molecular (log reduction of detectable *bcr-abl* transcripts below a standard baseline by RT-PCR) remissions.

CLINICAL FEATURES

CML is the most common MPN, accounting for 15% to 20% of all leukemias and occurring in 1 of 100,000 people. The median age of onset is 53 years, but patients of any age may be affected. Up to 40% of patients are initially asymptomatic. Other patients exhibit fatigue, lethargy, shortness of breath, weight loss, easy bruising, and early satiety. Physical examination usually shows splenomegaly.

The natural history of CML is characterized by a *chronic phase* that evolves into an acute blast crisis. Patients are typically diagnosed during the chronic phase, an indolent stage lasting 3 to 5 years. Peripheral white blood cell counts are elevated with eosinophilia and basophilia (>20%) but few blasts (<5%). With control of peripheral blood cell counts, patients are essentially asymptomatic during this period. Eventually, the disease enters an *accelerated phase* characterized by fever, weight loss, worsening splenomegaly, and bone pain related to rapid marrow cell turnover. Despite therapy, the white blood cell count rises with increased numbers of circulating blasts (between 10% and 19%). The presence of increased peripheral blood basophils (>20%) results in histamine production, with symptoms of pruritus, diarrhea,

and flushing. During accelerated phase, patients may also develop increasing splenomegaly, persistent thrombocytopenia, or thrombocytosis and leukocytosis, with new clonal cytogenetic abnormalities in marrow cells. The last phase of CML, termed *blast crisis*, marks an evolution to acute leukemia, in which marrow is replaced by 20% or more blasts, with accompanying loss of normal mature cellular elements in the marrow and periphery and extramedullary blast proliferation. Death occurs in a few weeks to months. Two thirds of patients develop AML, whereas the rest develop acute lymphoid leukemia, a finding confirming that the initial neoplastic cell is an early stem cell capable of multilineage differentiation.

LABORATORY STUDIES

Laboratory tests in CML patients typically demonstrate a markedly elevated white blood cell count (median, $170 \times 10^9/L$), with low leukocyte alkaline phosphatase levels, high uric acid and lactate dehydrogenase levels, and thrombocytosis. Review of the peripheral smear in chronic-phase CML demonstrates a full complement of myeloid cells in all stages of granulocytic development, including immature myeloblasts (usually numbering <5%), myelocytes, metamyelocytes, basophils, eosinophils, bands, and neutrophils. In contrast, the peripheral blood smear in reactive granulocytic hyperplastic states (termed *leukemoid reaction*) caused by acute infection or sepsis, consists predominantly of mature neutrophils and bands with few myelocytes, basophils, or eosinophils. The bone marrow in CML is densely hypercellular, with an overwhelming predominance of myeloid cells at all developmental stages and reticulin fibrosis (see **Web**

Fig. 48-2). Detection of the Philadelphia chromosome or abnormal *bcr-abl* transcripts by conventional or molecular testing will often confirm the diagnosis of CML.

TREATMENT

Historically, oral chemotherapeutic agents such as hydroxyurea and busulfan were used to reduce myeloid cell numbers in patients during the chronic phase of CML. Although these drugs decreased the rate of acute disease complications, they did not alter long-term prognosis or prevent progression to blast crises. Treatment with interferon results in hematologic remissions in 60% to 80% of patients with chronic-phase CML and was the first agent to induce cytogenetic responses in 20% to 30% of these patients. Achievement of cytogenetic remissions using interferon- α was associated with prolonged survival, with higher response rates obtained by combining chemotherapy with interferon. Although most patients treated with interferon still possessed cells with detectable *bcr-abl* translocation by PCR and remained at risk for disease relapse, many remained in hematologic and cytogenetic remission for several years. The mechanism by which the disease is controlled with interferon despite detectable *bcr-abl*-positive cells remains unknown. Unfortunately, patients with accelerated or blast crisis CML did poorly with interferon, and high-dose chemotherapy regimens in these patients induced only transient responses, with durations of less than 6 months.

The development of imatinib mesylate (Gleevec, formerly known as STI-571) for treatment of CML has been heralded

as the first successful targeted therapy for cancer. Gleevec is a rationally designed competitive inhibitor of multiple tyrosine kinases, including *abl*, *bcr-abl*, platelet-derived growth factor receptor, and *c-kit*. Inhibition of phosphorylation of *bcr-abl* results in blockade of downstream signaling and growth pathways and induces apoptosis of *bcr-abl* positive cells. Preclinical studies demonstrated that Gleevec potently inhibited the growth of *bcr-abl*-expressing CML cell lines and progenitor cells in vitro and prolonged survival in animal tumor models. Initial early clinical trials of this orally active drug were begun in 1998 in CML patients who had failed interferon- α . Not only was the drug well tolerated with manageable side effects, but also 96% of patients receiving a dose greater than 300 mg per day for 4 weeks achieved hematologic remissions, with 33% obtaining cytogenetic remissions after 8 weeks. These striking results have been confirmed in multiple trials, and Gleevec was subsequently shown to be superior to interferon- α and cytarabine in untreated patients with newly diagnosed chronic-phase CML. At a median of 5 years' follow-up, initial therapy with Gleevec was shown to result in complete cytogenetic responses in 87% of chronic phase CML patients with an estimated overall survival of 89%. Only 7% of patients progressed to accelerated or blast-phase CML, and both response rates and adverse events from Gleevec treatment diminished over time of therapy. No patient achieving a complete cytogenetic response and molecular remission (defined as a three-log reduction in *bcr-abl* transcripts) after 12 to 18 months of Gleevec therapy was found to have disease progression after 5 years. Based on this study, Gleevec therapy is now the standard of care for treatment of chronic-phase CML.

Despite these results, this agent does not cure disease. Similar to those receiving interferon treatment, most of patients achieving CCR on Gleevec still demonstrate persistence of *bcr-abl*-positive leukemic CML stem cells by sensitive molecular testing. Therefore, lifelong Gleevec therapy is required to control disease, and even patients with excellent control of chronic-phase CML on Gleevec therapy remain at risk for eventual disease progression and therapy failure. Although Gleevec at high doses can induce transient hematologic and cytogenetic responses in patients with accelerated or blast-phase CML, these responses are short lived at best, and resistance to Gleevec in these advanced disease stages is well documented. In half of patients with clinical resistance to Gleevec, single nucleotide mutations in the *bcr-abl* gene result in conformational changes in the *bcr-abl* kinase, which alter the binding of drug and hence its inhibitory effects. Finally, a small percentage of patients with CML are unable to tolerate the side effects of Gleevec, primarily gastrointestinal in nature. To address these issues, newer *bcr-abl* kinase inhibitors have been developed, specifically dasatinib (Sprycel) and nilotinib (Tasigna) for treatment of Gleevec-resistant or intolerant CML patients. Both agents display increased potency against the *bcr-abl* kinase in vitro than Gleevec and have demonstrated activity in CML cells expressing the majority of known *bcr-abl* mutations. Early-phase clinical trials with single-agent dasatinib or nilotinib in previously treated imatinib-failure patients have consistently resulted in cytogenetic responses up to 40% of patients. However, the lack of clinical trials directly comparing both agents and the need to await long-term clinical outcome data

for either drug currently leave the choice of a second-line *bcr-abl* inhibitor to individual patients and practitioners. Toxicity profiles for both drugs are largely nonoverlapping with Gleevec.

Presently, the only treatment modality known to result in complete eradication of all detectable *bcr-abl*-expressing cells remains allogeneic SCT. Before the advent of targeted *bcr-abl* kinase inhibitor therapy, young patients with an HLA-matched donor were routinely offered potentially curative allogeneic bone marrow transplantation at the time of diagnosis of chronic-phase CML. Up to 50% to 75% of such patients achieved long-term survival following transplantation, with an improved outcome (for reasons that are not clear) in patients undergoing the procedure within 1 year of diagnosis. Evidence indicated that the excellent response of patients with CML to SCT is partly related to the active suppression of the disease by the newly transplanted graft, referred to as the *graft-versus-leukemia* (GVL) effect. However, the excellent control and low overall toxicity of long-term *bcr-abl* inhibitors for chronic-phase CML as compared with 20% to 30% mortality and morbidity rates following SCT has effectively rendered SCT a therapeutic option only for those chronic phase CML patients failing upfront Gleevec (e.g., blast crisis, intolerance). The only notable exception to this is individuals with CML disease expressing *bcr-abl* kinase mutations (such as T3151) known to be resistant to all *bcr-abl* inhibitor therapy. These patients should be identified early in the disease process for consideration for curative SCT versus treatment with upfront experimental options. Transplantation continues to remain the only curative therapeutic option for advanced-stage CML. Patients with accelerated-phase CML may be treated with high-dose Gleevec while awaiting allogeneic transplantation (if feasible) or experimental therapies, whereas those in blast-phase CML should undergo induction chemotherapy based on acute leukemia regimens followed by transplantation or clinical trials.

Overall, the transformation of CML, from a progressively fatal cancer to one in which almost 90% of patients are alive with stable disease on oral kinase therapy after 5 years, remains one of the crowning achievements in cancer therapy in the past decade. The median overall survival for CML patients has risen dramatically from a few months to a few

years in the first half of the 20th century, to 6 years for interferon-treated patients, and has not yet been reached for *bcr-abl* inhibition therapy. Nevertheless, the search for a CML disease cure and for better treatment for those CML patients with disease refractory to Gleevec remains a therapeutic challenge for the years ahead.

Acute Leukemias

ETIOLOGY AND PATHOGENESIS

The *acute leukemias* are clonal hematopoietic malignant diseases that arise from the malignant transformation of an early hematopoietic stem cell. Leukemias occur in 8 to 10 of 100,000 people (in comparison with 42 of 100,000 for prostate cancer and 62 of 100,000 for breast cancer). Acute leukemias are classified by cell lineage into *acute myeloid/myelogenous leukemia* (AML) and *acute lymphoblastic/lymphocytic leukemia* (ALL) based on morphology, cytogenetics, cell surface and cytoplasmic markers, and molecular studies. Eighty to ninety percent of adult leukemia diagnoses are AML (with the rest being ALL), whereas most childhood leukemias are ALL (with 10% being AML).

The distinction between AML and ALL is crucial diagnostically, therapeutically, and prognostically. AML can be distinguished from ALL by cell morphology and by the presence of *Auer rods*, formed by the aggregation of myeloid granules (**Web Fig. 48-3**). Further immunophenotyping of blast cells using cell surface antigens, cytochemistry, and immunohistochemistry confirms cells as being of either myeloid or lymphoid origin (Table 48-7). Morphologic subgroups of both ALL and AML were originally defined by the French-American-British (FAB) group and, more recently, revised by the World Health Organization (WHO), incorporating newer biologic information (Table 48-8).

The pathogenesis of acute leukemia is under intense investigation. Many patients with acute leukemia have detectable characteristic clonal chromosomal abnormalities; however, the role of all but a few of these aberrations in malignant transformation is unknown. In general, unregulated proliferation of immature cells incapable of further differentiation (*blasts*) results in marrow replacement and hematopoietic failure. Known risk factors for leukemia are

Table 48-7 Laboratory Aids to Distinguish between Acute Myeloblastic Leukemia and Acute Lymphoblastic Leukemia

	Acute Myeloblastic Leukemia (AML)	Acute Lymphoblastic Leukemia (ALL)
Morphology of blasts	Granules in cytoplasm Auer rods* Multiple nucleoli	Agranular basophilic cytoplasm Regular, folded nucleolus
FAB subclassification	L ₁ -L ₃	M ₁ -M ₇
Histochemistry	Myeloperoxidase positive	Myeloperoxidase negative, PAS positive
Cytoplasmic markers	—	Tdt positive
Surface markers (% of cases)	—	B-cell markers (5%) T-cell markers (15%-20%): CD2, CD3, or CD5 CALLA (50%-65%): CD10

Table 48-8 French-American-British (FAB) and World Health Organization (WHO) Classifications of Acute Leukemia

FAB Classification of Acute Myeloid Leukemia (AML)

- M₀—Acute myelocytic leukemia with minimal differentiation
 M₁—Acute myelocytic leukemia without maturation
 M₂—Acute myelocytic leukemia with maturation (predominantly myeloblasts and promyelocytes)
 M₃—Acute promyelocytic leukemia
 M₄—Acute myelomonocytic leukemia
 M₅—Acute monocytic leukemia
 M₆—Erythroleukemia
 M₇—Megakaryocytic leukemia

FAB Classification of Acute Lymphoblastic Leukemia (ALL)

- L₁—Predominantly *small* cells (twice the size of normal lymphocyte), homogeneous population; childhood variant
 L₂—Larger than L₁, more heterogeneous population; adult variant
 L₃—*Burkitt-like* large cells, vacuolated abundant cytoplasm

WHO 2001 Classification of Acute Leukemia

- I. Acute myeloid leukemia (AML)
 - a. AML with recurrent genetic abnormalities
 - AML with t(8;21)(q22;q22); (AML [CBF- α /ETO])
 - AML with abnormal bone marrow eosinophils inv(16) (p13;q22) or t(16;16) (p13;q22); (CBF- α /*MYH-11*)
 - Acute promyelocytic leukemia [AML with t(15;17) (q22;q12) (PML/RAR- α)] and variants
 - AML with 11q23 (MLL) abnormalities
 - b. AML with multilineage dysplasia
 - c. AML and MDS, therapy related
 - Alkylating agent related
 - Topoisomerase II inhibitor related
 - d. AML not otherwise defined
 - AML minimally differentiated
 - AML without maturation
 - AML with maturation
 - Acute myelomonocytic leukemia
 - Acute monoblastic and monocytic leukemia
 - Acute erythroid leukemia
 - Acute megakaryoblastic leukemia
 - Acute basophilic leukemia
 - Acute panmyelosis with myelofibrosis
 - Myeloid sarcoma
 - e. Acute leukemia of ambiguous lineage
 - Undifferentiated acute leukemia
 - Bilineal acute leukemia
 - Biphenotypic acute leukemia
- II. Acute lymphocytic leukemia
 - a. Precursor B-lymphoblastic leukemia/lymphoblastic lymphoma
 - b. Precursor T-lymphoblastic leukemia/lymphoblastic lymphoma

CBF, core binding factor; ETO, "eight twenty-one"; MDS, primary myelodysplastic syndrome; MLL, mixed lineage leukemia; *MYH-11*, myosin heavy chain gene; PML, promyelocytic leukemia; RAR- α , retinoic acid α receptor.

high-dose radiation exposure and occupational exposure to benzene. Patients with secondary AML after exposure to prior chemotherapy have usually received alkylating agents (such as chlorambucil, melphalan, and nitrogen mustard) or topoisomerase II inhibitors (epidodophyllotoxins). An increased incidence of leukemia is also found in patients with chromosomal instability disorders such as Bloom syndrome, Fanconi anemia, Down syndrome, and ataxia telangiectasia.

CLINICAL FEATURES

Patients exhibit clinical evidence of bone marrow failure (similar to other hematopoietic disorders). Complications of disease include anemia, infection, and bleeding from peripheral cytopenias. In addition, proliferating blasts infiltrating the bone marrow may cause bone pain. Blasts also invade other organs and lead to peripheral, mediastinal, and abdominal lymphadenopathy, hepatosplenomegaly, skin infiltration, and meningeal involvement.

TREATMENT

Therapy of acute leukemias is divided into several stages. *Induction therapy* is directed at reducing the number of leukemic blasts to an undetectable level and restoring normal hematopoiesis (*complete remission*). At complete remission, however, significant subclinical disease persists, requiring further therapy. Subsequent *consolidation therapy* involves continuing chemotherapy with the same agents to induce elimination of further leukemic cells. With development of a wider range of effective agents, *intensification therapy* has been introduced, involving the use of high-dose therapy with different *non-cross-reactive* drugs, to eliminate cells with potential primary resistance to the induction regimen. *Maintenance therapy* employs low-dose intermittent chemotherapy given over a prolonged period to prevent subsequent disease relapse. The goal of therapy is to induce remission (defined as the presence of less than 5% blasts in the bone marrow and recovery of normal peripheral blood counts).

Adverse clinical prognostic factors for AML and ALL are similar despite widely different treatment approaches. In general, age exceeding 35 years, secondary or therapy-related disease, antecedent hematologic disorder, high initial leukocyte count, and prolonged time to achieve response to initial treatment are associated with poorer outcomes. Cytogenetic abnormalities represent the best independent predictor of overall survival in both acute leukemias (Tables 48-9 and 48-10).

Acute Myeloid Leukemia

CLINICAL FEATURES

AML represents a biologically heterogeneous group of neoplasms with widely divergent clinical outcomes. Long-term cure rates (defined as length of survival >5 years) range from 5% to 60% following chemotherapy alone, with an overall cure rate of 20% to 30%. AML occurs primarily in older adults, with a median age at diagnosis of 65 years. Patients most often present with complications related to progressively severe cytopenia, such as infection due to leukopenia, shortness of breath or fatigue due to anemia, or bleeding due to thrombocytopenia. AML patients may also exhibit unique acute clinical emergencies requiring immediate stabilization. *Leukostasis* (also called *hyperleukocytosis syndrome*) caused by high levels of circulating blasts (>80,000 to 100,000) leads to diffuse pulmonary infiltrates and acute respiratory distress. Blast cells may also injure surrounding vasculature, causing life-threatening CNS bleeding and thromboses. In addition, high blast cell numbers result in the release of cellular breakdown products (termed *tumor lysis syndrome*),

Table 48-9 Prognostic Factors in Acute Myeloid Leukemia

Clinical
Age >60 yr (median age for acute myeloid leukemia, 65 yr)
Therapy related or with antecedent hematologic disorder (e.g., myelodysplastic syndrome, myeloproliferative neoplasm, aplastic anemia)
Poor performance status
White blood cell count >20,000-30,000/mm ³
Presence of extramedullary disease sites
Biologic
Karyotype: favorable, intermediate, poor (see below)
Immunophenotype: biphenotypic
Abnormal fms-like tyrosine kinase 3 caused by mutation or internal tandem duplication
Multidrug resistance protein expression
Cytogenetic
Favorable
t(15;17)(q22;q12-21)
inv(16) or t(16;16) or del(16q)
t(8;21)(q22;q22)
Intermediate
Normal karyotype
Trisomy +8 only
t(9;11)(p22;q23)
Adverse
Complex (≥3 abnormalities)
Inv(3)(q21q26) or t(3;3)(q21;q26)
Deletion (5q- or 7q-), minus 5, minus 7
Translocations (6;9) or (9;22)
Abnormalities of 11q23 excluding t(9;11)

leading to hypokalemia, acidosis, and hyperuricemia with resultant renal failure. Treatment of leukostasis should be instituted as soon as possible in all patients with white blood cell counts in excess of 100 to 200 × 10⁹/L and consist of leukapheresis, hydroxyurea, and initiation of induction chemotherapy to inhibit further production of circulating tumor cells. Hydration, urine alkalinization to reduce urine crystallization, allopurinol, or rasburicase, or a combination, should be initiated as indicated. Red blood cell transfusions are often contraindicated in patients with high numbers of circulating blast cells because of the risk for further increases in blood viscosity. CNS complications such as intracranial bleeding, cranial nerve invasion, and leukemic meningitis are treated with emergency whole-brain irradiation or directed radiation to affected sites.

LABORATORY STUDIES

Laboratory evaluation of patients with AML typically shows white blood cell counts ranging from neutropenic levels (<1 × 10⁹/L) to extreme leukocytosis (>100,000 to 200,000 × 10⁹/L). Severe thrombocytopenia, normocytic anemia, and circulating peripheral blasts are common. Bone marrow aspirate and biopsy typically show a profusion of myeloblasts numbering 20% to 100% with depressed production of normal mature cells.

Diagnostic marrow aspirates are typically evaluated using morphology, flow cytometry, and routine cytogenetic-molecular analyses to (1) distinguish between AML and ALL, and (2) determine AML disease subsets. In the past, AML was divided based largely on morphologic criteria and immuno-

Table 48-10 Prognostic Factors in Acute Lymphoblastic Leukemia

Factor	Favorable	Unfavorable
Age	2-10 yr	<2 yr or >10 yr

Ethnicity	Caucasian	African American, Hispanic
Time to remission	Short (7-14 days)	Prolonged time to remission or failure to achieve remission

histochemical staining into FAB subtypes M₀ to M₇ defined by the stage of cellular differentiation of the abnormal cells (see Table 48-8 and **Web Fig. 48-3**). Some of these FAB subsets correlate with specific clinical syndromes that help determine treatment approaches as well as prognosis. The most common FAB subtype in adult AML is M₂. Patients with AML-M₃ (acute promyelocytic leukemia) often exhibit spontaneous bleeding from disseminated intravascular coagulation (see later). Patients with AML-M₄ or -M₅ disease (representing acute monocytic-myelomonocytic leukemias) have high levels of circulating white blood cells and may present with swollen gums resulting from tissue infiltration with leukemic blasts. Patients with megakaryoblastic leukemia (AML-M₇) have significant marrow fibrosis and usually exhibit organomegaly and pancytopenia similar to those seen in patients with myelofibrosis and myeloid metaplasia.

In 2001, AML was reclassified into new distinct subtypes defined by the presence of unique karyotypic abnormalities [specifically t(8;21), inv(16), and t(15;17)] in a dysplastic bone marrow, *independent of number of marrow blasts*. Because the presence of these specific cytogenetic abnormalities is crucial for diagnosis, therapy, and prognosis of AML patients, karyotypic analysis is now considered an essential part of any suspected AML diagnosis. In addition, any evidence of marrow dysplasia following prior chemotherapy, radiation, or other myeloablative therapy is now considered therapy-related AML (rather than MDS) independent of blast count (see Table 48-8).

TREATMENT

Chemotherapy for AML involves induction chemotherapy (administered in the inpatient setting) followed by multiple

cycles (two to four) of consolidation chemotherapy administered over 4 to 6 months. Standard induction regimens employing cytosine arabinoside (cytarabine) with high-dose anthracycline (daunorubicin or idarubicin) lead to complete remission in 60% to 80% of younger adults with de novo AML. Lower remission rates are achieved in older adults (>65 years of age) and in those patients with antecedent hematologic diseases evolving into AML. After achieving complete remission after induction, patients may be offered additional consolidation chemotherapy versus allogeneic or autologous SCT (see Chapter 47). Patients whose AML fails to respond to initial induction therapy have a grim overall prognosis and may be retreated with experimental agents or non-cross-reactive chemotherapy drugs such as epipodophyllotoxins, or both, to obtain remission.

AML prognosis can be predicted to some degree based on patient age, disease presentation (specifically white blood cell count), or history of antecedent hematologic or therapy-related disease (see Table 48-9). However, diagnostic AML cytogenetics remains the most robust independent prognostic indicator of clinical outcome after standard AML therapy and often constitutes the most crucial determinant of an appropriate therapeutic strategy for individual patients. AML cytogenetics is divided into three categories: favorable, intermediate, and poor. AML characterized by t(8;21), inv(16) or del(16q), or t(8;21) aberrations are unusually responsive to induction chemotherapy followed by two to four cycles of high-dose cytosine arabinoside consolidation. Long-term 5-year survival rates of 55% to 60% can be obtained. AML subtypes associated with poor prognosis include those with known deletions in chromosome 5 or 7, 11q23 aberrations, inv(3q), t(3;3), t(6;9), t(9;22) (the Philadelphia chromosome), or the presence of three or more karyotypic abnormalities (termed *complex karyotype*). Remission rates in these AML disease subtypes are low; if remission is achieved, patients remain at high risk for AML relapse with chemotherapy-refractory disease. Overall survival rates for poor prognosis AML are 5% to 15%. The remaining AML patients have intermediate-risk cytogenetics [defined as normal karyotype, trisomy 8, t(9;11), or other cytogenetic abnormalities not included in the other groups]. These patients demonstrate a 30% to 45% long-term survival rate with standard chemotherapy. Cytogenetically normal AML constitutes 40% to 49% of all AML diagnoses. Recent data have revealed that up to one third of patients with normal karyotype AML have constitutive activation of the *fms*-like tyrosine kinase 3 (FLT-3) receptor as a result of point mutations or internal tandem duplications (not seen on routine karyotypic testing) in FLT-3 kinase. Presence of FLT-3 aberrations in AML predicts for poor remissions, high relapse rates, and shorter overall survival compared with FLT-3-negative AML patients. The development and clinical use of FLT-3 inhibitors for AML therapy has not resulted in the impressive results seen with Gleevec in CML; the presence of multiple signaling pathways in AML cells and rapid proliferation of AML clones leads to rapid development of drug resistance over a short period of time. Combination FLT-3 inhibition with chemotherapy for relapsed and newly diagnosed FLT-3-positive AML patients is under active investigation.

Given that the median age at presentation of AML is 65 years, a sizable proportion of AML patients are elderly indi-

viduals with major comorbidities or antecedent hematologic or malignant diseases rendering them poor candidates for induction chemotherapeutic regimens. Infectious complications remain the major cause of morbidity and mortality during intensive inpatient chemotherapy despite recent advances in prophylactic growth factor support, antibiotics, and antifungal agents. The low expected remission rates (30% to 50%) and high mortality and morbidity associated with induction are additional reasons for many patients to decline such therapy. For these patients, therapeutic options include supportive therapy with hydroxyurea, transfusion support alone, and hospice. Patients unfit for and those who choose not to receive intensive therapy have been treated with low-dose subcutaneous cytarabine with remission rates of up to 18%; alternatively, hypomethylating agents (5-azacytidine, decitabine) have been administered to AML and high-risk MDS patients with some responses.

Once remission is achieved after induction, AML patients are offered additional therapy in the form of consolidation chemotherapy, autologous, or allogeneic SCT. Decisions about the best time to perform bone marrow transplantation in patients are probably best guided by cytogenetic and clinical data (see Table 48-9). Clinical outcomes are improved when patients undergo bone marrow transplantation after initial induction chemotherapy (i.e., during the first complete remission) rather than after disease relapse for multiple reasons. However, chemotherapeutic regimens are also more effective in first remission than they are after transplantation, and the cure rate from transplantation performed during second remissions is still 25%. In general, patients with known poor prognostic AML are recommended to undergo early transplantation, whereas those with favorable disease features potentially responsive to high-dose cytarabine chemotherapy are encouraged to delay SCT until time of relapse. Allogeneic SCT represents the best chance for long-term cure for AML associated with complex or unfavorable cytogenetics, antecedent hematologic disease, or therapy-related or primary refractory disease. Cure rates following conventional chemotherapy in these patients range from 5% to 20%. In contrast, AML patients younger than 60 years undergoing allogeneic bone marrow transplantation from a matched donor are reported to have long-term overall survival rates up to 40% to 60%, with a procedure-related mortality rate of 10% to 25%. Intermediate to high-risk AML patients based on clinical or cytogenetic data who are ineligible for allogeneic transplantation because of advanced age or lack of compatible HLA donors may be offered autologous SCT instead. Whether autologous transplantation improves AML outcomes compared with chemotherapy alone is still under debate. However, the long-term survival rates after autologous transplantation range from 20% to 40% and are at least equivalent to consolidation chemotherapy regimens employing single-agent cytarabine therapy.

AML patients with relapsed or refractory disease after standard therapy should be considered for allogeneic SCT and therapy on experimental protocols. Older patients with relapsed CD33⁺ AML may be treated with gemtuzumab ozogamicin (Mylotarg) an anti-CD33 antibody chemically linked to a cytotoxic agent calicheamicin, which binds to CD33-expressing myeloid leukemia and normal hematopoietic cells and induces cell death. Unfortunately, complete

remission rates after Mylotarg therapy are low (5% to 15%), and side effects include prolonged pancytopenia with risks for infectious complications and veno-occlusive liver disease due to CD33⁺ liver parenchyma cells. Experimental therapies for AML, particularly nonmyeloablative (mini-transplants) SCT (see Chapter 47), have resulted in durable long-term remissions in a proportion of older AML patients and should be pursued based on patient preference, overall health status, and availability of an appropriate HLA-matched donor.

Acute Promyelocytic Leukemia

ETIOLOGY AND PATHOGENESIS

Acute promyelocytic leukemia (APL), formerly known as AML FAB-M3 (see Table 48-8), represents 10% to 15% of adult AML, with an increased incidence in younger patients (median age, 40 years). APL differs from other acute leukemias because of its unique disease biology. Morphologically, APL blasts are distinctive immature promyelocytic cells containing large granules and typically high numbers of Auer rods diagnostic for AML. APL cells possess a chromosomal translocation, t(15;17)(q22; q12), which results in a fusion protein composed of a nuclear transactivation protein (PML) on chromosome 15 with the retinoic acid α receptor on chromosome 17. Sequestration of the PML RAR- α fusion protein with other proteins results in a complex that represses transcription of genes essential for granulocytic differentiation, effectively resulting in differentiation arrest of leukemia cells at the promyelocytic stage.

CLINICAL FEATURES

Clinically, patients with APL often exhibit life-threatening bleeding caused by disseminated intravascular coagulation related to high procoagulant factor levels released from APL granules. Even today, bleeding complications in the CNS and other sites can be rapidly fatal if the disease is not recognized and treated as a medical emergency. All patients suspected of an APL diagnosis should be started empirically on ATRA (discussed later) therapy and treated aggressively with transfusions of fresh-frozen plasma, fibrinogen, and platelets until resolution of coagulopathy and disease confirmation.

TREATMENT

Treated appropriately, APL is the most curable acute leukemia in adults. The centerpiece of APL treatment is all-*trans*-retinoic acid (ATRA), a biologic agent shown to overcome growth arrest and permit differentiation of immature APL blast cells into neutrophils by altering the configuration of PML RAR- α to allow normal gene transcription. Although ATRA alone induces clinical remissions in up to 90% of patients, high relapse rates observed after monotherapy have led to the standard practice of combining ATRA with anthracycline chemotherapy in upfront induction regimens. Patients initiated on ATRA with or without chemotherapy must be closely observed for development of *retinoic acid* or

APL differentiation syndrome, life-threatening acute cardiopulmonary distress characterized by bilateral pulmonary effusions and infiltrates in the setting of high levels of circulating leukocytes with leukostasis. This serositis-like syndrome is attributed to adhesion of differentiating neoplastic cells to the pulmonary vasculature and carries a 5% to 10% mortality rate. Treatment consists of early initiation of corticosteroids and aggressive diuresis. In severe cases, ATRA should be temporarily held. Complete remission rates in APL are 90% to 95%, and more than two thirds of patients with APL treated with standard ATRA-containing induction, consolidation, and maintenance chemotherapy regimens achieve long-term remission. Relapsed APL patients can be treated with *arsenic trioxide*, a naturally occurring compound used as both a poison and a drug in many countries. Low-dose arsenic therapy promotes APL cell differentiation and apoptosis and induces remission rates in up to 90% of relapsed APL cases. Both APL differentiation syndrome and prolongation of the QT interval are common side effects of arsenic therapy. Arsenic has also been used for consolidation therapy in APL patients with improved clinical outcome. Patients achieving a second remission after arsenic therapy and those who have residual PML RAR- α -positive cells after standard induction and consolidation therapy should be considered for autologous or allogeneic SCT, or both. Mylotarg (anti-CD33 antibody-toxin) therapy has also been used for APL therapy with some success because most APL cells express CD33 antigens.

Acute Lymphoblastic Leukemia

ETIOLOGY AND PATHOGENESIS

ALL is a neoplasm of immature lymphoblasts expressing markers of B- or T-cell lineage. The prior FAB classification system divided ALL into three subtypes (L₁, L₂, and L₃) based on the morphology of malignant cells (see **Web Fig. 48-4**). More recently, the WHO system has reclassified the disease as either precursor B or T ALL, based on the lineage of specific cell surface antigens found on these cells during normal maturation (see Table 48-7). T ALL represents 15% to 25% of ALL diagnoses and is traditionally associated with superior clinical outcomes compared with B ALL. More than 50% of T ALL cases have activating mutations in Notch1, a key regulator of T-cell fate, and trials of inhibitors of the Notch pathway for treatment of relapsed disease are already underway.

CLINICAL FEATURES

ALL is predominantly a pediatric malignancy, with most cases occurring in children younger than 6 years of age. Progress in the understanding and treatment of this disease in the 1990s has led to cure rates of up to 80% in children with ALL but only 20% to 40% in adult patients with ALL. These poorer outcomes in adults are attributed to differences in the biologic mechanisms of disease in these different age groups as well as the inability of older patients to tolerate the intensive chemotherapy or transplantation procedures

required to achieve long-term responses. Clinical and biologic features, particularly cytogenetics, at diagnosis have been identified as important prognostic factors (see Table 48-10). Of note, up to 50% of adult ALL (versus only 20% of pediatric ALL) cases are associated with presence of a Philadelphia chromosome abnormality, t(9; 22) (see earlier). Philadelphia chromosome expressing ALL is notoriously chemoresistant, with an increased risk for CNS involvement and overall 5-year survival rate of less than 10%.

TREATMENT

Treatment of ALL is lengthy and involves multiple chemotherapy agents given over a period of 2 to 3 years. Induction chemotherapy typically includes vincristine, corticosteroids, and L-asparaginase, with the addition of an anthracycline, cytarabine, or cyclophosphamide, or a combination, in adult patients. Given the propensity of ALL cells to reside in the CNS and testes (so-called sanctuaries for leukemia cells because standard systemic chemotherapy does not penetrate into these sites), most ALL patients undergo lumbar puncture at time of diagnosis, followed by routine administration of intrathecal methotrexate or whole-brain irradiation, or both, as a necessary adjunct to systemic induction and consolidation chemotherapy. Complete remission rates are 97% to 99% in children and 75% to 90% in adults. After normal hematopoiesis returns, patients then undergo consolidation and intensification therapy with multiple drugs to eradicate disease. For unknown reasons, ALL tends to relapse several months to years after initial remission. Studies have shown that the frequency of relapse is reduced by maintenance chemotherapy given for up to 2 to 3 years after initial remission achievement. Such prolonged treatment may eliminate slow-growing leukemic clones, prevent further transformation, or destroy occult disease in other (particularly CNS) sites. In addition to conventional chemotherapy, patients with Philadelphia chromosome-positive ALL also receive

therapy with high-dose Gleevec, the oral *bcr-abl* tyrosine kinase inhibitor used in CML. High-risk patients with B ALL may benefit from anti-CD20 antibodies (rituximab) directed against B-cell antigens on abnormal lymphoblasts.

In ALL, as in AML, the worse the prognosis, the earlier transplantation should be offered. Studies have shown that high-risk ALL patients (defined as older patients, Philadelphia chromosome-positive disease, high presenting white blood cell count, or prolonged time to first remission) clearly benefit from SCT, preferably from an HLA-matched sibling, in first remission. Early transplantation in adults has achieved 5-year survival rates of 40% to 44%, in comparison with 20% with other therapies. Unfortunately, outcomes for high-risk ALL patients without an available HLA-matched donor are poor, and these individuals should pursue HLA-matched unrelated donor allogeneic SCT or experimental therapies. No significant benefit has been seen with autologous transplantation over standard chemotherapy for these patients. Whether Philadelphia chromosome-positive ALL patients lacking SCT donors benefit more from conventional chemotherapy plus Gleevec or other *bcr-abl* inhibitors compared with autologous SCT remains to be determined. Standard-risk ALL patients, particularly pediatric patients, with high long-term remission rates after conventional chemotherapy and maintenance need not undergo allogeneic SCT unless disease recurs.

Most ALL relapses arise within 2 years of initial diagnosis, with recurrence of leukemic cells in the bone marrow, CNS, or testes. Although relapsed disease may respond to further chemotherapy and local irradiation, the duration of second remissions is usually less than 6 months. All patients with relapsed ALL should be considered for allogeneic SCT (which represents the only known cure for disease) or experimental treatment. Autologous SCT for refractory or relapsed ALL is not routinely recommended because ALL blasts appear to be more chemoresistant, with higher failure rates after treatment.

Prospectus for the Future

Our molecular understanding of the pathogenesis of MPN and acute leukemia is progressing rapidly and is already having a critical impact on the development of novel therapeutic approaches that promise to transform our clinical approach to these diseases in the coming years.

Myeloproliferative Disease

The importance of the spectacular success of Gleevec as targeted therapy of CML cannot be overstated. As the first successful therapy based on an understanding of pathogenesis, Gleevec has become emblematic of the translation of our understanding of disease pathogenesis into tangible clinical care innovations. Second-generation tyrosine kinase inhibitors with activity against Gleevec-resistant CML are now available, and SCT is now only rarely offered to patients with CML. Similarly, the discovery of the JAK 2 mutations in non-CML myeloproliferative diseases opens new avenues for targeted intervention in these diseases for which previous therapy has been largely supportive. JAK 2 kinase inhibitors are already

under development and will be a major focus of research in the coming years.

Acute Leukemia

Once again, molecular understanding of the pathogenesis of acute leukemia has led to important therapeutic advances in the treatment of disease. The discovery of the link between the retinoic acid receptor and the origins of APL has provided important insight into the unique sensitivity of this disease to ATRA. Gleevec and other oral *bcr-abl* kinase inhibitors has now been added to the armamentarium for treatment of Philadelphia chromosome-positive ALL. Identification of Notch-1 activating mutations in T ALL and FLT-3 kinase mutations in normal karyotype AML have led to ongoing clinical trials of targeted inhibitors for these pathways in both newly diagnosed and relapsed patients. Similar approaches may soon provide therapeutic entry points into the treatment of other acute leukemias associated with pathognomonic chromosomal translocations and genetic and molecular aberrations.

Disorders of Red Blood Cells

Michal G. Rose and Nancy Berliner

Normal Red Blood Cell Structure and Function

The red blood cells (RBCs, erythrocytes) deliver oxygen to all the tissues in the body and carry carbon dioxide back to the lungs for excretion. The erythrocyte is uniquely adapted to these functions. The RBC has a biconcave disk shape that maximizes the membrane surface area for gas exchange, and it has a cytoskeleton and membrane structure that allow it to deform sufficiently to pass through the microvasculature. Passage through capillaries that have a diameter that may be one fourth the resting diameter of the erythrocyte is made possible by interactions between proteins in the membrane (band 3 and glycophorin) and underlying cytoplasmic proteins that make up the erythrocyte cytoskeleton (spectrin, ankyrin, and protein 4.1).

The mature red cell contains no nucleus and is dependent throughout its life span on proteins synthesized before extrusion of the nucleus and release from the bone marrow into the peripheral circulation. About 98% of the cytoplasmic protein of the mature erythrocyte is hemoglobin. The remainder is mainly enzymatic proteins, such as those required for anaerobic metabolism and the hexose monophosphate shunt.

As discussed in the text that follows, defects in any of the intrinsic structural features of the erythrocyte can result in hemolytic anemia. Abnormalities of the membrane or cytoskeletal proteins are the causes of alterations in erythrocyte shape and flexibility. Inborn defects in the enzymatic pathways for glucose metabolism decrease the resistance to oxidant stress, and inherited abnormalities of hemoglobin structure and synthesis lead to polymerization of abnormal hemoglobin (sickle cell disease) or to the precipitation of unbalanced hemoglobin chains (thalassemia). All these changes result in decreased red cell survival.

Oxygen is transported by hemoglobin, a tetramer composed of two α chains and two β -like (β , γ , or δ) chains. In fetal life, the main hemoglobin is fetal hemoglobin (HbF [$\alpha_2\gamma_2$]); the switch from HbF to adult hemoglobin (HbA [$\alpha_2\beta_2$]) occurs in the perinatal period. By 4 to 6 months of age, the

level of HbF falls to about 1% of total hemoglobin. HbA₂ ($\alpha_2\gamma_2$) is a minor adult hemoglobin, representing about 1% of adult hemoglobin (Table 49-1).

Clinical Approach to Anemia

Anemia, the reduction in red cell mass, is an important sign of disease. It may reflect decreased production of erythrocytes, because of nutritional deficiencies or primary hematologic disease or in response to systemic illness. Alternatively, anemia may reflect increased blood loss or cellular destruction from hemolysis. Hemolysis may occur as a result of intrinsic abnormalities of the red cell or immune-mediated red blood cell destruction, or as a part of a systemic vascular process. The investigation of anemia is a critical component of the evaluation of the patient and commonly provides valuable insight into systemic illness. Figure 49-1 provides an overview of the differential diagnosis of anemia.

CLINICAL PRESENTATION

The symptoms of anemia reflect both the severity and the rapidity with which the reduction in erythrocyte mass has occurred. Patients with acute hemorrhage or massive hemolysis may exhibit symptoms of hypovolemic shock. However, most patients develop anemia more slowly and may have few symptoms. Usual complaints are fatigue, decreased exercise tolerance, dyspnea, and palpitations. In patients with coronary artery disease, anemia may precipitate angina. On physical examination, the major sign of anemia is pallor. Patients may be tachycardic and often have audible flow murmurs. Patients with hemolysis often exhibit jaundice and splenomegaly.

LABORATORY EVALUATION

The key components of the laboratory evaluation of anemia are the reticulocyte count, peripheral blood smear, erythro-

cyte indices, nutritional studies, and bone marrow aspirate and biopsy.

The *reticulocyte count* allows the critical distinction between anemia arising from a primary failure of red cell production and anemia resulting from increased red cell destruction or bleeding. Erythrocytes newly released from the marrow still contain small amounts of RNA; these are termed *reticulocytes* and can be detected by staining the peripheral blood smear with methylene blue or other supravital stains. In response to the stress of anemia, erythropoietin (EPO) production increases and promotes the production and release of increased numbers of reticulocytes. The number of reticulocytes in the peripheral blood therefore reflects the response of the bone marrow to anemia. The reticulocyte count can be expressed either as a percentage of the total red cell number or as an absolute number.

In patients without anemia, a normal reticulocyte count is 1%, with an absolute count of 50,000/mcL. When anemia is caused by decreased RBC survival, appropriate marrow response results in a reticulocyte count of more than 2%, with an absolute reticulocyte count of more than 100,000/mcL. When the reticulocyte count is not elevated, a search should begin for a cause of the failure of red cell production. Reticulocyte counts that are expressed as a percentage of total RBCs must be corrected for anemia because decreasing the number of circulating cells will increase the reticulocyte percentage without any increase in release from the marrow. The corrected reticulocyte count is calculated by multiplying the reticulocyte count by the ratio of the patient's hematocrit to a normal hematocrit. The advantage of the absolute reticulocyte count is that this correction is not necessary. The absolute reticulocyte count is becoming increasingly available and will probably supersede the standard reticulocyte count.

Evaluation of the *peripheral blood smear* (Fig. 49-2) may provide important clues to the causes of anemia. Red cell morphologic examination is especially critical in the evaluation of anemia associated with reticulocytosis, wherein an examination of the smear is essential to distinguish between immune hemolysis (which results in spherocytes) and microangiopathic hemolysis (which causes schistocytes or erythrocyte fragmentation). Changes associated with other causes of anemia include sickle and target cells that are characteristic of hemoglobinopathies, teardrop cells and nucleated red cells associated with myelofibrosis and marrow infiltration, intracorporeal parasites in malaria and

Table 49-1 Structure and Distribution of Human Hemoglobins

Name of Hemoglobin (Hb)	Distribution	Structure
A	95%-98% of adult Hb	$\alpha_2\beta_2$
A ₂	1.5%-3.5% of adult Hb	$\alpha_2\delta_2$
F	Fetal, 0.5%-1.0% of adult Hb	$\alpha_2\gamma_2$
Gower 1	Embryonic	$\zeta_2\varepsilon_2$
Gower 2	Embryonic	$\alpha_2\varepsilon_2$
Portland	Embryonic	$\zeta_2\gamma_2$

babesiosis, and pencil-shaped deformities associated with severe iron deficiency. In addition, examination of myeloid cells and platelets may also be helpful. Hypersegmented neutrophils and large platelets support the diagnosis of megaloblastic anemia, and the presence of immature blast forms may be diagnostic of leukemia. Figure 49-2 visualizes some common peripheral blood smear findings in patients with anemia.

In patients with anemia and an elevated reticulocyte count, the vigorous production of new erythroid cells suggests that marrow function is normal and is responding appropriately to the stress of the anemia. Bone marrow examination in this situation is rarely indicated because the marrow will simply show erythroid hyperplasia, usually without revealing any primary marrow pathologic anomaly. Evaluation should be focused on determining whether the cause of red cell consumption is either bleeding or hemolysis. In contrast, bone marrow examination is often required for the evaluation of hypoproliferative anemia. In patients in whom common abnormalities such as iron and other nutritional deficiencies have been ruled out, marrow aspiration and biopsy are indicated to search for abnormalities such as marrow infiltration, marrow involvement with granulomatous disease, marrow aplasia, or myelodysplasia.

The *mean corpuscular volume* (MCV) is an extremely helpful tool in the diagnosis of anemia with a low reticulocyte count (hypoproliferative anemia). The size of the red cells is used to characterize the anemia as microcytic (MCV < 80), normocytic (MCV 80 to 100), or macrocytic (MCV > 100).

Evaluation of Hypoproliferative Anemia

EVALUATION OF MICROCYTIC ANEMIA

The differential diagnosis of microcytic anemia is outlined in Table 49-2. Microcytosis and hypochromia are the hallmarks of anemias caused by defects in hemoglobin synthesis,

Table 49-2 Differential Diagnosis of Anemia with Low Reticulocyte Count

Microcytic Anemia (MCV < 80)

- Iron deficiency
- Thalassemia minor
- Anemia of chronic disease
- Sideroblastic anemia
- Lead poisoning

Macrocytic Anemia (MCV > 100)

Megaloblastic Anemias

- Folate deficiency
- Vitamin B₁₂ deficiency
- Drug-induced megaloblastic anemia
- Myelodysplasia

Nonmegaloblastic Macrocytosis

- Liver disease
- Hypothyroidism
- Reticulocytosis

Normocytic Anemia (MCV 80-100)

- Early iron deficiency
- Aplastic anemia
- Myelophthitic disorders
- Endocrinopathies
- Anemia of chronic disease
- Anemia of renal failure
- Mixed nutritional deficiency

MCV, mean corpuscular volume.

which can reflect either failure of heme synthesis or abnormalities in globin production. The leading cause of microcytic anemia is iron deficiency, in which lack of heme synthesis results from the absence of iron to incorporate into the porphyrin ring (iron deficiency is discussed in detail in the section that follows). Up to 30% of patients with anemia of chronic disease have microcytosis. Lead poisoning blocks incorporation of iron into heme, also resulting in a microcytic anemia. Sideroblastic anemias arise from failure to synthesize the porphyrin ring, usually as a result of inhibition of the heme synthetic pathway enzymes. Congenital sidero-

blastic anemia may respond to pyridoxine, a cofactor for several of the heme synthetic pathway enzymes. A more common cause of acquired sideroblastic anemia is alcohol abuse; ethanol inhibits most of the enzymes in the heme synthetic pathway. Failure of globin synthesis occurs in thalassemic syndromes, as described in detail in this chapter's section titled "Hemoglobinopathies." All these disorders lead to decreased mean corpuscular hemoglobin concentration, causing hypochromia and a decrease in red cell size (low MCV).

Iron Deficiency Anemia

Iron deficiency is the leading cause of anemia worldwide. Although the presentation of classic iron deficiency anemia is linked with a microcytic anemia, early iron deficiency is associated with a normocytic anemia. Consequently, iron deficiency should be considered in all patients with anemia, and iron indices should be a part of the evaluation of any patient with hypoproliferative anemia, regardless of the MCV.

Iron is acquired in the diet from either heme (found in meat) or nonheme (derived from vegetables such as spinach) sources. Iron from heme is better absorbed than nonheme iron. Iron absorption is increased in iron deficiency and in patients with ineffective erythropoiesis. Iron is absorbed from the proximal small intestine bound to transferrin, which mediates its uptake into red cell precursors through the transferrin receptor. The iron is released and incorporated into heme. Iron outside of hemoglobin-producing cells is stored in ferritin. Men and women have total-body iron of 50 mg/kg and 40 mg/kg, respectively. Between 60% and 75% of the iron is found in hemoglobin. A small amount (2 mg/kg) is found in heme and nonheme enzymes, and 5 mg/kg is found in myoglobin. The remainder is stored in ferritin, which resides primarily in liver, bone marrow, spleen, and muscle. The capacity for excreting iron is limited, and iron overload occurs in patients with excessive absorption from the gastrointestinal tract (as a result of ineffective erythropoiesis or congenital hemochromatosis) or from chronic transfusions. Iron overload leads to increased iron deposition in these tissues and secondary deposition in endocrine organs, resulting in liver dysfunction, diabetes, and other endocrine abnormalities.

The most frequent cause of iron deficiency is occult blood loss. All men and postmenopausal women who are found to be iron deficient should have an evaluation for a source of gastrointestinal blood loss, regardless of the detection of occult blood. In premenopausal women, iron deficiency is most frequently secondary to loss of iron with menstruation (about 15 mg per month) and during pregnancy (about 900 mg per pregnancy). *Helicobacter pylori* infection has also recently been recognized as a cause of iron deficiency even in the absence of intestinal bleeding. Dietary deficiency of iron is most commonly seen in young children whose growth outstrips their intake of iron and in babies who drink mostly milk at the expense of an intake of iron-containing foods.

Laboratory Evaluation

As previously stated, early iron deficiency does not exhibit the hallmark microcytosis and hypochromia that characterize classic iron deficiency. Evaluation of the blood smear in advanced iron deficiency often demonstrates hypochromic RBCs, target cells, and pencil-shaped elongated cells.

Early iron deficiency is frequently associated with reactive thrombocytosis.

The mainstay of the diagnosis of iron deficiency is the peripheral blood iron indices. These include iron and total iron-binding capacity (TIBC) and ferritin. The transferrin saturation is the ratio of serum iron to transferrin concentration (TIBC), and is normally at least 20%. Iron deficiency results in a decrease in serum iron and an increase in iron-binding capacity, leading to a decrease in this ratio to less than 10%. Chronic inflammatory conditions (e.g., infection, inflammation, malignancy) often decrease both iron and TIBC, but the transferrin saturation usually remains above 20%.

The ferritin level is a reflection of total-body iron stores. The liver synthesizes ferritin in proportion to total-body iron, and a level of less than 12 ng/mL strongly supports a diagnosis of iron deficiency. Unfortunately, ferritin is an acute-phase reactant, and levels rise in the setting of fever, inflammatory disease, infection, or other stresses. However, ferritin levels in response to stress do not often rise above 50 to 100 ng/mL; therefore ferritin levels higher than 100 ng/mL usually rule out iron deficiency.

If the indirect measurement of iron indices does not definitively confirm or refute a diagnosis of iron deficiency, a bone marrow examination can be performed to provide a direct assessment of marrow iron stores. Presence of iron in the marrow excludes iron deficiency anemia because marrow iron stores will be depleted before any fall in red cell production resulting from iron deficiency; conversely, complete absence of marrow iron confirms the diagnosis of iron deficiency.

Treatment

Oral iron supplementation, with administration of ferrous sulfate or ferrous gluconate 2 to 3 times daily, is the treatment for iron deficiency. Side effects include diarrhea or constipation, and patients should be treated symptomatically. Reduction of the dose and gradual reinstitution of full doses may allow oral therapy to be continued. Iron should be administered for several months after resolution of anemia to allow for the reconstitution of iron stores.

In patients with malabsorption, a complete inability to tolerate oral iron, or iron demands that outstrip replacement with oral supplements, parenteral iron may be administered. The parenteral administration of iron, especially iron dextran, has been associated with anaphylaxis. However, newer preparations such as sodium ferric gluconate and iron sucrose are significantly safer. As previously stated, all male patients and postmenopausal women with iron deficiency require evaluation for a source of gastrointestinal bleeding.

EVALUATION OF MACROCYTIC ANEMIA

Two categories of hypoproliferative macrocytic anemias exist: megaloblastic anemia and nonmegaloblastic macrocytic anemia. Megaloblastic anemia arises from a failure of DNA synthesis and results in lack of synchrony between the maturation of the nucleus and the cytoplasm of hematopoietic cells. Nonmegaloblastic macrocytic anemias usually reflect membrane abnormalities resulting from abnormalities in cholesterol metabolism and are most commonly found in patients with advanced liver disease or

severe hypothyroidism. Reticulocytosis greater than 10% will also cause an elevated MCV on automated blood counts because reticulocytes are larger than mature RBCs.

Megaloblastic Anemia

Megaloblastic anemia results from a block to synthesis of critical nucleotide precursors of DNA, which leads to a cell cycle arrest in S phase. Cytoplasmic maturation occurs, but maturation of the nucleus is arrested. Cells take on a bizarre appearance, with large immature nuclei surrounded by more mature-appearing cytoplasm. Interference with DNA synthesis affects all rapidly dividing cells, and therefore patients with megaloblastic syndromes often have pancytopenia and gastrointestinal symptoms such as diarrhea and malabsorption. In women, megaloblastic changes of the cervical mucosa occur and may cause abnormal Papanicolaou smears. The most common causes of megaloblastic anemia are deficiencies of vitamin B₁₂ or folate, medications that inhibit DNA synthesis or that block folate metabolism, and myelodysplasia.

Vitamin B₁₂ (Cobalamin) Deficiency

Cobalamin (Cbl) is absorbed from animal protein in the diet. The process of Cbl absorption and metabolism is complex because Cbl is always bound to other proteins. In the stomach, protein-bound vitamins are released by digestion with pepsin and are bound to transcobalamin I. Transcobalamins I and III, termed *R binders* because of their rapid electrophoretic mobility, are found in all secretions, in plasma, and within the secondary granules of neutrophils. Although presumed to be involved with the storage of Cbl, their function is unknown, and isolated congenital deficiency of R binders is clinically silent. Within the proximal duodenum, pancreatic proteases digest Cbl away from the R binder proteins, and Cbl binds to intrinsic factor (IF). IF is secreted by the parietal cells of the stomach and mediates absorption of Cbl through IF-specific receptors in the distal ileum. Within the ileal mucosal cell, the IF-Cbl complex is again digested, and Cbl is released into the plasma bound to transcobalamin II (TCII), the carrier protein that mediates cellular uptake of Cbl by TCII-specific receptors.

Within the cell, Cbl is a cofactor for two intracellular enzymes, methylmalonyl-coenzyme A (CoA) mutase, and homocysteine-methionine methyltransferase (Fig. 49-3). Methylmalonyl-CoA mutase is a mitochondrial enzyme that functions in the citric acid cycle to convert methylmalonyl-CoA to succinyl-CoA. The cytoplasmic enzyme homocysteine-methionine methyltransferase is necessary for the transfer of methyl groups from *N*-methyltetrahydrofolate to homocysteine to form methionine. Demethylated tetrahydrofolate is necessary as a carbon donor in the conversion of deoxyuridine to deoxythymidine. Absence of Cbl results in a *trapping* of tetrahydrofolate in its methylated form and blocks the synthesis of thymidine 5'-triphosphate for incorporation into DNA. The megaloblastic changes induced by Cbl deficiency are mediated through this functional folate deficiency, which explains the similarity in the hematologic abnormalities induced by Cbl and folate deficiency.

Causes of Cobalamin Deficiency

The most common cause of Cbl deficiency is pernicious anemia, an autoimmune disease associated with gastric pari-

Congenital Intrinsic Factor or Transcobalamin II Deficiency

etal cell atrophy, defective gastric acid secretion, and absence of IF. Antiparietal cell and anti-IF antibodies are frequently found in patients with pernicious anemia and other autoimmune conditions such as Graves disease, Addison disease, and hypoparathyroidism. Many other lesions in the gastrointestinal tract can interfere with the absorption of Cbl (Table 49-3). Gastrectomy causes loss of parietal cell function and IF secretion. Pancreatic insufficiency interferes with the digestion of the R binder-Cbl complex, hindering the binding of Cbl to IF and ileal absorption. Resection of the terminal ileum prevents vitamin B₁₂ absorption, as do diseases that affect ileal mucosal function, such as Crohn disease, sprue, intestinal tuberculosis, and lymphoma. Because the body stores of Cbl are large and daily loss of Cbl is low, the stores of Cbl are adequate for 3 to 4 years if intake stops abruptly; signs of Cbl deficiency do not develop until defective absorption has occurred for several years. Nutritional Cbl deficiency is rare and is only seen in individuals who have been on strict vegan diets, excluding all animal products for many years. Infants born to vegan mothers who are breastfed are also at risk for developing Cbl deficiency.

Folate Deficiency

Folate is widely present in food such as leafy vegetables, fruits, and animal protein. However, because it is destroyed

Methotrexate
Sulfa drugs

by prolonged cooking, fresh fruits and vegetables are the most reliable source of folate. Consequently, nutritional folate deficiency is common in malnourished individuals who eat very little fresh fruits and vegetables. Folate deficiency can also be caused by increased demand, as occurs with pregnancy, hemolysis, and exfoliative dermatitis, and by increased losses, which occur with dialysis (Table 49-4). Folate is absorbed in the proximal small intestine, and malabsorption of folate can also lead to folate deficiency.

Other Causes of Megaloblastic Anemia

Drugs and toxins are common causes of megaloblastic anemia. Some drugs, such as methotrexate and sulfa drugs, act as direct folate antagonists and mimic folate deficiency. Purine and pyrimidine analogue chemotherapeutic agents (e.g., azathioprine, 5-fluorouracil) are direct DNA-synthesis inhibitors. Antiviral agents cause megaloblastic changes by unclear mechanisms. Alcohol interferes with folate metabolism, increasing the effect of frequent concomitant nutritional folate deficiency. Myelodysplasia commonly appears as a macrocytic anemia, with megaloblastic changes primarily in the erythroid series.

Clinical Manifestations of Megaloblastic Anemia

The development of megaloblastic anemia is usually gradual, allowing adequate time for concomitant plasma expansion to prevent hypovolemia. Consequently, patients are frequently severely anemic at presentation. They may have yellowish skin as a result of a combination of pallor and jaundice. Some patients have glossitis and cheilosis. With severe anemia, patients usually have an MCV above 110, although concomitant iron deficiency, caused by malabsorption secondary to megaloblastic changes in the intestinal tract, may decrease the macrocytosis. Patients frequently have pancytopenia.

A peripheral smear demonstrates large, oval cells (macro-ovalocytes), hypersegmented neutrophils, and large platelets. The bone marrow is hypercellular, with megaloblastic changes and abnormally large precursors. In addition, intramedullary destruction of erythrocytes (ineffective hematopoiesis) causes elevated bilirubin and lactate dehydrogenase.

Cbl deficiency is associated with neurologic abnormalities that are not seen with other causes of megaloblastic anemia.

The neurologic signs may range widely from a subtle loss of vibratory sensation and position sense caused by demyelination of the dorsal columns to frank dementia and neuropsychiatric disease. The neurologic changes may be present without anemia, especially if a patient with Cbl deficiency is treated with folate, which may correct the hematologic manifestations of megaloblastic anemia but does not treat the neurologic abnormalities. The neurologic manifestations of Cbl deficiency are thought to be secondary to loss of function of the mitochondrial enzyme methylmalonyl-CoA mutase. One proposed explanation is that the failure to metabolize odd-chain fatty acids, which results in their improper incorporation into myelin, causes the neurologic dysfunction. This explains why these findings are uniquely seen in patients with Cbl deficiency and are not seen in those with the megaloblastic anemias caused by abnormalities in the folate pathway.

Measuring levels of Cbl and folate in the peripheral blood confirms the diagnosis of megaloblastic anemia. Because megaloblastic changes in the gut mucosa can cause concomitant malabsorption of folate in the presence of Cbl deficiency, and vice versa, both levels should be measured in the patient with megaloblastic hematopoiesis. RBC folate levels better reflect the body folate stores and should be measured when a deficiency is clinically suggested but the *serum* folate levels are normal. Homocysteine levels are elevated in Cbl and folate deficiency, and methylmalonic acid levels are elevated in Cbl deficiency. These levels can be measured when Cbl deficiency is suggested, but serum Cbl levels are in the low-normal range.

In the setting of Cbl deficiency, a Schilling test may help establish the cause of the deficiency. Radioactive Cbl is given orally with a large parenteral dose of unlabeled Cbl. The absorption of orally administered Cbl is then measured by determining the excretion of radioactivity into the urine. Cbl bound to IF and labeled with a different isotope can be given simultaneously. Selective absorption of IF-bound Cbl supports a diagnosis of pernicious anemia. If neither isotope is absorbed, the test may be repeated after a course of antibiotics to treat potential bacterial overgrowth or after administering pancreatic enzymes to rule out pancreatic insufficiency. The use of the Schilling test has decreased with the availability of assays for antiparietal cell antibodies and anti-IF antibodies, particularly because the necessity of an adequate urine collection makes it frequently unreliable.

Treatment of Megaloblastic Anemia

Patients with Cbl deficiency should initially receive daily or weekly parenteral therapy with 1 mg subcutaneously or intramuscularly for four to eight doses. Maintenance therapy should then be instituted with 1 mg parenterally monthly. Oral therapy with high-dose crystalline vitamin B₁₂ may overcome blocks to normal Cbl absorption, and oral therapy may be an option in patients who refuse parenteral supplementation. Therapy with Cbl should be accompanied by folate therapy because concomitant secondary folate deficiency may develop when RBC production increases with the availability of Cbl.

Patients with folate deficiency should receive replacement with 1 to 5 mg per day of oral folate. As previously noted, it is critical to be certain that patients are not Cbl deficient because replacement of folate may correct the hematologic

parameters in patients with Cbl deficiency, but it will not improve the neurologic sequelae.

After treating megaloblastic anemia, a rapid response usually occurs. Reticulocytosis is seen as early as 2 days after therapy and peaks within 7 to 10 days. Despite rapid resolution of neutropenia, hypersegmentation of neutrophils may persist for several days. During this period, rapid cellular proliferation and turnover occur, which may precipitate hypokalemia, hyperuricemia, or hypophosphatemia. Patients should also be monitored for the development of iron deficiency in the face of increased demand with the rapid cellular proliferation in response to replacement. Anemia and other cytopenias should respond completely within 1 to 2 months, but the neurologic manifestations of Cbl deficiency improve slowly and may be irreversible.

EVALUATION OF NORMOCYTIC ANEMIA

The differential diagnosis of a normocytic hypoproliferative anemia is extensive. Most nutritional anemias that cause microcytosis or macrocytosis begin as a normocytic anemia. Combined nutritional deficiencies may also cause normalization of the MCV. The measurement of EPO levels may be helpful in the diagnosis of normocytic anemia. In addition to helping in the diagnosis of anemia resulting from renal failure, many of the anemias associated with chronic inflammation and endocrinopathies exhibit a depressed EPO level. However, interpretation of EPO levels may be difficult in patients with mild anemia because the levels do not usually rise above the normal range until the hematocrit is depressed below 30%. Even below a hematocrit level of 30%, the EPO level will often be in the normal range, but such levels are inappropriately low in the setting of anemia. An elevated EPO level suggests inadequate marrow response to anemia and increases the likelihood of myelophthisis or primary bone marrow failure. In patients for whom the diagnosis is not clear upon routine nutritional and endocrine studies, a bone marrow examination is indicated to rule out primary marrow pathologic conditions.

Anemia of Chronic Disease

The anemia of chronic disease (now preferentially termed the *anemia of inflammation*) occurs in patients with chronic inflammatory, infectious, malignant, and autoimmune diseases. Patients have low-serum iron levels, but, in contrast to the iron indices in iron deficiency, the iron-binding capacity is also reduced, and the transferrin saturation is usually greater than 10%. Ferritin levels are often elevated, both as an acute-phase reactant and as a reflection of decreased iron incorporation. Recent studies have demonstrated that these patients have inappropriately high levels of hepcidin, a peptide produced by the liver, which is responsible for regulating intestinal iron absorption and iron mobilization from macrophages. Other abnormalities in patients with anemia of chronic disease include an absolute or relative EPO deficiency, poor iron incorporation into developing erythrocytes, and shortened erythrocyte survival.

Treatment of Normocytic Anemias

The mainstay of treatment of the anemia of chronic renal failure is EPO and iron replacement. The anemia of chronic disease will resolve if the underlying chronic condition is

treated. In the absence of primary treatment, anemia will often respond to therapy with EPO. EPO levels may be helpful in predicting which patients are likely to respond. Therapy with EPO may be successful in patients with levels below 150 U/L, although it is most successful if the level is below 50 U/L. Responses to EPO replacement are most dramatic in patients with multiple myeloma, rheumatoid arthritis, and in the anemia associated with HIV infection.

Treatment of other causes of normocytic anemia is dictated by the primary causes of the disorder. The evaluation and treatment of primary marrow failure syndromes and hematologic malignancies are discussed in Chapters 47 and 48, respectively.

Evaluation of Anemia with Reticulocytosis

An elevated reticulocyte count in the setting of anemia signals a compensatory response of a normal marrow to premature loss of erythrocytes. Hemolysis is the premature destruction of RBCs in the reticuloendothelial system (extrinsic hemolysis) or in blood vessels (intrinsic hemolysis). The only other condition that causes anemia with reticulocytosis is acute bleeding. The differential diagnosis of hemolytic anemia is outlined in Table 49-5.

Table 49-6 Drug-Induced Autoimmune Hemolytic Anemia

Type	Mechanism	Common Drugs Implicated	Direct Coombs Test—Positive Hemolytic Anemia	Indirect Coombs Test—Positive Hemolytic Anemia
1	Hapten mediated	Penicillin Cephalothin	IgG positive Complement positive or negative	Positive only in the presence of drug
2	Immune complex mediated	Quinine Quinidine Phenacetin Rifampin Isoniazid Tetracycline Chlorpromazine	IgG negative Complement positive	Positive only in the presence of drug
3	True anti-RBC antibody	Methyldopa Levodopa Procainamide Ibuprofen Interferon- α	IgG positive Complement negative	Positive also in absence of drug

Although examination of the peripheral blood smear is frequently helpful in characterizing any anemia, it is absolutely critical in the evaluation of patients with hemolytic anemia. As previously noted, the morphologic examination of the erythrocytes is helpful in distinguishing immune hemolysis from microangiopathic hemolytic anemia. In addition, other red cell morphologic abnormalities are characteristic for specific diseases such as sickle cell disease (sickled cells), enzyme defects (*bite* cells), or erythrocyte membrane abnormalities (spherocytes and elliptocytes).

IMMUNE HEMOLYTIC ANEMIA

Immune-mediated hemolysis results from the coating of the erythrocyte membrane with antibodies or complement, or both. It may be mediated by immunoglobulin G (IgG) antibodies (*warm* antibody) or by IgM antibodies (*cold* antibody). The designations *warm* and *cold* denote the temperature at which maximal antibody binding takes place, and the clinical syndromes caused by the two types of antibodies are distinct.

The diagnosis of hemolytic anemia is based on the direct and indirect antiglobulin (Coombs) tests. To perform a direct Coombs test, patient erythrocytes are mixed with rabbit antisera directed against either human IgG or human complement. The cells are then monitored for agglutination, the presence of which confirms the presence of antibody or complement on the patient's red cells. The indirect Coombs test is performed by mixing patient serum with ABO-compatible erythrocytes and then combining this mixture with rabbit antisera against IgG; the Coombs test allows for the evaluation of antibody in the patient's serum.

IgG-Mediated (Warm) Immune Hemolysis

Classic autoimmune hemolytic anemia (AIHA) is caused by IgG antibody directed against erythrocyte antigens. Warm-type hemolysis may be primary (idiopathic) or associated with autoimmune disease, lymphoproliferative disorders, or drugs. Patients exhibit acute anemia, jaundice, and an elevated reticulocyte count. Some patients have splenomegaly. The peripheral blood smear demonstrates spherocytes (see

Fig. 49-2E). Laboratory analysis confirms the presence of IgG on the erythrocyte membrane, as demonstrated by a positive Coombs test; in some patients, the erythrocytes will also be coated with complement. The occasional patient will not have reticulocytosis; in such patients, the antibody destroys reticulocytes and mature erythrocytes.

The mainstay of therapy for AIHA is corticosteroids. Patients are usually treated with 1 to 2 mg/kg of prednisone, and in responding patients, doses are tapered slowly over several months. Patients who fail to respond to prednisone or cannot be tapered off the prednisone can be treated with other immunosuppressive agents, such as cyclophosphamide, azathioprine, or chlorambucil. The occasional patient will respond to intravenous immunoglobulin. Splenectomy may be effective in some patients who are steroid refractory or steroid resistant; however, patients who do not respond and who have ongoing hemolysis after splenectomy are at high risk for secondary thromboembolic events.

Warm antibodies mediate *drug-induced hemolysis*. Several mechanisms exist through which drugs may induce AIHA (Table 49-6). Penicillin produces hemolysis by binding to erythrocytes and acting as a hapten; the antibody is directed against the drug, and hemolysis occurs only in the presence of the drug. Type 2 hemolysis is caused by the formation of an antibody-drug complex that binds to the erythrocyte membrane and activates complement. Drugs associated with this type of hemolysis include quinidine, quinine, and rifampin. Still other drugs, including methyldopa and procainamide, cause hemolysis by inducing the production of *true* antierythrocyte antibodies directed against Rh and other RBC antigens. Antibody may persist in the absence of the drug, but not all patients with a positive Coombs test will have evidence of hemolysis.

IgM-Mediated (Cold) Hemolytic Anemia

Cold-type immune hemolysis is usually postinfectious. The most common associated illnesses are *Mycoplasma pneumoniae* and Epstein-Barr virus (EBV). IgM antibodies are produced that are directed against the RBC antigen I (*Mycoplasma*) or i (EBV). The antibodies bind at lower temperatures, present in fingers and toes, and bind complement. During the return to the central circulation, the IgM falls off

the red cell, leaving complement bound. The Coombs test is negative for IgG or IgM but positive for complement. Hemolysis is self-limited, is rarely severe, and resolves with supportive therapy. In cases of severe hemolysis requiring transfusion, patients should be kept warm, and blood should be administered through a blood warmer to minimize further hemolysis.

Cold agglutinin disease is a chronic IgM antibody-mediated hemolysis usually seen in association with lymphoproliferative disease. Hemolysis is usually low grade; however, if severe, it responds poorly to steroids and splenectomy. Acute severe IgM-mediated hemolysis may respond to plasmapheresis. Supportive therapy includes avoidance of exposure to the cold. In the setting of lymphoproliferative disease, patients may respond to immunotherapy with rituximab (anti-CD20 antibody).

HEMOLYSIS FROM CAUSES EXTRINSIC TO THE ERYTHROCYTE

Microangiopathic Hemolysis

Microangiopathic hemolytic anemia (MAHA) is caused by traumatic destruction of RBCs as they pass through small vessels. The leading causes of MAHA include disseminated intravascular coagulation (DIC) and thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS) (see Table 49-5 and Fig. 49-1). Other causes include pregnancy-related syndromes such as preeclampsia, eclampsia, and the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets in association with preeclampsia); drugs; and metastatic cancers. A similar hemolytic picture can be seen in traumatic hemolysis on a damaged cardiac valve.

Finding schistocytes (fragmented erythrocytes) on the peripheral blood smear confirms the diagnosis of MAHA (see Fig. 49-2D). The presence of a normal prothrombin time and partial thromboplastin time supports a diagnosis of TTP/HUS over that of DIC. Diagnosis and management are described further in Chapter 53.

Infection

Hemolysis can be caused by direct infection of RBCs by parasites, as seen in malaria, babesiosis, and bartonellosis. Severe, overwhelming hemolysis can be seen in clostridial sepsis, in which bacterial toxins directly damage the membrane.

HEMOLYTIC ANEMIAS CAUSED BY DISORDERS OF THE ERYTHROCYTE MEMBRANE

Inherited Membrane Abnormalities

Hereditary spherocytosis (HS) is caused by heterogeneous congenital abnormalities in proteins of the erythrocyte cytoskeleton (Table 49-7). Most patients with HS have dominantly inherited mutations in spectrin or ankyrin. HS is characterized by hemolytic anemia, splenomegaly, and the presence of prominent spherocytes in the peripheral blood. Spherocytes are the result of *conditioning* of the erythrocytes in the spleen, whereby reticuloendothelial cells remove portions of the abnormal membrane that are the result of the

Table 49-7 Congenital Red Blood Cell Membrane Abnormalities

Name of Condition	Abnormal Membrane Proteins	Inheritance
Spherocytosis	Spectrin, ankyrin, band 3, protein 4.2	Autosomal dominant Recessive (rare)
Elliptocytosis	Spectrin, protein 4.1	Autosomal dominant Recessive (rare)
Pyropoikilocytosis	Spectrin	Recessive
Stomatocytosis	Sodium channel permeability defect	Autosomal dominant

disordered cytoskeleton. Spherocytes reflect membrane loss that decreases the membrane-to-cytoplasm ratio. Because a high membrane-to-cytoplasm ratio is responsible for the flexible, biconcave shape of the normal erythrocyte, the erythrocyte loses its biconcave morphologic characteristics and assumes a spherocytic shape with loss of membrane. Spherocytes are less flexible and may be destroyed in the microvasculature. The laboratory finding characteristic of HS is increased osmotic fragility, caused by the loss of distensibility associated with a decrease in surface membrane. HS is usually a mild disorder with well-compensated hemolysis. Patients typically have exacerbations during infections or when given marrow-suppressing medication. Patients with significant hemolysis should receive folate supplementation. Many patients require cholecystectomy for pigment stones. Severe, symptomatic anemia is treated with splenectomy.

Hereditary elliptocytosis (HE) is caused by dominantly inherited mutations affecting the interaction between membrane proteins and underlying cytoplasmic proteins (see Table 49-7). The most common abnormalities affect the interactions with spectrin and protein 4.1, which causes the RBCs to assume an elliptical shape. As in HS, patients usually have mild hemolysis and splenomegaly. *Hereditary pyropoikilocytosis* (HPP) is a rare recessive disorder that is frequently caused by the inheritance of two different membrane disorders (e.g., one allele for HS and one for HE). Patients have severe hemolysis with microspherocytes and elliptocytes on the smear. As with HS, treatment for symptomatic anemia in HE and HPP is splenectomy (see Table 49-7).

Acquired Membrane Abnormalities

Poxysmal Nocturnal Hemoglobinuria

Poxysmal nocturnal hemoglobinuria (PNH) is an acquired clonal disease that is associated with an abnormality of complement regulation. Normal erythrocytes are protected from complement-mediated cell lysis by the presence of membrane proteins, including delay-accelerating factor (DAF, CD55) and membrane inhibitor of reactive lysis (MIRL, CD59). Both these proteins are members of a family of proteins that are anchored to the membrane by a glycosylphosphatidylinositol (GPI) anchor. Patients with PNH have clonal mutations in phosphatidylinositolglycan A (PIG-A), the enzyme required for the synthesis of GPI. These mutations arise in the hematopoietic stem cell, and all hema-

topoietic cells lack GPI-anchored proteins. Absence of GPI-anchored proteins from erythrocytes renders these erythrocytes susceptible to complement-mediated lysis. Traditional tests for PNH are functional assays based on the increased susceptibility of erythrocytes to lysis by acidic serum (Ham test) or hypotonic medium (sucrose lysis test). Now that the underlying molecular abnormality in PNH has been defined, diagnosis can be made by flow cytometric documentation of the absence of CD55 or CD59 on the surface of RBCs or leukocytes.

PNH is a clonal stem cell disorder with several unique characteristics. Patients suffer from episodic acute intravascular hemolysis with a release of free hemoglobin that results in the hemoglobinuria for which the disease is named. Patients are also susceptible to venous thrombotic complications, including Budd-Chiari syndrome, portal vein thrombosis, cerebrovascular thrombosis, and peripheral veins. The disease is associated with a risk for developing myelodysplasia, myelofibrosis, acute leukemia, or aplastic anemia. Furthermore, patients with aplastic anemia who respond to immunosuppressive therapy frequently develop PNH-like clones. In the past, treatment has been largely supportive. However, treatment with eculizumab, a monoclonal antibody that binds to the C5 component of complement, has been shown to reduce hemolysis, transfusion requirements, and thromboembolic events in this disease and was recently approved by the U.S. Food and Drug Administration for this indication. Young patients, however, should be considered for allogeneic stem cell transplantation.

Spur Cell Anemia

Spur cells (acanthocytes) are cells with abnormal morphologic membrane found in patients with advanced liver disease, severe malnutrition, malabsorption, and asplenia. The membrane acquires protrusions as a result of abnormal lipids present in the membrane. The changes may be associated with mild hemolysis, although in patients with advanced liver disease, separating hemolysis from hypersplenism is difficult. Similar changes may be observed in patients with abetalipoproteinemia.

HEMOLYTIC ANEMIAS CAUSED BY DISORDERS OF ERYTHROCYTE ENZYMES

Glucose-6 Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) is a critical enzyme in the hexose monophosphate shunt pathway. By maintaining intracellular stores of reduced glutathione, it protects erythrocytes from membrane and hemoglobin oxidation (Fig. 49-4). The gene for G6PD resides on the X chromosome, and therefore nearly all patients with G6PD deficiency are male. Most G6PD mutations are found in African and Mediterranean populations, likely because they confer resistance to malaria. The African form of G6PD deficiency is relatively mild, whereas the Mediterranean form is severe.

Absence of G6PD renders erythrocytes sensitive to oxidative stress. In the setting of infection, acidosis, or oxidant drugs, hemoglobin may precipitate within the cells, causing

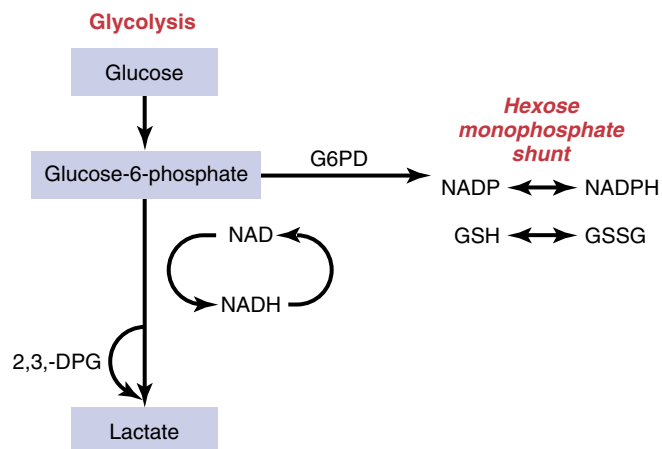

Figure 49-4 Metabolism of the red blood cell. 2,3-DPG, 2,3-diphosphoglycerate; G6PD, glucose-6-phosphate dehydrogenase; GSH, reduced glutathione; GSSG, reduced and oxidized glutathione; NAD, nicotinamide adenine dinucleotide; NADH, reduced form of NAD; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced form of NADP.

hemolysis. Many drugs are associated with hemolysis in the setting of G6PD deficiency, including sulfonamides, antimalarials, dapsone, aspirin, and phenacetin. Diagnosis should be considered in male patients of African American or Mediterranean extraction who have evidence of hemolysis in the setting of acute infection or recent exposure to oxidant drugs. Patients with the Mediterranean variant of G6PD deficiency may develop hemolysis on exposure to fava beans (favism). Cells with precipitated hemoglobin contain Heinz bodies that can be visualized with crystal violet staining of the peripheral blood smear. These inclusions are removed in the spleen, resulting in the additional finding of bite cells in the blood smear. Diagnosis can be confirmed with measurement of G6PD levels in the peripheral blood. However, reticulocytes and young RBCs in patients with G6PD deficiency have a higher enzyme level; consequently, if the diagnosis is probable, the patients with a normal G6PD level should be retested at a time removed from the acute episode, when the percentage of young RBCs is high. The mainstay of preventing hemolysis in these patients is the avoidance of oxidative stress, especially drugs implicated in causing hemolysis. Splenectomy is recommended only for patients with severe episodic or chronic hemolysis.

Other Enzyme Deficiencies

Enzyme deficiencies as rare causes of hemolytic anemia have been reported involving nearly all of the enzymes of the glycolytic pathway. The most common of these is pyruvate kinase deficiency. Autosomal genes encode these enzymes, and the pattern of inheritance is therefore autosomal recessive.

HEMOGLOBINOPATHIES

Hemoglobinopathies are mutations that result in the synthesis of quantitatively or qualitatively abnormal hemoglobins. The most common of these are the sickle syndromes and the thalassemias, which, like G6PD deficiency, arose in areas of the world in which malaria is endemic.

Sickle Cell Disease

Sickle cell disease is the most common of the sickle syndromes and arises from a point mutation that causes a glutamic acid-to-valine substitution in the sixth amino acid of the β -globin gene. It has arisen as an independent mutation in diverse populations in Africa, India, the Mediterranean, and the Middle East. The substitution of a hydrophobic for a hydrophilic residue renders the deoxygenated sickle hemoglobin (HbS) less soluble and therefore susceptible to polymerization and precipitation. The rate of precipitation of HbS is exquisitely sensitive to the intracorporeal concentration of deoxygenated hemoglobin. Sickling is therefore increased in settings in which that concentration is increased either by changes in cellular hydration (dehydration) or by changes in the oxygen dissociation curve (e.g., hypoxia, acidosis, high altitude).

Acute Manifestations of Sickle Cell Disease

Most of the acute complications of sickle cell disease are related to vaso-occlusion (Table 49-8). Painful crises, secondary to occlusions of the microvasculature and ischemia of organs and tissues, can occur anywhere, with pain most common in the extremities, chest, abdomen, and back. Painful crises are commonly precipitated by infections, dehydration, rapid changes in temperature, and pregnancy. However, no obvious precipitating cause is often found for an acute painful crisis. Vaso-occlusion in the pulmonary circulation can be a particularly ominous complication of sickle cell disease, resulting in the *acute chest syndrome*, which is characterized by chest pain, hypoxemia, and pulmonary infiltrates. The roles of infection, infarction, and in situ thrombosis in the acute chest syndrome are indistinguishable, but all patients should receive antibiotics for presumed pneumonia. Because hypoxemia predisposes to further sickling and increasing respiratory compromise, the acute chest syndrome is life-threatening and is an indication for emergent exchange transfusion.

Neurologic events are a major cause of morbidity in patients with sickle cell disease. Acute large vessel occlusions occur in children, with a recurrence rate of 70% if untreated; such strokes are an indication for long-term exchange transfusion, which has been shown to decrease the rate of repeated occlusions. For reasons that are poorly understood, such large vessel occlusions rarely occur in adults. Adults may suffer hemorrhagic strokes as a result of aneurysmal dilation of proliferative vessels that form in response to repeated micro-occlusions in the cerebral vessels.

Any toxic or infectious insult that transiently suppresses bone marrow activity may cause an *aplastic crisis*. The shortened survival of the RBC in sickle cell disease renders the patients highly dependent on vigorous ongoing marrow activity, and short intervals of decreased reticulocyte formation can cause profound anemia. Most dramatic are infections associated with parvovirus B19, which directly infects erythroid precursors. Supportive care is usually all that is required. However, some patients may go on to develop bone marrow necrosis, with a leukoerythroblastic picture; this development may be further complicated by bone marrow embolization to the lungs.

Certain vascular beds are especially prone to complications of sickle cell disease. The renal medulla is highly susceptible to damage by vaso-occlusion because high tonicity and low oxygen tension both significantly increase the concentration of HbS. All patients with sickle cell disease develop defects in urinary concentration ability, and by adulthood, they are uniformly isosthenuric. Acute episodes of hematuria secondary to papillary necrosis are common.

The spleen is also a site in which recurrent sickling uniformly occurs. By adulthood, all patients have become functionally asplenic from repeated infarctions of the microvasculature. This contributing factor increases the susceptibility of patients with sickle cell disease to infections with encapsulated organisms. Acute infection remains a significant cause of death in patients with sickle cell disease. For unclear reasons, patients with sickle cell disease are particularly prone to osteomyelitis, with an unusually high incidence of *Salmonella* as the responsible organism.

Table 49-8 Clinical Manifestations of Sickle Cell Disease

Acute Manifestations

- Vaso-occlusive crisis
 - Painful crisis
 - Acute chest syndrome
 - Priapism
- Cerebrovascular events
 - Thrombotic stroke
 - Hemorrhagic stroke
- Aplastic crisis
- Splenic sequestration
- Osteomyelitis

Chronic Manifestations

- Chronic renal disease
 - Isosthenuria
 - Chronic renal failure
- Chronic pulmonary disease
- Sickle hepatopathy
- Proliferative retinopathy
- Avascular necrosis
- Skin ulcers

Chronic Manifestations of Sickle Cell Disease

Sickle cell disease used to be a disease of childhood. As more patients with sickle cell disease survive to adulthood, it has become clear that repeated episodes of vaso-occlusion lead to damage to nearly every end organ (see Table 49-8). Renal failure and pulmonary failure are leading causes of death in adult patients with sickle cell disease. Other long-term complications include chronic skin ulcers, retinopathy, and liver dysfunction. In addition, most patients require cholecystectomy for pigment stones.

Treatment of Sickle Cell Disease

Treatment of sickle cell disease remains largely supportive. Painful crises are treated with fluid, oxygen supplementation, and analgesics. Patients with any indication of infection should receive antibiotics. Patients with symptomatic anemia should be transfused. Exchange transfusion is indicated for chest syndrome, stroke, bone marrow necrosis, and priapism. More controversial indications for exchange transfusion include intractable pain and slow response to other supportive measures. The goal of exchange transfusion is to

Table 49-9 **Thalassemic Syndromes**

Disorder	Genotypic Abnormality	Clinical Phenotype
β-thalassemia		
Thalassemia major (Cooley anemia)	Homozygous β^0 -thalassemia	Severe hemolysis, ineffective erythropoiesis, transfusion dependency, iron overload
Thalassemia intermedia	Compound heterozygous β^0 - and β^+ -thalassemia	Moderate hemolysis, severe anemia, but not transfusion dependent; iron overload
Thalassemia minor	Heterozygous β^0 - or β^+ -thalassemia	Microcytosis, mild anemia
α-thalassemia		
Silent carrier	α -/ α	Normal complete blood count
α -thalassemia trait	$\alpha\alpha$ - (α -thalassemia 1); or α -/ α - (α -thalassemia 2)	Mild microcytic anemia
Hemoglobin H	α -/-	Microcytic anemia and mild hemolysis; not transfusion dependent
Hydrops fetalis	-/-/-	Severe anemia, intrauterine anasarca from congestive heart failure; death in utero or at birth

achieve a level of 30% to 40% HbS. As previously noted, patients who have sustained a thrombotic large vessel stroke should undergo chronic exchange transfusion.

Treatment with hydroxyurea, an agent that increases the concentration of HbF in patients with sickle cell disease, reduces the incidence of vaso-occlusive crises. The efficacy of hydroxyurea in patients with recurrent crises has been demonstrated in a randomized study, and follow-up studies have revealed a survival advantage for patients treated with hydroxyurea. The effect is attributed to the formation of hemoglobin tetramers containing one B^s chain and one γ chain ($\alpha_2\beta^s\gamma_2$), which do not undergo polymerization. Studies have also suggested that response is related to decreases in leukocyte count and changes in endothelial adherence properties.

Other Sickle Syndromes

Hemoglobin C

Hemoglobin C (HbC) is caused by another substitution, glutamic acid to lysine, in the sixth position of the β -globin chain. Homozygous HbC causes very mild anemia symptoms and is usually clinically silent. Patients with hemoglobin S-C (HbSC) are compound heterozygotes for HbS and HbC. These patients are symptomatic, although the clinical manifestations are milder than in patients with homozygous HbS (HbSS). Patients have a higher hematocrit, and the higher viscosity increases the degree of retinopathy. They do not sustain splenic infarctions; unlike patients with HbSS, they usually have splenomegaly. Consequently, they occasionally have episodes of acute splenomegaly associated with profound decrease in hemoglobin and hematocrit (splenic sequestration crisis). Although such crises can also occur in children with HbSS, functional asplenia prevents this complication in adults with HbSS.

Sickle Cell β -Thalassemia

Patients who are double heterozygotes for HbS and β -thalassemia have a spectrum of disease dependent on the level of β globin that they produce. Sickle cell β^+ -thalassemia is a milder disease than HbSS, probably because of the decreased intracorporeal concentration of HbS. Patients with sickle cell β^0 -thalassemia (see discussion that follows)

produce no normal β chains and have essentially the same phenotype as patients with HbSS.

Thalassemia

The thalassemic syndromes (Table 49-9) are a heterogeneous group of disorders associated with decreased or absent synthesis of either α - or β -globin chains. Severe thalassemic syndromes are associated with severe hemolytic anemia and are diagnosed in early childhood. However, mild forms of thalassemia minor frequently cause mild microcytic anemia with little or no evidence of hemolysis. These syndromes are often confused with iron deficiency because of the decreased MCV.

β -Thalassemia

Over 100 mutations have been described that lead to β -thalassemia, causing a decrease or absence of expression from the β -globin locus. The decreased expression of β globin can be caused by structural mutations in the coding region of the gene, resulting in nonsense mutations, truncated messenger RNA (mRNA), and no expression of intact globin from the affected allele (β^0 -thalassemia). However, a large number of mutations that result in decreased transcription or translation or altered splicing of the β -globin mRNA may result in reduction but not elimination of globin-chain expression from the affected allele (β^+ -thalassemia).

Defective globin-chain synthesis in β -thalassemia causes both decreased normal hemoglobin production and the production of a relative excess of α chains. The decrease in normal hemoglobin synthesis results in a hypochromic anemia, and the excess α chains form insoluble α -chain complexes and cause hemolysis. In mild thalassemic syndromes, the excess α chains are insufficient to cause significant hemolysis, and the primary finding is a microcytic anemia. In severe forms of thalassemia, hemolysis occurs both in the periphery and in the marrow, with intense secondary expansion of the marrow production of red cells. The expansion of the marrow space causes severe skeletal abnormalities, and the ineffective erythropoiesis also provides a powerful stimulus to absorb iron from the intestine.

The clinical spectrum of β -thalassemia reflects the heterogeneity of the molecular lesions causing the disease (see

Table 49-9). β -thalassemia major results from homozygous β^0 -thalassemia, leading to severe hemolytic anemia; such patients are diagnosed in infancy and are transfusion dependent from birth. β -thalassemia intermedia patients also have two β -thalassemia alleles, but at least one of them is a mild β^+ mutation. These patients have severe chronic hemolytic anemia but do not require transfusions. Because of ineffective erythropoiesis, these patients chronically hyperabsorb iron and may develop iron overload in the absence of transfusions. β -thalassemia minor is usually due to heterozygous β -thalassemia, although it may reflect the inheritance of two mild thalassemic mutations. These are the patients in whom iron deficiency is often misdiagnosed. Iron studies will show normal to increased iron with normal iron saturation. Documenting a compensatory increase in HbA₂ and HbF will confirm the diagnosis.

α -Thalassemia

α -thalassemia is nearly always caused by mutations that delete one or more of the α -chain loci on chromosome 16. Four α -chain loci exist with two nearly identical copies of the α -globin gene on each chromosome. The spectrum of α -thalassemia therefore reflects whether the patient lacks one, two, three, or all four α -globin genes (see Table 49-9).

In general, the clinical manifestations of α -thalassemia are milder than those of β -thalassemia for two reasons. First, the presence of four α -chain genes allows for adequate α -chain synthesis unless three or four loci are deleted. Second, β -chain tetramers are more soluble than their α -chain counterparts and do not cause hemolysis. Patients with the loss of a single α -chain gene are silent carriers and have a normal hematocrit and MCV. Patients with the deletion of two α chains, either on the same chromosome ($- / \alpha \alpha$; α -thal 1) or on different chromosomes ($\alpha - / \alpha -$; α -thal 2), are microcytic and mildly anemic. Patients who inherit one α -thal 1 allele and one α -thal 2 allele ($- / \alpha -$) have hemoglobin H disease. Hemoglobin H is the product of excess β -chain production, specifically β_4 ; it causes mild hemolytic anemia and minimal or no intramedullary erythrocyte destruction. Inheritance of the homozygous α -thal 2 allele results in no functional α -chain loci and is incompatible with life. The fetus is unable to make any functional hemoglobin beyond embryonic development because HbF also requires α chains. Free γ chains form tetramers, termed *hemoglobin Barts*. Hemoglobin Barts have an extremely high oxygen affinity, and failure to release oxygen in peripheral tissues results in severe congestive heart failure and anasarca, a clinical picture termed *hydrops fetalis*. Affected fetuses are stillborn or die soon after birth.

Prospectus for the Future

Anemia is increasingly recognized as a marker of increased morbidity and mortality in adults with a wide range of medical conditions, including renal failure, malignancy, cardiac disease, inflammatory conditions, and other chronic diseases. Studies are ongoing to evaluate the effect of treating anemia on patients' outcome and quality of life. Furthermore, advances in our pathophysiologic understanding of anemia of chronic

disease are contributing to our knowledge of iron metabolism and the role cytokines play in hematopoiesis. These developments are paving the way for the development of new therapies for patients with anemia or iron overload. Ongoing progress in prenatal diagnosis and stem cell transplantation will contribute to our ability to prevent and treat the thalassemic syndromes and other hemoglobinopathies.

Clinical Disorders of Neutrophils

Michal G. Rose and Nancy Berliner

Leukocytes provide the main defense against bacterial infection. Monocytes and granulocytes are phagocytic cells that can kill ingested bacteria through the generation of reactive intermediates. Monocytes also release inflammatory mediators that increase the activity of lymphocytes. Lymphocyte function is discussed in Chapter 51.

Normal Granulocyte Development, Structure, and Function

NEUTROPHILS

Neutrophils (*polymorphonuclear leukocytes*) are the predominant white blood cell in the peripheral blood. They are morphologically recognizable by their characteristic segmented nucleus. They also contain various cytoplasmic granules that give them a characteristic appearance and are functionally important (Fig. 50-1).

Neutrophil killing of bacteria requires chemotaxis, phagocytosis, and intracellular killing (Fig. 50-2). *Chemotaxis* is the ordered movement of the cell toward an attracting stimulus, such as bacterial formyl peptides or complement fragments (C3b and C5a). Neutrophils adhere to endothelial cells by interaction of neutrophil surface glycoproteins (CD11b/CD18) with endothelial adhesion molecules (intracellular adhesion molecule-1 and endothelial leukocyte adhesion molecule-1), a process termed *margination*. In response to a chemotactic stimulus, these adherent neutrophils move toward the target along the endothelial surface. The syndrome of leukocyte-adhesion deficiency underscores the importance of neutrophil adhesion as the first step in bacterial killing. This rare congenital disease is caused by the absence of surface expression of the CD11b/CD18 complex on neutrophils. Neutrophils fail to adhere to endothelium, are unable to undergo chemotaxis, and do not phagocytose or kill bacteria. Patients have severe, life-threatening bacterial infections despite high levels of circulating neutrophils.

Phagocytosis requires recognition of target bacteria or debris by the neutrophil. Targets are *opsonized* by the surface binding of immunoglobulin or complement factor C3b. The neutrophil has surface receptors for C3b and the Fc portion of immunoglobulin G, which allows recognition and binding to the opsonized target. The target then becomes engulfed in a phagocytic vacuole, which fuses with neutrophil granules inside the cell.

Intracellular killing occurs by both oxygen-dependent and oxygen-independent mechanisms. Contents of the primary granules, including cathepsin G, defensins, and lysozyme, act to break down the bacterial cell wall and kill the target organism. The major mechanism of bacterial killing, however, is the *respiratory burst*. Stimulation of the neutrophil activates a membrane-bound oxidase complex, which generates superoxide through the transfer of an electron from reduced nicotinamide-adenine dinucleotide phosphate (NADPH). The interaction of superoxide with water generates hydroxyl ions. In addition, myeloperoxidase catalyzes the formation of hypochlorite ion from hydrogen peroxide and chloride. The NADPH oxidase is a multisubunit enzyme. Absence or decreased activity of any one subunit impairs bacterial killing and results in chronic granulomatous disease, another congenital illness in which patients are predisposed to life-threatening bacterial infections.

The granules that give neutrophils their characteristic appearance have important functions in the process of neutrophil-mediated activation and killing. *Primary granules* arise early in myeloid differentiation and are found in both neutrophils and monocytes. They contain a large number of proteins, including myeloperoxidase, acid hydrolases, and neutral proteases. These granules fuse with the phagocytic vacuole and aid in the digestion of ingested bacteria. *Secondary granules* arise later in the differentiation pathway and give the neutrophil its characteristic granular appearance. These granules contain lactoferrin, transcobalamin, and the matrix-modifying enzymes collagenase and gelatinase. On neutrophil stimulation, these granules are released into the extracellular space. Lactoferrin and transcobalamin act as antibacterial proteins by sequestering iron and vitamin B₁₂.

away from bacteria, and collagenase and gelatinase break down connective tissues at the site of inflammation. Abnormalities in neutrophil granules have been described in rare clinical syndromes. Absence of myeloperoxidase produces surprisingly mild symptoms and may be associated with defects in control of fungal infection. Secondary granule deficiency is extremely rare and is associated with a slight increase in the risk for bacterial infections.

EOSINOPHILS AND BASOPHILS

Eosinophils and basophils arise from myeloid precursors in the bone marrow. They transit rapidly from the marrow to the blood and into the peripheral tissues, where they play a role in allergic and inflammatory reactions. Like neutrophils, they have secondary granules that give them their characteristic appearance and are also functionally impor-

Primary Hypereosinophilic Syndrome

More than 6 months with eosinophils >1500, with no other apparent cause

tant. Both cell types are present in small numbers under normal conditions.

Although eosinophils are capable of phagocytosis, most of the activity of these cells is mediated through the release of their granules. Their numbers are elevated in parasitic and helminthic infections, in which these cells are thought to play a role in the allergic response to those organisms. Numbers of these cells are also elevated in allergic reactions and in collagen vascular diseases, again linking their function to immunomodulation. *Hypereosinophilic syndromes*, in which extremely high levels of eosinophils can be seen, are rare, and they can be associated with damage to the lung, peripheral nervous system, and endocardial tissues. The differential diagnosis of eosinophilia is outlined in Table 50-1. Basophils appear to play a role in immediate hypersensitivity reactions and chronic inflammatory conditions. Their levels are increased in chronic myeloid leukemia.

MONOCYTES

Monocytes arise from a common myeloid precursor with granulocytes, under the influence of granulocyte-macrophage colony-stimulating factor (GM-CSF) and macrophage colony-stimulating factor (M-CSF). Most circulating monocytes are marginated along the walls of vessels. They migrate from the vessels into tissues, where they develop into macrophages. The monocyte-macrophage lineage has many diverse functions. These phagocytic cells perform chemotaxis, phagocytosis, and intracellular killing in much the same manner as neutrophils. They are especially important in the killing of mycobacteria, fungi, and protozoal species.

In addition to their role in killing of infectious organisms, monocytes have important interaction with other components of the immune system. They are antigen-presenting cells for T lymphocytes, they are capable of cellular cytotoxicity, and they secrete certain cytokines. The macrophages that process antigens and present them to T lymphocytes take on different forms in different tissues. They include the

Langerhans cells of the skin, the interdigitating cells of the thymus, and the dendritic cells in the lymph nodes. Antigen-presenting cells are nonphagocytic, and the process by which they internalize antigen is not fully understood. Protein antigens are partially digested and expressed on the cell surface in association with human leukocyte or Ia antigens. This feature permits interaction with and activation of helper T cells. Other macrophages, such as Kupffer cells of the liver and alveolar macrophages of the lung, play an important role in removing particulate and cellular debris and senescent erythrocytes from circulation.

Monocytes also have a role in tumor cell cytotoxicity. They are capable of both antibody-dependent and antibody-independent cytotoxicity against tumor cells. The cytotoxicity is increased by tumor necrosis factor, interleukin-1, and interferon, all of which are also secreted by monocytes. Monocytes secrete a large number of proteins. These include immunomodulatory proteins (tumor necrosis factor, interleukin-1, and interferon), cytokines (granulocyte colony-stimulating factor [G-CSF] and GM-CSF), coagulation proteins, cell adhesion proteins, and proteases.

Determinants of Peripheral Neutrophil Number

Most granulocyte precursors are in the bone marrow, where maturation occurs over 6 to 10 days. Marrow precursors represent 20% of the granulocyte mass, and the storage pool represents 75% of the granulocyte mass. Therefore, peripheral neutrophils represent only 5% of the total granulocyte mass. Furthermore, neutrophils circulate in transit between the marrow and peripheral tissues. Of the circulating neutrophils, more than one half are adherent to the vascular endothelium. Again, this process is termed *margination*. The half-life of a neutrophil in the circulation is short, usually only 6 to 12 hours; the neutrophil may then migrate into tissues, where it survives another 1 to 4 days. Therefore, the peripheral neutrophil count represents a sampling of less than 5% of the total granulocyte pool and is taken during a period of less than 5% of the total neutrophil life span. The peripheral white cell count is therefore a poor reflection of granulocyte kinetics. Abnormalities in neutrophil number can occur rapidly and may reflect either a change in marrow granulocyte production or a shift among various cellular compartments. An elevated peripheral white cell count may result from increased marrow production, or it may reflect mobilization of neutrophils from the marginated pool or release from the marrow storage pool. Similarly, a low granulocyte count may reflect decreased marrow production, increased margination or sequestration in the spleen, or increased destruction of peripheral cells.

The *total peripheral white cell count* represents the sum of lymphocytes and granulocytes. The significance of an elevated or depressed leukocyte count therefore depends on the nature of the cellular elements that are increased or decreased. *Leukocytosis* is a nonspecific term that may denote an increase in either lymphocytes (*lymphocytosis*) or neutrophils (*granulocytosis*). In rare cases, increases may reflect excessive numbers of monocytes or eosinophils.

Leukocytosis related to an elevation in the neutrophil count is referred to as *neutrophil leukocytosis*, or *neutrophilia*. Extreme elevation of the white blood cell count to more than 50,000/mcL with the premature release of early myeloid precursors is termed a *leukemoid reaction*; this reaction may be associated with inflammatory reactions and infections, but it requires consideration of a diagnosis of myeloproliferative disease, especially chronic myelogenous leukemia. Evaluation of the peripheral blood smear may reveal characteristic changes that provide clues to the underlying disorder. A *leukoerythroblastic* smear shows the presence of immature granulocytes, teardrop-shaped erythrocytes, nucleated erythrocytes, and increased platelets. Such changes are reflective of marrow infiltration (*myelophthisis*) by fibrous tissue, granulomas, or neoplasm. As with leukocytosis, *leukopenia* may reflect either lymphopenia or *neutropenia*. Neutropenia is defined as an absolute neutrophil count of less than 1500/mcL.

Evaluation of Leukocytosis (Neutrophilia)

Leukocytosis is usually secondary to other processes, and it rarely indicates a primary hematologic disorder (Table 50-2). However, patients with persistent elevation of the neutrophil count, especially in association with elevation of the hematocrit or platelet count, should be evaluated to rule out a primary myeloproliferative disorder. A leukocyte alkaline phosphatase determination is helpful in ruling out chronic myelogenous leukemia because it tends to be low in this condition and normal or high in other myeloproliferative disorders and in leukemoid reactions.

Neutrophilia related to acute infection, stress, or acute steroid administration primarily reflects demargination and is usually transient. Persistent neutrophilia usually reflects chronic bone marrow stimulation. Nevertheless, bone

marrow aspirate and biopsy are rarely indicated in the workup of neutrophilia. The exception is in those patients who demonstrate leukoerythroblastic changes, in which a bone marrow examination and culture may be indicated to rule out tuberculosis or fungal infection, marrow infiltration with tumor, or marrow fibrosis. Cytogenetic and molecular studies should also be performed to help eliminate the diagnosis of chronic myelogenous leukemia and other myeloproliferative disorders.

Evaluation of Leukopenia (Neutropenia)

DIFFERENTIAL DIAGNOSIS OF NEUTROPENIA

Neutropenia can reflect decreased production, increased sequestration, or peripheral destruction of neutrophils (Table 50-3). Patients should first be evaluated for splenomegaly to rule out the possibility of sequestration. In patients who are completely asymptomatic and in whom previous studies are unavailable, the possibility of *constitutional* or *cyclic neutropenia* should be entertained and can be evaluated by serial peripheral blood counts. The normal neutrophil count varies among ethnic groups and is lower in African Americans (*constitutional neutropenia*) than it is in Caucasians. *Cyclic neutropenia* is a relatively benign disorder, in which cyclical changes occur in all hematopoietic cell lines but are most dramatic in the neutrophil lineage. At the nadir of the neutrophil counts, patients may have infections, but the disease is often clinically silent. In contrast, patients with congenital agranulocytosis or *severe congenital neutropenia* (SCN) exhibit profound neutropenia and infections in the perinatal period. *Kostmann syndrome* is a subset of SCN that was described 50 years ago as an autosomal recessive disorder; more recent studies have demonstrated that SCN may be autosomal dominant, autosomal recessive, and sporadic, and that the etiologies are also heterogeneous. About 50%

of autosomal dominant SCN, as well as virtually 100% of cyclic neutropenia, is associated with inherited mutations in the neutrophil elastase gene. These mutations are thought to result in the production of misfolded neutrophil elastase protein, which accumulates in the endoplasmic reticulum and activates the unfolded protein response. This complex cellular stress response coordinates the degradation of misfolded protein in the endoplasmic reticulum and can trigger cellular apoptosis if the stress is severe. Evidence suggests that different neutrophil elastase mutations activate the unfolded protein response to varying degrees, thus explaining how mutations in the same gene can cause both congenital agranulocytosis and the more benign cyclic neutropenia. More recent studies have established that autosomal recessive SCN (Kostmann syndrome) is caused by mutations in the *HAX-1* gene, a mitochondrial protein that is required for stabilization of the mitochondrial membrane. Absence of *HAX-1* results in loss of mitochondrial membrane potential and induction of apoptosis.

Until G-CSF became available, most patients with SCN died in early childhood, but the availability of cytokine therapy has prolonged survival. However, SCN is also associated with a significantly increased incidence of the development of acute leukemia, a complication that has become apparent as patients survive longer. Up to 20% of patients with SCN will develop acute myelogenous leukemia over 10 years. Acute myelogenous leukemia in these patients is often associated with truncation mutations in the G-CSF receptor. These are acquired somatic mutations that may contribute to the pathogenesis of leukemia but do not contribute to the congenital neutropenia. The role of these G-CSF receptor mutations in the pathogenesis of leukemic transformation is controversial.

Neutropenia may occur during or after viral, bacterial, or mycobacterial infections. *Postviral neutropenia* is especially common in children and probably reflects both increased neutrophil consumption and a viral suppression of marrow neutrophil production. Neutropenia may be seen as a complication of *overwhelming sepsis* and is associated with a poor prognosis.

Drug-induced neutropenia may reflect either dose-dependent marrow suppression or an idiosyncratic immune response. The former is one of the most common complications of chemotherapeutic drugs and is also common with antibiotics such as trimethoprim-sulfamethoxazole. Chloramphenicol causes dose-dependent marrow suppression, although its more ominous complication is the rare idiosyncratic reaction that gives rise to marrow aplasia. The drugs that are most commonly associated with neutropenia include clozapine, sulfasalazine, ticlopidine, and the thionamide antithyroid agents. Most drug-induced neutropenias respond rapidly to discontinuation of the offending agent. The administration of G-CSF speeds recovery.

Autoimmune neutropenia may be seen as a primary disease or as a secondary manifestation of systemic autoimmune disease or lymphoproliferative disease. Primary autoimmune neutropenia is a disorder of infants and young children that resolves spontaneously in more than 90% of patients within 2 years. Secondary autoimmune neutropenia is a common accompaniment to systemic lupus. Although not usually clinically severe, neutropenia is often a marker of disease activity. Neutropenia in rheumatoid arthritis is

seen in association with splenomegaly (Felty syndrome) and also as part of the spectrum of large granular lymphocyte leukemia (LGL). LGL leukemia is a clonal expansion of suppressor T cells. Patients who develop LGL in association with rheumatoid arthritis share a common HLA-DR4 haplotype with patients with Felty syndrome, suggesting that these are in a common spectrum of disease. LGL is also a relatively common cause of acquired neutropenia in elderly patients in the absence of rheumatoid arthritis.

LABORATORY EVALUATION OF NEUTROPENIA

Unless the diagnosis of benign or cyclic neutropenia is likely, the evaluation of the patient with neutropenia should include stopping all potentially offending drugs and performing serologic studies to rule out collagen vascular disease. Unlike in patients with leukocytosis, bone marrow examination is indicated early in the evaluation and is frequently diagnostic. Neutropenia more often reflects primary hematologic disease, and bone marrow examination enables one to diagnose marrow failure syndromes, leukemia, and myelodysplasia. In the absence of bone marrow failure, other causes of neutropenia also may give a characteristic bone marrow picture. Drug-induced neutropenia produces a characteristic *maturation arrest* of the myeloid series. Rather than an actual inhibition of neutrophil maturation, this feature reflects the immune destruction of myeloid precursors that leaves only the earliest cells behind. All patients should have cytogenetic studies performed to aid in the diagnosis of myelodysplasia.

MANAGEMENT OF NEUTROPENIA

The therapeutic approach to patients with neutropenia depends on the degree of depression of the neutrophil count. Neutrophil counts between 1000 and 1500/mcL are not usually associated with any significant impairment in the host response to bacterial infection and require no intervention beyond what is demanded for diagnosis and indicated therapy of the underlying cause. Patients with neutrophil counts between 500 and 1000/mcL should be alerted to their slightly increased risk for infection, although serious problems are rarely encountered in patients with functional neutrophils and counts higher than 500/mcL. Patients with neutrophil counts lower than 500/mcL are at significant risk for infection. Such patients must be instructed to notify the physician at the first signs of infection or fever, and they must be managed aggressively with intravenous antibiotics regardless of the documentation of a source or infecting organism. Patients with a significantly depressed neutrophil count may exhibit few signs of infection because much of the inflammatory response at the site of infection is generated by the neutrophils themselves. In patients with severe immune-mediated neutropenia, steroids and intravenous immunoglobulin may be helpful in elevating the neutrophil count and in preventing infectious complications. G-CSF may increase the peripheral white cell count and may help resolve infections in neutropenia induced by drugs, including chemotherapy. It has also been efficacious in some patients with immune neutropenia as well as in patients with myelodysplasia.

Prospectus for the Future

Significant progress has been made in recent years regarding the elucidation of the molecular pathogenesis of severe congenital neutropenia and cyclic neutropenia. Compounds that modulate the unfolded protein response may play a role in the treatment of these disorders. Other studies aimed at elucidating the molecular basis for myeloid differentiation are estab-

lishing the importance of transcription factor function in neutrophil maturation and are providing insights into the pathogenesis of leukemia and myelodysplasia. Such insights may delineate pathways with entry points for therapeutic intervention in myeloid malignancy.

Disorders of Lymphocytes

Jill Lacy and Stuart Seropian

The central cell of the immune system is the lymphocyte. Lymphocytes mediate the adaptive immune response, providing specificity to the immune system by responding to specific pathogens and conferring long-lasting immunity to reinfection. Lymphocytes are derived from pluripotent hematopoietic stem cells that reside in the bone marrow and give rise to all of the cellular elements of the blood. Two major functional classes of lymphocytes have been developed: (1) B lymphocytes, or B cells, and (2) T lymphocytes, or T cells, which are distinguished by their site of development, antigenic receptors, and function. The major disorders of lymphocytes include (1) neoplastic transformation of specific subsets of lymphocytes resulting in an array of lymphomas or leukemias, (2) congenital and acquired defects in lymphocyte development or function with resultant immunodeficiency syndromes, and (3) physiologic responses to infection or antigenic stimulation that may lead to lymphadenopathy, lymphocytosis, or lymphocytopenia.

Cells of the Immune System: Lymphocyte Development, Function, and Localization

B CELLS

B cells are characterized by the presence of cell surface immunoglobulin (or antibody). Their major function is to mount a humoral immune response to antigens by producing antigen-specific antibody. B cells develop in the bone marrow in a series of highly coordinated steps that involve sequential rearrangement of the heavy- and light-chain immunoglobulin genes and expression of B-cell-specific cell surface proteins (Fig. 51-1). Rearrangement of the immunoglobulin genes results in the generation of a huge repertoire of B cells that are each characterized by an

immunoglobulin molecule with unique antigenic specificity. Mature B cells migrate from the bone marrow to lymphoid tissue throughout the body and are readily identified by the presence of cell surface immunoglobulin and antigens that are B-cell specific, including CD19, CD20, and CD21. In response to antigen binding to cell surface immunoglobulin, mature B cells are activated to proliferate and undergo differentiation into end-stage plasma cells, which lose most of their B-cell surface markers and produce large quantities of soluble antibodies. Neoplastic disorders of B cells arise from B cells at different stages of development, and thus B-cell lymphomas can be highly varied in their morphologic mechanisms and cell surface expression of B-cell antigens, or immunophenotype.

T CELLS

T cells perform an array of functions in the immune response, including those that are classically regarded as cellular immune responses. T-cell precursors migrate from the bone marrow to the thymus, where they differentiate into mature T-cell subsets and undergo selection to eliminate autoreactive T cells that respond to self-peptides. In the thymus, T-cell precursors undergo a coordinated process of differentiation that involves rearrangement and expression of the T-cell receptor (TCR) genes and acquisition of cell surface proteins that are unique to T cells, including CD3, CD4, and CD8. As T cells mature in the thymus, they ultimately lose either the CD4 or CD8 protein, and thus mature T cells are composed of two major groups: CD4⁺ and CD8⁺ cells. After T-cell maturation and selection in the thymus, mature CD4 and CD8 T cells leave the thymus and migrate to lymph nodes, spleen, and other sites in the peripheral immune system. Mature T cells constitute about 80% of peripheral blood lymphocytes, 40% of lymph node cells, and 25% of splenic lymphoid cells.

Mature CD4 and CD8 T-cell subsets mediate distinct immune functions. CD8⁺ cells kill virus-infected or foreign cells and suppress immune functions; thus, CD8 cells are designated cytotoxic T cells. CD4⁺ cells activate other

(Adapted from Ferrarini M, Grossi CE, Cooper MD: Cellular and molecular biology of lymphoid cells. In Handin RI, Lux SE, Stossel TP [eds]: Blood Principles and Practice of Hematology. Philadelphia, JB Lippincott, 1995, p 643.)

immune response cells such as B cells and macrophages by producing cytokines and direct cell contact; thus, CD4 cells are considered helper T cells. Similar to B cells, T cells express unique TCR molecules that recognize specific peptide antigens. In contrast to B cells, T cells only respond to peptides that are processed intracellularly and bound to (or presented by) specialized cell surface antigen-presenting proteins, designated major histocompatibility complex (MHC) molecules. Furthermore, CD4 and CD8 T cells are MHC class restricted in their response to peptide-MHC complexes. CD4 cells recognize antigenic peptide fragments only when they are presented by MHC class II molecules, and CD8 cells recognize antigenic peptide fragments only when they are presented by MHC class I molecules. Antigenic peptides complexed with MHC class I and class II molecules originate from different sources. MHC class I molecules generally produce intracellular or endogenous antigens that are processed in the cytosol and traffic through the endoplasmic reticulum. MHC class II molecules generally produce antigens derived from extracellular sources taken up by endocytosis and processed in intracellular vesicles. Binding of the TCR by a specific peptide-MHC complex triggers activation signals that lead to the expression of gene products that mediate the wide diversity of helper functions in CD4⁺ cells or cytotoxic effector functions in CD8⁺ cells.

LYMPHOID SYSTEM

Lymphocytes localize to the peripheral lymphoid tissue, which is the site of antigen-lymphocyte interaction and lymphocyte activation. The peripheral lymphoid tissue is com-

posed of lymph nodes, the spleen, and mucosal lymphoid tissue. Lymphocytes circulate continuously through these tissues through the vascular and lymphatic systems.

The lymph nodes are highly organized lymphoid tissues that are sites of convergence of the lymphatic drainage system that carries antigens from draining lymph to the nodes, where they are trapped. A lymph node consists of an outer cortex and an inner medulla (Fig. 51-2). The cortex is organized into lymphoid follicles composed predominantly of B cells; some of the follicles contain central areas or germinal centers, where activated B cells are undergoing proliferation after encountering a specific antigen, surrounded by a mantle zone. The T cells are distributed more diffusely in paracortical areas surrounding the follicles. The spleen traps antigens from blood rather than from the lymphatic system and is the site of disposal of senescent red cells. The lymphocytes in the spleen reside in the areas described as the white pulp, which surround the arterioles entering the organ. As in lymph nodes, the B and T cells are segregated into a periarteriolar lymphoid sheath that is composed of T cells and flanking follicles composed of B cells. The mucosa-associated lymphoid tissues (MALTs) collect antigen from epithelial surfaces and include the gut-associated lymphoid tissue (tonsils, adenoids, appendix, and Peyer patches of the small intestine) as well as more diffusely organized aggregates of lymphocytes at other mucosal sites.

Lymphocytes circulate in the peripheral blood and represent 20% to 40% of peripheral blood leukocytes in adults (the proportion is higher in newborns and children). Eighty to 90% of peripheral blood lymphocytes are T cells, and the remainder are largely B cells. Most peripheral blood

Figure 51-2 The structure of the normal lymph node. The cortical area contains the follicles, which consist of a germinal center and a mantle zone. The medulla contains a complex of channels that lead to the efferent lymphatics.

lymphocytes are mature, resting lymphocytes that morphologically are small, with scant cytoplasm and inconspicuous nucleoli. A small percentage of peripheral blood lymphoid cells represent a third category of lymphoid cells that are referred to as natural killer (NK) cells. These cells do not bear the characteristic cell surface molecules of B or T cells, and their immunoglobulin or TCR genes have not undergone rearrangement. Morphologically, these cells are large, with abundant cytoplasm containing azurophilic granules, and thus they are often called *large granular lymphocytes*. Functionally, they are part of the innate immune system, responding nonspecifically to a wide range of pathogens without requiring prior antigenic exposure.

Neoplasia of Lymphoid Origin

Malignant transformation of lymphocytes can lead to a diverse array of neoplasms of lymphoid origin, including tumors that arise from T cells or B cells and tumors that represent different stages of lymphocyte development. Lymphoid malignancies usually involve lymphoid tissues, but they can arise in or spread to any site. The major clinical groupings of lymphoid malignancies include non-Hodgkin lymphomas (NHLs), Hodgkin disease (HD), lymphoid leukemias, and plasma cell dyscrasias.

The most common clinical presentation of a lymphoid malignancy in adults is painless enlargement of lymph nodes, or lymphadenopathy. Many causes of lymphadenopathy exist, in addition to lymphoid malignancies (Table 51-1). Thus, taking a thorough history and performing a careful physical examination is important before performing a lymph node biopsy. The investigation of lymphadenopathy

Table 51-1 Causes of Lymphadenopathy

Infectious Diseases

Viral: infectious mononucleosis syndromes (cytomegalovirus, Epstein-Barr virus), acquired immunodeficiency syndrome, rubella, herpes simplex, infectious hepatitis
Bacterial: localized infection with regional adenopathy (streptococci, staphylococci), cat-scratch disease, brucellosis, tularemia, listeriosis, bubonic plague (*Yersinia pestis*), chancroid (*Haemophilus ducreyi*)
Fungal: coccidioidomycosis, histoplasmosis
Chlamydial: lymphogranuloma venereum, trachoma
Mycobacterial: scrofula, tuberculosis, leprosy
Protozoan: toxoplasmosis, trypanosomiasis
Spirochetal: Lyme disease, syphilis, leptospirosis

Immunologic Diseases

Rheumatoid arthritis
 Systemic lupus erythematosus
 Mixed connective tissue disease
 Sjögren syndrome
 Dermatomyositis
 Serum sickness
 Drug reactions: phenytoin, hydralazine, allopurinol

Malignant Diseases

Lymphomas
 Metastatic solid tumors to lymph nodes: melanoma, lung, breast, head and neck, gastrointestinal tract, Kaposi sarcoma, unknown primary tumor, renal, prostate

Atypical Lymphoid Proliferations

Giant follicular lymph node hyperplasia
 Transformation of germinal centers
 Castlemans disease

Miscellaneous Diseases and Diseases of Unknown Cause

Dermatopathic lymphadenitis
 Sarcoidosis
 Amyloidosis
 Mucocutaneous lymph node syndrome
 Multifocal Langerhans cell (eosinophilic) granulomatosis
 Lipid storage diseases: Gaucher and Niemann-Pick diseases

can be organized according to the location of the enlarged nodes (localized or generalized) and the presence of clinical symptoms. Cervical lymphadenopathy is most often caused by infections of the upper respiratory tract, including infectious mononucleosis syndromes and other viral syndromes, as well as bacterial pharyngitis. Unilateral axillary, inguinal, or femoral adenopathy may be caused by skin infections involving the extremity, including cat-scratch fever. Generalized lymphadenopathy may be caused by systemic infections, such as HIV or cytomegalovirus infection, drug reactions, autoimmune diseases, one of the systemic lymphadenopathy syndromes, or lymphoma. If the cause of persistent lymphadenopathy is not apparent after a thorough evaluation, an excisional lymph node biopsy should be undertaken. An enlarged supraclavicular lymph node is highly suggestive of malignancy and should always be sampled.

The accurate diagnosis of lymphoma requires excisional biopsy of a lymph node or generous biopsy of involved lymph tissue. Fine-needle aspiration or needle biopsy is rarely sufficient for diagnosing malignant lymphoma. Analysis of the pathologic specimen should include routine histologic examination and immunophenotyping. Immunophenotyping involves the characterization of the immunologic cell surface antigens that are expressed on the malignant

lymphocyte by means of a panel of monoclonal antibodies. Immunophenotyping permits a determination of cell of origin (B cell, T cell, NK cell, or nonlymphoid cell) and the pattern of cell surface antigens. In the case of B-cell NHLs, immunophenotyping can also reveal whether the process is monoclonal in origin (i.e., neoplastic) by determining whether the surface immunoglobulin is restricted to either κ or λ light chains. Immunophenotyping has become an essential aspect of the diagnosis and classification of lymphomas and can be accomplished by flow cytometric analysis or by immunohistochemical studies on tissue specimens. In some cases, cytogenetic analysis or molecular studies for immunoglobulin or TCR gene rearrangement may be required to determine the pathologic subtype of lymphoma or to establish a monoclonal (i.e., malignant) process. If a lymph node biopsy is nondiagnostic and unexplained lymph node enlargement persists, the biopsy should be repeated.

Non-Hodgkin Lymphomas

The NHLs comprise a heterogeneous group of lymphoid malignancies that differ with respect to their histologic appearance, cell of origin and immunophenotype, molecular biologic factors, clinical features, prognosis, and outcome with therapy. In view of the heterogeneity of NHLs, classification systems have been devised to identify specific pathologic subtypes that correlate with distinct clinical entities. These systems have evolved steadily over the past 50 years, as correlations between histopathologic and biologic behavior have emerged. Until recently, the most widely used classification system in North America was the Working Formulation (WF). The WF classified NHLs based on the architecture of the node (the presence of follicles versus diffuse infiltrate) and the morphologic features of the malignant lymphocyte (small cell versus large cell, with cleaved or noncleaved nucleus) and organized the pathologic subtypes into low, intermediate, or high grade based on their natural history and clinical behavior. In general, the low-grade histologies were associated with an indolent course and relatively long survival but were incurable, whereas the intermediate- and high-grade histologies were biologically aggressive (i.e., short natural history if left untreated) but were potentially curable with appropriate treatment. With the advent of immunophenotyping and molecular characterization of lymphomas, it became apparent that the WF did not adequately define specific pathologic and clinical entities. The Revised European-American Lymphoma (REAL) classification system, introduced in 1994, incorporated not only histologic features as described by the WF but also immunophenotype, cytogenetics, and epidemiologic and etiologic factors. Thus, the REAL classification identified several NHL subtypes that were not easily classified within the WF. These subtypes included the mantle cell lymphomas—the MALT lymphomas, and monocytoid B-cell lymphomas, which are both derived from cells in the marginal zone of lymph nodes; and the various T-cell lymphomas, including human T-cell leukemia virus type 1 (HTLV-1)–associated leukemia and lymphoma, cutaneous T-cell lymphoma (mycosis fungoides or Sézary syndrome), and the biologically aggressive peripheral T-cell lymphomas. The REAL classification was updated in 2001 by the World

Table 51-2 Revised European-American Lymphoma/World Health Organization Classification of Lymphoid Neoplasms

B-Cell Neoplasms

Precursor B-cell neoplasm

Precursor B-lymphoblastic leukemia/lymphoma (precursor B-cell acute lymphoblastic leukemia)

Mature (peripheral) B-cell neoplasms

B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma

B-cell prolymphocytic leukemia

Lymphoplasmacytic lymphoma

Splenic marginal zone B-cell lymphoma (\pm villous lymphocytes)

Hairy cell leukemia

Plasma cell myeloma/plasmacytoma

Extranodal marginal zone B-cell lymphoma of MALT type

Nodal marginal zone B-cell lymphoma of MALT type

Follicular lymphoma

Mantle cell lymphoma

Diffuse large B-cell lymphoma

Mediastinal large B-cell lymphoma

Primary effusion lymphoma

Burkitt lymphoma/Burkitt cell leukemia

T- and NK-Cell Neoplasms

Precursor T-cell neoplasm

Precursor T-lymphoblastic lymphoma/leukemia (precursor T-cell acute lymphoblastic leukemia)

Mature (peripheral) T-cell neoplasms

T-cell prolymphocytic leukemia

T-cell granular lymphocytic leukemia

Aggressive NK-cell leukemia

Adult T-cell lymphoma/leukemia (HTLV-1)

Extranodal NK-/T-cell lymphoma, nasal type

Enteropathy-type T-cell lymphoma

Hepatosplenic gamma-delta T-cell lymphoma

Subcutaneous panniculitis-like T-cell lymphoma

Mycosis fungoides/Sézary syndrome

Anaplastic large cell lymphoma, T-/null cell, primary cutaneous type

Peripheral T-cell lymphoma, not otherwise characterized

Angioimmunoblastic T-cell lymphoma

Anaplastic large cell lymphoma, T-/null cell, primary systemic type

Only major categories are included. Common entities are shown in bold type.

B- and T-/NK-cell neoplasms are grouped according to major clinical presentations (predominantly disseminated/leukemic, primary extranodal, predominantly nodal).

HTLV-1, human T-cell leukemia virus; MALT, mucosa-associated lymphoid tissue; NK, natural killer.

Health Organization (WHO), and the REAL/WHO classification has replaced all previous classification systems (Table 51-2). The most common NHLs encountered in the United States are the follicular lymphomas, small lymphocytic lymphoma or leukemia (also known as *chronic lymphocytic leukemia* [CLL]), mantle cell lymphoma, and diffuse large B-cell lymphoma.

The cause of most NHLs is not known. In most patients with NHL, no apparent genetic predisposition or epidemiologic or environmental factor can be identified. Many of the NHL subtypes carry pathognomonic chromosomal translocations that often involve an immunoglobulin locus (or *TCR* locus in the case of T-cell–derived NHLs) and an oncogene or growth regulatory gene. The cause of these

aberrant chromosomal rearrangements is unknown. Patients with congenital immunodeficiency syndromes or autoimmune disorders are at increased risk for developing NHL. Oncogenic human viruses play a causal role in some of the less common NHL variants. Epstein-Barr virus (EBV) is associated with several biologically aggressive NHLs, including AIDS-related diffuse aggressive lymphomas, the lymphoproliferative disorders that arise in patients who are immunosuppressed after organ transplantation, and the form of Burkitt lymphoma that is endemic in Africa. HTLV-1 is causally linked with an aggressive form of T-cell leukemia or lymphoma that is endemic in areas of Japan and the Caribbean basin. The herpesvirus of Kaposi sarcoma has been implicated in a variant of diffuse aggressive NHL that arises in serosal cavities and is encountered almost exclusively in patients infected with HIV. *Helicobacter pylori* infection is causally linked to gastric MALT lymphomas, and eradication of infection with antibiotics is often associated with regression of the lymphoma.

CLINICAL PRESENTATION, EVALUATION, AND STAGING

As described in the preceding section, most patients with NHL exhibit painless lymphadenopathy involving one or more of the peripheral nodal sites. Additionally, NHL can involve extranodal sites, and thus patients can exhibit a variety of symptoms reflective of the site of involvement. The most common sites of extranodal disease are the gastrointestinal tract, bone marrow, liver, and Waldeyer ring, although virtually any site potentially can be involved with NHL. In general, the aggressive subtypes of NHL (diffuse large cell, lymphoblastic, and Burkitt) are more likely than are the indolent lymphomas to involve extranodal sites. Central nervous system involvement, including leptomeningeal spread, rarely occurs in the indolent subtypes but does occur in the aggressive variants. The most aggressive NHLs (Burkitt and lymphoblastic) have a particular propensity to spread to the leptomeninges. Constitutional symptoms such as fever, weight loss, or night sweats occur in about 20% of patients with NHL at the time of onset, and these symptoms are more common in patients with aggressive subtypes of NHL.

The diagnosis of NHL requires an adequate biopsy of the involved nodal tissue or extranodal site. In patients with bone marrow and peripheral blood involvement, such as small lymphocytic lymphoma or CLL, making the diagnosis from immunophenotyping of peripheral blood lymphocytes by flow cytometry is often possible. Once the diagnosis of a lymphoma has been made, patients should undergo a complete staging evaluation (Table 51-3). Staging determines the extent of involvement, provides prognostic information, and may influence the choice of therapy. The modified Ann Arbor staging classification is used to stage patients with both NHL and Hodgkin disease (Table 51-4). Standard staging evaluation includes a thorough history to elicit symptoms referable to the lymphoma, including the presence of constitutional symptoms (fevers, night sweats, or weight loss, designated as *B* symptoms); a complete physical examination, with documentation of the size and distribution of enlarged lymph nodes; blood work, including lactate dehydrogenase (LDH) evaluation; computed tomography

Table 51-3 Staging Evaluation for Lymphomas

Required Evaluation Procedures

Biopsy of lesion with review by an experienced hematopathologist
 History with attention to the presence or absence of *B* symptoms
 Physical examination with attention to node-bearing areas (including Waldeyer ring) and size of liver and spleen
 Standard blood work, including:
 Complete blood cell count
 Lactate dehydrogenase and β_2 -microglobulin
 Evaluation of renal function
 Liver function tests
 Calcium, uric acid
 Bilateral bone marrow aspirates and biopsies
 Radiologic studies, including:
 Chest radiograph (posteroanterior and lateral)
 Chest, abdomen, and pelvic CT scan
 PET scan (in Hodgkin and intermediate- and high-grade lymphomas)

Procedures Required under Certain Circumstances

Bone scan if bone symptoms
 Plain bone radiographs of symptomatic sites or abnormal areas on bone scan
 Brain or spinal CT or MRI if neurologic signs or symptoms
 Serum and urine protein electrophoresis
 Lumbar puncture with cerebrospinal fluid cytology (Burkitt and lymphoblastic lymphoma)

CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

Table 51-4 Staging System for Lymphomas

Stage	Description
I	Involvement of a single lymph node region or structure (I) or a single extralymphatic site (IE)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of a contiguous extralymphatic site and lymph node region (IIE)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may be accompanied by localized involvement of one extralymphatic site (IIIE) or spleen (IIIS) or both (IIISE)
III ₁	With or without involvement of splenic, hilar, celiac, or portal nodes
III ₂	With involvement of para-aortic, iliac, and mesenteric nodes
IV	Diffuse or disseminated involvement of one or more extralymphatic organs with or without associated lymph node involvement

Identification of the presence or absence of symptoms should be noted with each stage designation: A, asymptomatic; B, fever, sweats, weight loss >10% of body weight.

(CT) scans of chest, abdomen, and pelvis; and bone marrow aspirate and biopsy. Positron emission tomographic (PET) scans or gallium scans can be helpful in assessing response to therapy in lymphomas that are metabolically active (usually the aggressive subtypes such as diffuse large cell lymphoma, lymphoblastic lymphoma, and Burkitt lymphoma) and are often included in the staging evaluation of

the aggressive NHLs. Lumbar puncture for cytologic analysis should be performed only in patients who are at risk for leptomeningeal disease, which includes all patients with Burkitt and lymphoblastic lymphoma and patients with diffuse large cell lymphoma with involvement of bone marrow, testes, or structures directly abutting the central nervous system (e.g., paranasal sinus, calvarium). A variety of ancillary tests may be performed in specific situations. For example, a test for HTLV-1 or HIV should be performed if adult T-cell leukemia or lymphoma or AIDS-related lymphoma is thought to exist, respectively. A gastrointestinal series or endoscopic evaluation may be warranted in all patients with gastrointestinal symptoms or in patients at risk for gastrointestinal tract involvement (lymphomas involving the Waldeyer ring). Serum protein electrophoresis and determination of β_2 -microglobulin and quantitative immunoglobulins should be performed in patients who are thought to have plasma cell dyscrasias. A laparotomy for the sole purpose of staging patients with NHL is never performed because it rarely influences therapeutic decision making.

A variety of prognostic variables have been identified for NHL. In general, the predictors for poor survival in most subtypes of NHL include advanced stage at onset (stage III or IV), involvement of multiple extranodal sites of disease, elevated LDH levels, the presence of B symptoms, and poor performance status.

NATURAL HISTORY, PROGNOSIS, AND TREATMENT

Indolent Non-Hodgkin Lymphomas

The common low-grade or indolent histologic conditions include the follicular lymphomas (small cleaved cell and mixed cell types) and small lymphocytic lymphoma (the latter is identical to CLL and is discussed later), which account for about 30% and 5% of all NHLs, respectively. The low-grade follicular lymphomas are mature clonal B-cell neoplasms with an immunophenotype that is positive for surface immunoglobulin (κ - or λ -chain restricted) and the mature B-cell markers (CD19, CD20, CD21) and negative for CD5. Follicular lymphomas are characterized cytogenetically by the t(14;18) translocation that juxtaposes the immunoglobulin heavy chain with the antiapoptotic gene *BCL-2*; *BCL-2* is uniformly expressed in follicular lymphomas. Although the follicular lymphomas are low grade, indolent neoplasms with a long natural history (median survival approaches 10 years), most patients (80% to 90%) exhibit an advanced stage (stage III or IV), often with bone marrow involvement and cannot be cured with standard treatment modalities. Factors associated with shortened survival include older age, advanced stage, anemia, multiple lymph node sites (more than four), and elevated LDH. Patients with three or more of these factors have a median survival of 5 years, roughly one half that of patients with zero or one risk factor. Most patients with follicular NHL eventually experience transformation of their disease to a more aggressive lymphoma, characterized pathologically by a diffuse large cell infiltrate and clinically by rapidly expanding nodes or other tumor masses, rising LDH levels, and the onset of disease-related symptoms.

The management of the follicular lymphomas is determined by the stage. For the few patients who are considered to have early-stage (I or nonbulky II) disease after clinical staging, the appropriate treatment is radiation therapy. With the use of subtotal or total lymphoid irradiation, more than one half of patients with early-stage disease will achieve a durable remission and appear to be cured. For patients with advanced-stage disease, the management is more controversial. Although advanced-stage indolent NHL is responsive to a variety of treatment modalities, the incurability and the long natural history has led to the practice of deferring treatment until the patient develops symptoms. This strategy is referred to as the *watch and wait* approach. Indications for treatment include cosmetic or mechanical problems caused by enlarging lymph nodes, constitutional symptoms, and evidence of marrow compromise. The appropriate treatment of advanced-stage disease, when necessary, is systemic chemotherapy. The follicular lymphomas are responsive to a variety of single and multidrug programs. Single alkylating agents (cyclophosphamide or chlorambucil), multidrug regimens containing an alkylating agent (e.g., cyclophosphamide, vincristine, and prednisone [CVP]), or fludarabine-based regimens (i.e., fludarabine and mitoxantrone, fludarabine, and cyclophosphamide) are all effective initial regimens for this disease. The addition of the chimeric (mouse-human) anti-CD20 monoclonal antibody rituximab to chemotherapy regimens has become commonplace and is associated with improvements in response rate and duration of remission. Most patients respond to treatment, and at least one third achieves a clinical complete remission that may last 1 to 3 years. Treatment should be discontinued when the maximum response has been achieved to minimize cumulative toxicity. Once a patient relapses, subsequent remissions may be achieved but are usually less durable compared with the first remission. Therapeutic options for patients who relapse include retreatment with chemotherapy, often with a different drug or combination than that used initially. Patients in relapse can also be treated with rituximab as a single agent. Rituximab is a highly effective nontoxic agent for use in patients with relapsed follicular lymphoma, inducing responses that are often durable in over one half of patients. Patients who respond to rituximab are often successfully retreated with rituximab at subsequent relapse, and, in contrast to the experience with second- or third-line chemotherapy, these patients may experience remissions that actually exceed the duration of their first remission from rituximab. Two radioactively labeled anti-CD20 antibodies, ibritumomab tiuxetan (yttrium-labeled) and iodine-131 tositumomab are now also in use for patients with relapsed or refractory follicular lymphoma and have been associated with a high response rate. For patients who have clinical or pathologic evidence of transformation to a higher grade of lymphoma, treatment that is appropriate for a diffuse aggressive histology should be offered (discussed later). The role of high-dose chemotherapy with autologous or allogeneic stem cell transplantation for follicular NHLs remains unclear and should be considered experimental. Long-term follow-up of patients undergoing allogeneic transplantation suggests that some patients are cured with this modality. However, the morbidity associated with allogeneic transplantation has limited its widespread use for refractory indolent lymphomas.

In addition to the follicular NHLs, the MALT lymphomas and closely related marginal zone lymphomas are also considered low-grade, indolent subtypes. Given the excellent prognosis, localized nature, and long natural history of the MALT lymphomas, they are generally managed conservatively with local treatment modalities (irradiation or surgery) and avoidance of systemic chemotherapy. Importantly, the gastric MALT lymphomas are highly associated with *H. pylori* infection, and remissions can often be achieved with eradication of this infection. Thus, antibiotic therapy is the first-line treatment for early gastric MALT lymphoma.

Diffuse Aggressive Non-Hodgkin Lymphomas

The aggressive NHLs are characterized by effacement of lymph node architecture with a diffuse infiltrate of large lymphocytes and include the diffuse large B-cell lymphoma (accounting for about one third of all NHLs), anaplastic large cell lymphoma, and peripheral T-cell lymphoma. Most of the diffuse aggressive large cell lymphomas are B cell in origin (diffuse large B-cell lymphoma); the T-cell diffuse aggressive lesions, or peripheral T-cell lymphomas, are managed similarly but have an overall worse prognosis compared with their B-cell counterparts. Burkitt lymphoma and lymphoblastic lymphoma are among the most aggressive lymphomas and are discussed separately later in this chapter (see “High-Grade Non-Hodgkin Lymphomas”).

Diffuse aggressive NHLs exhibit clinically aggressive behavior, and, if left untreated, the median survival is less than 1 to 2 years. Compared with the follicular NHLs, a higher percentage of patients with diffuse aggressive histology will exhibit early-stage disease (30% to 50%) or involvement of an extranodal site (50%). The outcome and likelihood of cure of patients with diffuse aggressive histology is directly related to the total number of adverse prognostic features at onset: age older than 60 years, advanced stage (III or IV), elevated LDH levels, poor performance status, and the presence of two or more extranodal sites of disease. The likelihood of cure and long-term disease-free survival ranges from more than 75% in patients with one or fewer adverse factors to less than 30% in patients with four or more adverse factors.

In contrast to patients with low-grade follicular NHLs, all patients with diffuse aggressive histology should be offered immediate therapy because these lymphomas are potentially curable. The standard initial therapy for all patients with diffuse aggressive NHL is a multidrug chemotherapy regimen that includes an anthracycline in combination with the anti-CD20 monoclonal antibody rituximab. The most widely used chemotherapy regimen is a combination of cyclophosphamide, doxorubicin, vincristine, and prednisone (designated as CHOP). This regimen appears to be equivalent to more complex and intensive regimens such as m-BACOD, Pro-MACE, and MACOP-B, and thus CHOP plus rituximab remains standard initial therapy. Patients with early-stage disease (I or nonbulky stage II) may be treated with local radiation therapy after a minimum of three cycles of CHOP if exposure to chemotherapy is limited. Patients with advanced-stage disease require six cycles of CHOP plus rituximab; the role of local radiation to sites of bulky disease in the setting of advanced-stage disease is not established. Complete remissions can be achieved with CHOP plus ritux-

imab or similar regimens, and more than 50% of patients are cured. Patients who experience relapse after achieving a remission often can be cured with high-dose chemotherapy with autologous peripheral blood stem cell support, or *transplantation*, particularly if their relapsed disease remains responsive to standard doses of chemotherapy. The morbidity and mortality of this procedure have diminished substantially since 1990 with the use of peripheral blood stem cells and colony-stimulating factor support, and transplantation can be safely performed in patients without serious comorbid conditions. High-dose chemotherapy with autologous stem cell transplantation is superior to standard doses of a salvage regimen and is considered standard therapy for patients with relapsed chemosensitive diffuse aggressive NHL.

Mantle Cell Lymphoma

Mantle cell lymphoma has been recognized with increasing frequency since immunophenotyping has become standard practice for classifying NHLs, and it is included in the REAL/WHO classification. Mantle cell NHL was not recognized in the WF and was often designated as a diffuse small cleaved cell or diffuse mixed cell lymphoma in the WF classification. It accounts for 5% to 8% of all NHLs. Mantle cell lymphomas are mature B-cell neoplasms that appear to arise in the mantle zone of the lymphoid follicle and display a highly characteristic immunophenotype. Mantle cells express the CD5 antigen, as well as the mature B-cell markers (CD19, CD20, and CD21), but typically are negative for CD23 expression. Because mantle cell lymphomas can be easily confused pathologically and clinically with CLL, which is the only other B-cell NHL that is CD5⁺, the absence of CD23 is important for distinguishing mantle cell lymphoma from CLL, which is typically CD23⁺. Mantle cell lymphomas are also characterized by a pathognomonic t(11;14) chromosomal translocation that juxtaposes the immunoglobulin heavy chain with the *BCL-1* or *PRAD-1* gene, which encodes the growth-promoting protein cyclin D1. Mantle cell lymphomas are in many ways similar to indolent lymphomas in that patients usually exhibit advanced-stage disease with frequent bone marrow involvement. These lymphomas are far more common in men than women and have a peculiar propensity to involve the Waldeyer ring and gastrointestinal tract. As with the low-grade follicular lymphomas, mantle cell lymphomas are treatable but not curable. However, in contrast to the indolent lymphomas, these neoplasms are biologically aggressive, with a median survival of only 2 to 3 years. These patients are generally treated with systemic chemotherapy with rituximab at diagnosis, because of the more aggressive nature of mantle cell lymphomas compared with follicular lymphomas, but durable remissions are difficult to achieve. The optimal therapy for this challenging subtype remains to be established, and these patients should be considered for experimental therapies, including immunotherapy or transplantation.

High-Grade Non-Hodgkin Lymphoma

The two high-grade subtypes, Burkitt or small noncleaved cell and lymphoblastic lymphoma, are quite rare in the adult population. Nonetheless, these subtypes are important because they are potentially curable with appropriate therapy and often require urgent, inpatient treatment at the time of

diagnosis because of their highly aggressive nature, rapid growth, and tendency to develop tumor lysis on initiation of therapy. Lymphoblastic lymphoma is an aggressive lymphoma that is closely related to T-cell acute lymphocytic leukemia and readily distinguished from most NHLs by its T-cell immunophenotype and the presence of terminal deoxynucleotide transferase. It usually afflicts young adult males and involves the mediastinum and bone marrow, with a propensity to relapse in the leptomeninges. Burkitt, or small noncleaved cell, lymphoma is a rare B-cell lymphoma in adults that is highly aggressive, with a propensity to involve the bone marrow and central nervous system. Burkitt lymphoma is characterized cytogenetically by the pathognomonic t(8;14) translocation that juxtaposes the *Ig* locus with the *myc* oncogene. In central Africa, where Burkitt lymphoma is endemic in children, it is usually associated with EBV. However, in the United States, it is uncommon for sporadic Burkitt lymphoma to be EBV positive. Burkitt lymphoma and lymphoblastic lymphomas both require treatment with intensive multiagent chemotherapy, including intrathecal chemotherapy to prevent leptomeningeal relapse. These lymphomas undergo rapid tumor lysis on initiation of chemotherapy, and all patients must receive prophylaxis against tumor lysis syndrome before and during their first course of chemotherapy. Prophylaxis includes hydration, alkalization of the urine, and allopurinol.

Hodgkin Disease

HD is the most common lymphoma in young adults. It has a bimodal age distribution in the United States and industrialized countries, with the larger peak occurring between ages 15 and 35 years and a second smaller peak occurring in patients older than 50 years. The cause of HD remains enigmatic. Although EBV is frequently present in the malignant cell of HD, a direct causal link between EBV and HD has not been established. HD does not appear with increased frequency in patients with congenital immunodeficiency syndromes or in immunosuppressed organ transplant recipients, and the risk for HD does not appear to increase in patients infected with HIV.

The diagnosis of HD is made by identifying the Reed-Sternberg (RS) cell in involved lymphoid tissue. The classic RS cell is large and binucleate, with each nucleus containing a prominent nucleolus, suggesting the appearance of *owl eyes*. Although the cellular origin of the RS cell was debated for many decades, molecular studies have confirmed that RS cells are B cell in nature with clonal rearrangement of the germline *Ig* locus, despite the absence of cytoplasmic or cell surface immunoglobulin. In contrast to NHL and other malignancies, the bulk of the infiltrate in lymph nodes involved with HD is usually composed of benign reactive inflammatory cells, and often the diagnostic RS cells can be difficult to find. Immunophenotyping of classic RS cells reveals that they are CD30 (Ki-1) and CD15 positive and are negative for CD20, CD45, and cytoplasmic or surface immunoglobulin; EBV is identified in the RS cells in about one half of patients with HD.

Four pathologic variants of HD have been identified. Nodular sclerosing (NS) is by far the most common (80% of patients with HD) and is characterized by the presence of

fibrous bands separating the node into nodules and the *lacunar* type of RS cells. It is the predominant type encountered in adolescents and young adults and typically involves the mediastinum and other supradiaphragmatic nodal sites. In the mixed cellularity (MC) type, which accounts for about 15% of patients with HD, band-forming sclerosis is absent, and RS cells are easily identified in a diffuse infiltrate that is more heterogeneous compared with that seen in the NS variant. The MC variant may be encountered in any age group, and advanced-stage disease with subdiaphragmatic involvement is more common with MC-variant HD than it is with NS-variant HD. The lymphocyte-depleted type is rare, accounting for less than 1% of the HD cases, and is characterized by sheets of RS cells with a paucity of inflammatory cells. This variant is most common in older adults, in patients infected with HIV, and in persons in nonindustrialized countries. The lymphocyte-predominant (LP) type has emerged as a distinct entity that may be more closely related to indolent NHL than it is to HD, although it is managed as true HD. The LP type is characterized by a nodular growth pattern with variants of RS cells that have polylobated nuclei and are referred to as *popcorn* cells; classic RS cells are usually absent. The immunophenotype of the atypical cells is distinct from classic RS cells, with expression of B-cell antigens (CD19 and CD20) and CD45 but absence of the classic RS markers CD15 and CD30. The presence of CD20 on the surface of LP-type Hodgkin cells has allowed therapeutic use of the monoclonal antibody rituximab, an agent not typically active in other subtypes of HD. The LP type of HD accounts for about 5% of cases, has a strong male preponderance, and tends to involve peripheral nodes with sparing of the mediastinum. The prognosis is excellent, although late relapses are more common than they are in the other types of HD.

HD arises in lymph nodes, most commonly in the mediastinum or neck, and spreads to adjacent contiguous or noncontiguous nodal sites, including retroperitoneal nodes and the spleen. As the disease progresses, it spreads hematogenously to involve extranodal sites, including bone marrow, liver, and lung. In contrast to NHL, HD rarely arises in extranodal sites, although HD can involve extranodal sites by contiguous spread from an adjacent lymph node (e.g., involvement of vertebrae from adjacent retroperitoneal lymph nodes, involvement of pulmonary parenchyma from adjacent hilar nodes).

HD usually produces painless enlargement of lymph nodes, most often in the neck. Mediastinal adenopathy may be found incidentally in a patient who is asymptomatic on routine chest radiography. Massive mediastinal or hilar adenopathy, with or without adjacent pulmonary involvement, may cause respiratory symptoms such as cough, shortness of breath, wheezing, or stridor. About one third of patients with HD have constitutional symptoms of fever, night sweats, or weight loss (*B* symptoms), which can be the presenting complaint. In addition to the *B* symptoms, generalized pruritus is also associated with HD and correlates with the NS type. Occasionally, patients give a history of troubling pruritus for months to years before the diagnosis of HD. Although HD is associated with functional T-lymphocyte defects, exhibited as cutaneous anergy to intradermal skin tests, patients rarely have opportunistic infections. If left untreated, the natural history of HD is one

of inexorable, albeit often slow, progression to involve multiple nodal sites, followed by hematogenous spread to bone marrow, liver, and other viscera. As the disease advances, patients experience *B* symptoms, malaise, cachexia, and infectious complications, and patients with progressive HD ultimately die from complications of bone marrow failure or infection.

Accurate staging of patients with newly diagnosed HD is important for treatment planning, prognosis, and assessing response to therapy. A modification of the Ann Arbor classification is used (see Table 51-4), and the suffix *A* or *B* is appended to denote the absence or presence, respectively, of fever, night sweats, or weight loss. The staging work-up of a patient with newly diagnosed HD is similar to that of patients with NHL (see Table 51-3). Patients should undergo a thorough history and physical examination; complete blood work, including an erythrocyte sedimentation rate; chest radiography; CT scan of the chest, abdomen, and pelvis; bone marrow aspirate and biopsy; and PET scan (or gallium scan if PET scan is not available). Lymphangiograms have been used historically in assessing subdiaphragmatic adenopathy; however, the expertise to perform and interpret this test is no longer widely available and has been replaced by the combination of CT scanning and nuclear imaging techniques. Additional tests, such as bone films, bone scan, and spinal magnetic resonance imaging (MRI), should be obtained only if symptoms suggest involvement of these structures. The information derived from this noninvasive work-up defines the clinical stage of a patient with HD. The role of the staging laparotomy to determine involvement below the diaphragm waned substantially during the 1990s as therapy for early-stage disease evolved. This procedure entails a laparotomy with splenectomy, liver biopsy, and a sampling of retroperitoneal nodes. The information derived from this procedure defines the pathologic stage of the disease, and occult HD can be found below the diaphragm in as many as 30% of patients with clinical stage I or II disease, mandating treatment with chemotherapy. Staging laparotomy has largely been abandoned, given that treatment has evolved away from the use of primary radiotherapy (discussed later). However, if a patient with clinical stage I or II supradiaphragmatic disease will be treated with radiation therapy as the sole modality, a staging laparotomy is an option to rule out occult involvement of the spleen and retroperitoneal nodes. Patients who do undergo staging laparotomy with splenectomy are at risk for overwhelming bacterial infection with encapsulated organisms and should receive pneumococcal and *Haemophilus influenzae* vaccine before surgery.

A variety of prognostic factors that influence risk for relapse or survival have been identified in HD. The most important adverse prognostic factors are MC or lymphocyte-depleted histology, male sex, large number of involved nodal sites, advanced stage (age >40 years), presence of *B* symptoms, high erythrocyte sedimentation rate, and bulky disease (widening of the mediastinum by more than one third or the presence of a nodal mass measuring more than 10 cm in any dimension). The presence of any of these factors in patients with early-stage disease places the patients at increased risk for occult abdominal involvement or relapse after primary radiation therapy and thus influences the decision to include chemotherapy in the initial treatment.

The treatment of HD has evolved considerably since 1980. HD is highly curable; the cure rate exceeds 80% with the use of current treatment modalities. Because most patients with HD are young adults and will experience long-term disease-free survival, the emphasis has shifted toward using therapies that minimize treatment-related morbidity and mortality without sacrificing curative potential. Radiation therapy in moderate doses (>35 Gy) to involved sites of disease plus contiguous nodal regions is curative for most patients with low-risk, early-stage disease (nonbulky stage I and IIA without adverse risk factors) and remains a viable treatment option for these patients. However, the long-term follow-up of patients treated with standard doses of radiation therapy has revealed a substantially increased risk for developing a variety of solid tumors within or at the margin of the radiation field more than a decade later. Chest irradiation for HD is associated with a particularly high risk for breast cancer in women and for lung cancer in both men and women. Additional long-term sequelae of standard radiation therapy for HD include thyroid dysfunction (usually hypothyroidism) and accelerated coronary artery disease. Thus, enthusiasm for primary radiation therapy in standard doses for low-risk, early-stage HD is diminishing in patients who will require chest irradiation, which represents the overwhelming majority of patients in the early stage.

In response to the recognition of the long-term carcinogenic effects of standard-dose radiation, the approach to treating patients with low-risk, early-stage HD is evolving. Increasingly, the trend has been to combine chemotherapy (e.g., doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine, designated as the [ABVD] regimen) with a low dose of radiation therapy (<30 Gy), which has not been associated with an increased risk for secondary solid tumors. The optimal duration of chemotherapy in combination with low-dose irradiation for early-stage HD remains unsettled.

Patients with advanced-stage HD (III or IV) or with early-stage disease with adverse risk factors (e.g., bulky disease, *B* symptoms, MC type) are not candidates for radiation therapy as the sole treatment modality because of the high rate of relapse. These patients should be treated with chemotherapy. The multiagent chemotherapy program nitrogen mustard, vincristine (Oncovin), procarbazine, and prednisone (designated as MOPP) was demonstrated to be highly curative in patients with advanced-stage disease in the 1970s. MOPP remains a highly effective regimen, but it is rarely used in current practice because of the long-term toxic effects associated with MOPP. These effects include sterility in nearly all men and infertility in a significant percentage of women who receive MOPP and a high risk for developing acute myeloid leukemia. The ABVD regimen is now the most widely used program in the United States. ABVD is as effective as is MOPP but does not cause sterility, infertility, or treatment-induced leukemias. Roughly 60% of patients with stage III or IV disease are cured with ABVD. ABVD has been associated with pulmonary fibrosis in a small percentage of patients (<5%) because of the inclusion of bleomycin in this regimen; the risk for pulmonary fibrosis is highest in patients who have underlying lung disease or who receive chest irradiation as a part of the treatment program. Patients who have an underlying cardiomyopathy are not candidates for ABVD because of the potential risk for further cardiac injury from doxorubicin, and alternate regimens are required

in these patients. More recently, the intensive regimen BEACOPP (Bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine, prednisolone, and procarbazine) has been associated with higher rates of complete response and freedom from treatment failure in patients with advanced disease and may be appropriate for selected patients. Infertility is a common side effect of treatment with BEACOPP, however, and further long-term follow-up is needed to study late sequelae of this effective regimen. Radiation therapy in combination with chemotherapy is not generally used to treat advanced-stage HD. However, in patients with bulky mediastinal disease, consolidative radiation to the mediastinum after completion of chemotherapy has been shown to decrease the rate of relapse. Thus, combined-modality therapy (chemotherapy plus radiation therapy) is considered standard for patients with bulky mediastinal disease.

Evaluating the patient's response to therapy in HD involves repetition of the staging evaluation (physical examination, CT, PET scan, and bone marrow biopsy if positive at diagnosis) during and at the completion of treatment. The presence of PET-avid disease, as measured after two cycles of ABVD therapy, has been shown to correlate with eventual resistance or relapse of disease. Conversely, patients may be cured despite the presence of a residual radiographic abnormality on chest radiography or CT (e.g., enlarged nodes, residual mediastinal mass) when the apparent residual disease is PET negative. Patients with residual radiographic abnormalities after an initial response to therapy should not be subjected to salvage therapy without additional corroborating evidence of persistent HD, such as biopsy confirmation or radiographic progression over time. A persistently positive PET scan after treatment in patients with residual radiographic abnormalities is also associated with a high rate of subsequent relapse, and these patients should be monitored closely or considered for immediate repeat biopsy or salvage therapy, or both. Most patients destined to relapse will do so within 2 years; relapses after 5 years are exceedingly rare.

Patients who relapse or fail to respond after initial therapy should be offered salvage therapy, given that many of these patients can now be cured if treated appropriately. About 20% of patients with early-stage HD who receive standard-dose radiation therapy (without chemotherapy) will relapse. These patients can be salvaged with standard chemotherapy (e.g., ABVD). Patients who relapse after standard chemotherapy should be treated with high-dose chemotherapy with autologous peripheral stem cell support. More than 50% of patients with recurrent, chemosensitive HD can be cured with this approach.

Lymphoid Leukemias

ACUTE LYMPHOCYTIC LEUKEMIAS

The acute lymphocytic leukemias that arise from precursor B or T cells are described in detail in Chapter 48.

CHRONIC LYMPHOCYTIC LEUKEMIA

B-cell CLL is a malignant disorder of lymphocytes characterized by expansion and accumulation of small lymphocytes

of B-cell origin. CLL is essentially identical to B-cell small lymphocytic lymphoma in the REAL and WF classifications but represents the leukemic form of the disease. CLL is the most common form of leukemia in the United States and affects twice as many men as it does women. Although it can occur at any stage of life, the incidence increases with age, and more than 90% of cases are diagnosed in adults older than 50 years of age. The cause of CLL is unknown. No apparent genetic basis for the disease has been found, and environmental factors, such as radiation and exposure to carcinogens, have not been implicated.

The common form of CLL is a clonal proliferation of mature B cells, expressing characteristic mature B-cell markers and low levels of surface immunoglobulin M (IgM) that is light-chain restricted, reflecting the clonal origin of this malignancy. In addition, CLL B cells express the CD5 molecule, which marks a minor subset of normal B cells, and CD23 (the Fc receptor for IgE). Thus, the diagnostic immunophenotype of CLL is that of a mature B-cell population that is clonal (by light-chain restriction or *Ig* gene rearrangement studies) expresses the characteristic mature B-cell markers (CD19, CD20, and CD21) and is positive for both CD5 and CD23. Although a pathognomonic chromosomal abnormality has not been identified in CLL, 30% to 50% of patients have cytogenetic abnormalities. The most frequent abnormalities involve chromosome 12 (often trisomy 12), 13, or 14. The presence of cytogenetic abnormalities of chromosomes 17 and 11 is associated with a very poor prognosis. Smears of the bone marrow or peripheral blood reveal a predominance of small lymphocytes with inconspicuous nucleoli, and involved lymph nodes reveal a diffuse infiltrate of these cells ablating normal architecture.

CLL cells accumulate in bone marrow, peripheral blood, lymph nodes, and spleen, resulting in lymphocytosis, decreased bone marrow function, lymphadenopathy, and splenomegaly. CLL is also frequently associated with immune dysregulation, exhibiting as hypogammaglobulinemia with an increased risk for bacterial infections and autoimmune phenomena such as Coombs-positive hemolytic anemia or immune thrombocytopenia. The diagnosis is often made incidentally on a routine blood cell count that shows a leukocytosis with a predominance of small lymphocytes; flow cytometric analysis of peripheral blood or a bone marrow aspirate will reveal the characteristic clonal B-cell population that is CD5 and CD23 positive. Some patients exhibit lymphadenopathy, symptoms related to cytopenias, or, occasionally, recurrent infections. As the disease progresses, patients develop generalized lymphadenopathy, hepatosplenomegaly, and bone marrow failure. Death often results from infectious complications or bone marrow failure in patients who have become refractory to treatment. In about 5% of instances, CLL transforms to a highly malignant diffuse large cell lymphoma, which is usually rapidly fatal; this transformation is commonly referred to as *Richter syndrome*.

CLL is a low-grade leukemia or lymphoma that is typically characterized by a long natural history with slow progression over years or even decades; median survival is in excess of 6 years. The extent of disease, or stage, at onset is the best predictor of survival. Table 51-5 shows the widely used Rai and Binet staging systems for CLL; most patients exhibit stage 0, I, or II disease. Given that standard therapy

Table 51-5 Staging System for Chronic Lymphocytic Leukemia

Stage	Lymphocytosis	Lymphadenopathy	Hepatomegaly or Splenomegaly	Hemoglobin (g/dL)	Platelets ($\times 10^3/\mu\text{L}$)
RAI System					
0	+	–	–	≥ 11	≥ 100
I	+	+	–	≥ 11	≥ 100
II	+	\pm	\pm	≥ 11	≥ 100
III	+	\pm	\pm	< 11	≥ 100
IV	+	\pm	\pm	Any	< 100
BINET System					
A	+	\pm (< 3 lymphatic groups* positive)	\pm	≥ 10	≥ 100
B	+	\pm (≥ 3 lymphatic groups* positive)	\pm	≥ 10	≥ 100
C	+	\pm	\pm	< 10	< 100

*Cervical, axillary, inguinal nodes, liver, and spleen are each considered one group whether unilateral or bilateral.

is not curative, and because CLL may have a long asymptomatic phase lasting years, specific treatment can be withheld until the patient develops symptoms (e.g., bulky lymphadenopathy, constitutional symptoms such as fevers, cytopenias caused by either bone marrow infiltration or autoimmune phenomenon). When treatment is required, initial therapy is begun either with the nucleoside analogue fludarabine or an alkylating agent such as chlorambucil or bendamustine. Most patients respond to either of these interventions with significant reductions in tumor burden. Fludarabine therapy is associated with a higher rate of complete remissions compared with therapy with chlorambucil, and combination regimens (e.g., fludarabine, cyclophosphamide, and rituximab) have shown particularly encouraging results. Patients with recurrent or refractory disease may respond to alemtuzumab, a humanized monoclonal antibody to the CD52 molecule, which is present on most lymphocytes. Rituximab is also an active agent for patients with recurrent CLL. Patients with poor-risk cytogenetic abnormalities are more likely to demonstrate resistance to standard therapies and have shortened survival. Such patients may be candidates for allogeneic transplantation, which appears to exert therapeutic effect through a strong immune or “graft-versus-leukemia” phenomenon. Patients who develop autoimmune phenomena require treatment with corticosteroids, and intravenous gamma-globulin may be used to reduce the frequency of infections in patients who have developed hypogammaglobulinemia. The development of a rapidly enlarging mediastinal mass, constitutional symptoms, and high serum LDH suggests transformation of disease to a diffuse large cell lymphoma, which is associated with a poor prognosis.

HAIRY CELL LEUKEMIA

Hairy cell leukemia is a rare biologically indolent neoplastic lymphoid disorder characterized by an accumulation of neoplastic B cells in the bone marrow, peripheral blood, and spleen that morphologically have a characteristic appearance described as *hairy*. Hairy cells are lymphoid cells with fine cytoplasmic projections that are readily identified by the presence of tartrate-resistant acid phosphatase, B-cell immu-

nophenotype, and rearranged heavy- and light-chain immunoglobulin genes. The diagnosis is made by identifying typical hairy cells in the peripheral blood or on bone marrow biopsy. The bone marrow is often inaspirable because of the extensive reticulin fibrosis typically present.

This disease may resemble CLL superficially, but it has unique clinical features and requires different therapy. Hairy cell leukemia may be diagnosed in a patient who is asymptomatic on routine blood cell count; patients who are symptomatic usually exhibit symptoms referable to splenomegaly, infection caused by impaired host defenses, or associated autoimmune syndromes such as vasculitis or arthritis. Osteolytic bone lesions can occur and may cause pain. *B* symptoms are rare. On examination, splenomegaly is present in more than 80% of patients; hepatomegaly is less common, and lymphadenopathy is distinctly unusual. Pancytopenia is typically present at diagnosis. The course of hairy cell leukemia is generally indolent, with slowly progressive pancytopenia and splenomegaly. However, a considerable variability can be found in severity and rate of disease progression. Before effective therapy, bacterial and fungal infections occurred frequently and were the major cause of death.

Asymptomatic patients without significant cytopenias or other complications of the disease require no immediate therapy and can be monitored closely for progression or infectious complications. Patients who exhibit moderate cytopenias, history of infections, rapidly progressive disease, symptomatic splenomegaly, bone involvement, or autoimmune syndromes should undergo therapy. First-line therapy is the purine nucleoside analogue 2-chlorodeoxyadenosine (2-CDA). In 90% of patients, one course of treatment given as a continuous infusion over 7 days results in a complete response that is often durable. Relapse may occur but may respond to retreatment with 2-CDA or an alternative purine analogue, pentostatin. Because the malignant cells express the cell surface antigen CD20, the anti-CD20 antibody rituximab may also be employed. Splenectomy or treatment with interferon- α is rarely required. The availability of several effective therapies and the indolent nature of hairy cell leukemia have resulted in survival that is similar to the age-matched population.

Plasma Cell Disorders

The plasma cell disorders, or *dyscrasias*, represent a group of B-cell neoplasms that are related to each other by virtue of their production and secretion of monoclonal immunoglobulin (or part of an immunoglobulin molecule), or M protein. The tumor cell of these disorders exhibits features of a differentiated plasma cell that is adapted to synthesize and secrete immunoglobulin at a high rate. The laboratory hallmark of plasma cell dyscrasias is the presence of a homogeneous immunoglobulin molecule (or part of an immunoglobulin molecule) that can be detected in the serum or urine by protein electrophoresis. Clinically, these disorders are often characterized by the systemic effects of the M protein as well as by the direct effects of bone and bone marrow infiltration. The classification of plasma cell dyscrasias is determined in part by the immunoglobulin class (IgG, IgA, IgD, IgE, or IgM) or component of immunoglobulin (heavy chain or light chain) that is produced (Table 51-6). The most common plasma cell neoplasms are multiple myeloma and the closely related plasmacytoma, which is a solitary myeloma of bone or extramedullary soft tissue; other less common plasma cell neoplasms include

Waldenström macroglobulinemia, heavy-chain disease, and primary amyloidosis.

M proteins can be found in benign and malignant conditions other than the plasma cell dyscrasias (see Table 51-6). About 10% of patients with CLL have detectable monoclonal IgG or IgM in their serum. M proteins can be detected in a variety of autoreactive or infectious disorders. In addition, an M protein can be found on serum protein electrophoresis in individuals with no apparent associated disease and in the absence of any other laboratory or clinical evidence of a plasma cell dyscrasia. This finding is designated *monoclonal gammopathy of unknown significance* (MGUS) and is defined by the presence of low levels of serum M protein (<3 g/dL), no urinary Bence Jones protein, less than 10% bone marrow plasma cells, and absence of anemia, hypercalcemia, renal failure, and lytic bone lesions. MGUS is more common than myeloma and increases in frequency with aging, occurring in 1% to 2% of the population older than 50 years. MGUS is often considered a premalignant condition, and these patients are at increased risk (sevenfold) for developing overt myeloma or related malignant plasma cell neoplasms compared with the general population. Nonetheless, progression of MGUS to a frank plasma cell neoplasm only

Table 51-6 Classification of Disorders Associated with Monoclonal Immunoglobulin (M Protein) Secretion

Disorder	M Protein	Antibody Activity of M Protein
Plasma Cell Neoplasms		
Multiple myeloma	IgG > IgA > IgD; \pm free light chain or light chain alone ($\kappa > \lambda$)	
Solitary myeloma of bone	IgG > IgA > IgD; \pm free light chain or light chain alone ($\kappa > \lambda$)	
Extramedullary plasmacytoma	IgA > IgG > IgD; \pm free light chain or light chain alone ($\kappa > \lambda$)	
Waldenström macroglobulinemia	IgM \pm free light chain ($\kappa > \lambda$)	
Heavy-chain disease	γ , α , or μ heavy chain or fragment	
Primary amyloidosis	Free light chain ($\lambda > \kappa$)	
Monoclonal gammopathy of unknown significance	IgG > IgM > IgA, usually without urinary light-chain secretion	
Other B-Cell Neoplasms		
Chronic lymphocytic leukemia	M protein occasionally secreted; IgM > IgG	
B-cell non-Hodgkin lymphomas; Hodgkin disease	M protein occasionally secreted; IgM > IgG	
Nonlymphoid Neoplasms		
Chronic myelogenous leukemia	No consistent patterns	
Carcinomas (e.g., colon, breast, prostate)	No consistent patterns	
Autoimmune or Autoreactive Disorders		
Cold agglutinin disease	IgM κ most common	Anti-I antigen
Mixed cryoglobulinemia	IgM or IgA	Anti-IgG
Sjögren syndrome	IgM	
Miscellaneous Inflammatory, Storage, or Infectious Disorders		
Lichen myxedematosus	IgG λ	
Gaucher disease	IgG	
Cirrhosis, sarcoid, parasitic diseases, renal acidosis	No consistent pattern	

IgA, immunoglobulin A; IgD, immunoglobulin D; IgG, immunoglobulin G; IgM, immunoglobulin M.

Modified from Salmon SE: Plasma cell disorders. In Wyngaarden JB, Smith LH Jr (eds): Cecil Textbook of Medicine, 18th ed. Philadelphia, WB Saunders, 1988, p 1026.

occurs in about 1% of patients per year. Distinguishing patients with stable, nonprogressive MGUS from patients in whom multiple myeloma will eventually develop is difficult. The risk for progression is greater in patients with IgA or IgM M proteins and in patients with initial concentrations of M protein in excess of 1.5 g/dL. Although no definitive evidence has been found that monitoring patients with the diagnosis of MGUS improves survival, patients should undergo annual evaluation, including serum electrophoresis, to detect progression to multiple myeloma before the onset of overt symptoms or complications.

MULTIPLE MYELOMA

Multiple myeloma is a malignant plasma cell disorder characterized by neoplastic infiltration of the bone marrow and bone and the presence of monoclonal immunoglobulin or light chains in the serum or urine. The diagnosis of multiple myeloma is made by identifying an increase in the number of plasma cells in the bone marrow (>30%) and a serum M protein other than IgM exceeding 3 g/dL for IgG or 2 g/dL for IgA or a urine M protein exceeding 1 g per 24 hours. Patients with lower levels of M protein or less than 30% bone marrow plasmacytosis may still be diagnosed with myeloma based on the presence of a combination of other features such as hypogammaglobulinemia, lytic bone lesions, or plasmacytoma. For patients lacking these features, the major differential diagnosis is usually between MGUS and myeloma; in some cases, the distinction can only be made by serial follow-up of the patient with evidence of rising M protein levels or the development of associated clinical manifestations of myeloma. About 20% of patients with multiple myeloma do not have detectable serum M protein by standard electrophoresis but have circulating free light chains that appear in the urine (Bence Jones protein) that can be detected in a 24-hour urine collection by urine protein electrophoresis (*light-chain disease*). In rare cases, patients with *nonsecretory* myeloma have neither detectable serum nor urine M protein. However, in these patients, a monoclonal population of plasma cells can be detected by immunohistochemical identification of cytoplasmic light-chain–restricted immunoglobulin. Quantitative assays for detection of free light chains in the serum of patients with multiple myeloma have now become widely available and may be used to assess disease in a similar fashion to electrophoretic measurements. These assays are quite sensitive and may provide measurement of clonal protein in patients thought to have nonsecretory disease by other methods. Free light chains have a relatively short half-life in the circulation, 2 to 6 hours, in comparison with weeks for intact immunoglobulin molecules and may therefore be used to obtain a more rapid assessment of disease response for patients on therapy.

The clinical manifestations of multiple myeloma relate to the direct effects of bone marrow and bone infiltration by malignant plasma cells, the systemic effects of the M protein, or the effects of the concomitant deficiency in humoral immunity that occurs in this disease. The most common symptom in multiple myeloma is bone pain. Bone radiographs typically show pure osteolytic *punched-out* lesions, often in association with generalized osteopenia and pathological fractures. Bony lesions can show as expansile masses

associated with spinal cord compression. Hypercalcemia caused by extensive bony involvement is common in myeloma and may dominate the clinical picture. Anemia occurs in most patients as a result of marrow infiltration and suppression of hematopoiesis and results in fatigue; granulocytopenia and thrombocytopenia are less common. Patients with myeloma are susceptible to bacterial infections because of impaired production and increased catabolism of normal immunoglobulins. Respiratory tract infections from *Streptococcus pneumoniae*, *Staphylococcus aureus*, *H. influenzae*, and *Klebsiella pneumoniae*, and gram-negative urinary tract infections are common. Renal insufficiency occurs in about 25% of patients with myeloma. The cause of renal failure in these patients is often multifactorial; hypercalcemia, hyperuricemia, infection, and amyloid deposition can contribute. However, direct tubular damage from light-chain excretion is invariably present. M proteins can also cause a host of diverse effects because of their physicochemical properties. These effects include cryoglobulinemia, hyperviscosity, amyloidosis, and clotting abnormalities resulting from interaction of the M protein with platelets or clotting factors.

Several staging or classification systems exist for myeloma. The three-tier staging system for myeloma is a functional system that correlates with survival (Table 51-7). In contrast to the anatomic staging systems used for lymphomas and solid tumors, myeloma staging is based on clinical tests (bone radiographs) and laboratory tests (hemoglobin, serum calcium, serum or urine M protein levels, and serum creatinine) that correlate with tumor burden. Adverse prognostic factors include advanced stage, impaired renal function, elevated LDH levels, abnormal bone marrow cytogenetics, depressed serum albumin levels, and elevated β_2 -microglobulin levels. The last is the single most powerful predictor of survival. Recently, a simplified prognostic scheme, the International Staging System for Myeloma, identified three stages with distinct prognosis based on only two variables: β_2 -microglobulin and albumin levels. A classification system proposed by the International Myeloma

Table 51-7 Myeloma Staging System

Stage	Criteria
I	All of the following: 1. Hemoglobin >10 g/dL 2. Serum calcium <12 mg/dL 3. Normal bone radiograph or solitary lesion 4. Low M-component production a. IgG level <5 g/dL b. IgA level <3 g/dL c. Urine light chain <4 g/24 hr
II	Fitting neither I nor III
III	One or more of the following: 1. Hemoglobin <8.5 g/dL 2. Serum calcium >12 mg/dL 3. Advanced lytic bone lesions 4. High M-component production a. IgG level >7 g/dL b. IgA level >5 g/dL c. Urine light chains >12 g/24 hr
Subclassification: A Serum creatinine <2 mg/dL. B Serum creatinine <2 mg/dL.	

Working group divides patients with myeloma into two groups—asymptomatic and symptomatic myeloma—based on the presence or absence of four basic features termed myeloma-related organ or tissue impairment (ROTI). These factors include hypercalcemia, renal insufficiency, bone lesions, and anemia, and their presence provide sufficient evidence to initiate therapy.

Most patients with myeloma exhibit symptomatic, advanced-stage disease and require therapy. However, about 10% of patients have stage I disease or asymptomatic myeloma and an indolent course. These patients do not require immediate therapy, but they should be monitored for disease progression by serial quantification of the M protein. For patients with solitary bone or extramedullary plasmacytomas, particularly in the head and neck region, local radiation therapy can induce long-term remissions and is the treatment of choice. Patients with a solitary plasmacytoma of bone are often found on routine MRI of the spine to have asymptomatic bone disease and are at higher risk for subsequent development of myeloma.

Patients with symptomatic, advanced-stage (II or III) myeloma require systemic therapy as well as meticulous attention to supportive care. Although myeloma is not a curable malignancy, systemic therapy can prolong survival and dramatically improve quality of life. Options for treatment have expanded in the past decade to include three potent nonchemotherapeutic agents: thalidomide and lenalidomide (referred to as *immunomodulatory agents* or *Imids*) and bortezomib (a proteasome inhibitor), all of which are typically administered in combination with dexamethasone. These agents have largely supplanted traditional chemotherapeutic agents as initial and secondary therapies because they are efficacious and generally well tolerated.

The most commonly employed initial therapy is the combination of thalidomide and dexamethasone. Thalidomide was initially used as a sedative in the United Kingdom in the 1960s but was found to cause birth defects when used to combat nausea during pregnancy. The antiangiogenic properties of thalidomide subsequently led to its development as an anticancer agent. Although the mechanism of action of thalidomide in myeloma is unclear, one third of patients with recurrent or refractory disease following transplantation responded to thalidomide. In contrast to chemotherapy, thalidomide is infrequently myelosuppressive and has a unique side-effect profile, including peripheral neuropathy, constipation, somnolence, and rash. The combination of thalidomide and dexamethasone is highly active as initial therapy in treating myeloma and has the advantage of an all-oral treatment program. A troublesome unique side effect of the combination is the development of deep vein thrombosis in up to 25% of patients, and some form of preventative therapy is typically prescribed.

Lenalidomide, which is chemically related to thalidomide, is a more potent agent with a side-effect profile distinct from thalidomide. Myelosuppression is the main side effect of lenalidomide, and this drug is therefore not administered continuously. Lenalidomide therapy is also associated with an increased risk for deep vein thrombosis. Lenalidomide is indicated as second-line therapy for myeloma and is often employed as an alternate to thalidomide if troublesome side effects, such as neuropathy, dictate a change in therapy.

Bortezomib may be used as initial therapy for myeloma in combination with the alkylating agent melphalan plus prednisone. Because melphalan causes stem cell injury, this therapy may typically be avoided in patients who are eligible for stem cell transplantation. Bortezomib, in combination with dexamethasone, is an active drug for patients with recurrent or refractory disease and is associated with neuropathy, asthenia, and thrombocytopenia.

Most patients respond to initial therapy with a reduction in bone pain, hypercalcemia, and anemia in association with a decline in the M protein level. The use of high-dose chemotherapy with alkylating agents followed by autologous peripheral stem cell infusion has been shown to improve survival and quality of life compared with standard doses of chemotherapy. Although this approach is not curative, it does represent an important treatment option for some patients and has been shown to have an acceptable toxicity profile, even in older patients. Allogenic bone marrow transplantation may represent the only potentially curative treatment for myeloma, but the associated excessive morbidity and mortality in elderly patients and heavily pretreated patients have limited its use in this disease.

Patients who experience relapse after standard therapy or transplantation may be treated with alternate chemotherapy regimens or with novel combination therapies including both new agents (thalidomide, lenalidomide, bortezomib) and chemotherapy drugs.

Supportive care directed toward anticipated complications of myeloma is an important aspect of the management of this disease. Bone resorption can be reduced with regular injections of the diphosphonates zoledronic acid or pamidronate, reducing pain and pathologic fractures. Bony lesions, particularly those involving weight-bearing bones, may require palliative radiation for controlling pain and preventing pathologic fractures. Vertebral bony lesions may lead to spinal cord compression, with increasing back pain and neurologic symptoms. Any symptoms suggestive of cord compression require prompt evaluation with spinal MRI and, if necessary, local radiation to involved areas. Avoidance of nephrotoxins, including intravenous dyes, is important to prevent renal failure. Acute renal failure caused by light-chain deposition may improve with plasmapheresis to acutely reduce protein load. All patients should receive pneumococcal and *H. influenzae* vaccines, and intravenous gamma-globulin may be useful in preventing recurrent infections in patients with profound hypogammaglobulinemia. Use of erythropoietin may alleviate anemia and decrease the need for blood transfusions.

WALDENSTRÖM MACROGLOBULINEMIA

Waldenström macroglobulinemia is a malignancy of plasmacytoid lymphocytes that secrete large quantities of IgM. It is a chronic disorder affecting elderly patients (median age is 64 years) that shares features of the low-grade lymphomas and myeloma. In contrast to myeloma, Waldenström macroglobulinemia is associated with lymphadenopathy and hepatosplenomegaly, and, although bone marrow involvement is invariably present, lytic lesions and hypercalcemia are distinctly rare. The major clinical manifestation of Waldenström macroglobulinemia is usually the hypervis-

cosity syndrome caused by the physical properties of IgM. In contrast to IgG, IgM remains largely confined to the intravascular space, and, as IgM levels rise, plasma viscosity increases. Epistaxis, retinal hemorrhages, dizziness, confusion, and congestive heart failure are common symptoms of the hyperviscosity syndrome. About 10% of IgM proteins have properties of cryoglobulins, and these patients show symptoms of cryoglobulinemia or cold agglutinin syndrome demonstrated as acrocyanosis, Raynaud phenomenon and vascular symptoms, or hemolytic anemia precipitated by exposure to cold. Some patients with Waldenström macroglobulinemia may develop a peripheral neuropathy that may antedate the appearance of the neoplastic process.

The approach to and treatment of Waldenström macroglobulinemia are similar to those of other low-grade B-cell lymphomas. The use of nucleoside analogues (2-CDA and fludarabine) or an alkylating agent, alone or in combination with prednisone, is effective in decreasing adenopathy and splenomegaly and controlling the M spike but is not curative. Rituximab has been found to have activity in Waldenström macroglobulinemia as has the novel proteasome inhibitor bortezomib. Plasmapheresis is highly effective in acutely decreasing serum IgM levels and is often needed initially to treat hyperviscosity. Although complete remissions are rare, patients who respond to therapy have median survivals of 4 years, and some patients survive more than a decade.

RARE PLASMA CELL DISORDERS

Heavy-chain disease is a rare lymphoplasmacytoid neoplasm characterized by production of a defective heavy chain of the γ , α , or μ type. The clinical manifestations vary with the type of heavy chain secreted. γ heavy-chain disease is associated with lymphadenopathy, Waldeyer ring involvement with palatal edema, and constitutional symptoms. α heavy-chain disease, also known as *Mediterranean lymphoma*, is characterized by lymphoid infiltration of the small intestine with associated diarrhea and malabsorption. μ heavy-chain disease is associated with CLL. Primary amyloidosis is a systemic illness characterized by deposition of immunoglobulin light chain in organs and tissue, resulting in an array of symptoms caused by organ dysfunction. Congestive heart failure, bleeding diathesis, nephrotic syndrome, and peripheral neuropathy are common complications. Patients with primary amyloidosis respond poorly to the treatments used for myeloma. Encouraging results have been reported with high-dose chemotherapy and autologous stem cell support, particularly if patients are treated before the development of significant end-organ dysfunction such as cardiomyopathy.

CONGENITAL AND ACQUIRED DISORDERS OF LYMPHOCYTE FUNCTION

A significant number of congenital disorders affect lymphocyte maturation or function, resulting in immunodeficiency disorders. Acquired disorders of lymphocyte function are far more common compared with congenital disorders. HIV infection is the most important infectious cause of acquired immunodeficiency and is discussed in Chapter 109. Patients

with HIV infection are at increased risk for developing NHL. NHLs that occur in the setting of HIV have the diffuse aggressive B-cell histology and include diffuse large B-cell lymphoma and Burkitt lymphoma; they are also frequently associated with EBV and are often advanced stage (III or IV) at initial diagnosis, with extranodal sites of involvement. Patients with HIV-associated NHL are potentially curable with the multidrug chemotherapy regimens used for treating these NHL subtypes in the general population. In addition, treatment of the underlying HIV infection with highly active antiretroviral therapy has improved the outcome and prognosis of patients with HIV-associated NHL.

Patients who have undergone an allogeneic organ transplantation require potent immunosuppressive drugs (e.g., cyclosporine, tacrolimus, mycophenolate, corticosteroids, methotrexate) to prevent graft-versus-host disease in the case of bone marrow transplantation or allograft rejection in the case of solid organ transplantation. These medications can cause profound defects in T-cell function with an associated acquired immunodeficiency state, and transplant recipients are susceptible to a host of viral and protozoal infections. In addition, patients who receive potent immunosuppressive drugs are at risk for developing a lymphoproliferative disorder (post-transplantation lymphoproliferative disorder [PTLD]) that can behave clinically as an aggressive lymphoma. PTLD is an EBV-associated lymphoproliferative disorder characterized by a polymorphous or monomorphous population of B cells that can be monoclonal or polyclonal. Patients who develop PTLD are treated by reducing the doses of immunosuppressive drugs whenever possible; this intervention alone will result in regression of PTLD in about one half of the patients, obviating the need for cytotoxic therapy. Patients who are not candidates for withdrawal of immunosuppression because of allograft rejection or who fail to respond to this strategy can be treated with rituximab alone or in combination with chemotherapy.

INFECTIOUS DISORDERS

Lymphocytes play an essential role in the adaptive response to infection. This response can be shown clinically with an increase in lymphocytes in the peripheral blood (reactive lymphocytosis) and lymph node enlargement. Reactive lymphocytosis is always polyclonal, usually predominantly T cell, and usually easily distinguishable from the common monoclonal B-cell neoplastic processes. Some infections are typically associated with a prominent lymphocytosis (e.g., EBV-associated infectious mononucleosis, cytomegalovirus, toxoplasmosis in immunocompetent hosts, viral hepatitis). Enlargement of lymph nodes, either local-regional or generalized lymphadenopathy, is a common manifestation of some infections (see Table 51-1). Lymph node enlargement may be striking and associated with tenderness. In most cases, the adenopathy is reactive, and the organism cannot be readily cultured from the node; in other cases (e.g., tuberculosis, fungal disease), culture or appropriate staining in lymph node tissue can identify the organism. Biopsy of the node generally will confirm the non-neoplastic nature of the process, showing a normal architecture and cellular pattern and absence of a monoclonal population of lymphoid cells.

Prospectus for the Future

Further advances in our understanding of lymphoproliferative diseases are likely to come from molecular studies such as DNA microarray analyses used to create profiles of gene expression in malignant cells. Such analyses will aid in further subclassifying lymphoproliferative diseases and will help define prognosis and response to therapy; such data are already available in limited form for diffuse large B-cell lymphoma and CLL. An understanding of gene expression profiles unique to specific disease will also provide additional targets for pharmacologic or immunologically based therapies.

The advent of humanized chimeric monoclonal antibodies targeted to CD20 has changed the therapy of some lympho-

mas, and antibodies to other cell surface antigens, including radiolabeled antibodies, are in development.

For multiple myeloma, combinations of both new agents (thalidomide, lenalidomide, bortezomib) and chemotherapeutic agents are likely to improve outcomes by achieving higher rates of complete remissions.

For allogeneic transplantation, reduced-intensity conditioning regimens are improving the therapeutic index of this procedure for curative treatment of multiple myeloma and lymphomas.

Normal Hemostasis

Christine S. Rinder and Henry M. Rinder

Hemostasis is the physiologic balance of procoagulant and anticoagulant forces that maintain both liquid blood flow and the structural integrity of the vasculature. Vascular damage results in initiation of clotting with the goal of producing a *localized* platelet-fibrin plug to prevent blood loss; this action is followed by processes that lead to clot containment, wound healing, clot dissolution, tissue regeneration, and remodeling. In healthy persons, all these reactions occur continuously and in a balanced fashion such that bleeding is contained, yet blood vessels simultaneously remain patent to deliver adequate organ blood flow. When any of these hemostatic processes is disrupted because of inherited defects or acquired abnormalities, disordered hemostasis may result in either bleeding or thromboembolic complications.

Blood flow in the arterial and venous systems is disparate and imposes different needs on the coagulation system. In the pressurized arteries, relatively minor vascular damage can rapidly result in massive blood loss; thus, the procoagulant response in arteries must rapidly arrest bleeding. Platelets are critical to this arterial response; they initially contain blood loss and then provide an active surface for soluble coagulation factors to both localize and accelerate fibrin and, ultimately, clot formation. By contrast, in the venous circulation, the slower flow rates produce slower bleeding, a feature that makes platelets less critical; instead, controlling the balance of venous hemostasis is most dependent on the rate of thrombin generation. These differences are further underscored clinically by the anticoagulant agents used in these distinct settings, that is, antiplatelet agents such as aspirin and clopidogrel to prevent coronary and cerebral artery thrombus, compared with interventions that inhibit thrombin, including the heparins and warfarin, for treatment and prophylaxis of venous thromboembolic disease.

This chapter briefly details the physiologic and interdependent mechanisms of vascular hemostasis, including the normal balance of procoagulant and anticoagulant functions of the blood vessel wall, platelet physiologic factors and receptor-ligand interactions critical for hemostasis, and the

highly complex, interwoven pathways that represent the coagulation cascade.

Vascular Wall Physiology

Vascular endothelial cells (ECs) are capable of orchestrating both procoagulant and anticoagulant events depending on circumstances. When the vasculature is intact, healthy ECs exert tonic anticoagulant activity, helping to maintain blood fluidity. This is partially due to a passive barrier function separating the blood from subendothelial procoagulants such as collagen and tissue factor (TF). In addition, healthy ECs actively regulate the hemostatic balance of activity in their microenvironment through their secreted products (Table 52-1). These include prostacyclin and nitric oxide, both of which induce vascular smooth muscle relaxation and reduced shear when released in an abluminal direction. When secreted into the blood, they promote platelet cyclic adenosine monophosphate (cAMP) generation, thus inhibiting platelet activation and aggregation. ECs also secrete adenosine diphosphatase (ADPase), which degrades extracellular platelet-released adenosine diphosphate (ADP), thereby inhibiting platelet recruitment into the growing platelet clot. Soluble coagulation factors are also regulated by ECs in both tonic and inducible fashion. Tissue factor pathway inhibitor (TFPI) in its nascent circulating form blunts initiation of coagulation; TFPI is subsequently primed for increased activity by exposure to small amounts of factor Xa. Quiescent thrombomodulin and tissue plasminogen activator are localized at the EC extracellular matrix, ready to be activated by local formation of thrombin and fibrin, respectively, to carry out their anticoagulant and fibrinolytic functions.

When ECs are physically damaged or become activated, their balance of coagulant properties is shifted to favor a procoagulant state. This function is mediated both by the ECs themselves and by the underlying subendothelial matrix that is exposed by vascular injury. Activated (e.g., by toxins or secreted factors) ECs express adhesive ligands on their surface, including the selectins (both E-selectin and

P-selectin), β_1 and β_2 integrins, platelet endothelial cell adhesion molecule-1 (PECAM-1), and von Willebrand factor (vWF) multimers (see Table 52-1). On the EC surface, vWF multimers localize and promote platelet adhesion, whereas integrins mediate adhesion and subsequent transendothelial migration of leukocytes into the tissues. Exposed subendothelial matrix also binds vWF multimers (Fig. 52-1) and contains other procoagulant, adhesive proteins, including thrombospondin, fibronectin, and collagen. These moieties function both as ligands to capture platelets and as activators of adherent platelets; collagen, in particular, is both a platelet ligand and a strong platelet agonist; the latter capability causes platelets to undergo dense granule release and to express conformationally active ligands such as glycoprotein IIb/IIIa (GPIIb/IIIa; see later discussion). Another critical procoagulant mediator exposed by EC damage is TF, which is constitutively expressed by subendothelial smooth muscle cells and fibroblasts. As outlined later (see “Soluble Coagulation”), TF is the major initiator of the soluble coagulation system that, with activated platelets, results in the formation of a definitive platelet-fibrin clot (Fig. 52-2).

Platelet Physiology

The platelet functions as the cellular-based platform for hemostasis. Platelet surface receptors mediate primary

hemostasis and allow platelets to bind directly to endothelium and subendothelium at sites of damage. Platelet interaction with their ligands causes transmembrane signaling through surface receptors to induce platelet activation and promote procoagulant function through pathways, including translocation of additional receptors to the membrane surface, receptor conformational change to active forms, release of granule contents that recruit platelet adhesion, and exposure of procoagulant membrane phospholipids. The procoagulant surface of the platelet then serves as a platform for enhanced assembly of the coagulation cascade to generate thrombin, which (1) feeds back on platelets and the clotting cascade to amplify the procoagulant response, and (2) produces fibrin to provide secondary, long-lasting hemostasis. Finally, the platelet further assists thrombin in clot consolidation and protection from fibrinolysis by contributing factor XIII and platelet factor 4, respectively, to the clot milieu (Table 52-2).

PLATELET HEMOSTASIS

Platelets are anucleate cells between 2 and 4 μm in diameter with a volume between 6 and 11 fL. Platelets are derived from the megakaryocyte cytoplasm after a maturation time of about 4 days, with each megakaryocyte contributing about 1000 circulating platelets in its lifetime. When platelets are released into the circulation, they survive between 7 to 10 days; platelets leave the circulation through a combination of senescence and the normal maintenance of vascular structural integrity. For the latter, very few platelets are needed; approximately 7100 platelets/mcL are required for hemostasis per day when vascular structures are intact (e.g., no recent surgery or trauma) and when there is no increase in normal platelet consumption (e.g., sepsis). The normal platelet count range is between 150,000 and 450,000/mcL. With platelet counts in the normal range and normal platelet function, the bleeding time, an in vivo measure of platelet function, is generally less than 8 minutes. However, when normal functioning platelets are less than 100,000/mcL, the bleeding time is prolonged. Thus, in the presence of thrombocytopenia, the bleeding time cannot be used to determine whether bleeding is caused by abnormal platelet function or

Table 52-1 Endothelial Cell Coagulant Properties

Procoagulant	Anticoagulant
Collagen	Vasodilation
Factor VIII	Adenosine diphosphatase
Fibronectin	Heparan sulfates
Integrins	Nitric oxide
Platelet-endothelial cell adhesion molecule-1	Prostacyclin
Selectins (E and P)	Thrombomodulin
Vasoconstriction	Tissue factor pathway inhibitor
von Willebrand factor	Tissue plasminogen activator

Figure 52-1 The adhesive interactions producing stable platelet attachment to subendothelial von Willebrand factor (vWF). The initial attachment between platelet glycoprotein Ib (GPIb) and its binding domain on vWF is rapid but has a short half-life, and the result is a rolling movement from torque generated by flowing blood. The vWF-GPIb interaction produces transmembrane signaling that activates the platelet to undergo shape change and simultaneously transforms GPIIb/IIIa into an activated conformation capable of binding to a distinct arginine-glycine-aspartate domain on vWF. This secondary adhesion causes the platelet to firmly adhere to the exposed subendothelial vWF. EC, endothelial cell.

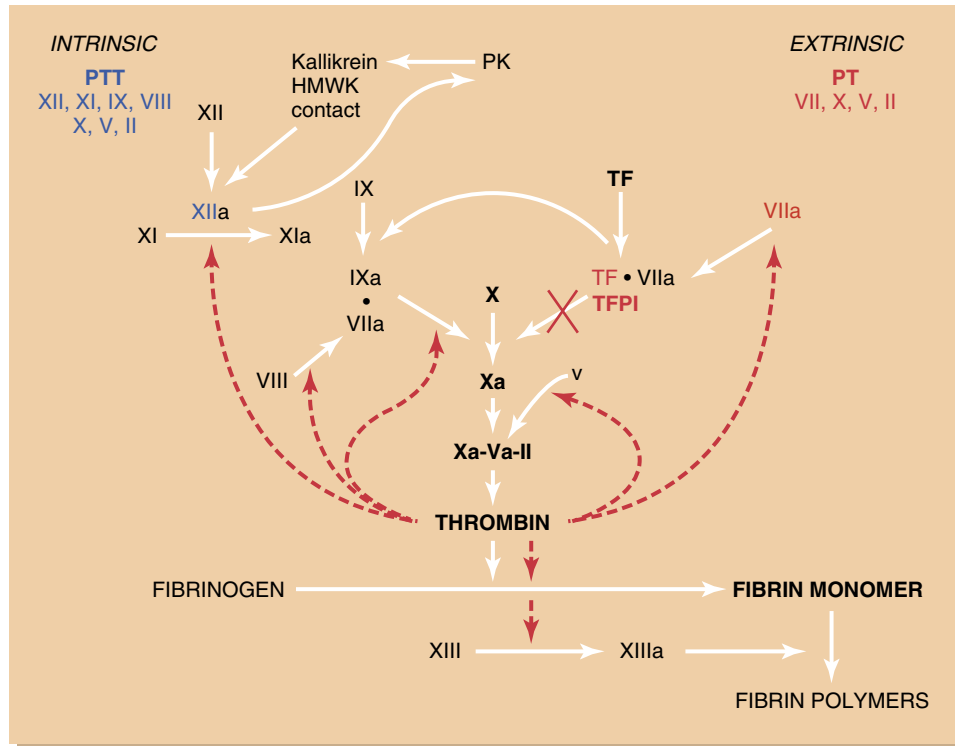

Figure 52-2 The coagulation cascade. The laboratory-defined *extrinsic* and *intrinsic* pathways allow monitoring of anticoagulation by the prothrombin time (PT) and partial thromboplastin time (PTT), respectively. The PT primarily monitors factor VII activity, whereas the PTT is the best measure of XI and the hemophilic factors IX and VIII; both assays will detect deficiency of the common pathway factors (X, V, and II). Initiation of clotting begins with TF exposure, which then combines with small amounts of circulating VIIa to form the extrinsic Xase complex and generate Xa. Xa forms the prothrombinase complex with Va and II, generating small amounts of thrombin, which begin to cleave fibrinogen into weak fibrin monomers in the initiation phase of coagulation. Thrombin's ability to activate factors, especially when carried out on the activated platelet surface, is responsible for propagation of the coagulant response. Thrombin generates XIa, which, in turn, activates IX; the TF-VIIa complex (before its shutdown by TFPI) also generates IXa. Thrombin-activated VIIIa then combines with IXa to form the intrinsic Xase complex, generating large amounts of Xa and prothrombinase complex on the platelet surface to further amplify thrombin generation. The large amounts of thrombin now generate enough fibrin monomers to form stable polymers and fibrin clot. HMWK, high-molecular-weight kininogen; PK, prekallikrein; TF, tissue factor; TFPI, tissue factor pathway inhibitor.

Table 52-2 Procoagulant Properties of Platelets

Receptor-Ligand Interactions Promoting Adhesion

GPIIb/IX/V-vWF
 GPIIb/IIIa-fibrinogen and GPIIb/IIIa-vWF
 GPIa/IIa-collagen
 P selectin–P selectin glycoprotein ligand-1

Receptor-Ligand Interactions Mediating Activation

GPV-thrombin
 GPVI-collagen

Secreted α -Granule Proteins

Ligands (fibrinogen, fibronectin, thrombospondin, vitronectin, vWF)
 Enzymes (α_2 -antiplasmin, factors V, VIII, and XI)
 Antiheparin (platelet factor 4)

Secreted Dense-Granule Agonists

ADP, serotonin

Secreted Cytosolic Factor XIII—Membrane Components

Thromboxane A₂ formation, phosphatidylserine expression

ADP, adenosine diphosphate; GP, glycoprotein; GPIa/IIa, complex of glycoprotein Ia and CD29; GPIIb/IX/V complex, CD42; GPIIb/IIIa (α_2 - β_3) complex, CD41; P selectin, CD62P; P selectin glycoprotein ligand-1, CD162; vWF, von Willebrand factor.

connective tissue disease. The bleeding time is an operator-dependent, highly variable *in vivo* assay that can leave scars; many laboratories have therefore switched to a so-called *in vitro* bleeding time test, for example, the Platelet Function Analyzer-100 (PFA-100), which uses anticoagulated whole blood to examine “closure time.” However, the PFA-100 and other like-minded tests are similar to the bleeding time test in that they are unable to distinguish between thrombocytopenia and abnormal platelet function when platelet counts are below 100,000/mcL.

SHEAR-INDUCED ADHESION

Platelet–vessel wall interaction has been well characterized at the high flow velocities of the arterial circulation. The interaction between the vasculature and flowing blood, as shown on the left side of Figure 52-1, creates parallel planes of blood moving at different velocities; the blood closest to the vessel wall moves slower than blood closer to the center of the vessel. These different velocities create shear stress that is greatest at the vessel wall and is least at the center of the vessel. Shear rate therefore changes inversely with the vessel diameter, with levels estimated to vary between 500 per second in larger arteries and 5000 per second in the smallest

arterioles. Shear rates at the surface of atherosclerotic plaques with modest (50%) stenosis reach 3000 to 10,000 per second, with even greater shear in more clinically significant stenoses. The high-velocity aspect of arterial blood flow actually opposes the tendencies to clot by (1) limiting the time available for procoagulant reactions to occur, and (2) disrupting cells and proteins that are not tightly adherent to the vessel wall. However, once the vessel wall is damaged and bleeding occurs, platelets can rapidly and decisively respond to the loss of endothelial integrity while they simultaneously resist the tendency to be swept downstream.

One of the forces enhancing platelet readiness for wall adhesion in the arterial circulation is radial dispersion, the tendency of larger cells (erythrocytes and leukocytes) to stream in the center of the vessel, where shear is lowest; this process effectively pushes the smaller platelets toward the vessel wall and optimally positions them to respond to hemostatic challenges. This size-dependent flow may also explain the seemingly paradoxical ability of red blood cell transfusions to slow or stop bleeding in patients with severe uremia (see Chapter 53). This effect also underscores the importance of platelets in arterial hemostasis; reductions in platelet number or function may be associated with severe arterial hemorrhage after surgery or trauma. By contrast, the lesser shear forces experienced in the venous circulation permit more random cell movement and greater time for coagulation reactions to occur; thus, the minimum requirements for platelet number and function in venous hemostasis are correspondingly less stringent.

In the setting of high-velocity blood flow at an arterial bleeding site, platelets must activate and adhere to the injured vessel nearly instantaneously. Two molecules present in the subendothelium are critical for this process: vWF and collagen. Control of bleeding in vessels under the highest shear stresses absolutely depends on the presence and function of vWF. vWF is a large molecule synthesized as multimeric *strings* in ECs and megakaryocytes, and multimeric vWF is both constitutively secreted into blood and stored in Weibel-Palade bodies of ECs. The *ultralarge* vWF multimers are the most active at binding platelets, particularly when *unfolded* by either shear stress or after tethering to the vessel surface. The multimeric forms of vWF, which are immobilized by adherence to exposed subendothelial collagen, bind to the GPIb/IX-V complex on the platelet surface when normally cryptic loci are exposed by high shear stress (see Fig. 52-1). This binding is extremely rapid but low affinity, thus slowing the platelets at this interface but leaving them only weakly adherent to subendothelial vWF. With platelets no longer streaming by, but instead tumbling or sliding over the subendothelium, the high shear stress in tandem with transmembrane signaling produced by the GPIb-V-IX-vWF interaction results in loss of the normal platelet discoid shape (shape change) and conformational change in another platelet receptor, GPIIb/IIIa.

LIGANDS

The activated GPIIb/IIIa receptor now binds either to fibrinogen or to the larger vWF multimers at a site distinct from the GPIb/IX-V-binding site. This secondary adhesion is a higher-affinity interaction than the latter, thereby securing platelets firmly to the subendothelium. At shear rates that

approximate arterial occlusion, platelet adhesion to vWF multimers can be mediated entirely through GPIb-V-IX-vWF binding without platelet activation. One important regulator of this process of platelet binding and activation through vWF is the circulating vWF-cleaving protease present in plasma: a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS-13). ADAMTS-13 modulates the activity of vWF by cleaving the ultralarge multimers into smaller fragments that have reduced overall affinity for platelet binding. Besides directly activating platelets, thrombin causes proteolysis of ADAMTS-13, thereby promoting large vWF multimer persistence and enhanced platelet recruitment into areas of vessel injury. However, pathologic loss of the ADAMTS-13 cleaving protease activity results in unchecked platelet adhesion to ultralarge vWF multimers and widespread microvascular thrombosis (see the discussion of *thrombotic thrombocytopenic purpura* in Chapter 54).

At more moderate shear rates, GPIb-V-IX-vWF adhesion is supplemented by platelet binding to subendothelial collagen, an adhesive moiety that is capable of arresting the platelet by binding to GPIa/IIa (see Table 52-2). Thus, subendothelial vWF and collagen act cooperatively to initiate platelet adhesion, with the former predominating at higher shear. Collagen is unique in that it can anchor platelets at one locus by binding to platelet GPIa/IIa and can activate platelets at a second locus by binding to platelet GPVI, and both platelet receptors are critical for physiologic platelet function. Indeed, the congenital absence of any of the critical platelet adhesion receptors—GPIIb/IIIa, GPIb/IX-V, GPVI, or GPIa/IIa—results in a significant hemostatic defect, correctable only by platelet transfusion. This finding is further reinforced by the α chain of GPIb normally serving as a cofactor for thrombin activation of platelets through both the GPV receptor and the protease activated receptor (PAR). Similarly to defects in platelet receptors, decreases in the vWF ligand, especially the larger multimeric forms, can lead to bleeding.

Once a layer of platelets is adherent to the site of injury, vWF bound to GPIb/IX-V on the luminal side of the adherent platelets serves to recruit additional platelets from the flowing blood into the growing platelet plug. Platelet recruitment is further enhanced by platelet activation and release of serotonin and ADP, which serve to activate and adhere platelets from the circulation to the growing platelet clot. Platelet activation is actually a series of interdependent processes with five major effects: (1) local release of ligands essential to stabilizing the platelet-platelet matrix, (2) continued recruitment of additional platelets, (3) vasoconstriction of smaller arteries to slow bleeding, (4) localization and acceleration of platelet-associated fibrin formation, and (5) protection of the clot from fibrinolysis.

The basis of the platelet plug is a platelet-ligand-platelet matrix with fibrinogen, fibronectin, and vWF serving as bridging ligands (Fig. 52-3). Both fibrinogen and vWF are endocytosed from plasma and stored in α granules inside the resting platelet. Both molecules are released with activation, and both can bind to a GPIIb/IIIa receptor on each of two platelets, thereby linking them. As mentioned earlier, platelet GPIIb/IIIa undergoes a calcium-dependent conformational change that allows it to bind to a locus containing the amino acid sequence arginine-glycine-aspartate (RGD)

Figure 52-3 Endogenous anticoagulant pathways. In addition to tissue factor pathway inhibitor (TFPI) shutting off tissue factor (TF) stimulation and blocking the TF-VIIa-X complex, the clotting cascade is further downregulated by the natural anticoagulants. This inhibition is partly generated by thrombin, which activates thrombomodulin. Circulating antithrombin inhibits thrombin activity and Xa generation of thrombin. The complex of thrombin and thrombomodulin activates protein C (APC), which combines with protein S (PS) to cleave and inactivate VIIIa and Va, further blocking thrombin generation.

on fibrinogen, fibronectin, or vWF. Each fibrinogen molecule has two RGD sites on its polar ends, and the larger vWF multimers have several RGD sites, all capable of binding to conformationally altered GPIIb/IIIa and creating the platelet-ligand-platelet matrix. GPIIb/IIIa is the most abundant glycoprotein on the platelet surface, with about 50,000 copies on the *resting* platelet and additional GPIIb/IIIa receptors within the platelet cytosol that are mobilized to the surface after activation.

ACTIVATION

Platelets are also recruited into the platelet plug by local agonists (collagen, epinephrine, and thrombin) and by platelet release of agonists into the local microenvironment. Both collagen (as noted previously) and thrombin interact with their specific platelet receptors to activate platelets strongly; although epinephrine alone is not a powerful platelet agonist, stimulation of the α -adrenergic receptor on platelets primes them for synergistic activation by even relatively weak agonists such as ADP. Activating compounds released directly from the platelet include thromboxane A_2 (TXA $_2$), which is formed in the platelet cytosol after cyclooxygenase-1 (COX-1)-mediated cleavage of arachidonic acid and then released into the clot milieu. TXA $_2$ is both a platelet agonist and a vasoconstrictor, and it is rapidly degraded to its inert by-product, thromboxane B $_2$. Platelet COX-1 activity is *irreversibly* inhibited by aspirin, thereby blocking TXA $_2$ formation for the lifetime of that platelet. Aspirin irreversibly and covalently binds to a specific serine residue on COX-1 and causes steric hindrance of the active site, a tyrosine molecule across from the serine residue. Nonsteroidal anti-inflammatory drugs (NSAIDs) do not covalently bind through acetylation at serine. Instead, they reversibly and competitively bind at the active, catalytic tyrosine site. Thus, the antiplatelet

effects of NSAIDs are dependent on the continual presence of plasma levels of the NSAID, unlike aspirin. COX-2 is an induced isoform within leukocytes that mediates inflammation and pain. Because mature platelets do not appear to possess COX-2 activity, one rationale for development of the highly selective COX-2 inhibitors for inflammatory diseases was the avoidance of bleeding caused by platelet dysfunction by not affecting platelet COX-1 activity. However, it appears that vascular ECs use COX-2 activity to synthesize the anti-thrombogenic compound, prostacyclin (see Table 52-1 and Chapter 55). Downregulation of EC prostacyclin, coupled with preserved platelet prothrombotic function, may tip the hemostatic balance in favor of clot formation, and large-scale clinical trials have now shown that some highly selective COX-2 inhibitors increase the likelihood of hypertension and vascular arterial events, including myocardial infarction and stroke.

Other platelet agonists are liberated into the extracellular fluid by fusion of the dense and α granules with the platelet canalicular membrane, and the result is extrusion of granule contents. The dense granules contain serotonin that, similar to TXA $_2$, is both a platelet agonist and a vasoconstrictor. Another dense granule constituent, ADP, acts purely as a platelet agonist through the G-protein-linked P2Y $_{12}$ receptor and has no vasoactive properties (see Table 52-2). The importance of TXA $_2$ - and serotonin-induced vasoconstriction is not entirely clear. However, vasoconstriction, by decreasing the vessel diameter, may increase shear stress and thereby facilitate recruitment of platelets to the injured site. The importance of dense granule release to the maintenance of hemostasis is underscored by the severe bleeding seen in congenital dense granule deficiencies (e.g., Hermansky-Pudlak syndrome). Platelet activation therefore serves to amplify platelet adhesion and, as detailed later, optimize the platelet surface for interaction with soluble coagulation

factors that results in explosive generation of thrombin and fibrin.

Soluble Coagulation

COAGULATION MODELS

The “cascade” model of soluble coagulation (see Fig. 52-2), as first described more than 40 years ago, features two starting points that converge to a common pathway leading to thrombin and fibrin generation. This model allowed great strides to be made in identifying the proteolytic reactions that culminate in fibrin clot and dovetailed well with the prothrombin time (PT) and activated partial thromboplastin time (aPTT) assays that guide warfarin and heparin dosing, respectively. Although workable for some clinical scenarios, bleeding in a disease such as hemophilia contradicts the model’s prediction that when one of these pathways is dysfunctional, activity of the other should be sufficient to maintain adequate clot formation. More recent models have made significant strides in clarifying the dynamics of coagulation. Regulation of coagulation proteins is characterized by continuous low-grade factor activation and coordinated assembly of enzyme complexes, which are downregulated by circulating inhibitor proteins. These enzyme complexes consist of serine proteases, their cofactors, and zymogen substrates. In the absence of overt blood vessel disruption, enzyme complex formation and the resultant thrombin generation are both minimal and relatively slow; circulating anticoagulants are sufficient to inactivate these procoagulant complexes and prevent clot formation. However, once a procoagulant stimulus occurs that generates significant amounts of activated factors, formation of these enzyme complexes is rapidly amplified (partly by its assembly on a favorable membrane (phospholipid) surface), leading to intense thrombin, and subsequent fibrin, formation.

CLOT INITIATION

Coagulation *in vivo* follows exposure of the blood to a source of TF, typically on the surface of a fibroblast coming into contact with blood through a break in the vessel wall. The intrinsic or contact pathway of coagulation has no role in the earliest events in clotting. TF-initiated coagulation has two phases: an *initiation* phase and a second referred to as the *propagation* phase (see Fig. 52-2). The initiation phase begins as the exposed TF binds to factor VIIa, picomolar amounts of which are present in the circulation at all times. This VIIa-TF complex catalyzes the conversion of very small amounts of factor X to Xa, which in turn, generates nanomolar amounts of thrombin. The seemingly trivial amount of thrombin formed during the initiation phase sparks the inception of the propagation phase, successful completion of which culminates in explosive thrombin generation and, ultimately, fibrin deposition. More than 96% of the total thrombin that is generated during clotting occurs during the propagation phase.

CLOT PROPAGATION

Thrombin generated during the initiation phase is a potent platelet activator, supplying the developing clot with an acti-

vated platelet surface membrane and abundant platelet-released factor V, which is promptly activated to Va by thrombin. Factor VIII, conveniently brought to the bleeding site by its carrier, vWF, is also activated by thrombin, a step that causes its release by vWF. VIIIa then complexes with the picomolar amounts of factor IXa generated by the TF-VIIa complex during the initiation phase to create the VIIIa-IXa complex. The formation of this complex on the platelet surface heralds the switch of the primary path of Xa generation from the TF-VIIa complex (the extrinsic Xase) to the intrinsic Xase (the VIIIa-IXa complex). This switch is of significant kinetic advantage, with the intrinsic Xase complex exhibiting 50-fold higher efficiency than the extrinsic Xase. The bleeding diathesis associated with hemophilia is testament to the physiologic importance of the exuberant thrombin generation engendered by the switch from extrinsic to intrinsic Xase. The aPTT, which measures the initiation phase of clotting begun by an artificial *in vitro* stimulant, is prolonged by severe deficiencies in either VIII or IX, but it is thrombin generation during the propagation phase, a function not evaluated by the aPTT, that is most impaired in hemophilia.

The activated platelet expresses receptors for VIIIa, and IXa, and binding of these active proteases in complex with membrane phosphatidylserine enhances the binding of the enzyme’s substrate, factor X, enhancing the kinetic efficiency of the intrinsic Xase complex. Assembly of the prothrombinase complex is similarly dependent on the activated platelet surface for optimal activity. Like the Xase complex, the membrane-bound prothrombinase complex activates prothrombin with a rate enhancement 300,000-fold higher than free Xa acting on prothrombin in solution. Platelet-bound Xa is the rate-limiting enzyme in prothrombin cleavage for both the initiation and propagation phases of clotting; its substrate, prothrombin, binds to GPIIb/IIIa on both activated and unactivated platelets. The net kinetic advantage conferred by platelet binding is such that assembly of the entire reaction on the platelet membrane is a 13 million-fold increase in catalytic efficiency over that of proteases free in solution.

What role do other intrinsic pathway factors play in coagulation? Evidence is growing that factor XI further amplifies the propagation phase of coagulation. Factor Xa is particularly rate limiting once the switch is made to the intrinsic Xase. Although small amounts of IXa are generated by the TF-VIIa complex, IXa generation in this manner is limited by TFPI. To generate Xa in amounts sufficient to fuel the propagation phase, a kinetically superior source of IXa is required. Factor XI is another zymogen activated by very small amounts of initiation phase-generated thrombin, but this activation is restricted to the activated platelet surface. Platelet-bound XIa activates IX on the platelet surface, thereby favoring assembly of the intrinsic Xase complex. Moreover, binding to the platelet surface protects XIa from its inhibitor, protease nexin 2. Thus, XIa generation on the activated platelet is instrumental for providing IXa in amounts sufficient to maintain peak Xa generation through the efficient intrinsic Xase complex.

LIMITING SOLUBLE COAGULATION

Endogenous anticoagulants can either inactivate formed thrombin or prevent thrombin generation. The most impor-

Figure 52-4 Balanced fibrinolysis limiting the platelet-fibrin clot. The platelet plug and fibrin matrices are strengthened by incorporating factor XIIIa into the fibrin clot. Factor XIIIa also binds α_2 -antiplasmin to the clot to protect it from plasmin-mediated fibrinolysis. At the same time, nearby intact endothelial cells (ECs) secrete tissue-type plasminogen activator (t-PA). t-PA that evades plasminogen activator inhibitor-1 (PAI-1) converts clot-bound plasminogen to plasmin and leads to fibrin clot degradation and release of soluble fibrin peptides and D-dimer. Thus, detection of circulating D-dimer generally indicates active fibrinolysis.

tant of the former is antithrombin (AT). AT is physiologically present at over twice the concentration ($3.2 \mu\text{mol/L}^{-1}$) of the highest local thrombin concentration ($1.4 \mu\text{mol/L}^{-1}$) that can be reached during clotting, and AT activity against thrombin is potentiated 1000-fold by endogenous EC-associated heparan sulfate proteoglycans. Platelet surface membranes and platelet-released platelet factor 4 protect thrombin from inactivation at the clot. However, any thrombin that escapes into the circulation is immediately (<1 minute) inhibited by plasma AT, and in the microenvironment of healthy ECs that bind about 60,000 molecules of AT per cell, free thrombin is neutralized almost instantaneously. Thus, early thrombin generation is critically dependent on protection by the activated platelet membrane for sufficient time to transition from initiation to the propagation phase.

Among endogenous anticoagulants that target thrombin generation, the earliest in the coagulation process is TFPI, mentioned previously, which inactivates factor Xa and the TF-VIIa complex. TFPI is constitutively released by EC into the microvasculature. Under normal conditions, TFPI is largely localized to the endothelial surface by binding to EC-associated glycosaminoglycans but can be displaced by heparin. Nascent TFPI has direct activity only against Xa, but following exposure to Xa, TFPI acquires activity against the TF-VIIa complex. During the initiation phase, platelet-bound Xa is protected from inactivation by both TFPI and antithrombin. Preservation of the small amounts of Xa that are generated during this early stage of coagulation is critical to formation of the nanomolar amounts of thrombin needed to begin the propagation phase of clotting.

Activated protein C (APC) has anticoagulant, anti-inflammatory, and profibrinolytic properties that make it an important regulator of both thrombosis and inflammation. Like TFPI, protein C becomes activated only after coagulation is underway. Formed thrombin binds to thrombomodulin, a proteoglycan associated with endothelial and monocyte cell surfaces. Thrombomodulin-bound thrombin loses its ability to activate platelets and instead activates protein C. On the EC surface, nascent protein C binds to endothelial cell protein C receptor (EPCR), which posits it for activation by the adjacent thrombomodulin-bound

thrombin. In a reaction that is enhanced by EPCR and protein S, APC inactivates factors VIIIa and Va, components of the Xase and prothrombinase complexes, respectively, thereby limiting procoagulant self-amplification (Fig. 52-4). As with other coagulation factors, the activated platelet membrane protects VIIIa and Va from APC inactivation. In addition to its effects on thrombin generation, APC neutralizes plasminogen activator inhibitor-1 (PAI-1) to enhance clot remodeling. APC has anti-inflammatory properties as well; recombinant APC reduces tumor necrosis factor- α production after endotoxin challenge, and protein C-deficient mice (heterozygotes) exhibit higher levels of pro-inflammatory cytokines with systemic endotoxemia.

The liver is the major site of synthesis of all coagulation factors. In liver disease, however, factor VIII levels are not generally diminished because VIII is also produced by EC and the reticuloendothelial system. The subset of coagulation factors dependent on vitamin K for synthesis include prothrombin (II), VII, IX, and X, and the anticoagulants, proteins C and S. Post-translational modification (through a vitamin K-dependent carboxylase) of the amino-terminal domain of these proteins adds 10 to 12 γ -carboxyglutamate residues; these residues are critical for calcium binding and for determining the functional three-dimensional structure of the proteins and their proper binding orientation to membrane surfaces. Warfarin blocks vitamin K epoxide reductase and thereby decreases generation of vitamin K (from vitamin K epoxide) in the vitamin K cycle.

LABORATORY TESTING OF COAGULATION

For purposes of laboratory testing, the coagulation cascade is artificially divided into extrinsic (PT) and intrinsic (PTT) pathways, which converge to form a common pathway leading to thrombin and fibrin generation (see Fig. 52-2). In the laboratory, the *extrinsic* pathway (PT) is assessed by measuring the interaction of circulating VIIa with exogenously added TF (also known as *thromboplastin*). The PT is highly sensitive to deficiencies of factors VII, V, X, and II, all of which are associated with significant bleeding. Because II,

VII, and X are also vitamin K dependent, with VII having the shortest circulating half-life, the PT is currently the best test for monitoring warfarin (Coumadin) therapy. The PT is unaffected by intrinsic pathway deficiencies of XII, XI, IX, or VIII. The degree of prolongation of the PT by warfarin depends on the strength of the particular thromboplastin (based on its international sensitivity index [ISI]) and the specific coagulation instrument used for the assay. The international normalized ratio (INR) takes these factors into account to standardize among laboratories for variations in the prolongation of the PT induced by warfarin. The INR is calculated for each patient as follows: (patient PT/mean control PT^{ISI}). Therapeutic INRs with warfarin allow for global application of anticoagulant recommendations; these vary according to the specific disease indication and are covered in Chapter 53. In contrast to warfarin, the PT is relatively insensitive to therapeutic anticoagulation with unfractionated heparin.

The PTT measurement is based on *in vitro* contact activation (e.g., plasma stimulation with a negatively charged compound such as kaolin). The PTT is sensitive to deficiencies of contact factors (prekallikrein [PK], high-molecular-weight kininogen [HMWK], and factor XII), and coagulation factors of the intrinsic (XI, IX, and VIII) and common pathways (V, X, and prothrombin). Deficiencies of PK, HMWK, and XII prolong the PTT but do not result in clinical bleeding, implying that these factors are irrelevant to physiologic hemostasis. By contrast, severe deficiencies of XI, and especially IX and VIII, cause significant bleeding. The PTT is also highly sensitive to unfractionated heparin and is used to monitor therapeutic heparin anticoagulation. Unlike the INR for anticoagulation with warfarin (Coumadin), the range for therapeutic PTT levels with unfractionated heparin is much wider and not as easily standardized. Therapeutic unfractionated heparin levels can be measured by sensitive assays of anti-Xa activity; therapeutic levels of 0.3 to 0.7 anti-Xa U/mL generally correspond to a PTT of between 1.8 and 2.5 times either the patient's baseline PTT (before starting heparin) or the mean PTT of a control population.

It is worth noting that most of the commonly used laboratory tests of soluble coagulation measure the kinetics of the initiation phase only. The PT and PTT have as their endpoints the first appearance of fibrin gel, which occurs with less than 5% of the total reaction complete, and only minimal levels of prothrombin have been activated. The PT and PTT are very sensitive for detecting congenital abnormalities associated with severe factor deficits (e.g., hemophilia) and for guiding heparin and warfarin therapy. However, these tests fail to give information relevant to thrombin generation during the propagation phase, which determines whether a persistent clot forms or the endogenous anticoagulants and fibrinolytic regulators constrain it from excess growth.

Clot Viability and Maturation

Evidence is growing that initial formation of a thrombus does not ensure sustained hemostasis. Events initiated during thrombus generation that are critical to its stability operate after the clot is formed, whether fibrin rich in the venous or platelet rich in the arterial circulation.

FIBRIN CLOT ARCHITECTURE

The architecture of a fibrin clot is surprisingly variable, and although genetic factors unquestionably play a role in determining clot structure, two dominant factors are the local thrombin and fibrinogen concentrations, whose reaction yields the fibrin strands. A thrombin-rich microenvironment typically results in thinner, more tightly cross-linked fibers, making the overall fibrin clot virtually impermeable to lytic enzymes, as opposed to thrombin-poor locations where the fibrin strands are thicker and the structure more porous, making the clot vulnerable to thrombolysis. Similarly, high fibrinogen concentrations are associated with large thrombi whose tight, rigid meshwork makes them less deformable and more lysis resistant. Low fibrinogen concentrations, by contrast, produce a less compact clot that is highly lysis prone.

FIBRIN CROSS-LINKING BY FACTOR XIIIa

Factor XIII also plays a critical role in stabilizing the forming clot. XIII circulates in the plasma and is also stored within platelets; indeed, fully 50% of total fibrin-stabilizing activity in blood resides in the platelet and is released by activation. In plasma, XIII is a tetrameric molecule consisting of two α subunits, containing the active site of the enzyme, and two β subunits, which increase the zymogen's plasma half-life but must be dissociated for full enzyme activity. Platelet factor XIII, by contrast, is a dimer that contains only the two α subunits. Both forms of the zymogen require thrombin cleavage and fibrin as a cofactor, but plasma XIII activation proceeds at a considerably slower rate owing to the need for dissociation of the β subunits. Thrombin-activated XIIIa binds to fibrin and cross-links the fibrin units, thereby rendering them less permeable and more resistant to lysis. Furthermore, XIIIa cross-links the major plasmin inhibitor, α_2 -antiplasmin, directly to fibrin, positing it for neutralization of any invading plasmin.

FIBRINOLYSIS

The fibrinolytic system operates to prevent fibrin from occluding healthy vessels. During clot formation, Xa and thrombin stimulate healthy ECs to release tissue plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA), both capable of cleaving plasminogen into plasmin. The vast excess of plasminogen present in the plasma dictates that under normal circumstances, the concentration of these enzymes is rate limiting for plasmin formation. The kinetic efficiency of t-PA is improved by at least an order of magnitude by the presence of fibrin, thus helping keep t-PA most active in the microenvironment of the clot. By contrast, u-PA appears to require binding to activated platelets for its ability to liberate plasmin.

Acting to contain fibrinolysis are plasma mediators that either inactivate formed plasmin (e.g., α_2 -antiplasmin and possibly α_2 -macroglobulin) or block plasmin formation, foremost of which is PAI-1. PAI-1 is present in several-fold molar excess in the plasma and is also released by activated platelets, thereby protecting clots from premature lysis. PAI-1 plasma levels can be highly variable, in part because of its circadian pattern of secretion, but also because of

polymorphisms of the PAI-1 gene. The 4G promoter region polymorphism of PAI-1 is associated with higher PAI-1 levels and a higher risk for thromboembolic disease (see Chapter 54). Another mediator that limits fibrinolysis in the vicinity of the clot is thrombin activator fibrinolysis inhibitor (TAFI). TAFI is synthesized in an inactive form by the liver and circulates in the plasma, possibly in a complex with plasminogen. TAFI cleaves specific fibrin lysine residues that would otherwise promote binding of fibrinolytic enzymes (e.g., plasmin). TAFI requires either plasmin or thrombin for activation; however, thrombin activation of TAFI requires extraordinarily large amounts of *free* thrombin. By contrast, EC-associated thrombomodulin potentiates thrombin-induced TAFI activation 1250-fold, making this an essential cofactor and one that is predominantly available only at the blood-vessel interface. In addition to the EC surface, macrophages are also critical to fibrinolysis. Macrophages degrade fibrin clot through lysosomal proteolysis by a plasmin-independent mechanism. The macrophage binds to fibrin and fibrinogen through its surface

integrin receptor, CD11b/CD18; this binding is followed by internalization of the complex into the lysosome, where fibrin and fibrinogen are degraded.

Tissue repair and regeneration are the physiologic end-points of clotting, eventually leading to dissolution of the fibrin-based clot. Besides t-PA and urokinase, the intrinsic pathway activators kallikrein, XIIa, and XIa also generate active plasmin from plasminogen. Plasminogen binding to cell surface receptors promotes its own activation to plasmin by placing it in proximity to t-PA and fibrin clot and protects plasmin from inactivation by circulating (not clot-bound) α_2 -antiplasmin (see Fig. 52-4). Plasmin eventually dissolves the fibrin matrix to produce soluble fibrin peptides and D-dimer and also activates metalloproteinases that further degrade damaged tissue. Fibroblasts and leukocytes migrate into the wound, the latter mediated by selectin binding, and these inflammatory cells act in concert with growth factors secreted by leukocytes and activated platelets (e.g., transforming growth factor- β) to enhance vascular repair and tissue regeneration.

Prospectus for the Future

Interindividual Variability and the Extremes of “Normal”

The understanding of hemostasis physiology has been advanced by kinetic models using the interplay of cells and soluble coagulation factors. In such models, thrombin is clearly an important, if not central, coordinator of hemostatic function and thus is a target for measurement to assess hemostatic function and risk. However, as noted previously, the PT and PTT do not begin to measure the full physiology of the hemostatic response, and the platelet contribution to clotting is absent in such tests. It remains to be seen whether newer measurements such as endogenous thrombin potential or older methods such as thromboelastography can better quantitate global hemostatic function. Furthermore, the concept of the normal range for

hemostasis factors may not be adequate for predicting outcomes. Indeed, measuring an individual’s capacity to generate activated mediators and their kinetics has shown an extreme range of biologic variability. For example, total amounts and peak rate of thrombin formation and platelet amplification of thrombin generation demonstrate a remarkable breadth of “normal.” The evolution of more sophisticated coagulation testing may demand more than a simple normal range, perhaps paralleling our clinical understanding of risk factors instead as a continuous predictor of a patient’s response to hemostatic challenge. The goal would be to better identify patients whose coagulation response, although appropriate for most situations, may be insufficient to protect them, under stress, from either excessive bleeding or pathologic thrombosis.

Disorders of Hemostasis: Bleeding

Christopher A. Tormey and Henry M. Rinder

Clinical Evaluation of Bleeding

The evaluation of bleeding requires a careful history, physical examination, and laboratory evaluation. The patient's history should include a description of bleeding (e.g., epistaxis, menorrhagia, hematoma formation), the circumstances under which bleeding occurs (e.g., association with trauma, surgery, dental procedures), and whether any blood products (and what kind) are required to staunch bleeding. The temporal addition of medications, such as aspirin, can be associated with bleeding, as can concomitant medical illnesses such as infection or liver disease. Finally, determining a family history of bleeding is critical; the physician may need to query several generations and second-degree relations, such as maternal uncles, when hemophilia is suggested in the proband.

The physical examination may yield some clues as to the origin of bleeding by distinguishing between small vessel bleeding, such as petechial (pinpoint) hemorrhage, from larger vessel bleeding, which usually produces hematomas and purpura (large bruises). Small vessel bleeding in the skin, in the mucous membranes, or in the gastrointestinal (GI) tract tends to occur more often in patients with thrombocytopenia, qualitative platelet defects, vascular abnormalities, and von Willebrand disease (vWD). In women, menorrhagia may be the only symptom of a bleeding disorder and should never be assumed to be solely attributed to a gynecologic etiology. Large vessel bleeding in organs, joints, or muscles is more commonly associated with factor deficiencies, such as hemophilia. Screening laboratory assays are useful in the initial assessment of the bleeding patient (Table 53-1) and should include (1) *blood cell counts* (especially the platelet count) and examination of the peripheral blood smear; (2) *prothrombin time* (PT), which is highly sensitive to defects in vitamin K–dependent coagulation factors; and (3) *partial thromboplastin time* (PTT), which detects deficiencies in factors VIII, IX, and XI. Abnormalities of factors X, V, and II (prothrombin) result in elevations of both the PT and the PTT. If the PT or PTT is prolonged, the

patient's plasma should be combined with normal plasma (*mixing study*) and the clotting time study repeated. The mixing study distinguishes between factor deficiency (the PT or PTT corrects into the normal range) and a circulating inhibitor (the clotting time remains prolonged). Another readily available test for the patient with bleeding is the *thrombin time*, which assays the functional fibrinogen level.

Platelet function has been traditionally assessed by the *in vivo bleeding time*, an invasive measure of the time to halt bleeding in a skin incision. The bleeding time is prolonged by qualitative platelet defects and by rare connective tissue disorders. The bleeding time test is dependent on the expertise of the technician performing the test, and its poor reproducibility and the difficulty of performing the test in infants and neonates have limited its use. Several instruments use phlebotomized whole blood for *in vitro* assessment of platelet function. One such instrument that delivers an *in vitro bleeding time* is the Platelet Function Analyzer-100 (PFA-100); in this instrument, citrate-anticoagulated whole blood is passed through a small orifice in a cartridge impregnated with platelet activators such as collagen, adenosine diphosphate (ADP), and epinephrine. As the platelets activate and adhere, the orifice gradually becomes obstructed, and the time to complete occlusion by the platelet plug is measured as the closure time. The closure time is prolonged by qualitative platelet defects such as caused by aspirin and by vWD. Although thrombocytopenia (<100,000 platelets/mcL) obviates use of the closure time similar to the *in vivo* bleeding time, these *in vitro* tests are gradually supplanting the bleeding time.

Another laboratory study for evaluation of a prolonged PTT, especially in the inpatient setting, is performing the PTT with an added substance (polybrene, protamine, heparinase) to neutralize any contaminating heparin as a result of drawing the blood through an intravenous line. A prolonged PTT that does not correct with the mixing study may also be observed in patients with a lupus anticoagulant (often in the context of thrombosis). In this setting, the diagnosis of a lupus anticoagulant can be confirmed by documenting the correction of the PTT with the addition of

Table 53-1 Screening Hemostasis Assays

Laboratory Test	Aspect of Hemostasis Tested	Causes of Abnormalities
Blood counts and peripheral blood smear	Platelet count and morphologic features	Thrombocytopenia; thrombocytosis; gray platelet and giant platelet syndromes
Prothrombin time	Factor VII–dependent pathways	Vitamin K deficiency and warfarin; liver disease; DIC; factor deficiency (VII, V, X, II), factor inhibitor
Partial thromboplastin time	Factor XI–, IX–, and VIII–dependent pathways	Heparin; DIC; lupus anticoagulant*; vWD; factor deficiency (XI, IX, VIII, V, X, II), factor inhibitor
Thrombin time	Fibrinogen	Heparin; DIC; hypofibrinogenemia; dysfibrinogenemia
Platelet function analysis	Platelet and vWF function	Aspirin; vWD; storage pool disease
Mixing study	Presence of an inhibitor	Abnormal clotting time corrects with a deficiency; does not correct with an inhibitor

*Lupus anticoagulant is not associated with bleeding.
 DIC, disseminated intravascular coagulation; vWD, von Willebrand disease; vWF, von Willebrand factor.

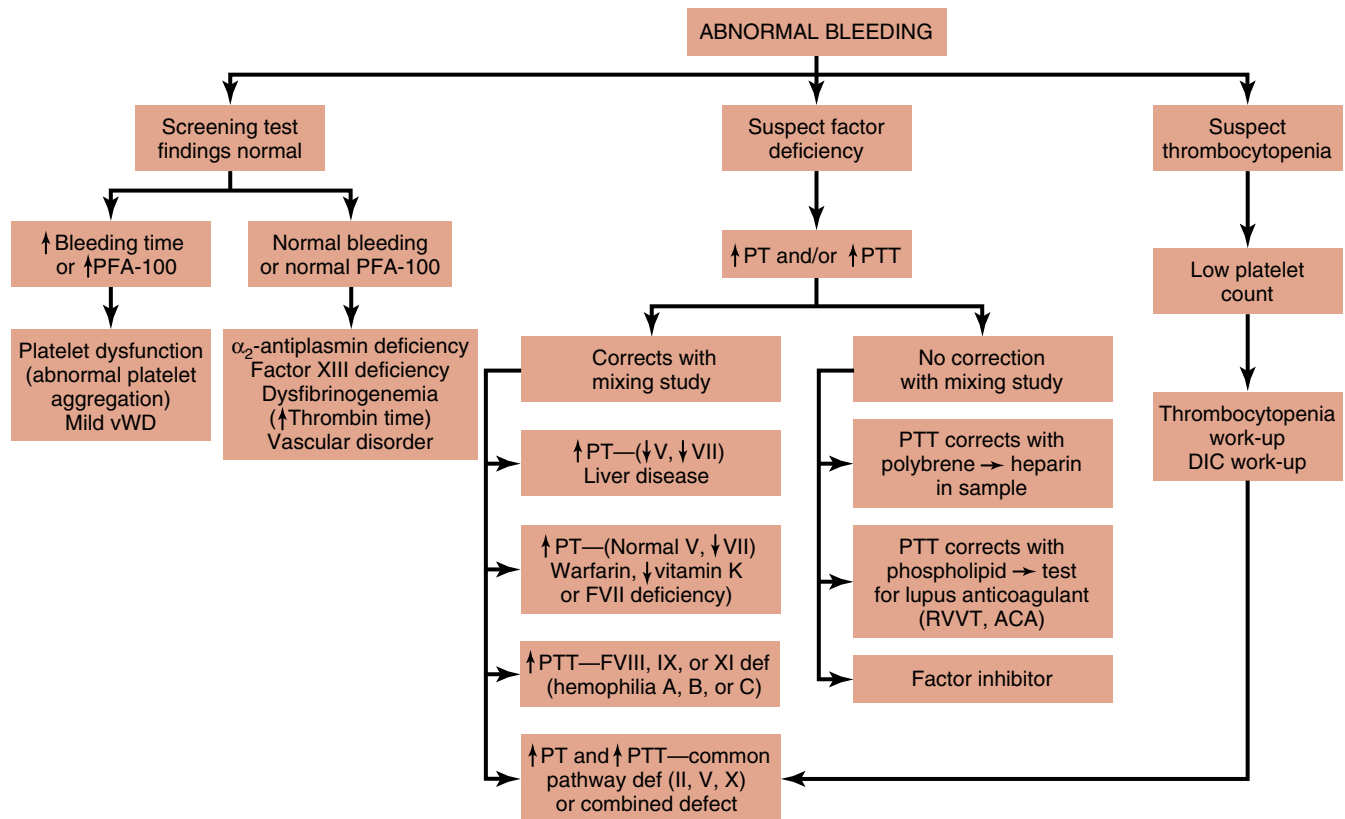

Figure 53-1 Algorithm for the evaluation of bleeding. Screening laboratory tests for platelet and factor deficiencies are used to narrow the work-up for bleeding, followed by specific factor and other coagulation studies (e.g., mixing studies, D-dimer) to confirm the diagnosis. ACA, anticardiolipin antibody; DIC, disseminated intravascular coagulation; FVIII, factor VIII; PFA-100, Platelet Function Analyzer-100; PT, prothrombin time; PTT, partial thromboplastin time; RVVT, Russell viper venom time; vWD, von Willebrand disease.

excess phospholipid as well as other specific tests for lupus anticoagulant (see “Antiphospholipid Antibody Syndrome” in Chapter 54).

A rapid approach to identifying possible causes of bleeding (Fig. 53-1) should consider the following major disease categories: (1) vWD, thrombocytopenia, or abnormal platelet function; (2) low levels of multiple coagulation factors resulting from vitamin K deficiency, liver disease, or disseminated intravascular coagulation (DIC); (3) single-factor deficiency, generally inherited; and more rarely, (4) an

acquired inhibitor to a coagulation factor such as factor VIII. The laboratory evaluation is most efficient when performed in this context.

Vascular Causes of Bleeding

Vascular purpura (bruising) is defined as bleeding caused by intrinsic structural abnormalities of blood vessels or

by inflammatory infiltration of blood vessels (*vasculitis*). Although vascular purpura usually causes bleeding in the setting of normal platelet counts and normal coagulation studies, vasculitis and vessel damage may be severe enough to cause secondary consumption of platelets and coagulation factors. Collagen breakdown and thinning of the subcutaneous tissue that overlies blood vessels is often observed in older patients and is termed *senile purpura*; similar atrophic skin changes are also common effects of steroid therapy. Another acquired cause of vascular purpura is scurvy, or vitamin C deficiency. *Scurvy* is characterized by bleeding around individual hair fibers (*perifollicular hemorrhage*) and corkscrew-shaped hairs. Bruising occurs in a classic *saddle* pattern, distributed over the upper thighs. The bleeding gums with scurvy are caused by gingivitis and not by the subcutaneous tissue defect. Thus, edentulous patients with scurvy do not have bleeding gums, and scurvy should not be excluded on this basis.

Congenital defects of the vessel wall may cause bruising. These rare syndromes include *pseudoxanthoma elasticum*, a defect of the elastic fibers of the vasculature that is associated with severe GI and genitourinary bleeding, and *Ehlers-Danlos syndrome*, characterized by abnormal collagen molecules in both blood vessels and subcutaneous tissue. Both syndromes exhibit bruising in the skin, but only patients with *pseudoxanthoma elasticum* develop significant GI bleeding. Another inherited vessel wall defect associated with GI bleeding is *hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome)*. This disorder is characterized by degeneration of the blood vessel wall that results in angiomatous lesions resembling blood blisters on mucous membranes, including the lips and GI tract. The frequency of bleeding caused by a breakdown of these lesions increases with age, and GI lesions commonly cause significant, chronic bleeding, often resulting in iron deficiency.

The sudden onset of *palpable purpura* (localized, raised hemorrhages in the skin) in association with rash and fever may be caused by vasculitis, either aseptic or septic. *Septic vasculitis* may be caused by meningococemia and other bacterial infections and is often accompanied by thrombocytopenia and prolongation of clotting times. One cause of aseptic vasculitis in young children and adolescents is *Henoch-Schönlein purpura*, a vasculitis of the skin, GI tract, and kidneys, which is usually accompanied by abdominal pain caused by bleeding into the bowel wall. This syndrome may occur after a viral prodrome and appears to be caused by an immunoglobulin A (IgA) hypersensitivity reaction, as evidenced by serum IgA immune complexes and renal histopathologic features resembling IgA nephropathy. *Drug hypersensitivity*, for example, to allopurinol can exhibit extensive cutaneous purpura as well.

The therapy of bleeding from vascular disorders is straightforward. Senile purpura and steroid-induced purpura do not usually require treatment. Scurvy is corrected by oral ascorbic acid. In the case of congenital disorders, including Ehlers-Danlos syndrome, hereditary hemorrhagic telangiectasia, and *pseudoxanthoma elasticum*, patients should avoid medications that may aggravate their bleeding tendencies (e.g., aspirin), and they should receive supportive therapy (e.g., iron supplementation, red blood cell transfusion). Systemic administration of estrogen in hereditary hemorrhagic telangiectasia may help decrease

epistaxis by inducing squamous metaplasia of the nasal mucosa and thereby protecting lesions from trauma. Treatment of septic vasculitis focuses on appropriate antibiotic therapy; in the case of aseptic vasculitis, steroids and immunosuppressive agents are most effective. When vasculitis is severe enough to cause consumption of platelets and coagulation factors (see discussion of DIC), transfusions of platelets, cryoprecipitate, or fresh-frozen plasma (FFP) may be indicated.

Bleeding Caused by Platelet Disorders: Thrombocytopenia

Thrombocytopenia (platelet count $<150,000/\text{mcL}$) is one of the most common problems in hospitalized patients. The initial diagnostic approach to thrombocytopenia involves classifying whether the low platelet count is caused by (1) decreased platelet production, (2) increased platelet sequestration, or (3) increased platelet destruction (Fig. 53-2). An evaluation of the number and morphologic features of marrow megakaryocytes has been the traditional diagnostic test for differentiating between decreased platelet production and peripheral sequestration (e.g., splenomegaly) or destruction (e.g., immune thrombocytopenic purpura [ITP]). The reticulated platelet count is used as a peripheral blood index of platelet kinetics in the evaluation of thrombocytopenia.

THROMBOCYTOPENIA CAUSED BY DECREASED MARROW PRODUCTION

Decreased production of platelets from the bone marrow is characterized by decreased or absent megakaryocytes on the bone marrow aspirate and biopsy and a low percentage of circulating reticulated platelets. Suppression of normal megakaryocytopoiesis occurs after (1) marrow damage and destruction of stem cells, such as with cytotoxic chemotherapy; (2) destruction of the normal marrow microenvironment and replacement of normal stem cells by invasive malignant disease, aplasia, infection (e.g., miliary tuberculosis), or myelofibrosis; (3) specific but rare intrinsic defects of the megakaryocytic stem cells; and (4) metabolic abnormalities affecting megakaryocyte maturation.

Thrombocytopenia may result from cytotoxic or immunosuppressive chemotherapy for malignant or autoimmune disease. Thrombocytopenia is usually reversible, and platelet production rebounds as megakaryocytic stem cells eventually recover and regenerate. However, repeated or intensive chemotherapy (e.g., stem cell transplantation) may permanently damage the megakaryocytic stem cells and supporting stromal environment and may cause chronic thrombocytopenia. This condition may be accompanied by leukopenia and anemia, similar to the presentation of *de novo myelodysplasia*. Commonly used drugs such as thiazide diuretics, alcohol, and estrogens may also damage bone marrow megakaryocytes. Nutritional disorders, especially alcoholism and abnormal folate or vitamin B₁₂ metabolism, are also commonly associated with thrombocytopenia; platelet counts

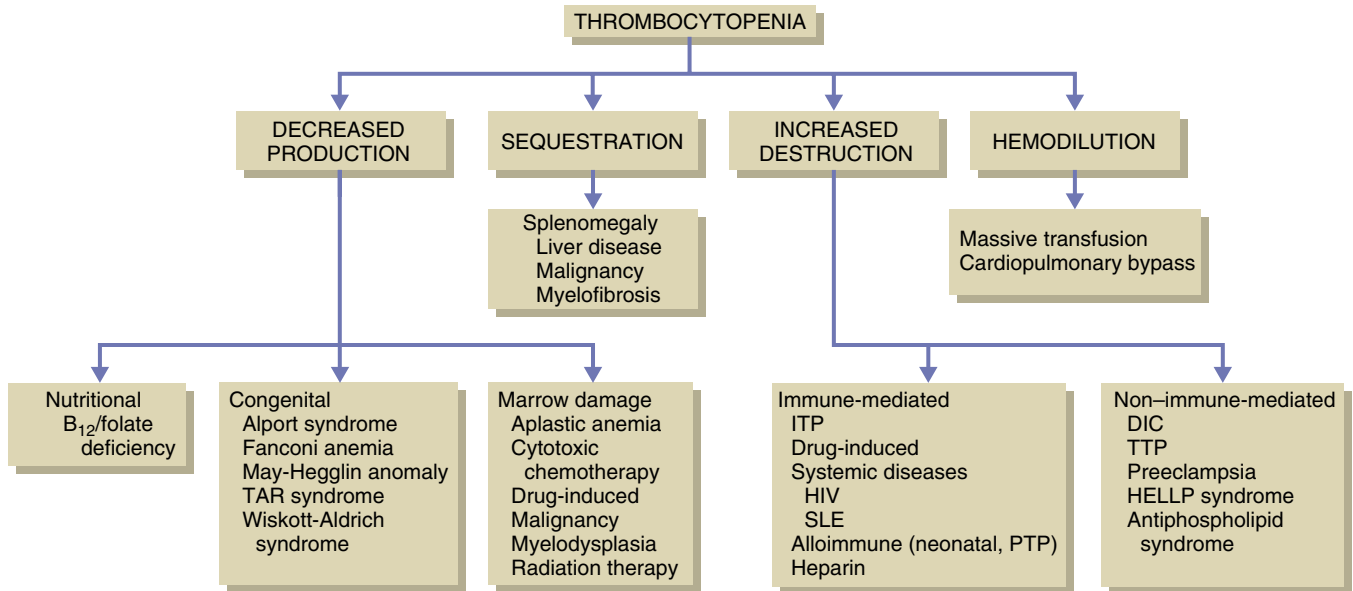

Figure 53-2 Differential diagnosis of thrombocytopenia. Disorders resulting in a decrease in circulating platelet number can be divided into four main pathophysiologic mechanisms: hypoproduction, sequestration, peripheral destruction, and hemodilution. The history, physical examination, and bone marrow evaluation usually narrow the range of possible causes. DIC, disseminated intravascular coagulation; HELLP, hemolysis, elevated liver enzymes, and low-platelet count in association with pregnancy; HIV, human immunodeficiency virus; ITP, immune thrombocytopenic purpura; PTP, post-transfusion purpura; SLE, systemic lupus erythematosus; TAR, thrombocytopenia-absent radius syndrome; TTP, thrombotic thrombocytopenic purpura.

respond to abstinence from alcohol and to appropriate multivitamin replacement therapy. Thrombocytopenia is also observed in patients with severe aplastic anemia, and the bone marrow shows decreased or absent megakaryocytes with other cell lineages similarly affected.

Platelet production is suppressed by intrinsic malignant diseases of the bone marrow such as leukemia and multiple myeloma and by malignant diseases that secondarily invade the bone marrow (non-Hodgkin lymphoma, small cell lung cancer, breast and prostate cancers, among others). The bone marrow aspirate under these circumstances shows decreased megakaryocytes and, occasionally, malignant cells; bone marrow biopsy has a much higher yield for diagnosing malignant involvement of the marrow. Flow cytometric evaluation for clonal B cells in the marrow aspirate is highly sensitive for detecting monoclonal B-cell lymphoproliferative disease (non-Hodgkin lymphoma).

Myelofibrosis, an increase in the reticulin fibers (and sometimes collagen) of the marrow, may lead to thrombocytopenia or pancytopenia. Myelofibrosis occurs most commonly in myeloproliferative disorders, in mastocytosis, and in mycobacterial and other infections involving the marrow. It may also occur occasionally in patients with myelodysplasia or acute megakaryocytic leukemia and rarely on a congenital basis (*osteogenesis imperfecta*).

Thrombocytopenia in children can result from congenital defects of megakaryocyte production as seen with *thrombocytopenia-absent radii syndrome*, *congenital amegakaryocytic thrombocytopenia* (secondary to a mutation in the thrombopoietin receptor), and *Fanconi anemia* (congenital aplastic anemia with renal hypoplasia and skin hyperpigmentation). Other disorders that are intrinsic to the bone marrow include the *May-Hegglin anomaly* and related myosin IIA/MYH9 gene diseases, characterized by giant platelets and Döhle

bodies (basophilic inclusions in leukocytes and platelets). Thrombocytopenia with small platelets is characteristic of *Wiskott-Aldrich syndrome*, an X-linked disorder with eczema and immunodeficiency that can be diagnosed by the lack of CD43 expression on T lymphocytes. When accompanied by nerve deafness and nephritis, congenital hypoproliferative thrombocytopenia is termed *Alport syndrome*.

THROMBOCYTOPENIA CAUSED BY SEQUESTRATION

Up to 30% of circulating platelets are normally sequestered within the spleen at any given time. Conditions that lead to splenomegaly cause increased trapping of platelets and thrombocytopenia, often dropping the platelet count into the range of 50,000 to 100,000/mcL but rarely lower. Thrombocytopenia from sequestration is common in advanced liver disease, myeloproliferative disorders accompanied by splenomegaly (e.g., chronic myelogenous leukemia, chronic idiopathic myelofibrosis), and malignant disease involving the spleen. Splenectomy may be indicated in the latter but is rarely used to treat thrombocytopenia resulting from portal hypertension. The decision to perform splenectomy for thrombocytopenia in patients with myeloproliferative syndromes must be individualized and weighed against surgical complications, loss of the spleen's extramedullary hematopoietic ability, and even rebound thrombocytosis.

THROMBOCYTOPENIA CAUSED BY PLATELET DESTRUCTION

Increased platelet destruction can be caused by immune and nonimmune mechanisms. Autoimmune thrombocytopenia may be a primary disorder directed only at platelets or a

secondary complication of another autoimmune disease, such as systemic lupus erythematosus. Immune platelet destruction is caused by increased levels of polyclonal anti-platelet antibodies directed against platelet membrane glycoprotein receptors, most often cryptic neoepitopes of glycoprotein IIb/IIIa (GPIIb/IIIa) and less commonly GPIb. Coating of the platelet with these antibodies leads to opsonization of the platelets by Fc receptors on cells of the reticuloendothelial system (RES). Antibody-coated platelets are cleared by the spleen and, to a lesser extent, by the liver. These disorders generally involve a dramatic increase in marrow platelet production reflected by increased numbers of marrow megakaryocytes. The younger platelets produced have relatively high granule contents, providing increased hemostatic function. Bone marrow examination for the presence of increased or normal megakaryocyte numbers is the traditional means of distinguishing platelet destruction from decreased production. However, increased percentages of *reticulated platelets* are associated with destructive, especially immune-mediated, thrombocytopenia and may be sufficient for diagnosing platelet destruction. Thrombocytopenia resulting from immune clearance may be severe, and platelet survival is often reduced from the normal 7 to 10 days to less than 1 day. Despite severe thrombocytopenia, serious bleeding or hemorrhagic death is uncommon, partly because the function of young platelets is increased and partly because the number of circulating platelets required to maintain vascular integrity is relatively low, estimated at 7100/mcL per day.

IMMUNE THROMBOCYTOPENIC PURPURA

In children, acute ITP is often preceded by a viral infection, such as varicella. Patients with ITP exhibit petechial hemorrhage and mucosal bleeding; platelet counts are often lower than 20,000/mcL. The blood smear shows large platelets but no other abnormal cells such as blasts, which would accompany childhood leukemia. The bone marrow demonstrates increased or occasionally normal numbers of megakaryocytes. The diagnosis of ITP is partly made by exclusion. Fever, organomegaly, pancytopenia, lymphadenopathy, or abnormal peripheral blood cells should prompt an evaluation for malignant disease, such as leukemia, neuroblastoma, or Wilms tumor, or other bone marrow disorders. Laboratory tests may complement the clinical evaluation but are not required to make the diagnosis of ITP. These tests include the demonstration of an increased percentage of reticulated platelets in the peripheral blood or the detection of platelet autoantibodies in serum or on the platelet (*platelet-associated immunoglobulin*). However, assays of platelet-associated antibodies, though sensitive, are not specific for ITP because immunoglobulins that bind nonspecifically to platelets are often increased in patients with thrombocytopenia secondary to liver disease or HIV infection. In contrast, techniques that measure serum antibodies to specific platelet glycoproteins have greater specificity but are relatively insensitive. An increase in mean platelet volume is also a relatively insensitive indicator of destructive thrombocytopenia, in part because of the wide range of normal values. An increase in the reticulated platelet percentage is consis-

tent with increased platelet destruction but cannot distinguish between ITP and other causes of platelet destruction such as heparin-induced thrombocytopenia (HIT) and thrombotic thrombocytopenic purpura (TTP) (both discussed in greater detail in Chapter 54). Thus the diagnosis of ITP remains largely clinical and does not require laboratory confirmation.

Acute ITP in children can resolve without therapy, but most clinicians prefer to treat children with steroids or intravenous immunoglobulin (IVIG). IVIG therapy for ITP is thought to work by multiple mechanisms: (1) high IgG concentrations block Fc receptors on phagocytes of the RES and on cellular effectors of antibody-dependent cytotoxicity; (2) infusion of IgG increases the fractional rate of IgG catabolism and thereby increases the destruction of anti-platelet IgG in direct proportion to its concentration; and (3) clearance of antiplatelet immunoglobulin may increase through anti-idiotypic effects (i.e., generating an immunologic response to the ITP antibodies). More than 80% of children with acute ITP have a rapid remission, and ITP does not recur. A subset of 10% to 20% of children eventually develops recurrent thrombocytopenia (i.e., chronic ITP); however, more than 70% of such children respond completely to splenectomy. For those with chronic courses after splenectomy, episodic IVIG, RhoGAM (see later discussion in this chapter), and in severe cases, immunotherapy with rituximab (Rituxan) are used. Hemorrhagic deaths are rare in acute childhood ITP (<2%), but some mortality (2% to 5%) is associated with chronic, refractory ITP.

As with children, the diagnosis of ITP in adults is made largely by exclusion, but unlike with children, acute ITP in adults rarely remits spontaneously and is more likely to become a chronic disorder, evolving to chronic ITP in more than 50% of patients. Petechial hemorrhage and mucosal bleeding are accompanied by platelet counts commonly lower than 20,000/mcL and often as low as 1000 to 2000/mcL. Hemorrhagic deaths occur in fewer than 10% of adults with ITP. In adults, ITP may be associated with other diseases, such as HIV or hepatitis C infection. ITP may be the presenting manifestation of HIV infection, whereas thrombocytopenia in more advanced stages of HIV infection is more often caused by bone marrow failure resulting from megakaryocyte infection with HIV, mycobacterial infection of the bone marrow, and nutritional deficiencies of end-stage HIV disease. ITP also occurs in patients with autoimmune disorders such as systemic lupus erythematosus, inflammatory bowel disease, and nonviral hepatitis. In some patients, ITP is accompanied by autoimmune hemolytic anemia, otherwise termed *Evans syndrome*; the direct Coombs test is usually positive indicating the presence of a warm-reactive autoantibody. Initial treatment may not be significantly different from that for ITP alone, but chronic Evans syndrome is thought to generally respond poorly to splenectomy, unlike ITP alone. In the setting of systemic lupus erythematosus, ITP may be secondary to factors associated with the autoimmune disease itself, including immune complex deposition on the platelet surface, as well as active vasculitis, both of which may lead to increased platelet clearance and low counts. Therapy of both ITP and the underlying autoimmune disorder is usually complementary. When the lupus anticoagulant or anticardiolipin antibody is present

in association with systemic lupus erythematosus and thrombocytopenia, the diagnosis of secondary antiphospholipid antibody syndrome is made; this entity is most commonly associated with thromboembolic complications (see Chapter 54).

The first-line treatment of acute ITP in adults is steroids, usually prednisone, 1 to 2 mg/kg per day. Recent studies have suggested that high-dose dexamethasone given in pulses every 14 or 28 days for six to eight doses may result in superior control of disease. Platelet transfusions are not generally used in ITP because transfused-platelet survival is brief and bleeding complications are uncommon. However, in patients with significant bleeding or requiring surgery, platelet transfusions have been safely used and may transiently increase the platelet count, although usually for less than 24 hours. In patients with acute ITP with severe thrombocytopenia (<5000/mcL) or with life-threatening bleeding, high-dose methylprednisolone (1 g per day for 3 days) may be administered alone or in combination with IVIG (2 g/kg in divided doses over 2 to 5 days) and platelet transfusion. In recurrent ITP, chronic steroid treatment is often necessary but is usually accompanied by significant side effects. High-dose pulse dexamethasone given for 4 days every 2 weeks is associated with prolonged responses in about two thirds of chronic ITP patients. Children and adults with chronic ITP who initially respond to IVIG therapy generally respond well to splenectomy, whereas those who do not respond to IVIG are less likely to have disease remission after splenectomy. For all chronic ITP patients, more than 50% have some degree of disease remission after splenectomy. If ITP does recur after splenectomy, the presence of an accessory spleen must be ruled out, usually by liver and spleen scanning, because Howell-Jolly bodies may still be present. Recurrent disease may often be episodic, especially after viral infections, and these patients can be treated with IVIG. Alternatively, patients who are positive for the blood group Rh(D) antigen can be treated with Rh immunoglobulin (RhoGAM), a preparation of IgG class anti-Rh(D) antibodies. Anti-D induces red cell hemolysis (usually mild), thereby presumably causing Fc receptor blockade of the RES and decreased platelet uptake by the spleen and liver. Some patients with ITP, especially those with HIV infection, have experienced significant, even fatal, hemoglobinemia or hemoglobinuria after anti-D therapy, and this therapy should be carefully monitored. RhoGAM is generally ineffective in patients who have undergone splenectomy. In patients who fail to respond to splenectomy, steroid dose may be spared by the addition of a combination of IVIG, vincristine, and anti-D, with danazol and immunosuppressive therapy (e.g., azathioprine). Some patients with chronic ITP have responded to infusions of the anti-CD20 monoclonal antibody rituximab. Finally, chronic ITP with normal marrow cellularity can respond to stimulation of thrombopoiesis using thrombopoietin mimetics and agonist antibodies, which are showing promise in late-phase trials. However, because many patients with chronic ITP will never achieve normal platelet counts, the goal for therapy is often to keep platelet counts higher than 30,000/mcL to avoid significant bleeding. About 5% of adults with ITP die from chronic, refractory disease and the complications of its therapy.

DRUG-INDUCED IMMUNE THROMBOCYTOPENIA

Immune-mediated platelet destruction associated with specific drugs is an often overlooked cause of thrombocytopenia. One mechanism of drug-induced immune thrombocytopenia is the development of an antibody response against soluble drug molecules. When these soluble drugs bind to the platelet membrane, drug-induced antibodies subsequently act to destroy circulating platelets through the RES. Other mechanisms of drug-induced thrombocytopenia include formation of an immunogenic neoantigen through drug-platelet interactions (also known as the *hapten response*) with autoantibodies directed against drugs that cross-react with platelet antigens. Regardless of the mechanism of induction, development of thrombocytopenia is temporally related to exposure to the drug and is usually rapid. Discontinuation of the offending drug generally results in an equally rapid rise in the platelet count. Occasionally, for patients with prolonged thrombocytopenia after drug removal, immunosuppression with agents like IVIG (2 g/kg in two to three divided doses) or steroids may restore baseline platelet counts. Although confirmation of drug-induced thrombocytopenia can often be made by testing for the presence of antibodies with drug specificities, these tests are generally only routinely performed by specialty reference laboratories. Therefore, in cases in which drug-induced thrombocytopenia is suspected, clinicians should not await specific antibody testing before discontinuing potential offending agents.

Historically, quinidine or quinine-based formulations were among the first classes of drugs to be associated with platelet antibodies; such antibodies can be detected by tests using drug coupled to a carrier protein. As awareness of drug-induced thrombocytopenia has grown, scores of drugs including antibiotics, anticonvulsants, psychotropic drugs, and antiplatelet agents have been reported to mediate platelet destruction (Table 53-2). Heparin is also well known to induce thrombocytopenia; however, unlike other drugs, this reaction paradoxically leads to a prothrombotic state. The mechanism of heparin-induced thrombocytopenia and its prothrombotic effects are discussed in greater detail in Chapter 54. Overall, when eliciting the medical history from patients with acute-onset thrombocytopenia, a careful review of all medications, particularly those initiated just before the development of low platelet counts, may help to deduce more quickly the cause and reverse the platelet count decline.

ALLOIMMUNE THROMBOCYTOPENIA

Neonatal alloimmune thrombocytopenia occurs when the mother is homozygous for an uncommon platelet alloantigen, most often human platelet antigen 1b (HPA-1b) on the platelet GPIIb/IIIa receptor, and the child expresses the HPA-1a haplotype inherited from the father. The pathogenesis of alloimmune thrombocytopenia is analogous to the mechanism by which Rh(D) sensitization induces hemolytic disease of the newborn. The mother is exposed to the HPA-1a antigen during a first pregnancy, and during that or subsequent pregnancies, she produces high-titer IgG antibody

against HPA-1a. These antibodies cross the placenta, react with HPA-1a–positive fetal platelets and cause peripheral-platelet destruction by the RES. Neonatal alloimmune thrombocytopenia may be severe, but the presence of antibody does not necessarily predict whether bleeding will occur in utero, at delivery, or in the first days of life. Transfusion of maternal platelets or random platelets lacking the HPA-1a antigen and IVIG are used to treat bleeding and to restore platelet count.

Alloimmune thrombocytopenia can also occur in adults after transfusion (*post-transfusion purpura*). As in neonates, this condition is based on exposure to a common platelet alloantigen such as HPA-1a that is not present on the patient's native platelets. This disorder can occur after transfusion of any blood product in a female who is homozygous for HPA-1b and who is alloimmunized to HPA-1s as a result of a previous pregnancy, or, more rarely, in any patient alloimmunized because of prior transfusions. More than

95% of blood donors express HPA-1a, and this antigen is shed by platelets. Consequently, any blood product can contain HPA-1a. The anamnestic response to the blood product causes destruction of residual donor platelets and, even more interestingly, destruction of native platelets *that do not express the HPA-1a alloantigen*. The pathophysiology of post-transfusion purpura is unclear, although evidence suggests that native platelets may be destroyed either non-specifically by the RES or by adsorption of HPA-1a onto host platelets. As with neonates, these patients are treated with IVIG, and any further transfusions must be derived from homozygous HPA-1b donors. Although HPA-1a is the most common cause of alloimmune thrombocytopenia, other platelet alloantigens have been found to cause this clinical syndrome (Table 53-3).

Thrombocytopenia in neonates can also be caused by maternal ITP. Antiplatelet antibodies are commonly IgG class and may cross the placenta inducing thrombocytopenia in the fetus. However, significant neonatal thrombocytopenia is rare with maternal ITP and occurs in fewer than 10% of those at risk, although some evidence indicates that the incidence of neonatal thrombocytopenia is increased when the mother has ITP and maternal platelet counts are lower than 75,000/mcL. Sometimes, the mother needs to be treated for ITP with a secondary goal of decreasing placental transfer of the maternal autoantibody, although in most instances of maternal ITP, fetal thrombocytopenia is uncommon or mild, and safe vaginal delivery may be accomplished.

DISSEMINATED INTRAVASCULAR COAGULATION

One of the most common and potentially life-threatening causes of nonimmune platelet destruction is DIC, which is associated with sepsis, malignancy, advanced liver disease, and other disorders that trigger endotoxin release or cause severe tissue damage (Table 53-4). In DIC caused by bacterial sepsis, circulating endotoxin induces expression of tissue factor on circulating monocytes and endothelial cells, a process leading to overwhelming thrombin and fibrin generation. Deposition of fibrin occurs throughout the vasculature, with relatively inadequate concurrent fibrinolysis leading to a thrombotic or microangiopathic vasculopathy and subsequent organ damage. Thrombin activation of platelets and circulating factors eventually overwhelms the bone marrow and liver synthetic capability, respectively, resulting in thrombocytopenia and prolongation of the PT

Table 53-2 Commonly Used Drugs Associated with Immune Thrombocytopenia

Drug Class	Examples
Antibiotics	Penicillins Cephalosporins (cephalothin, ceftazidime) Vancomycin Sulfonamides (sulfisoxazole) Rifampin Linezolid Quinine
Antiepileptics, antipsychotics, and sedative-hypnotics	Benzodiazepines (diazepam) Haloperidol Carbamazepine Lithium Phenytoin
Antihypertensives	Diuretics (chlorothiazide) Angiotensin-converting enzyme inhibitors (ramipril) Methyldopa
Analgesics and anti-inflammatories	Acetaminophen Ibuprofen Naproxen
Antiplatelet agents	Abciximab Tirofiban
Anticoagulants	Heparin Low-molecular-weight heparin

Table 53-3 Molecular Basis for Alloimmune Thrombocytopenia

Glycoprotein	Alleles (Alloantigens)	Phenotype/Frequency	Amino Acid and Location
IIla	HPA-1a/1b	0.98/0.25	Leucine/proline; 33
Ib	HPA-2a/2b	0.99/0.14	Threonine/methionine; 145
IIb	HPA-3a/3b	0.91/0.70	Isoleucine/serine; 843
IIIa	HPA-4a/4b	0.99/0.01	Arginine/glutamine; 143
Ia	HPA-5a/5b	0.99/0.21	Glutamic acid/lysine; 505
IIIa	HPA-6a/6b	NA	Proline/glutamic acid; 407
IIIa	HPA-7a/7b	NA	Proline/glutamic acid; 407
IIIa	HPA-8a/8b	NA	Arginine/cystine; 636

HPA, human platelet antigen; NA, data not available.

and PTT. Thus, although the primary lesion of DIC is thrombin and clot generation, the clinical endpoint is usually a *consumptive coagulopathy* with depletion of platelets and coagulation factors. Mucosal bleeding, especially in the GI tract, and oozing from intravenous puncture sites are early signs of DIC.

Fibrinogen levels are usually low but may be normal or even slightly high in DIC because the acute-phase reaction to sepsis or the underlying disorder may increase fibrinogen secretion. Therefore, DIC should not be ruled out because fibrinogen is in the normal range. Fibrinolysis in DIC is triggered by fibrin clot formation and the action of tissue-type plasminogen activator; laboratory testing shows increased levels of fibrin split products to more than 40 mcg/mL (cleavage of fibrin monomers) and D-dimer to more than 0.5 mg/mL (cleavage of fibrin-fibrin bonds). Although fibrin split products are usually elevated in patients with DIC, this finding is nonspecific; in contrast, an elevated D-dimer is more specific for DIC and is often used to confirm (and even replace) the elevated fibrin split product screening assay. The blood smear may also help in the diagnosis of DIC by showing significant numbers of schistocytes; however, this finding is not specific to DIC and is present in other microangiopathies such as TTP (see Chapter 54).

Chronic DIC may be triggered by consumption of platelets and factors in large clots associated with aneurysms, hemangiomas, and mural thrombi. Another unique cause of chronic DIC is malignant disease, often adenocarcinoma or acute promyelocytic leukemia; malignant cells in these disorders promote thrombin formation through (1) secretion of tissue factor; (2) elaboration of cysteine proteases that activate factor X; (3) induction of platelet-ligand binding; and (4) upregulation of endothelial cell plasminogen activator inhibitor-1 (PAI-1) or cyclo-oxygenase-2 (COX-2) (see later discussion of COX-2 prothrombotic effects). Chronic DIC associated with malignancy usually causes enough factor consumption that both the PT and the PTT are prolonged. Clinically, such patients exhibit *migratory thrombo-*

phlebitis (Trousseau syndrome) or *nonbacterial thrombotic (marantic) endocarditis*.

Therapy of DIC should be aimed at (1) treatment of the underlying disorder, such as antibiotics for sepsis or chemotherapy for malignant disease; (2) supportive hemostatic therapy, including platelets, cryoprecipitate (for fibrinogen), and FFP; and (3) disrupting activation of coagulation factors and platelets. For the last approach, anticoagulation is generally not indicated unless the balance of procoagulant versus anticoagulant activity actively favors clotting, such as arterial thromboemboli with mural thrombus or migratory thrombophlebitis with Trousseau syndrome. These specific thrombotic complications of chronic DIC are often resistant to warfarin therapy and generally require more intensive antithrombin and anti-Xa therapy with heparin (either unfractionated or low-molecular-weight heparin). In DIC precipitated by sepsis, pharmacologic activated protein C has been shown to significantly decrease mortality.

THROMBOCYTOPENIA WITH PREGNANCY-INDUCED HYPERTENSION

Mild thrombocytopenia in pregnant women is related to hemodilution, the normal physiology of pregnancy, that can bring platelet counts into the range of 100,000 to 150,000/mcL; these counts are not associated with maternal or fetal complications. In contrast, autoimmune causes of platelet destruction during pregnancy (as noted earlier) and pregnancy-induced hypertension can result in platelet counts lower than 100,000/mcL, and these conditions can be associated with complications. The spectrum of *pregnancy-induced hypertension* includes hypertension progressing to proteinuria and renal dysfunction (*preeclampsia*) and even to cerebral edema and seizures (*eclampsia*). Thrombocytopenia may appear as a late finding accompanying pregnancy-induced hypertension, often at the time of delivery or late in the third trimester. The related *HELLP syndrome* in pregnancy is characterized by hemolysis, elevated liver enzymes, and low platelet counts occasionally in association with hypertension. The thrombocytopenia associated with pregnancy-induced hypertension or HELLP may be related to abnormal vascular prostaglandin metabolism or placental dysfunction that leads to platelet consumption, vasculopathy, and microvascular occlusions. Both disorders are usually reversed by delivery of the fetus and placenta. Occasionally, IVIG or plasmapheresis has been required when the disorder does not resolve postpartum.

There are several other conditions, sometimes associated with pregnancy, which mediate nonimmune platelet destruction such as TTP, hemolytic uremic syndrome (HUS), and antiphospholipid syndrome. However, these platelet consumptive processes generally yield a thrombotic state rather than a tendency to bleed. More detailed discussion of these medical problems associated with thrombocytopenia can be found in Chapter 54.

DILUTIONAL THROMBOCYTOPENIA

In addition to sequestration, hypoproductive, and destructive causes of thrombocytopenia, low platelet counts can occasionally result from *hemodilution*. This circumstance usually follows resuscitative efforts after trauma and results

Table 53-5 Disorders Causing Abnormal Platelet Aggregation

	Response to Agonist				
	Epinephrine	ADP	Collagen	Arachidonic Acid	Ristocetin
Aspirin and NSAIDs	#	#	NL, ↓*	↓	NL
Glanzmann disease	Absent	Absent	Absent	Absent	#
Bernard-Soulier syndrome	NL	NL	NL	NL	Absent
Storage pool disease	↓	#	↓	NL, ↓	#
Hermansky-Pudlak syndrome	↓	#	↓	NL	#
Gray platelet syndrome	↓	↓	↓	NL	NL
von Willebrand disease	NL	NL	NL	NL	↓, NL [†]

*Aspirin results in decreased aggregation with low-dose collagen, but aggregation is normal with high-dose collagen.

[†]In von Willebrand disease type 2B, patients have increased aggregation with low-dose ristocetin, and decreased or normal aggregation with standard doses of ristocetin.

↓, Decreased; #, primary wave aggregation only; ADP, adenosine diphosphate; NL, normal; NSAIDs, nonsteroidal anti-inflammatory drugs.

from the infusion of massive volumes of intravenous solutions, red blood cells, and FFP. Hemodilution is also commonly seen during or immediately following cardiopulmonary bypass in which significant dilution occurs by the addition of the extracorporeal circuit volume to the normal circulatory system. Moreover, in addition to the hemodilution of bypass, platelets exposed to the cardiopulmonary bypass circuit can be cleared, whereas those that remain in the circulation become temporarily dysfunctional because of activation and loss of membrane receptors. This bypass defect may be mild and transient but occasionally is severe enough to lead to platelet-related bleeding, especially after long bypass procedures. After the conclusion of bypass or once the acute trauma is resolved, the platelet count rebounds within 48 to 72 hours; however, platelet transfusions may be needed to treat significant bleeding in such patients until the platelet count recovers. In trauma patients, recent data suggest that platelet transfusions may provide greatest benefit when given in higher ratios with red blood cell and plasma transfusions (see later discussion of FFP).

Bleeding Caused by Qualitative Platelet Defects

ASPIRIN AND ACQUIRED CAUSES OF PLATELET DYSFUNCTION

The ability of platelets to adhere to damaged vasculature and to recruit additional platelets into the clot is critical for primary hemostasis, especially when patients are challenged by trauma or surgery. One critical question in the patient history or for preoperative screening is whether patients are taking medications that interfere with platelet function, such as aspirin. *Aspirin* irreversibly blocks normal arachidonic acid metabolism such that all exposed platelets are irreversibly affected and do not respond to arachidonic acid even after aspirin is discontinued. The characteristic aspirin-induced platelet aggregation pattern is shown in Table 53-5. In contrast, other *nonsteroidal anti-inflammatory drugs* (NSAIDs) (e.g., indomethacin) *reversibly* inhibit COX, and platelet function is restored within 24 to 48 hours after discontinuing the drug. Bleeding after most surgical procedures

that is associated with aspirin or NSAIDs is usually mild, and aspirin may not need to be discontinued before surgery, especially because aspirin-induced platelet dysfunction is desirable in patients at risk for stroke or myocardial infarction. However, when bleeding caused by aspirin requires treatment, infusion of desmopressin acetate (DDAVP) has been shown to be effective at decreasing the bleeding time; occasionally, transfusion of platelets is also appropriate. In most cases, a single-platelet transfusion of 4 to 6 random donor units contributes enough normal platelets (>10% of total circulating number) to restore primary hemostasis. Platelet dysfunction and bleeding caused by other drugs is similarly treated by discontinuing the drug and platelet transfusion when needed (Table 53-6).

Whereas the aspirin effect is restricted to COX-1, the different NSAIDs have variable relative affinity for COX-1 and COX-2. COX-2 is an inducible enzyme synthesized in endothelial cells in response to inflammatory cytokines. Suppression of COX-2 results in a reduction of endothelial cell prostaglandin I₂ (prostacyclin), a molecule that, among other functions, has antithrombotic effects through inhibition of platelet aggregation. The net effect of nonselective NSAIDs on the prothrombotic or antithrombotic balance

favors bleeding because NSAID-induced COX-1 inhibition means that thromboxane A₂ (TXA₂) production in platelets is blocked. By contrast, the increase in cardiovascular risk seen with the more selective COX-2 inhibitors is probably attributable to the COX-2–induced lack of endothelial cell prostacyclin production, coupled with intact platelet function (no inhibition of TXA₂ by COX-2 blockade). Recent data also show that NSAIDs given before aspirin will compete for COX-1 binding sites and diminish aspirin's antiplatelet effect, another possible factor in the coagulant balance of concomitant NSAID and aspirin use.

Uremic platelet dysfunction is caused by toxic proteins that accumulate in renal failure, most importantly guanidinosuccinic acid (GSA), which induces high levels of nitric oxide formation by vascular endothelial cells; it is nitric oxide that inhibits platelet function. Control of renal failure with dialysis and maintenance of the hematocrit are usually adequate to preserve platelet function. However, uremic bleeding is a common inpatient problem, especially in the setting of acute renal failure. Short-term treatment of uremic platelet dysfunction includes DDAVP, which has been shown to shorten the bleeding time significantly, and cryoprecipitate. Conjugated estrogens are of some benefit for long-term treatment. Platelet transfusions may be useful in patients with life-threatening bleeding and acute renal failure, but the effect of this treatment is short lived because the transfused platelets rapidly acquire the uremic defect.

CONGENITAL PLATELET DYSFUNCTION

Inherited qualitative platelet defects include abnormalities of platelet receptors and granules. Two rare but well-characterized platelet receptor disorders are *Bernard-Soulier syndrome* and *Glanzmann thrombasthenia*. Bernard-Soulier syndrome is caused by decreased surface expression of platelet GPIb (the primary von Willebrand factor [vWF] receptor) and more rarely by diminished GPIb function. The syndrome is characterized by mild thrombocytopenia, increased bleeding time, large platelets, and mild-to-moderate bleeding symptoms. The diagnosis is usually made in children but may not show symptoms until adulthood. Laboratory testing for Bernard-Soulier syndrome shows an absent platelet aggregation response to ristocetin (see Table 53-5) despite adequate vWF levels and function, such as normal ristocetin cofactor (Rcof) activity. Glanzmann thrombasthenia is characterized by an increased bleeding time and abnormally low levels of expression of platelet GPIIb/IIIa (the receptor for both vWF and fibrinogen) or, more rarely, normal expression but absent GPIIb/IIIa function. Patients commonly exhibit bleeding in childhood. Platelet aggregation testing in Glanzmann thrombasthenia shows an absent or a diminished response to all agonists except ristocetin (see Table 53-5). Platelet transfusions correct the bleeding in both Bernard-Soulier syndrome and Glanzmann thrombasthenia. However, because of the high risk for alloimmunization with frequent platelet transfusions, this therapy should be used sparingly.

Inherited platelet granule disorders are defined by the type of granule that is absent or defective. *Storage pool disease* is characterized by a relative decrease or absence of dense granules and correspondingly moderate to severe mucosal bleeding. Release of dense granule constituents that recruit

and activate platelets is impaired. Thus, storage pool disease is characterized by a diminished or absent secondary wave of aggregation in response to most agonists (see Table 53-5). *Hermansky-Pudlak syndrome* is dense granule deficiency associated with oculocutaneous albinism and mild thrombocytopenia; patients have significant bleeding, which may occur spontaneously but more often occurs in association with surgical procedures. *Chédiak-Higashi syndrome* is a rare general granule disorder characterized by mild bleeding, partial albinism, and recurrent pyogenic infections; large, irregular, gray-blue inclusions are seen in neutrophils and monocytes. Gray platelet syndrome is characterized by colorless or gray platelets that lack normal staining on the peripheral smear; electron microscopy confirms the loss of α granules or their contents. Patients with gray platelet syndrome have a mild bleeding history, and aggregation testing exhibits diminished responses to epinephrine, ADP, and collagen. All the platelet granule disorders are successfully treated by avoiding aspirin and other antiplatelet drugs, by hormonal control of menses in women, and by platelet transfusions when bleeding occurs.

PLATELET TRANSFUSION THERAPY

Platelet transfusions, derived from the whole blood of healthy donors, can be used to stop or prevent bleeding. There are two broad categories of platelet transfusion support based on the conditions discussed in this chapter: (1) *prophylactic* platelet transfusions for thrombocytopenia in nonbleeding patients, and (2) platelet transfusion for the acutely bleeding patient. For the nonbleeding thrombocytopenic patient, there are several “triggers” that prompt platelet transfusion in the absence of frank hemorrhage. Patients receiving chemotherapy may be severely thrombocytopenic and should be transfused when their platelet counts are less than 10,000/mcL to prevent spontaneous bleeding. This is a safe and appropriate threshold for patients with relatively uncomplicated clinical pictures, without fever, sepsis, or GI bleeding. This threshold of 10,000/mcL significantly decreases the frequency of platelet transfusion and thereby reduces risks associated with multiple blood product exposures. If complicating circumstances are present, or if the patient is being managed on an outpatient basis, prophylactic transfusions should be given when platelet counts are lower than 20,000/mcL. For patients undergoing invasive procedures, such as a surgical intervention, it is reasonable to transfuse platelets when counts are lower than 50,000/mcL. Higher platelet counts are suggested for patients undergoing neurologic or ophthalmologic surgeries; platelet counts higher than 100,000/mcL are recommended, if possible, owing to the catastrophic nature of bleeding in these anatomic locations.

For the acutely bleeding patient, the decision to transfuse platelets should depend on several factors, but thrombocytopenia is the most straightforward. Platelet counts higher than 50,000/mcL are a reasonable goal for most cases of acute bleeding, whereas counts higher than 100,000/mcL might be necessary for neurologic bleeds. Congenital or acquired platelet dysfunction must also be considered for the acutely bleeding patient. Patients with significant bleeding who have taken an antiplatelet drug, such as aspirin, may benefit from platelet transfusion regardless of baseline

counts. Another consideration for the acutely bleeding patient is the volume of blood products and fluids received. It is not uncommon for trauma patients to receive more than 10 units of red blood cells by transfusion in addition to plasma, volume expanders, and saline. As mentioned previously, the effects of large fluid volume resuscitation are reductions in the platelet count to less than 50% of baseline, resulting in a significant *dilutional coagulopathy*. In these scenarios, it is vitally important to obtain repeated platelet counts and to liberally transfuse platelets to maintain adequate hemostasis.

When the decision to transfuse platelets has been made, platelet units can be requested from the blood bank or transfusion service. In general, blood banks provide *pooled platelets*, which consist of 4 to 6 random donor platelet concentrates combined into one large dose. For the patient with uncomplicated thrombocytopenia, each unit of random donor-platelet concentrate ideally raises the platelet count by about 10,000/mcL. Thus, 6 pooled units of platelets transfused into a patient with a platelet count of 10,000/mcL would be expected to raise the count to nearly 50,000 to 60,000/mcL. Another commonly used platelet product is the *apheresis platelet* unit, which is a large single dose collected from one donor using apheresis technology. The dose from these *single-donor* or apheresis platelets is nearly equivalent to that of a 6-unit platelet pool and is estimated to increase platelet counts by up to 60,000/mcL in the uncomplicated patient. Usually, 1 platelet pool or 1 single-donor platelet unit should sufficiently raise platelet counts to correct thrombocytopenia. These doses should also be sufficient to stop or prevent bleeding associated with platelet dysfunction or invasive procedures. For the complicated patient, additional platelet doses may be necessary over time to achieve adequate hemostasis.

PLATELET TRANSFUSION FAILURE AND PLATELET REFRACTORINESS

Platelet transfusions in thrombocytopenic patients will not be successful in all cases. Uremia, as mentioned previously, will cause dysfunction of transfused platelets, limiting their function *in vivo*. Patients who are thrombocytopenic due to conditions like ITP will not generally show increases in platelet counts after transfusion because circulating autoantibodies cause rapid destruction of both endogenous and infused platelets. Many other underlying conditions can severely limit the effectiveness of platelet transfusion. This phenomenon, known as *platelet refractoriness*, can be caused by a wide variety of recipient problems, including fever, sepsis, splenomegaly, and DIC. These conditions generally decrease transfused platelet survival but not *immediate platelet recovery*. Thus, the patient with fever may have an initial increase in platelet count 1 hour after transfusion, but a subsequent decline in platelet counts at a steeper rate than expected owing to concomitant factors. For patients with this type of platelet refractoriness, addressing the underlying illness will often cause platelet transfusions to be more effective.

Platelet refractoriness can also be immune mediated. In a patient who is chronically transfused with platelets, alloantibodies against platelet antigens (e.g., human leukocyte antigen [HLA]), can be formed. Over time, and with multiple transfusion exposures, these antibodies can increase

sharply in titer and cause the rapid destruction of platelets after infusion. For the *alloimmunized patient*, platelet counts performed 1 hour after transfusion show virtually no change above baseline, pretransfusion levels. Generally, immunosuppression fails to decrease platelet alloantibodies, and efforts to improve platelet recovery are focused on finding compatible platelet units. The first step in transfusion management of the alloimmunized patient is to provide ABO antigen-matched platelets to minimize any clearance caused by naturally occurring ABO antibodies. If this step fails to yield increases in platelet counts, donor platelets that lack target antigens for the alloantibodies can be transfused. One such strategy is to use patient serum to *cross-match* for platelet donor units, with selection of those units most compatible for transfusion. If cross-match compatible platelets fail to induce an adequate platelet recovery, blood banks ultimately must provide platelets that are matched to the recipient's HLA system in the hope of evading HLA-based antibodies.

VON WILLEBRAND DISEASE

Disorders of the functional ligands for platelet adhesion to the vasculature cause bleeding that clinically resembles the bleeding associated with platelet or vascular disorders (e.g., epistaxis, GI bleeding). vWF is synthesized in endothelial cells and megakaryocytes and functions in plasma to mediate platelet adhesion to the damaged site (see Fig. 53-1). vWF is a large multimeric protein of varying size; the largest multimers contain the greatest number of adhesive sites and thus confer greater hemostatic ability than smaller vWF molecules. In patients with abnormal or low vWF levels, platelet adhesion to damaged vessels is delayed and results in mucosal bleeding and a prolonged bleeding time. vWF also serves as the carrier protein for factor VIII; deficiency of vWF or abnormal vWF-VIII binding leads to rapid clearance of factor VIII, decreased factor VIII levels, and a prolonged PTT. Many mutations in the vWF gene have been described; these have been phenotypically grouped into three major subtypes of vWD (Table 53-7).

Most patients have *type 1 vWD*, a mild-to-moderate *quantitative* decrease in all vWF multimers. This condition is commonly caused by a heterozygous mutation and shows a dominant pattern of inheritance. Type 1 vWD is characterized by equivalent decreases in factor VIII, vWF antigen, and Rcof activity; Rcof measures the ability of patient plasma (which contains vWF) to agglutinate normal platelets in the presence of ristocetin. Patients with type 1 vWD usually have mild to moderate bleeding, often only in relation to surgery or dental procedures. Patients with type 1 vWD are treated with DDAVP, which stimulates endothelial cells to release stored vWF and leads to an increase in plasma vWF antigen, Rcof, and factor VIII levels. DDAVP, at 0.3 mcg/kg given subcutaneously, usually yields excellent results. However, tachyphylaxis to DDAVP occurs because endothelial cells require time to synthesize new vWF after repeated DDAVP dosing. Thus, vWF concentrates must sometimes be used in patients with more severe type 1 vWD or in those who are undergoing a more prolonged hemostatic challenge (see later for details). Bleeding in type 1 vWD during pregnancy is exceedingly rare. Because vWF rises significantly in pregnancy, vWF antigen and Rcof levels

usually normalize during the second or third trimester and eliminate the bleeding risk for that time. Most pregnant women with type 1 vWD have no bleeding complications with delivery and do not require therapy during pregnancy or in the early postpartum period.

Type 2 vWD is characterized by heterozygous mutations of variable penetrance that produce a *qualitative* defect in the vWF molecule; the most common type 2 disorders are characterized by a relative lack of the larger vWF multimers (see Table 53-7). High-molecular-weight vWF multimers are absent in *type 2A disease*, and patients with type 2A vWD show disproportionately low Rcof activity compared with the vWF antigen level. The molecular defect is related to mutations in the A2 domain of vWF that render the molecule more susceptible to the vWF-cleaving protease (ADAMTS-13). Patients with type 2A vWD respond to vWF concentrate and less commonly to DDAVP. The abnormal vWF molecule in *type 2B vWD* has increased affinity for platelets, a situation that causes loss of high-molecular-weight multimers from the circulation and often produces thrombocytopenia. Platelet aggregometry in type 2B vWD (see Table 53-7) shows an abnormal increase in low-dose ristocetin-induced platelet agglutination; in the laboratory, the addition of patient vWF to normal platelets similarly increases ristocetin-induced platelet agglutination and confirms the abnormal vWF. DDAVP induces release of the abnormal vWF in patients with type 2B vWD, causing thrombocytopenia, and therefore is contraindicated; vWF concentrate should be used instead.

Type 2M vWD demonstrates laboratory findings similar to those in type 2A, but high-molecular-weight multimers are present. The defect in this rare type of vWF is most often a mutation in vWF *reducing* binding to its platelet ligand GPIIb α . Some patients with type 2M vWD respond to DDAVP, but most require vWF concentrate. In *type 2N vWD*, the abnormal vWF molecule has decreased binding affinity for *factor VIII*, a characteristic that decreases factor VIII survival and produces a bleeding phenotype similar to hemophilia A. The low factor VIII levels do not respond to high-purity factor VIII infusions, unlike in true hemophilia A, but they improve with vWF concentrate. Rcof and vWF antigen levels are normal in type 2N vWD because the mutation in the factor VIII binding site does not affect vWF function or survival. Type 2N vWD should be

considered in females who present with hemophilia A; tests for vWF binding to factor VIII are available in reference laboratories.

The rare patient with *type 3 vWD* has a complete deficiency of vWF, often as a result of the inheritance of two abnormal vWF alleles (compound heterozygote). Patients with type 3 vWD have absent or extremely low levels of both Rcof and vWF antigen and factor VIII levels of 3% to 10% and usually have severe bleeding that may mimic hemophilia. Type 3 vWD does not respond to DDAVP and requires vWF concentrates for bleeding.

vWD can appear as an acquired defect, usually as a severe, type 2A–like defect with absent larger vWF multimers in a patient with no history of bleeding. *Acquired vWD* is caused by abnormal clearance of the larger vWF multimers and is associated with monoclonal gammopathies, lymphoproliferative disorders, myeloma, and other malignant and myeloproliferative diseases characterized by thrombocytosis. In these cases, acquired vWD has been successfully treated with IVIG and therapy of the underlying disease. One other cause of abnormal vWF multimer clearance resulting in acquired vWD is critical aortic stenosis, which is corrected with successful surgical repair.

FIBRINOGEN DISORDERS

Fibrinogen functions as a bridging ligand for the platelet receptor GPIIb/IIIa in the platelet-platelet matrix at sites of vascular damage. Fibrinogen also functions in the final steps of the coagulation cascade to form fibrin clot. Low fibrinogen levels are most commonly seen with consumptive disorders such as *DIC*, although rare congenital hypofibrinogenemias and afibrinogenemias are recognized. *Dysfibrinogenemia* is defined as an abnormal fibrinogen protein. Patients with dysfibrinogenemia usually bleed because of decreased adhesive function, but some patients have a hypercoagulable state. Dysfibrinogenemia is occasionally inherited, but it is more often acquired with liver disease. Both the PT and the PTT are prolonged by abnormalities of fibrinogen quantity or function (Table 53-8). A prolonged thrombin time is more specific for a low fibrinogen level or abnormal molecule, although inhibitors such as heparin and fibrin split products also prolong the thrombin time. The *reptilase time*, which is insensitive to heparin, can be used to

Table 53-8 Screening Laboratory Results in Coagulation Factor Deficiencies

Deficient Factor	Frequency	PT	PTT	TT
I (Fibrinogen)	Rare	↑	↑	↑
II (Prothrombin)	Very rare	↑	↑	↑

eliminate the possibility of an increased thrombin time resulting from heparin contamination of the sample.

Bleeding Caused by Coagulation Factor Disorders

HEMOPHILIA AND OTHER INHERITED FACTOR DEFICIENCIES

Normal platelet hemostasis initiates plugging of vascular lesions and maintains mucosal integrity. However, if abnormalities of coagulation factors are present, the initial platelet plug is not solidified by secondary hemostasis, and the effects are clot breakdown and bleeding. This bleeding differs from platelet-type bleeding; coagulation factor deficiencies lead to bleeding in deep tissues and joints, and milder deficiencies result in bleeding in a delayed fashion after surgery. Most patients with significant factor deficiencies exhibit abnormal results of screening laboratory tests (see Table 53-8 and Fig. 53-1), although patients with mild deficiencies can still exhibit bleeding and normal coagulation screens.

The X-linked deficiencies of factor VIII (*hemophilia A*) and factor IX (*hemophilia B*) are the most common factor deficiencies after vWD. Hemophilia A is about 6 times more frequent than hemophilia B. About 50% or more of cases of severe hemophilia A arise as a result of an inversion of a major portion of the gene that results in complete loss of activity. Other mutations tend to result in milder disease. Most patients with hemophilia B have mutations that result in a functionally abnormal factor IX with absent activity. The combined results of antigenic and functional assays can resolve whether deficiency is due to loss of the protein or loss of its normal function. Both hemophilia A and hemophilia B are categorized by their factor levels: severe deficiency is characterized by absent (<1%) factor VIII or IX, whereas patients with moderate and mild hemophilia have factor levels of 1% to 5% and more than 5%, respectively.

Symptoms and signs of severe hemophilia A and hemophilia B develop in childhood with bleeding into muscles, joints, and soft tissue. Because they are X-linked disorders, they are observed primarily in male patients; the mother of an affected male patient is a carrier, and 50% of maternal uncles have the disease. About 25% to 30% of cases of hemophilia, however, result from new mutations and hence have no relevant family history. In exceedingly rare instances, a female carrier with extremely skewed X-inactivation may have a mild bleeding disorder with factor levels lower than 30%. Bleeding in severe hemophilia is often spontaneous and is also common after any type of surgery or even mild trauma. Bleeding in hemophilia frequently occurs in joints and in the retroperitoneum; hematuria and mucosal and intracranial bleeding also occur. Patients with moderate hemophilia have less spontaneous bleeding, but they are still at significant risk for hemorrhagic complications of surgery or trauma. Patients with mild hemophilia may be undetected into adulthood and diagnosed only with bleeding after major surgery. The complications of hemophilia stem from chronic bleeding into joints and muscles, which leads to severe deformities, arthritis, muscle atrophy, and contractures; these complications require intensive physical therapy and orthopedic care, often culminating in joint replacement. In addition, patients with hemophilia who received pooled-factor concentrates before the era of viral inactivation have complications related to transfusion-transmitted infections, including HIV and hepatitis B and C. Current therapy uses factor concentrates that are virally inactivated or recombinant.

INHERITED FACTOR DEFICIENCIES OTHER THAN HEMOPHILIA A OR B

Inherited bleeding disorders caused by deficiencies of coagulation factors V, VII, X, and XI (see Table 53-8) are much rarer than hemophilia A and B. Patients with *factor V deficiency* usually lack both plasma factor V and platelet factor V and have joint and muscle bleeding similar to patients with hemophilia. Some patients who are plasma V deficient are asymptomatic until they are challenged with the stress of surgery or trauma, and these patients are thought to have normal platelet factor V levels. Rarely, patients inherit factor deficiencies in tandem, such as combined factors V and VIII deficiencies.

Patients with *factor XI deficiency* generally have a milder bleeding disorder (even with factor XI levels <5%) than patients with hemophilia A or B, whereas *factor X deficiency* is usually more severe. *Factor XI deficiency* is an autosomal recessive disorder seen with increased frequency among Ashkenazi Jews, often manifesting late in adulthood and in clinical settings of increased fibrinolysis such as after prostate surgery. *Acquired factor X deficiency* can occur in association with amyloidosis, a condition in which the abnormal circulating light chains adsorb to and clear factor X and produce low levels and occasional bleeding.

ACQUIRED COAGULATION FACTOR DISORDERS

Factor Inhibitors

About 25% of patients with hemophilia A develop antibodies to transfused factor VIII. An inhibitor acts functionally

and can be measured in the laboratory as Bethesda units (BU); 1 BU is defined as the amount of inhibitor that neutralizes 50% of factor activity. High-level inhibitors (>10 BU) completely neutralize the activity of infused factor concentrates, negating their effectiveness in bleeding episodes. Bleeding therefore requires therapy using different regimens such as factor VIII inhibitor bypass activity (FEIBA) or recombinant factor VIIa (see later for details). For long-term treatment, suppression of an inhibitor is accomplished by a combination of IVIG, immunosuppressive therapy, plasmapheresis, and induction of *immune tolerance* using high-dose concentrate infusions. Patients with hemophilia B have a lower incidence of inhibitors (2% to 6%), but these inhibitors are treated in a similar fashion with high-dose FEIBA or recombinant VIIa and with similar strategies for long-term suppression of the antibody.

Acquired inhibitors to factor VIII (and more rarely to other coagulation factors) occasionally occur in patients (usually older) who do not have a history of bleeding. Acquired factor VIII inhibitor titers in this setting can be extremely high and are sometimes associated with pregnancy, autoimmune disorders, and malignant diseases, especially lymphoproliferative disorders. Patients with acquired inhibitors to factor VIII are similarly treated with factor VIIa or FEIBA. Intensive immunosuppressive therapy (Rituxan, an anti-CD20 agent) has become the mainstay of successful treatment and should be started as soon as possible to eradicate the inhibitor.

Vitamin K Deficiency

Inpatients and outpatients who are severely ill may have bleeding resulting from acquired coagulation factor deficiencies. Foremost among the causes of low factor levels is vitamin K deficiency. Vitamin K deficiency may be caused by (1) biliary tract disease interfering with enterohepatic circulation, leading to decreased absorption of vitamin K; (2) drugs, especially antibiotics, that sterilize the gut and reduce bacterial sources of vitamin K or other drugs (cholestyramine) that directly block vitamin K absorption—this category also includes cephalosporins, which interfere with intrahepatic metabolism of fat-soluble vitamin K; and (3) poor nutritional status induced by malabsorption, chronic disease, or poor oral intake in patients who are acutely ill. As noted previously, factors II, VII, IX, and X are vitamin K–dependent procoagulant factors, as are proteins C and S. Warfarin blocks vitamin K–dependent γ -carboxylation of these factors and causes an acute decrease in functional factor VII levels because factor VII has the shortest half-life (6 hours) of all vitamin K–dependent factors in vivo.

Dilutional Coagulopathy

As with platelets, coagulation factors can also be depleted through the dilutional effects of pure red blood cell transfusion, or with administration of massive amounts of volume expanders or saline solutions. It has been demonstrated that for every 10 units of red cells acutely transfused, there is a concomitant increase in INR to greater than 2. This is also occurring in conjunction with depletion and consumption of circulating coagulation factors secondary to the acute bleed. Therefore, in the setting of trauma, it is important to maintain adequate coagulation factor activity through plasma transfusion. In fact, there is recent evidence from the trauma literature to suggest that transfusion ratios of red

cells to plasma should approach 1:1 to optimize hemostasis. The best means to monitor for the effects of dilutional coagulopathy is through repeated testing of PT and PTT with a liberal plasma transfusion strategy.

Bleeding in Patients with Liver Disease

Unlike patients with vitamin K deficiency or those receiving warfarin, patients with liver disease have low levels of nearly all factors, not just the vitamin K–dependent factors; the exception is factor VIII. Although liver transplantation increases factor VIII levels in patients with hemophilia, factor VIII levels are usually normal or increased with liver disease, a finding corresponding to RES and megakaryocytic sources of factor VIII production. If factor VIII levels are decreased in liver disease, consideration should be given to superimposed DIC. When a prolonged PT is evaluated for its cause, measurement of factor VII and a non–vitamin K–dependent factor, such as factor V, is most useful. In vitamin K deficiency, factor VII is low, and factor V is normal; both factors are low in patients with generalized liver disease. The PT is a sensitive measure of liver function and becomes elevated in patients with even mild liver disorders; this elevation precedes a significant decrease in the albumin or prealbumin levels and is usually coincident with transaminase changes. In patients with mild to moderate liver disease, the PT is prolonged, but the PTT usually remains within the normal range. When severe liver disease is present, the PT becomes even more prolonged, and the PTT becomes abnormal as well. Causes of bleeding in liver disease other than decreased factor synthesis include (1) decreased clearance of fibrin split products or associated DIC, (2) inhibition of platelet function, and (3) increased tissue plasminogen activator levels.

Bleeding in Patients with a Normal Laboratory Screen

Occasional patients with factor- or platelet-dependent bleeding disorders do not exhibit any abnormalities in screening laboratory assays (e.g., PT, PTT, platelet count). Besides vascular purpuras, other bleeding variants exhibit in this fashion (see Fig. 53-1). Patients with bleeding caused by mild vWD may have a normal PTT, but additional studies usually show mild decreases in factor VIII, vWF antigen, or vWF Rcof; multimeric analysis may also be abnormal in patients with mild type 2A vWD. Similarly, mild factor deficiencies (factor II, V, VII, VIII, IX, or XI) may not prolong the PT or PTT, but specific-factor assays demonstrate levels lower than the normal range. Mild bleeding, often with a delayed onset after surgery or trauma, may occur in patients with clot instability resulting from factor XIII deficiency or dysfibrinogenemia; in neonates, XIII deficiency presents with late umbilical stump bleeding. Factor XIII deficiency is diagnosed in the laboratory by screening for increased clot solubility in urea; if the clot dissolves

abnormally quickly in 8 mol/L urea, then an enzyme-linked immunosorbent assay for the actual XIII level should be performed. Factor XIII deficiency is currently treated with FFP, but recombinant factor XIII-A2 domain has promise for future therapy. Low fibrinogen levels or abnormal fibrinogen function will prolong both the thrombin time and the heparin-independent reptilase time. Low fibrinogen levels and dysfunction are treated with cryoprecipitate. Finally, bleeding in patients with normal platelet counts and clotting times should be evaluated by testing platelet qualitative function using platelet aggregometry or platelet function analysis. Inherited deficiencies of platelet receptors or granules and platelet abnormalities acquired with drugs or uremia can be diagnosed by demonstrating abnormal platelet aggregation or prolonged closure time results, respectively.

PLASMA AND COAGULATION FACTOR TRANSFUSION THERAPY

For patients with one or multiple defects in coagulation proteins, there are several options for replacement therapy. The most widely used product for replacement of coagulation factors is FFP. This product from healthy blood donors is frozen within a few hours of collection. As such, it contains normal (i.e., therapeutic) levels of all coagulation factors necessary to maintain hemostasis. FFP is the best choice for replacement of coagulation factors for a number of conditions, including liver failure or deficiencies of factors II, V, X, and XI. As such, FFP is commonly used for the reversal of warfarin therapy before invasive procedures or with the advent of bleeding. Appropriate dosing of FFP should be weight based and not dependent on the extent of prolongation of coagulation studies alone. Dosing of FFP at 10 to 15 mL/kg should be sufficient to replace deficient coagulation factors and correct abnormal coagulation studies. Thus, assuming a volume of about 200 mL per unit of FFP, a reasonable dose for a 70 kg individual would be 3 to 4 units of FFP. It is also important to recognize that dosing is time sensitive in that coagulation factors will degrade at standard half-lives upon infusion. Therefore, appropriate dosing of FFP also includes providing this product immediately before an intended procedure to ensure adequate hemostasis.

In some cases, patients may not be able to tolerate the infusion of large volumes of FFP required to reverse coagulopathic states. In these cases, other treatment modalities are available. One such product, *prothrombin complex concentrate* (PCC), quickly reverses prolonged PT studies without the need for large volumes of FFP. PCC is concentrated, lyophilized human-derived factors II, VII, IX and X that can

be reconstituted in small volumes and provided by intravenous bolus injection. A variant human-derived PCC, *FEIBA*, contains factors II, IX, and X and activated factor VII and is administered in doses of 75 U/kg every 8 to 12 hours, not to exceed 200 U in 24 hrs. Both products can be used effectively for vitamin K–dependent factor replacement when FFP is not a feasible option. Vitamin K should also be considered as an alternative to plasma infusion. Oral or parenteral replacement of vitamin K (1 to 10 mg per day for 3 days) restores coagulation factor synthesis in the presence of normal liver function and can be effectively used in the coagulopathic patient.

For patients with hemophilia A or B, several virally inactivated and recombinant factor VIII and IX concentrates are available. These products were developed because of the high rates of morbidity and mortality secondary to HIV and hepatitis viruses arising from pooled products used during the 1980s. For hemophilia, factor replacement is the key to effective therapy. Patients with severe hemophilia often infuse themselves with low doses of prophylactic factor on a regular basis (25 to 40 U/kg 3 times per week) and boost their dose or frequency of infusion when they sense internal bleeding, sustain trauma, or undergo dental procedures (Table 53-9). Patients with mild hemophilia A may not need factor infusions for minor surgery; indeed, such patients are often managed with ϵ -aminocaproic acid, 4 g every 4 to 6 hours, with or without infusions of DDAVP, 0.3 mcg/kg. However, most patients with hemophilia require factor infusions, if not prophylactically, then at times of surgery or trauma. Factor VIII products are infused every 8 to 12 hours, and 1 U/kg of factor VIII concentrate raises plasma factor VIII activity by 2%; thus, 50 U/kg of factor VIII theoretically will yield 100% factor VIII activity in a patient with severe hemophilia A. Factor IX has a longer half-life and is infused every 18 to 24 hours; factor IX requires 2 U/kg for a 2% increase in factor IX activity (i.e., 100 U/kg for 100% activity). Major surgery in patients with hemophilia requires intensive factor therapy to achieve normal factor levels (>80%) in both the intraoperative period and the early postoperative period to prevent wound hematoma formation. The dosing of factors (see Table 53-9) is adjusted downward from this intensity, depending on the severity of the insult, the patient's response to previous factor infusions, and whether inhibitors to factors have developed.

Unfortunately, as previously noted, patients with severe hemophilia A or B can develop inhibitors, antibodies directed against factor VIII or IX. In these cases, provision of standard doses of factor does not reverse coagulopathy, and bleeding persists. No specific factor product is clearly less immunogenic than others. Fortunately, several therapies have been developed to overcome, or bypass, the intrinsic

Table 53-9 Factor Replacement Guidelines in Hemophilia A and B

Injury	Initial Dosing	Maintenance	Factor VIII (U/kg) Initial Dosing	Factor IX (U/kg) Maintenance
Dental prophylaxis	20	10-20 every 12 hr	10-20	20 every 12 hr
Hemarthrosis	10-20	10-20 every 12 hr	30-60	20 every 24 hr
Muscle hematoma	20-30	20 every 12 hr	30-50	30 every 24 hr
Trauma or surgery	50	20-30 every 8 hr	60-100	40-80

pathway of coagulation, thereby eliminating the need for active factor VIII or IX in the coagulation cascade. The previously discussed agent, FEIBA, has been employed for this purpose at doses of 50 to 100 U/kg. Another widely used bypass agent is activated factor VII (fVIIa), a recombinant factor protein. For a patient with hemophilia A and B and a strong factor inhibitor who presents with bleeding, fVIIa is generally dosed at 90 to 120 mcg/kg every 2 hours (and sometimes more frequently in pediatric patients) until the bleeding is controlled. This agent has been quite successful at controlling bleeding in hemophilia inhibitor populations as well as in patients with congenital factor VII deficiency and those with acquired coagulation factor inhibitors. Based on its success in treating bleeding associated with hemophilia, trials of fVIIa have been performed for non-hemophilia-associated bleeding with varied success. To date, the U.S. Food and Drug Administration has approved use of fVIIa only in the setting of factor VII deficiency (15 to 20 mcg/kg) or for treatment of bleeding associated with a factor inhibitor.

Several virally inactivated, *intermediate-purity* factor VIII concentrate products (not recombinant or monoclonal antibody purified) are also available for use. These factors generally contain large amounts of vWF (e.g., Humate-P) and are particularly useful for bleeding or prophylaxis in severe vWD, as effective replacement immediately before major invasive procedures, or in vWD patients who have failed DDAVP therapy.

CRYOPRECIPITATE TRANSFUSION THERAPY

Cryoprecipitated antihemophilic factor (better known as *cryoprecipitate*) is an underused but important blood product for the treatment of a variety of bleeding disorders. Cryoprecipitate is prepared by thawing frozen plasma at very cold temperatures and removing the precipitated portion. As such, it contains relatively high levels of fibrinogen, fibronectin, factor VIII, vWF, and factor XIII. A major advantage of cryoprecipitate is that the average single unit is only 10 to 15 mL. Based on its contents and small volume, cryoprecipitate is very useful for the replacement of fibrinogen in DIC or in patients demonstrating hypofibrinogenemia or dysfibrinogenemia. The product may be helpful for isolated factor XIII deficiency or factor XIII consumption in DIC. There is also mounting evidence to suggest that the vWF/factor VIII in cryoprecipitate can be used to overcome bleeding in uremia by enhancing the adhesive properties of circulating platelets.

Cryoprecipitate is most appropriately dosed by considering a patient's plasma volume and baseline fibrinogen levels. However, from a practical standpoint, for a 70-kg adult, a 10-unit pool (total volume, 150 mL) should be sufficient to provide adequate fibrinogen and enhance other hemostatic properties. For more advanced dosing protocols, consultation with the transfusion service is strongly recommended.

Prospectus for the Future

Novel modalities continue to be developed for the diagnosis of patients with bleeding disorders. For instance, application of assays measuring thrombin generation represents a distinct, and more specific, view of coagulation from a laboratory standpoint that may provide greater insight into the source of abnormal bleeding than current tests. Alternatives to transfusion are also being developed. For thrombocytopenic patients, this includes fibrin-coated albumin particles that could evade immune-mediated platelet destruction while yielding important therapeutic impact. Additionally, there has been renewed

interest in chemical and cytokine-based stimulation of the bone marrow to produce endogenous platelets. These newer agents, known as *nonpeptide platelet growth factors*, appear to have none of the side effects associated with earlier generations of thrombopoietic drugs. Progress also continues to be made in the development and application of recombinant coagulation factors for the treatment of hemophilia with a focus on preparation of factors that are less immunogenic and therefore less prone to induce the development of significant inhibitors.

Disorders of Hemostasis: Thrombosis

Richard Torres and Henry M. Rinder

Clinical Evaluation of Thrombosis

The approach to patients with thromboembolism is defined by clinical history, laboratory studies, and occasionally physical findings. Events that trigger venous thromboembolic (VTE) disease include immobilization, orthopedic and other surgical procedures, use of oral contraceptives, and pregnancy. VTE that is recurrent (thrombophilia) may present at an early age or at unusual thrombotic sites (e.g., cerebral vessels) or be accompanied by a family history of VTE suggesting an inherited disorder. Acquired VTE risk may be associated with systemic disorders such as hemolysis (paroxysmal nocturnal hemoglobinuria and autoimmune hemolytic anemia), collagen vascular disorders (lupus), or various malignant diseases (adenocarcinoma). In contrast, arterial thromboembolic (TE) disease is more commonly superimposed on ruptured atherosclerotic plaque (e.g., coronary artery disease) and atheroembolic disorders (e.g., ischemic stroke, peripheral arterial disease). Arterial vascular disease is mainly associated with metabolic risk factors including hypertension, hypercholesterolemia, and diabetes, but arterial event risk may also be compounded by a congenital propensity to clot. The clinical approach to thrombotic disease is tailored to the location of the disease (arterial versus venous and the specific vascular bed) and whether there are abnormalities of the vascular endothelium, platelets, or soluble coagulation factors that predispose the patient to TE risk.

Vascular Causes of Thrombosis

The Virchow triad defines the pathologic mechanisms underlying thrombosis: diminished blood flow, damage to the vascular wall, and an imbalance favoring procoagulant over anticoagulant factors. The first two factors are clearly localized to specific vascular beds; although the last element

of the triad may be systemic, data now show at least partial vascular bed-specific regulation of the hemostatic balance. For example, congenital deficiencies of antithrombin (AT), protein C, or protein S generally lead to VTE of the lower extremities. In contrast, the inherited hypercoagulable disorders associated with factor V Leiden (FVL) and the prothrombin G20210A mutation not only produce lower extremity VTE but also are associated with thrombosis of the cerebral veins and sinuses. This hemostatic regulation in vascular tissues is mediated by multiple factors that include (1) microenvironmental signals, such as shear stress, that affect endothelial cell (EC) expression of thrombomodulin, tissue factor, and nitric oxide synthase; (2) EC subtype-specific signaling (e.g., shear stress upregulates aortic, but not pulmonary artery, nitric oxide synthase); (3) differences in EC transcriptional regulation of proteins such as von Willebrand factor (vWF) and its cleaving protease, ADAMTS-13; and (4) the increasingly important link between inflammation and thrombosis that is mediated by selectin and integrin ligands functioning in both physiologies.

Atherothrombosis

This section briefly discusses hematologic factors that predispose to thrombosis in the setting of atherosclerotic plaque (atherothrombosis); the pathophysiologic mechanisms of atherogenesis are discussed in Chapter 9.

FIBRINOLYTIC SYSTEM

In addition to EC-intrinsic regulation of hemostasis, the interaction of EC with the fibrinolytic system is important in the development of atherothrombotic disease because it affects the balance point of clot propagation. The breakdown of stable fibrin polymers into fibrin split products (FSPs) is mediated by plasmin. Plasmin is converted from its inactive form, plasminogen, by tissue-type plasminogen activator (t-PA), the activity of which is regulated in turn by plasminogen activator inhibitor-1 (PAI-1). Abnormalities of

both t-PA and PAI-1 are associated with an increased risk for arterial thrombosis, but the degree to which absolute levels contribute to arterial thrombosis remains controversial. Curiously, it is high t-PA levels that are associated with higher rates of atherothrombosis, specifically acute myocardial infarction and stroke. This phenomenon may be a manifestation of upregulation of t-PA serving as a surrogate marker for high de novo PAI-1 levels, although a direct correlation of PAI-1 levels and overall arterial thrombosis rates remains weak. Still, there exists a strong association between abnormal hemostasis and high PAI-1 levels in patients with the metabolic syndrome or vascular disease in type II diabetes. Furthermore, the risk for acute myocardial infarction is elevated in the subset of angina pectoris patients with increased PAI-1 activity levels, and there is evidence for the direct contribution of PAI-1 to stent restenosis after angioplasty. From a genetic risk standpoint, the 4G isoform of PAI-1 (versus the 5G form) results in higher levels of PAI-1, but the association of the 4G isoform with increased relative risk for arterial thrombosis is small. Even in those instances in which there is a stronger link, the role of testing for fibrinolytic component levels in arterial thrombosis evaluation remains largely prognostic because directed therapies are not available. Aprotinin, which decreases blood loss during cardiopulmonary bypass through its antifibrinolytic effects, is also associated with increased risk for vein graft occlusion and myocardial infarction after bypass. For their part, t-PA polymorphisms and plasminogen levels do not correlate with atherothrombotic risk. Controversy remains as to any role in arterial thrombosis for thrombin activatable fibrinolysis inhibitor (TAFI), a fibrinolysis modulator (see “Prospectus for the Future” for the potential role of TAFI in VTE).

HYPERHOMOCYSTEINEMIA

Increased levels of plasma homocysteine (HCY) are linked to atherothrombosis. Extremely high plasma HCY levels, as are found in rare congenital syndromes characterized by homocystinuria and hyperhomocysteinemia (e.g., cystathionine β -synthase deficiency), are associated with thromboembolism and severe premature atherosclerosis. Elevated HCY induces EC dysfunction and apoptosis, triggering normal coagulation pathways designed to respond to EC damage but without the corresponding upregulation of EC-dependent anticoagulant function such as activated protein C. However, epidemiologic studies support the assertion that even moderate elevations in HCY contribute to coronary, peripheral, and cerebral arterial disease. HCY in plasma can be measured after patients have fasted or after they have received a methionine load. Evidence indicates that both measures are important in that they are affected by different abnormalities of HCY metabolism, involving either the remethylation cycle or the trans-sulfuration pathway, respectively. In some cases, elevated HCY levels are partly due to a thermolabile form of the methylene tetrahydrofolate reductase (MTHFR) enzyme resulting from a polymorphism (C677T) in the coding region of the MTHFR binding site. This isoform occurs in up to 30% to 40% of the general population and introduces a higher set point for regulating HCY concentration (the substrate for MTHFR), particularly with relative folate deficiency. In fact, deficiency of any of

the vitamin cofactors of HCY metabolism (folate, vitamin B₆, and vitamin B₁₂) may lead to mild hyperhomocysteinemia. Reduction in HCY levels by supplementation with vitamin B₆, vitamin B₁₂, and folate is probably the most effective therapy for reducing the HCY level, but multiple randomized studies have shown that supplementation does not decrease atherothrombotic risk, regardless of the cause of hyperhomocysteinemia and the presence of the MTHFR polymorphism.

ROLE OF PLATELETS

Although EC-associated abnormalities clearly influence hemostasis, platelet activation and adhesion are also critical to the development of atherothrombosis, especially in patients with acute coronary syndromes and ischemic stroke. In addition, antiplatelet therapies are primary modalities for maintaining short- and long-term patency after coronary revascularization. Antiplatelet therapy can be targeted against specific platelet functions, including cyclooxygenase-mediated thromboxane A₂ formation, interaction of adenosine diphosphate (ADP) with its platelet receptor, and glycoprotein IIb/IIIa (GPIIb/IIIa)-fibrinogen binding for aggregation (Table 54-1). Aspirin has long been a mainstay in treatment of myocardial infarction, angina, and stroke because of its irreversible inhibition of platelet cyclooxygenase, a process leading to blockade of thromboxane A₂ release. Aspirin effectively blocks platelet aggregation to weak physiologic agonists over the lifetime of a platelet of about 7 to 10 days (see Chapter 53, Table 53-5); however, aspirin is only partially inhibitory to platelet stimulation by thrombin and strong agonists such as collagen. Thus, blockade of platelet activation pathways other than through thromboxane A₂ has become an important modality for therapy of patients at risk for arterial thrombosis. Some drugs used to treat stroke and coronary disease specifically block the platelet P2Y₁₂ ADP receptor from interaction with ADP in the clot milieu and thereby blunt platelet recruitment by preventing locally released ADP from activating additional platelets. Two thienopyrimidine derivatives, ticlopidine and clopidogrel, antagonize ADP-induced

platelet effects through their metabolites, which block ADP from binding to the platelet receptor. Both drugs are highly inhibitory to platelet function and produce bleeding times that are more prolonged than those produced with aspirin. Both are effective in combination with aspirin for preventing ischemic stroke and for blocking stent thrombosis after revascularization; however, the hematologic side effects of ticlopidine (TTP) have made clopidogrel the favored drug in this category. Some patients appear to have resistance to clopidogrel, defined as the lack of inhibition of platelet function; there is some evidence that this patient subset is heterozygous for a loss of function polymorphism in the *CYP2C19* gene.

A third avenue for blocking platelet activation targets GPIIb/IIIa, the primary platelet receptor for binding to fibrinogen and vWF. The modified monoclonal antibody abciximab prevents GPIIb/IIIa from binding to fibrinogen and blocks platelet aggregation after angioplasty, stent placement, and pharmacologic thrombolysis. Abciximab has been shown to reduce the incidence of recurrent acute ischemic events after percutaneous coronary revascularization in myocardial infarction and unstable angina patients mainly by decreasing the incidence of platelet-mediated thrombosis within the infarct related vessel during and after the procedure. Other GPIIb/IIIa blockers (e.g., eptifibatid [Integrilin] and tirofiban [Aggrastat]) that interfere with the GPIIb/IIIa arginine-glycine-aspartate (RGD) binding sites are also effective in treating acute coronary syndrome. Currently, GPIIb/IIIa inhibitors are indicated for acute parenteral use in patients with acute coronary syndromes and for maintaining coronary patency after revascularization. Thrombocytopenia is an uncommon (<2%) complication with all of the GPIIb/IIIa inhibitors, most likely related to exposure of neoepitopes on the receptor and immune-mediated platelet destruction. Clearance of the drug typically resolves the thrombocytopenia within 1 week. Platelet transfusion should be considered only if there is significant thrombocytopenic bleeding because of platelet transfusion's association with a high incidence of stent thrombosis after stent implantation.

Oral anti-GPIIb/IIIa formulations are not available because of two randomized trials in which mortality was increased in the GPIIb/IIIa inhibitor arms.

Not only is GPIIb/IIIa clearly critical for platelet-dependent atherothrombosis, it is apparent that a specific platelet GPIIb/IIIa allotype, human platelet antigen-1b (HPA-1b; see Chapter 53, Table 53-3), is a risk factor for coronary thrombosis. Studies have shown that the HPA-1b allotype of the GPIIIa molecule is associated with an increased incidence of coronary events, both myocardial infarction and unstable angina, as well as with coronary and cerebral injury after cardiac surgery. A large, long-term Danish study has shown that homozygosity for the HPA-1b allotype confers a threefold to fourfold increased risk for myocardial infarction in men. Evidence suggests that this and other platelet receptor allotypes associated with thrombosis promote increased platelet responsiveness to agonists and shear.

Inherited Risk Factors for Venous Thrombosis

The balance between thrombin formation and anticoagulant pathways has been extensively studied in patients with inherited deficiencies of naturally occurring anticoagulants (Table 54-2). These patients are predisposed to venous thromboembolism (VTE) and pulmonary embolism (PE).

FACTOR V LEIDEN

The most common inherited disorder leading to VTE is the FVL mutation. About 5% of individuals with European ancestry are heterozygous for FVL. The FVL mutation occurs at a site where activated protein C (APC) cleaves and inactivates normal factor Va (Arg506); abolition of this cleavage site results in APC resistance. Failure to inactivate the mutant factor Va allows the prothrombinase complex to be relatively uninhibited and leads to increased thrombin generation and

Table 54-2 Prevalence and Thrombotic Relative Risk (RR) Associations of Laboratory Findings

Prevalence in General Population	Venous RR	Arterial RR
Hyperhomocysteinemia ± MTHFR homozygosity C677T (10%-15%)*	3	1.16
Activated protein C resistance (5%)*		
Heterozygous FVL	7	1
Homozygous FVL	20-80	1
Prothrombin G20210A (1%-2%)		
Heterozygous G20210A	2-5	1
Homozygous G20210A	>5	1
Platelet GPIIb/IIIa HPA-1b homozygosity (2%-3%)		4 (MI in men)
Protein C deficiency (0.2%-0.5%)	7	1
Protein S deficiency (0.1%)	8.5	1
Antithrombin III deficiency (0.02%-0.05%)	8	1
t-PA (very high level/low activity) (rare)	~1	2 (stroke)/10 (MI) Plasminogen activator inhibitor (PAI-1) excess (rare)
Dysfibrinogenemia (rare)	~1	1.5?

Note: Data on prevalence and relative risk vary widely, often with conflicting results. This information represents an interpretation of data collected from various sources, mainly meta-analyses.

*MTHFR frequency in European-American population.

FVL, factor V Leiden; HPA-1b, human platelet antigen-1b; MI, myocardial infarction; MTHFR, methylene tetrahydrofolate reductase; PAI-1, plasminogen activator inhibitor-1; t-PA, tissue-type plasminogen activator.

a thrombophilic phenotype. About one fourth of patients with an initial occurrence of VTE or PE will have heterozygous FVL, and this percentage increases to nearly 60% in those with recurrent VTE or a strong family history of VTE or PE. APC resistance can be demonstrated by specialized clotting tests showing that the addition of APC fails to prolong the partial thromboplastin time (PTT). Genotyping can then confirm whether FVL is present and whether heterozygous or homozygous.

Inheritance of heterozygous FVL conveys an about sevenfold increased risk for VTE or PE. However, at 50 years of age, only 25% of persons with heterozygous FVL have had VTE or PE compared with much higher percentages in persons with other inherited thrombophilias. It is with concomitant *acquired* risk factors such as immobilization, pregnancy, or oral contraceptive use that the risk for VTE or PE in persons with FVL becomes more significant. Parenthetically, MTHFR mutations do not demonstrate a synergistic effect with FVL, but the prothrombin mutation (see below) does. Homozygotes for FVL have an increased risk for VTE that is estimated to be between 20- and 80-fold. Only occasional reports exist of patients with homozygous FVL who are asymptomatic into old age. It is worth noting that APC resistance *without* the FVL mutation can occur rarely. Factor V Cambridge, although much less common than FVL, has a similar mutation at an APC cleavage site (Arg306) and is associated with APC resistance and thrombosis. *Acquired* APC resistance can also occur and may be caused by the presence of a lupus anticoagulant or cancer and can also be seen with pregnancy, hormone replacement therapy, and oral contraceptives.

PROTHROMBIN G20210A

Another mutation associated with inherited thrombophilia is the prothrombin G20210A mutation, which occurs in the 3'-untranslated region of the prothrombin gene; this mutation leads to higher than normal prothrombin levels and about a twofold increased risk for VTE or PE. The heterozygous mutation is present in about 3% of European-derived populations but is identified in about 15% of patients with VTE or PE. Homozygous prothrombin G20210A patients are rare, but their relative risk for VTE is thought to be about 10-fold. How the prothrombin mutation exactly affects thrombus development has not been fully defined, but it appears to be related to changes in polyadenylation of the prothrombin messenger RNA (mRNA) during transcription. The diagnosis of the G20210A genotype is made by examining DNA for this specific mutation; no screening or functional assays are available.

INHERITED DEFICIENCY OF NATURAL ANTICOAGULANT PROTEINS

Deficiencies in the naturally occurring anticoagulants (AT, protein C, and protein S) are less common than FVL or prothrombin G20210A, but they are more likely to produce symptomatic venous thrombosis at an earlier age. Only about one half the thromboses that occur with these deficiencies are associated with acquired risk factors such as pregnancy, surgery, or immobilization. Deficiencies of AT, protein C, or protein S are detected by functional or anti-

genic assays because some mutations cause a quantitative decrease in the factor, whereas others produce a dysfunctional protein. Many gene mutations have been associated with these deficiencies, but none is predominant. Deficiencies of AT, protein C, and protein S in the aggregate account for fewer than 5% to 10% of all patients with VTE or PE.

AT is a naturally occurring anticoagulant that complexes with endogenous heparan sulfates to inhibit both formed thrombin and factor Xa. Heterozygous AT deficiency leads to AT levels of less than 50% and is generally associated with VTE or PE. However, reports have noted a homozygous mutation in the heparin-binding site of AT that results in arterial thrombosis. Thrombosis occurs by the age of 25 years in 50% of patients who are heterozygous for AT deficiency. AT has a low molecular weight and is lost in the proteinuria of nephrotic syndrome, leading to symptomatic acquired AT deficiency. Acquired AT deficiency (as well as protein C deficiency) may also be associated with severe hepatic veno-occlusive disease after stem cell transplantation; AT and protein C may be excessively consumed in the damaged hepatic microvasculature. It is not surprising, then, that low levels of AT are associated with poor outcomes in such severely ill patients. AT replacement with or without heparin appears to be useful in resolving both platelet consumption and the fluid disorders of veno-occlusive disease after stem cell transplantation. Successful treatment of symptomatic patients with heterozygous AT deficiency has included short-term replacement of AT with fresh-frozen plasma or the recombinant AT protein, usually coupled with unfractionated heparin (UFH) anticoagulation; prophylaxis studies of recombinant AT in deficient patients are ongoing. Long-term therapy for congenitally deficient patients has consisted primarily of warfarin.

The complex of thrombin and thrombomodulin on the EC surface activates protein C; APC coupled with its cofactor, protein S, cleaves and inactivates factors Va and VIIIa. These actions downregulate the prothrombinase and tenase complexes, respectively, to slow the rate of thrombin generation. Similar to AT deficiency, heterozygous protein C and protein S deficiencies are observed with venous, and occasionally arterial, thrombosis at a young age (median occurrence, 20 to 40 years). Homozygous protein C deficiency does occur and presents in the neonate as *purpura fulminans* with widespread venous thrombosis and skin necrosis. A similar clinical presentation has been reported in heterozygous protein C-deficient adults after instituting warfarin therapy *without* simultaneous heparinization, called *warfarin-induced skin necrosis*. About one third of these patients are deficient in protein C on a hereditary basis, whereas the rest appear to have acquired protein C deficiency. Warfarin inhibits production of vitamin K-dependent protein C synthesis, and because of the factor's short half-life, protein C levels rapidly fall before a decline in the levels of the procoagulant factors II, IX, and X. This imbalance shortly after starting warfarin may favor a procoagulant state and occasionally results in widespread microvascular thrombosis. Although protein C deficiency, either inherited or acquired, is infrequent, guidelines recommend that patients with active VTE be fully anticoagulated with UFH or low-molecular-weight heparin (LMWH) before concurrent warfarin therapy is begun, and heparin should be continued until warfarin is therapeutic for at least

48 hours. Inherited deficiency of protein S has similarly been implicated in warfarin-induced skin necrosis. Protein S deficiency is commonly acquired in acute illness. Protein S circulates in a free form and is bound to C4b-binding protein; only free protein S is active as a cofactor for protein C. C4b-binding protein is an acute-phase reactant, and thus, increased C4b-binding protein levels with severe illness can decrease free protein S levels. A similar effect is seen in normal pregnancy. Short-term therapy for homozygous C deficiency or doubly heterozygous protein C or S deficiency, especially in the setting of neonatal *purpura fulminans*, has included plasma or protein C concentrate with full-dose UFH anticoagulation. Functional levels of AT, protein S, and protein C are readily measured in clinical laboratories. Antigenic levels of these proteins can also be assessed to define whether a functional deficiency is caused by a dysfunctional protein versus diminished synthesis. As with AT deficiency, long-term treatment with warfarin has been successful in heterozygous protein C or S deficiency. As expected, both protein C and S levels are decreased during warfarin therapy, rendering their evaluation invalid when warfarin has been instituted.

Acquired Risk Factors for Venous Thrombosis

SURGERY

Medical and surgical illnesses convey increased thrombotic risk; these *acquired* risk factors are acknowledged, even though the pathophysiologic features favoring thrombosis may be uncertain (Table 54-3). Stasis of blood flow is a clear risk factor for thrombus formation (e.g., in the left atrial appendage with nonvalvular atrial fibrillation) and for systemic thromboembolism (e.g., stroke in this case) in non-anticoagulated patients. Other high-risk situations, including surgery (especially orthopedic) and trauma, are associated with immobilization with resultant stasis of lower extremity blood flow. When evidence of thrombosis is actively sought,

Table 54-3 Acquired Causes of Thrombosis

Medical and Surgical Illnesses

Antiphospholipid antibody, lupus anticoagulant
 Artificial heart valves
 Atrial fibrillation (nonvalvular)
 Hemolytic anemias (autoimmune hemolysis, sickle cell, thrombotic thrombocytopenic purpura, paroxysmal nocturnal hemoglobinuria)
 Hyperlipidemia
 Immobilization
 Malignancy
 Myeloproliferative disorders with thrombocytosis
 Nephrotic syndrome
 Orthopedic procedures
 Pregnancy
 Trauma, fat embolism

Medications

Heparin-induced thrombocytopenia
 Oral contraceptives, hormone replacement therapy
 Prothrombin complex concentrates

both surgery and trauma can be shown to be associated with extremely high (>50%) incidences of VTE. Besides immobilization, other pathophysiologic factors may contribute to the risk for VTE with surgery and trauma, including fat embolism and tissue damage, the latter especially after closed head injuries that result in massive tissue factor release. Prophylactic, permanent or temporary, inferior vena cava (IVC) filters are often placed in trauma patients to protect against PE, especially in high-risk patients in whom anticoagulation is contraindicated because of the increased risk for bleeding.

PREGNANCY AND FETAL LOSS

Pregnancy is a hypercoagulable state associated with venous stasis; increases in procoagulant proteins, such as fibrinogen, vWF, and factors VII, VIII, and X; decreased protein S; and increased fibrinolytic inhibitors, PAI-1, and TAFI. VTE can occur at any time during pregnancy or the puerperium. Inherited maternal thrombophilia can compound the procoagulant state of pregnancy and, in addition to the VTE risk in the mother, may predispose to fetal loss. The principal associated risk factors for fetal loss or stillbirth are FVL, the G20210A prothrombin mutation, AT deficiency, and protein C or S deficiency. Relative risks are markedly higher in mothers with a history of prior VTE, and the risk for fetal loss appears restricted to after 9 weeks of gestation. In fact, inherited thrombophilia appears to be protective against fetal loss in the first 9 weeks, possibly by means of limiting oxygen toxicity to the early embryo. As such, recommended indications for evaluating for inherited thrombophilia risk in women seeking to become pregnant are a history of VTE or recurrent fetal loss after 9 weeks of gestation when no specific cause can be identified. Both AT deficiency and hyperhomocysteinemia have also been associated with placental abruption. Aside from fetal loss due to thrombophilia, the risk for VTE and PE during pregnancy and in the postpartum period for women with identified thrombophilia is about fivefold higher than it is for nonpregnant women.

ORAL CONTRACEPTIVES AND HORMONE REPLACEMENT

Oral contraceptive use conveys an increased risk for VTE and PE, and a similar increased risk is seen early after instituting hormone replacement therapy (HRT). Concomitant heterozygosity for FVL further increases the risk for VTE and PE in women who take oral contraceptives or HRT. Cigarette use in women using oral contraceptives also significantly increases thrombosis risk, and this increase is thought to result from increased platelet reactivity, mediated in part by increased thromboxane synthesis. On the arterial side, epidemiologic evidence clearly points to smoking as the main cardiovascular risk factor but similarly implicates some risk attributable to long-term use of both the estrogen and progestin components of oral contraceptives and HRT; third-generation pharmaceuticals have not erased the thrombosis risk. As noted previously, acquired activated protein C resistance can be seen both in pregnancy and with oral contraceptive use, and both free and functional protein S levels decrease throughout pregnancy and with oral contraceptive use.

PROTHROMBOTIC DISEASE STATES

As noted earlier, thrombosis in nephrotic syndrome is associated with loss of AT through the kidneys. Hemolysis is a general prothrombotic state that appears to be mediated through blood cell destruction, perhaps by increasing exposure to procoagulant membrane phospholipids; hemolysis with TE complications has been noted with artificial heart valves, sickle cell disease, and other hemolytic anemias, including Coombs-positive autoimmune hemolytic anemia. In the case of paroxysmal nocturnal hemoglobinuria (PNH), complement activation may directly mediate platelet activation, and therapy with the complement inhibitor eculizumab has significantly decreased the rate of TE disease in PNH. Platelet activation and clearance appear to be the primary prothrombotic manifestations of heparin-induced thrombocytopenia and thrombotic thrombocytopenic purpura (TTP; see later). Although chronic disseminated intravascular coagulation is present in some malignancies (Trousseau syndrome), malignant diseases in general are associated with an increased risk for VTE and PE that is not related to disseminated intravascular coagulation. Such malignancies are not limited to mucinous adenocarcinomas or promyelocytic leukemia, and thrombosis occurs in a wide spectrum of malignancies, especially lung, breast, gastrointestinal, and any metastatic solid tumor. When idiopathic VTE or PE occurs in a cancer-free individual, an intensive work-up to find an occult malignancy is not warranted because this does not affect any subsequent cancer-related morbidity and mortality. However, once a cancer diagnosis is established in patients with prior VTE, they are at increased risk for subsequent VTE events, especially if the FVL or G20210A prothrombin mutation is present. UFH therapy in malignancy-associated VTE or PE appears to achieve outcomes superior to those provided by treatment with LMWH, direct thrombin inhibitors, or warfarin, possibly because of multiple beneficial anticoagulant effects mediated by the longer glycosaminoglycan sequences in UFH. In the special case of myeloproliferative disorders (e.g., essential thrombocythemia), abnormal platelet physiologic mechanisms causing hyperaggregability are often present and require platelet-specific inhibition (See “Hypercoagulability and Platelet Disorders” later).

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

Another acquired prothrombotic disorder is the antiphospholipid (aPL) syndrome. The aPL syndrome may exhibit as a primary disorder, or it may be associated with other autoimmune diseases such as systemic lupus erythematosus (SLE). The etiologic character of this connection with lupus has not been fully defined, but replacement of the host immune system after hematopoietic stem cell transplantation for refractory SLE has the potential to eradicate the lupus anticoagulant and TE risk. All the manifestations of aPL syndrome are related to hypercoagulability, including recurrent venous or arterial thrombosis, thrombocytopenia caused by microcirculatory platelet clearance, and recurrent fetal loss resulting from placental vascular insufficiency. The serologic markers of aPL syndrome include *anticardiolipin antibodies*, *anti- β_2 glycoprotein I antibodies*, or the *lupus anti-*

coagulant. The Sydney Consensus Criteria for Antiphospholipid Syndrome is the current standard for diagnosis of aPL. It includes the clinical criteria of radiologically or pathologically confirmed thrombosis or fetal loss when thrombosis is the etiology, and the laboratory criteria of at least one of the three potential laboratory findings being positive on two or more occasions at least 12 weeks apart. The anticardiolipin antibodies are usually detected by enzyme-linked immunosorbent assay (ELISA), whereas lupus anticoagulants are defined by prolongation of a phospholipid-dependent clotting test (prothrombin time [PT], PTT, or Russell viper venom clotting time), which is then corrected by the addition of excess phospholipid. Thus, *lupus anticoagulant* is actually a misnomer because its presence predisposes the patient to clotting rather than to bleeding. Another misleading aspect of this nomenclature is that phospholipid-reactive antibodies are actually directed against phospholipid-binding proteins in plasma, β_2 -GPI, annexin V, and prothrombin. The anti- β_2 -GPI can be detected by immunoassay, and this marker is most correlated with TE risk. The risk for thrombosis correlates best with the presence of the lupus anticoagulant and is highest if all three serologic markers are present when the relative risk has been estimated to be greater than 50.

Hypercoagulability and Platelet Disorders

Essential thrombocythemia and polycythemia vera are clonal myeloproliferative disorders associated with the *Jak-2* mutation. They are wholly (essential thrombocythemia) or partially (polycythemia vera) characterized by thrombocytosis, and patients with these disorders are at increased risk for thrombosis. Platelet aggregometry in these disorders often shows abnormal responses, especially to epinephrine and ADP; however, the abnormal aggregation does not correspond to either bleeding or thrombosis risk. Patients with polycythemia vera in particular have a high incidence of thrombosis in the mesenteric, portal, and hepatic venous circulation. Thrombotic complications, both arterial and venous, occur in essential thrombocythemia, even in young patients. However, no clear clinical risk factors predict which myeloproliferative patients will develop thrombosis. Platelet counts greater than 1,000,000/mcL are thought to increase the risk for thrombosis, and increased platelet turnover in thrombocytosis is also associated with thromboembolic complications. The latter has been demonstrated by radioactive platelet survival studies and an increase in the percentage of reticulated platelets. Antiplatelet agents may cause bleeding in patients with myeloproliferative disorders; thus, aspirin is indicated only in patients with *symptomatic* thrombosis, including those with erythromelalgia. Successful treatment of symptomatic patients with aspirin increases platelet survival by decreasing platelet clearance. Concomitant therapy to prevent thrombotic complications of thrombocytosis includes lowering the platelet count with hydroxyurea. Evidence suggests that patients with essential thrombocythemia who are at high risk for arterial thrombosis are most effectively treated with the combination of hydroxyurea and low-dose aspirin and should not receive anagrelide, which

may actually increase the incidence of arterial thromboses. Patients with reactive (secondary) thrombocytosis resulting from iron deficiency anemia, chronic infection, rheumatoid arthritis, or the postsplenectomy state do not generally have increased thrombotic risk.

HEPARIN-INDUCED THROMBOCYTOPENIA

Although also immune in nature, heparin-induced thrombocytopenia (HIT) must be distinguished from other drug-induced forms of thrombocytopenia because of its potentially catastrophic *thrombotic* complications and its unique pathophysiologic features. Nearly 25% of patients who are exposed to UFH will develop antibodies (detected by ELISA) that recognize the complex of heparin and platelet factor 4 (PF4), the latter being released from activated platelets. When such patients receive heparin again, between 5% and 10% will develop HIT, most with platelet counts between 50,000 and 100,000/mcL. HIT rarely occurs in patients who have not been previously exposed to heparin (0.3% incidence). Surgery is a specific risk factor for HIT; the incidence of HIT in surgical patients is about 2.6%, compared with 1.7% in medical patients. HIT antibodies occur with high frequency in patients undergoing either cardiac surgery with cardiopulmonary bypass or orthopedic procedures like hip replacement. In contrast to UFH, the incidence of HIT in patients who have received only LMWH is far lower—only about one-tenth the rate seen with UFH. However, the mechanism of thrombocytopenia for both UFH and LMWH appears to be similar: platelet Fc-receptor binding of the heparin-PF4 antibody complex causes signal transduction and platelet activation with an enhanced ability for thrombin generation on the platelet surface. The diagnosis is predominantly clinical, but the rapid ELISA test will detect heparin-PF4 antibodies in serum. The main drawback of ELISA is that it does not indicate whether the antibody complex is a functional activator of platelets; thus, it is sensitive but not specific for HIT. The serotonin release assay is the functional test for HIT, detecting platelet activation after exposure to serum antibody in the presence of a therapeutic heparin level.

The thrombin-based procoagulant response in HIT incorporates platelets into microcirculatory clots, leading to thrombocytopenia; about 30% of HIT patients have overt TE complications, which may be severe or life-threatening. TE events can occur before, concurrent with, and after development of thrombocytopenia in HIT, with about equal frequency. Although thrombosis is more frequent in patients with both HIT and concomitant cardiovascular disease and in those receiving full-dose heparin, any heparin dose (even heparin flushes) can result in thrombosis in HIT. Arterial and venous TE can even occur weeks after heparin has been discontinued, an effect perhaps mediated by EC glycosaminoglycan binding to PF4 serving as a target for circulating HIT antibodies. Discontinuation of heparin, however, is critical; moreover, although the antibody may have been induced by treatment with UFH, more than 80% of these antibodies cross-react with LMWH. Thus, the preferred therapy for short-term anticoagulation in patients with HIT is a direct thrombin inhibitor (DTI), such as lepirudin

and argatroban, which are not targets for the heparin-PF4 antibodies. Indeed, because the event rate for subsequent thrombosis, limb amputation, and death is increased in HIT patients even if they do not present with thrombosis, the case can be made for always instituting DTI therapy after discontinuing heparin. Lepirudin is given intravenously at 0.10 mg/kg per hour and adjusted to prolong the PTT to 1.5 to 2.5 times the baseline value. Renal insufficiency slows lepirudin clearance, increasing the level for a given dose and corresponding to an increase in PTT and bleeding risk. The alternative to decreasing the lepirudin dose is to substitute argatroban, which is cleared by hepatic metabolism. In patients who develop HIT after warfarin has already been started, vitamin K should be administered to correct the levels of protein C and to ensure adequate dosing of DTIs.

The current recommendation for HIT management is to continue DTI therapy until the platelet count is higher than 150,000/mcL. Warfarin can then be added, and the two therapies should overlap for at least 5 days. The DTI should not be stopped until the INR is therapeutic for at least 48 hours. Because DTIs prolong the INR, therapeutic warfarin will result in a supertherapeutic INR (usually >4); once DTIs are stopped, it is essential to repeat the INR 4 to 6 hours later to confirm that the INR is in the therapeutic range. If there is no thrombosis with HIT, the total duration of anticoagulation should be 4 weeks. When thrombosis is present, anticoagulation should be continued for 3 to 6 months. Warfarin should never be used primarily to treat HIT and should not be instituted without simultaneous DTI coverage; warfarin may induce acquired protein C deficiency in HIT, similar to the skin necrosis syndrome, resulting in venous limb gangrene. One hallmark of protein C depletion in HIT after warfarin is a too rapid rise in the INR to more than 3.5; in that circumstance, warfarin should be discontinued and the patient repleted with vitamin K. Patients with a history of HIT who need surgery requiring cardiopulmonary bypass can be safely re-exposed to brief systemic UFH if ELISA testing is negative for the antibody at least 100 days from the previous UFH exposure. Another important consideration in retreating patients with a history of HIT is the development of antibodies against lepirudin in at least one third of exposed patients; because fatal anaphylaxis has been reported, lepirudin cannot be used twice. Argatroban does not, by contrast, provoke an antibody response.

THROMBOTIC THROMBOCYTOPENIC PURPURA

Another nonimmune cause of thrombocytopenia resulting from platelet activation and clearance is TTP. In patients with congenital or familial TTP, mutations in the vWF-cleaving protease, ADAMTS-13, abrogate its activity. Patients with acquired TTP without a family history usually have an antibody, often immunoglobulin G (IgG), that blocks the normal function of this vWF-cleaving protease to less than 10% of normal. Ultralarge vWF multimers released by EC normally anchor to EC through P-selectin and form long strings that adhere and aggregate platelets in the microcirculation. ADAMTS-13 downregulates the size of these multimers by docking to the A1/A3 vWF domains and cleaving

within the A2 site. Deficient cleaving protease function in TTP leads to higher circulating levels of the larger, high-molecular-weight vWF multimers; these, in turn, cause increased platelet adhesion and clearance *without* activating the coagulation cascade. Therefore, both the PT and PTT are normal in TTP, unlike DIC. TTP after chemotherapy (mitomycin C) and in association with pregnancy, stem cell transplantation, lupus, or HIV infection appears to have a similar pathogenic mechanism of thrombosis. Thrombocytopenia (often severe) is accompanied by microangiopathy with schistocytes on the peripheral smear and increased serum lactate dehydrogenase. Microvascular occlusions in multiple organs cause many of the symptoms, especially in the kidney and brain. The classic pentad of signs (fever, thrombocytopenia, microangiopathic hemolysis, neurologic symptoms, and renal insufficiency) is present in fewer than 25% of patients with TTP. The diagnosis is generally made on the clinical assessment of thrombocytopenia and microangiopathic hemolytic anemia; assays for ADAMTS-13 activity and inhibitor are not yet widely available and do not have a rapid turn-around time.

Treatment of familial TTP is based on replenishment of cleaving protease activity with plasma transfusion; acquired TTP additionally requires removal of the antibody. The latter is accomplished by plasma exchange, whereby patient plasma is removed (plasmapheresis) and replaced with fresh-frozen plasma, often “cryo-poor” to reduce ultralarge vWF multimers in transfused plasma. Steroids and antiplatelet drugs (e.g., aspirin, dipyridamole) are often administered simultaneously, but the added benefit to plasma exchange remains unclear. Platelet transfusions are contraindicated in TTP because fatal thrombosis (e.g., myocardial infarction) has occurred in association with platelet transfusion. When plasma exchange fails to remit acquired TTP or when early relapse occurs, immunosuppressive therapy with anti-CD20 may be successful. The associated mortality of severe TTP (defined as undetectable ADAMTS-13 activity) is still significant, nearly 10% at 18 months after therapy with steroids and plasma exchange. Recombinant and purified forms of ADAMTS-13 are being investigated as potential therapeutic agents for treatment.

The *hemolytic uremic syndrome* (HUS) is part of the TTP spectrum of disease; however, the hemolytic anemia and renal failure of HUS are not usually accompanied by neurologic impairment, and HUS generally does not have the same degree of thrombocytopenia or schistocytosis as TTP. Moreover, less than 3% of HUS cases are associated with decreased vWF-cleaving protease activity. Unlike TTP, HUS is primarily diagnosed in children, and less commonly in adults, presenting with hemorrhagic colitis caused by Shiga-like, toxin-producing bacteria, especially the *Escherichia coli* 0157.H7 serotype. Atypical HUS (i.e., no diarrhea or Shiga-like toxin) is rarely associated with complement dysregulation due to mutations or polymorphisms in factors H, I, and B; these appear to increase platelet activation through complement (C3) deposition on the platelet surface. The similar pathophysiologic features of microvascular platelet thrombi place HUS within the TTP continuum, and indeed, some HUS patients, especially those with atypical disease, respond to plasmapheresis with plasma exchange as well as to maintenance hemodialysis until renal function recovers.

Table 54-4 Laboratory Evaluation of Venous Thrombosis

Antithrombin III activity
Protein C activity
Protein S activity, if abnormal reflex antigenic levels (total/free)

Laboratory Evaluation of Thrombosis

Recurrent venous thromboembolism (VTE) is a strong indication for laboratory testing for causes of thrombophilia, especially in patients younger than 50 years of age, in patients with unexplained VTE, and in those with a family history of venous thrombosis. In these patients, any risk factors that may predispose the individual to recurrence must be defined, as well as any inherited disorders that may necessitate family counseling or avoidance of additional environmental risks. The current assays in the work-up of venous thrombophilia include the following: (1) APC resistance using a dilute factor V method, (2) genotyping for prothrombin G20210A, (3) lupus anticoagulant assay and anticardiolipin and anti- β_2 -GPI antibodies, (4) functional AT level, and (5) functional protein C and protein S levels (Table 54-4). Genotyping for the FVL mutation should be done when APC resistance is present to define whether FVL is truly present and, if so, to determine whether the patient is heterozygous or homozygous. There has been little standardization of lupus anticoagulant testing. Hence, testing for antibodies specific to β_2 -GPI can be helpful when the aPL syndrome is strongly suspected and no lupus anticoagulant is detected.

The utility of laboratory testing in the setting of atherothrombosis and arterial thromboembolism is unclear. Platelet-specific risk factors for both arterial and venous thrombosis have not been defined adequately for available laboratory tests to give meaningful or prognostic data. Therefore, platelet aggregation studies and examination of platelet receptor allotypes are not routinely indicated. In the setting of a myeloproliferative disorder, the platelet count and platelet aggregation, as well as platelet closure times, are the only available useful tests that might additionally justify hydroxyurea therapy. In patients with recurrent thromboses or a strong family history, other assays can be justified, including testing for t-PA and PAI-1 levels, and dysfibrinogenemia (prolonged thrombin or reptilase time), all of which should be done in consultation with specialists in hemostasis.

Therapy for Venous Thromboembolism

Prophylaxis for VTE should be administered in patients undergoing surgical procedures that carry an increased

risk for producing venous thrombosis, especially orthopedic procedures or major operations requiring significant postoperative immobilization. Prophylactic therapies include lower extremity intermittent compression and pharmacologic treatment with UFH or LMWH. Once thromboembolism is diagnosed, immediate therapy is required. In most patients with venous thrombosis, anticoagulation is accomplished on a short-term basis with heparin compounds and on a long-term basis with warfarin. Thrombolytic therapy is indicated for patients with extensive proximal venous clots or PE. IVC filters are used in patients with contraindications to anticoagulation, complications of anticoagulation (usually active bleeding), or failure of anticoagulation (recurrent PE). IVC filters clearly decrease the incidence of early PE, but their use is also associated with thrombosis at the insertion site and late complications of IVC thrombosis and a 10% to 20% incidence of postphlebotic syndrome; whether simultaneous low-dose anticoagulation will prevent these complications is unknown. Temporary IVC filters are often used in trauma patients and appear to be most efficacious when they are placed for fewer than 7 to 10 days.

UFH is often the inpatient therapy of choice for acute anticoagulation because of its low cost, ease of monitoring, and short half-life. Heparin is begun as a bolus intravenous infusion of 80 U/kg, followed by a continuous infusion of 18 U/kg per hr; heparin doses in excess of 30,000 U per day have been shown to be most efficacious at preventing recurrent thrombosis. Heparin is monitored by the PTT. A therapeutic PTT for heparin is between 1.8 and 2.5 times the patient's initial PTT value. This PTT range should correspond to therapeutic anti-Xa levels of 0.3 to 0.7 U/mL. Adjustment of the heparin infusion should be based on the patient's weight and the PTT (Table 54-5); discontinuation of the heparin infusion, even for a brief period, may allow the PTT to normalize because of heparin's short half-life (about 4 hours). UFH should be continued for 4 days or more (longer in patients with extensive clots), and UFH can be discontinued when patients are fully anticoagulated with warfarin (INR ≥ 2 for 2 consecutive days). Some patients may receive large doses of heparin (usually $>40,000$ U per day), and yet the PTT does not become therapeutic. This *heparin resistance* is caused by a dissociation of the PTT and the true heparin activity; thus, monitoring of anti-Xa levels is generally indicated in heparin resistance. Heparin resis-

tance is only rarely caused by AT deficiency; more often, heparin resistance occurs in patients with coexistent inflammatory disease and is caused by increased plasma levels of factor VIII and other heparin-binding proteins.

LMWH is an excellent alternative to UFH in the management of thromboembolism and acute coronary events. The advantages of LMWH over UFH include the following: (1) reduced binding to macrophages and EC, a process that increases the plasma half-life of LMWH; (2) less nonspecific binding to plasma proteins that leads to a more predictable dose response and allows for intermittent fixed dosing; (3) reduced binding to platelets and PF4, with a resulting lower de novo incidence of HIT (10% to 20% of the rate for UFH); and (4) reduced bone loss. Although the incidence of HIT is lower with initial use of LMWH than with UFH, once HIT is established, antibody cross-reactivity with all the LMWH preparations precludes subsequent use of LMWH in HIT (see earlier). All the LMWH preparations (dalteparin, enoxaparin, nadroparin, and tinzaparin) have been shown to be as safe and effective as UFH in prophylaxis for VTE, treatment of uncomplicated VTE, and treatment of symptomatic PE when given in a subcutaneous, weight-adjusted dose. In particular, outpatient therapy with LMWH for uncomplicated VTE provides a significant cost saving (when compared with hospitalization for intravenous UFH) without compromising patient outcome. Because of its predictable dose-response curve, LMWH therapy does not require monitoring. LMWH therapy does not prolong the PTT and can only be monitored (e.g., in renal failure) by anti-Xa levels. Peak anti-Xa levels generally occur between 3 and 5 hours after subcutaneous LMWH injection. LMWH anti-Xa levels at that time point are 0.5 to 1 U/mL for twice-daily dosing and 1 to 2 U/mL for once-daily dosing; significant anti-Xa activity persists in plasma for 12 hours after subcutaneous injection. As with UFH, switching from LMWH to warfarin for long-term management can be accomplished after therapeutic INR values are present for 2 to 3 days.

Warfarin is still the current treatment of choice for long-term anticoagulation and for preventing early recurrence of thrombus. Warfarin should be begun in the first 24 hours after presentation with VTE, concurrent with heparin treatment. The PT is prolonged within hours by warfarin because of a rapid decrease in factor VII levels; however, therapeutic warfarin anticoagulation does not occur until other vitamin K-dependent factors (II, IX, and X) also decrease. Therapeutic warfarin anticoagulation usually requires at least 4 to 5 days of adequate warfarin dosing starting at 5 mg daily for 2 to 3 days; UFH or LMWH can be discontinued after at least 4 days of therapy and only when the INR is more than 2 for at least 2 consecutive days. One long-standing problem with warfarin anticoagulation is the interindividual variability in INR response to the same dosing among similar-sized individuals; at least 50% of this variability in sensitivity to warfarin may be explained by polymorphisms in the *CYP2C9* and *VKORC1* genes (see "Prospectus for the Future"). Accounting for genetic differences in these enzymes that metabolize and clear warfarin, as well as for age and body surface area, has yielded useful models for predicting safe and therapeutic warfarin dosing.

The intensity of warfarin dosing, evaluated by the INR, depends on the condition predisposing the patient to thromboembolism. Treatment of uncomplicated VTE in a patient

Table 54-5 Unfractionated Heparin Dose Adjustment Based on Partial Thromboplastin Time (PTT) and Weight*

PTT Value (Times Baseline)	Heparin Adjustment
1.2-1.5	40 U/kg bolus, \uparrow infusion by 4 U/kg/hr
$>1.5-2.4$	No change
$>2.4-3.0$	\downarrow Infusion by 2 U/kg/hr
>3.0	Hold infusion for 1 hr, \downarrow infusion by 3 U/kg/hr

*After initial therapy with 80 U/kg bolus and 18 U/kg/hr infusion.
 \uparrow , Increase; \downarrow , decrease.

Table 54-6 Therapeutic International Normalized Ratio (INR) Ranges for Warfarin According to Patient Subgroup

Subgroup	INR Range
Venous Thrombosis	
Treatment	2.0-3.0
Prophylaxis	1.5-2.5
Artificial Heart Valves	
Tissue	2.0-2.5
Mechanical	3.0-4.0
Atrial Fibrillation (Nonvalvular)	
Prophylaxis	1.5-2.5
Lupus Anticoagulant	
Treatment, prophylaxis	2.0-3.0
Refractory thromboembolism	3.0-4.0

without known risk factors does not require an INR exceeding 3; in contrast, warfarin for recurrent thrombosis in treated patients with aPL syndrome may require INR values between 3 and 4 (Table 54-6).

The duration of warfarin treatment also varies depending on the circumstances of the VTE, the estimated clinical risk for bleeding, and the potential for recurrence. In general, the longer the period of anticoagulation with warfarin, the less the chance of recurrence; short-term warfarin (6 weeks) is not as effective at preventing recurrence compared with longer courses (6 months). Patients with definite, transient risk factors such as orthopedic surgery have low recurrence rates, even with short-term therapy; in contrast, patients with idiopathic thromboembolism have significant recurrence rates, even after 3 to 6 months of warfarin. Recent studies suggest that patients with idiopathic thromboembolism can be monitored for recurrence risk using the D-dimer measurement. For patients who have had their first unprovoked VTE episode, an elevated D-dimer 1 month after stopping anticoagulation conveys an increased risk for VTE recurrence compared with matched patients with a normal result. Resuming anticoagulation in that patient subset should decrease the D-dimer into the normal reference range. Evidence also indicates that inherited hypercoagulable disorders, such as FVL, probably confer a lifelong increased risk for VTE or PE. Some studies have shown that the bleeding risks incurred by long-term, but low-intensity, warfarin use are favorably balanced by the decreased incidence of recurrent thrombosis. Therefore, the presence of inherited thrombophilia may warrant continuing warfarin for a longer period, depending on the patient's other medical illnesses and whether transient circumstances may have predisposed the patient to VTE. Patients who develop recurrent VTE after discontinuation of warfarin should receive long-term anticoagulation, regardless of whether they have a defined cause of thrombophilia. Patients with aPL syndrome and a first episode of VTE are at very high risk for recurrent VTE (up to 50% per year) after anticoagulation is discontinued, clearly supporting the rationale for testing for aPL. Table 54-7 suggests broad guidelines for the duration of warfarin therapy in specific patient subgroups. Because

Table 54-7 Guidelines for Duration of Anticoagulation in Venous Thromboembolism

Condition	Duration of Therapy
Distal or superficial vein thrombus	3 mo
First Proximal VTE/PE	
No risk factors	Long-term*
Correctable risk factor (e.g., surgery, trauma)	3-6 mo
Malignancy	Long-term
Antiphospholipid syndrome	Long-term
Inherited risk factor [†]	>6 mo
Recurrent VTE/PE	Lifelong

*Long-term therapy must be adjusted individually according to other diseases, risks for bleeding, presence of transient risk factors, and ease of compliance.
[†]Inherited risk factors include factor V Leiden; prothrombin 20210A; deficiencies of antithrombin III, protein C, or protein S.
 VTE/PE, venous thromboembolism/pulmonary embolism.

Table 54-8 Drugs that Affect Warfarin Levels

Drugs that Increase Warfarin Levels: Prolonged INR

↓ Warfarin clearance
 Disulfiram
 Metronidazole
 Trimethoprim-sulfamethoxazole
 ↓ Warfarin-protein binding
 Phenylbutazone
 ↑ Vitamin K turnover
 Clofibrate

Drugs that Decrease Warfarin Levels: Subtherapeutic INR

↑ Hepatic metabolism of warfarin
 Barbiturates
 Rifampin
 ↓ Warfarin absorption
 Cholestyramine

↑, Increased; ↓, decreased; INR, international normalized ratio.

warfarin is a teratogen; effective contraception should be used concurrently in women of childbearing age.

Supratherapeutic INR levels commonly occur with warfarin therapy, with or without bleeding. In patients with moderately elevated INR values (>5) with little or no bleeding, temporary discontinuation of warfarin and reinstitution of the drug at a lower maintenance dose may be sufficient. Patients with higher INR values (5 to 9) without serious bleeding should have warfarin withheld and receive low doses (1 to 2.5 mg per day) of oral vitamin K to reach therapeutic INR levels; parenteral vitamin K can be given if gastrointestinal function is problematic. When serious active bleeding occurs with high INR values, especially if surgery is required to correct the bleeding, a combination of vitamin K and transfusion of plasma (see Chapter 53) will rapidly correct the INR. The INR can become elevated as a result of concurrent use of drugs that increase free warfarin levels (Table 54-8). Whenever bleeding occurs as a complication of anticoagulation, serious consideration must be given to

future bleeding risks and to whether the patient requires prophylactic IVC filter placement.

Antithrombotic Therapy during Pregnancy

Heparins, both UFH and LMWH, are the safest therapy for venous thrombosis during pregnancy; heparin does not cross the placenta, unlike warfarin, which causes a characteristic fetal embryopathy. Warfarin also causes fetal hemorrhage and placental abruption and should be avoided during pregnancy. VTE or PE during pregnancy should be treated with intravenous UFH for 5 to 10 days, followed by an adjusted-dose regimen of subcutaneous UFH, starting with 20,000 U every 12 hours and adjusted to achieve a PTT higher than 1.5 times baseline at 6 hours after injection. An attractive alternative to UFH during pregnancy is LMWH, which can be given subcutaneously once or twice daily and does not require monitoring. Suprarenal IVC filters have also been used successfully during pregnancy without significant morbidity. In women with aPL syndrome who become pregnant, therapy is critical to prevent fetal loss; aspirin (160 mg) is combined with prophylactic doses of either subcutaneous UFH (10,000 to 15,000 U per day in divided doses) or LMWH (to achieve an anti-Xa level of 0.1 to 0.3 U/mL). When such women have a history of TE disease, therapeutic doses of LMWH or UFH plus aspirin are employed.

Heparin should be discontinued at the time of labor and delivery, although the risk for hemorrhage is not high during delivery, especially if anti-Xa levels are less than 0.7 U/mL. One concern with residual anticoagulation at delivery is the risk for spinal hematoma with epidural anesthesia; this concern has been reported with both UFH and LMWH. The anti-Xa level that is safe for an epidural procedure is not known. Protamine sulfate can be used to neutralize UFH if the PTT is prolonged during labor and delivery; however, LMWH is only partially (10%) reversed by protamine.

Anticoagulation during the postpartum period can be carried out with heparin or warfarin; neither drug is contraindicated during breastfeeding. Women receiving long-term warfarin therapy (e.g., for valvular heart disease) who wish to become pregnant need to be switched to a fully anticoagulating dose of UFH or LMWH; warfarin treatment can be restarted postpartum.

Perioperative Anticoagulation

A common clinical problem is the management of anticoagulation in patients who require surgery. The principles of care in this situation reflect the need for adequate hemostasis during and immediately after surgical procedures and the critical importance of restarting anticoagulation as soon as possible postoperatively, especially because surgery itself represents a relative hypercoagulable state. In patients with VTE who are anticoagulated on a short-term basis (<1 month), elective surgical procedures should be postponed; if such patients must undergo surgery, discontinuation of anticoagulation and placement of a temporary IVC filter may be the best option. In most patients receiving long-term anticoagulation for VTE, preoperative heparin is not generally used; warfarin should be discontinued for at least 4 days preoperatively to allow the INR to decrease gradually to less than 1.5, a level that is safe for surgery. Postoperatively, intravenous heparin can be safely used for anticoagulation until therapeutic INR levels are reached after restarting warfarin. These guidelines obviously should be tailored to individual patient care. Patients with arterial thromboembolic disease may need heparin therapy right up until the time of the surgical procedure and shortly thereafter. In contrast, heparin therapy immediately after a major surgical procedure may be contraindicated because of the high risk for hemorrhage; anticoagulation may need to be delayed in this instance for 12 to 24 hours postoperatively.

Prospectus for the Future

Therapy for hypercoagulable states is increasingly being tailored to individual needs, that is, “personalized medicine”:

- New labeling of warfarin includes information about how variations in the *CP2C9* and *VKORC1* genes account for differences in drug metabolism. Optimal maintenance dosing of warfarin will likely drive testing for these polymorphisms as part of future practice.
- Abnormalities in platelet aggregability and vWF multimer distribution have been noted in cancer, autoimmune disease, and pregnancy, with the potential for using these measures for overall thrombotic risk assessment.
- Similar stratification of thrombosis risk may involve TAFI, which inhibits fibrinolysis by protecting fibrin from the

cleaving effect of t-PA. High TAFI levels correlate with cardiovascular disease and stroke, and polymorphisms may be responsible.

With respect to therapy, an antithrombotic effect of C1q-TNF receptor protein (CTRP) has been demonstrated in animal models. CTRP blocks vWF binding sites on collagen, thereby preventing platelet interaction with collagen at arterial shear rates, and CTRP may also inhibit platelet aggregation directly. Because CTRP preserves overall hemostatic function as assessed by the activated clotting time, it has promise for treating arterial vascular disease.

Cancer Biology and Etiologic Factors

Alok A. Khorana and Barbara A. Burtness

Cancer is primarily a genetic disease. For most human cancers, a complex succession of multiple genetic mutations is necessary for the transformation of a normal cell into a tumor cell. Tremendous strides have been made in understanding the classes of genes responsible for the pathogenesis of cancers, epigenetics, the principles governing aberrant signal transduction in cancer cells, and cancer stem cells. This revolution in the understanding of cancer biology has led to a new wave of research into the design of drugs directed against specific targets and pathways in the cancer cell. This chapter reviews the cancer phenotype and principles of cancer biology.

Hallmarks of the Cancer Phenotype

More than 100 distinct types and subtypes of human cancer exist, involving nearly every organ and tissue of the body. Pathologically, these cancers may resemble the tissue from which they have arisen, for example, adenocarcinomas of the gastrointestinal tract show glandular formation similar to normal gastrointestinal mucosa. Despite this diversity, most cancers share essential traits that must be acquired for malignant growth. In this sense, tumor cells resemble other tumor cells much more than they resemble the normal cells of their tissue of origin. Hanahan and Weinberg have described the six essential acquired capabilities essential for tumor growth (Table 55-1). *Autonomy*, or self-sufficiency in growth signals, is most apparent when cells are grown in culture: normal cells require the addition of mitogenic growth factors, whereas tumor cells generate many of their own growth signals, and proliferate with little dependence on exogenous growth stimulation. In normal tissues, tight control of proliferation is achieved by the use of multiple growth inhibitors. Tumor cells, in contrast, display *insensitivity to anti-growth signals*. In addition, tumor cell populations maintain continued expansion by reducing the rate of cell attrition—primarily by acquiring *resistance to apoptosis*, or programmed

cell death. Normal cells stop growing after a certain number of doublings. Tumor cells, in contrast, are immortalized in culture because of the acquisition of *limitless replicative potential*. The induction of *angiogenesis*, or the establishment of a blood supply, is essential for tumors to grow beyond a size of 1 to 2 mm. This process is regulated by a balance between proangiogenic and antiangiogenic molecules. The proangiogenic vascular endothelial growth factor (VEGF-A) is a major mediator of tumor angiogenesis. Most human cancers express VEGF, as do various host cells. Bevacizumab, an anti-VEGF antibody, and sorafenib and sunitinib, oral small molecule VEGF receptor tyrosine kinase inhibitors, are all U.S. Food and Drug Administration–approved antiangiogenic agents used in a variety of cancers (see Chapter 59). Finally, the capacity for *invasion and metastasis* allows tumor cells to escape their primary sites and establish colonies at sites where nutrients and space are not limiting. Metastatic disease is the cause of death in more than 90% of cancer patients. Separate mutations are not required to acquire each of these characteristics (e.g., loss of the *p53* tumor suppressor gene can confer both uncontrolled growth and resistance to apoptosis). In the following section, the alterations in genes that are responsible for the acquisition of these common tumor characteristics are discussed.

Cancer Genetics: The Pathways to Cancer

The development of most human cancers is a multistep process, involving a complex succession of multiple genetic mutations (with some notable “one-hit” exceptions, e.g., *bcr-abl* translocation in chronic myelogenous leukemia). At each step, the cell undergoing transformation acquires a capability that provides a growth or survival advantage relative to the other, normal cells in the population, similar to darwinian evolution. Most invasive cancers develop only when several genes are mutated; this differentiates cancer from other genetic diseases such as cystic fibrosis in which

mutations in one gene alone cause disease. Studies suggest that four to seven mutational events must occur for progression to the malignant phenotype. Mutations can occur upon exposure to environmental carcinogens, in the setting of dysregulated DNA repair, as a consequence of random replication errors, or, occasionally, in families with hereditary germline mutations in a cancer gene. Broadly, mutations in three classes of genes are responsible for cancer: oncogenes, tumor suppressor genes, and stability or caretaker genes. Table 55-2 shows the clinical consequences of selected mutations in these classes of genes.

ONCOGENES

Oncogenes are evolutionarily conserved genes that play an important role in normal cellular proliferation. Oncogene activation can result from chromosomal translocations, gene amplifications, or intragenic mutations. Activation of an oncogene leads to increased activity of the gene product. For example, chronic myelogenous leukemia (CML) occurs when the proto-oncogene *abl* from chromosome 9 translocates to the *bcr* gene on chromosome 22. The new protein formed by the union of the *bcr* and *abl* oncogenes, called *bcr-abl*, plays a role in coupling cell surface receptors to the signal transduction pathway, with resulting unchecked growth-promoting signals to the nucleus. An activating mutation in one allele of an oncogene is generally sufficient for enhancing tumorigenesis. Oncogene research has led to the use of oncogenes as targets of specifically designed drugs. Oncogenes are also used as biomarkers to predict prognosis and select therapy. The presence of *t(8;21)* or *inv(16)* translocations in patients with acute myelogenous leukemia

(AML) is usually predictive of a good response to standard antileukemic therapy. In patients with breast cancer, overexpression of *HER-2* is overall predictive of a poor prognosis but also of an excellent response to the anti-*HER-2* monoclonal antibody, trastuzumab.

Certain classes of signaling proteins are targeted much more frequently by oncogenic mutations. Recent research has focused particularly on *protein tyrosine kinases* (TKs), enzymes that catalyze the transfer of phosphate from adenosine triphosphate (ATP) to tyrosine residues in polypeptides. TKs normally regulate important cellular processes, including proliferation, survival, differentiation, function, and motility. Mutations in this small group of genes are responsible for a significant portion of human tumors. TKs can be perturbed in cancer by multiple mechanisms: overexpression of a normal receptor TK or its ligand, constitutive activation of receptor TK (in absence of ligand), or fusion of TK with a partner protein as a consequence of a chromosomal translocation or deletion (common in hematologic malignancies, such as the *bcr-abl* translocation in CML discussed previously). Inhibition of TK activity has emerged as a leading avenue for new cancer drug development. Imatinib, a small molecule directed against the kinase domain of the *bcr-abl* oncoprotein has been remarkably successful in inducing responses in patients with chronic-phase CML (see Chapter 59). Other anti-TK drugs include antibodies against receptor TKs or their ligands to interrupt TK signaling.

TUMOR SUPPRESSOR GENES

Tumor suppressor genes are recessive genes that keep cellular growth in check. When tumor suppressor genes undergo mutation or deletion, the rate of neoplastic transformation is much higher. Tumor suppressor genes are targeted in a different way than oncogenes: mutations in these genes result in a decreased activity of the gene product. Unlike oncogene activation, mutations in both alleles of a tumor suppressor gene are required to induce tumorigenesis. For instance, a germline (inherited) mutation in a single retinoblastoma gene (*RB-1*, a tumor suppressor gene) may not, by itself, cause retinoblastoma in a young child. However, if that child's genome suffers a "second hit" after birth (an *RB-1* somatic mutation), multiple tumors including bilateral retinoblastomas may occur. Single mutations in

Table 55-2 Cancers Associated with Selected Genetic Mutations

Gene	Associated Hereditary Syndrome	Major Tumor Types
A. Oncogenes		
<i>bcr-abl</i> Translocation	—	Chronic myelogenous leukemia
<i>BCL-2</i>	—	Chronic lymphocytic leukemia
<i>KIT, PDGF-RA</i>	Familial gastrointestinal stromal tumors	Gastrointestinal stromal tumors
B. Tumor Suppressor Genes		
<i>p53</i>	Li-Fraumeni syndrome	Breast, sarcoma, adrenal, brain, multiple others
<i>APC</i>	Familial adenomatosis polyposis	Colon, stomach, intestine
<i>VHL</i>	von Hippel-Lindau syndrome	Kidney
C. Stability Genes		
<i>BRCA-1, BRCA-2</i>	Hereditary breast cancer	Breast, ovary
<i>MSH-2, MLH-1</i>	Lynch syndrome	Colon, uterus, stomach

the *RB-1* tumor suppressor gene may predispose to osteosarcoma, soft tissue sarcoma, melanoma, and brain tumors later in life. The tumor suppressor gene *p53* is the most commonly mutated gene in sporadic human cancers. This gene deletion can also be inherited, and progeny have a much higher rate of a variety of cancers, including breast and brain tumors, leukemia, and sarcoma, a pattern termed the *Li-Fraumeni syndrome*. If an environmental insult results in mutation or deletion and loss of function of the remaining normal copy of *p53* in any cell, a tumor may arise in that organ; this mechanism of carcinogenesis has been described for breast cancer, leukemia, and sarcoma, among other cancers. Suppressor gene mutations are also the most common cause of hereditary cancer.

STABILITY GENES

Accumulating evidence suggests that, in addition to oncogenes and tumor suppressor genes, mutations in a third class of genes called *stability or caretaker genes* can also promote tumorigenesis. Stability genes are responsible for the repair of errors in normal DNA replication and include mismatch repair genes, base-excision repair genes, and nucleotide-excision repair genes. Mutations in stability genes lead to increased errors in replication. Eventually, mutations in oncogenes and tumor suppressor genes occur, and this drives malignant transformation. The Lynch syndrome, or hereditary nonpolyposis colon cancer, is an example of an inherited syndrome of defects in DNA mismatch repair genes. Colon and endometrial cancers are two of the most commonly observed cancers in families afflicted by the Lynch syndrome. Somatic mutations in these genes are responsible for 10% to 15% of sporadic colon cancers as well. Similar to tumor suppressor genes, both alleles of stability genes must be inactivated for tumorigenesis to occur.

ADENOMA-TO-CARCINOMA SEQUENCE

The cascade of genetic events that leads to the transformation of normal colonic mucosa through development of preneoplastic polyps into colon cancer provides an excellent example of tumorigenesis in an epithelial organ (Fig. 55-1). The earliest change, or “gatekeeper” mutation, associated with adenomatous polyps is in the tumor suppressor *APC*

gene. *K-ras* mutations occur relatively early and appear to correlate with early to late adenomas. Mutations in *p53* occur later in this sequence and may mark the transition from adenoma to carcinoma. As discussed previously, mutations in DNA mismatch repair genes create a mutator phenotype in which mutations in *APC* can occur, initiating neoplastic transformation and subsequent mutations. The genetic pathway responsible for tumorigenesis has clinical consequences: colon cancers that are initiated by defects in stability genes (the so-called microsatellite instability pathway) are characterized by a better prognosis but possible resistance to adjuvant 5-fluorouracil chemotherapy, in contrast to those primarily initiated by *APC* mutations (the so-called chromosomal instability pathway).

CANCER EPIGENETICS

The term *epigenetics* refers to changes in gene expression without alteration in the DNA sequence. Epigenetic changes in gene expression are hallmarks of malignancy. For instance, tumor suppressor genes can be silenced by DNA hypermethylation. Gene expression can also be altered by histone acetylases, which influence how tightly genomic DNA is spooled around histones, and alter the interaction of chromatin proteins with DNA. These epigenetic patterns are being studied as diagnostic, prognostic, and predictive markers and are also emerging as therapeutic targets. The demethylating agents 5-azacytidine and decitabine have activity in myelodysplastic syndromes and leukemia. Histone deacetylase inhibitors have modest activity in certain lymphomas.

Cancer Stem Cells

A newer view of cancer biology suggests that only a rare subpopulation of cancer cells has the capacity for self-renewal, differentiation, and unlimited proliferation. These rare cells have been termed *cancer stem cells*. In hematologic malignancies and some solid tumors, these cancer stem cells have the ability to re-form the tumor, whereas most other malignant cells do not. This has important consequences for understanding cancer biology, drug resistance, prognosis, and treatment. Cancer stem cell biology is an area of intense research.

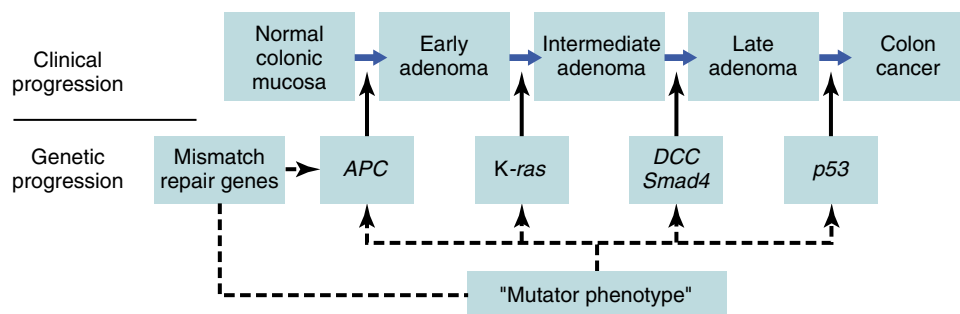

Figure 55-1 Adenoma to carcinoma sequence. Development of colon cancer from normal colonic epithelium is an example of multistep progression of neoplasia. In most patients, mutation of the tumor suppressor *APC* gene is the initial step, followed by mutations in *K-ras*, *DCC*, and *p53* genes. However, defects in DNA mismatch repair genes (hereditary or acquired), as shown on the left, can create a mutator phenotype, which can initiate and possibly accelerate this multistep progression.

Prospectus for the Future

The completion of the human genome project and continued advances in technologies for gene discovery will allow further rapid progress in cancer molecular genetics. Transforming these discoveries into meaningful advances in therapies for cancer patients, so-called translational research, remains, however, an extraordinary challenge for which no clear road map exists. Research endeavors that bridge gaps in knowledge between the bench and bedside will preoccupy oncologists for the next generation. In addition, discoveries in cancer genetics and epigenetics will be used even more effectively to develop

sophisticated diagnostic tests (such as fecal DNA analysis or detection of circulating tumor cells) that can lead to discovery of cancers at much earlier, curative stages. In the meantime, cancer-related mortality continues to rise worldwide, and cancer is expected to become the leading cause of death in the United States in the next decade. Despite recent promising successes, we are only at the threshold of understanding and treating the complex and heterogeneous group of diseases collectively known as cancer.

Cancer Epidemiology and Cancer Prevention

Paula M. Lantz and Jennifer J. Griggs

Cancer Epidemiology

Each year, there are more than 11 million cancer cases diagnosed, 7 million cancer deaths, and 22 million cancer survivors worldwide, with significant increases projected because of population aging. Population-based estimates of cancer incidence are derived from tumor registry data. *Cancer incidence rates* are expressed as the number of new cases per 100,000 people. The risk for developing a particular type of cancer can be described as a *lifetime risk* or as an *age group-specific risk* (Table 56-1). Population-based estimates of cancer mortality are derived from cause of death information on death certificates. *Disease-specific mortality rates* are also expressed as rate per 100,000. Because age distributions change both within and across populations over time, cancer incidence and mortality rates are age adjusted.

Survival rates are usually expressed as relative survival rates, which consider mortality from other causes when describing cancer survival. For example, the 5-year *relative survival rate* is the percentage of people who did not die from their specific type of cancer within 5 years of diagnosis, taking into account expected age-specific mortality from other causes. Survival rates are reported by the stage of disease at diagnosis. People who have limited-stage disease (confined to the organ of origin) have higher 5-year survival rates than those with regional disease (involving regional lymph nodes), and people with regional disease have higher survival rates than do people with metastatic disease.

Cancer mortality rates in the United States and most other developed countries are consistently greater among people of lower socioeconomic position and among those from racial and ethnic minority groups, especially African Americans. Differences in mortality and survival rates across racial and ethnic groups are not fully accounted for by differences in the stage at diagnosis; even within the same stage, mortality differences persist. Socioeconomic factors, differences in treatment, and comorbidities are likely the greatest determinants of racial and ethnic disparities in cancer mortality and survival.

Cancer Prevention

The three levels of disease prevention are primary, secondary, and tertiary. *Primary* prevention keeps a disease from occurring by reducing exposure to risk factors. *Secondary* prevention detects a disease before it is symptomatic and when early intervention can change the natural history of the disease. *Tertiary* prevention reduces the complications of a disease once it becomes clinically evident. Tertiary prevention measures are addressed in Chapters 58 and 59.

It is estimated that more than 50% of cancer deaths in the United States could be prevented through behavioral risk factor modifications and increased use of proven cancer screening tests. Studying the effectiveness of cancer prevention measures requires large numbers of participants in both intervention and control groups, close monitoring for adherence in the intervention group and “contamination” of the control group, long-term follow-up, and appropriate ascertainment of disease and disease-free status. Such studies are challenging because of the effort and cost involved in the enrollment, retention, and treatment of study participants. Nonetheless, a significant number of effective cancer prevention and control strategies have been identified, many through controlled trials.

PRIMARY PREVENTION

Primary prevention of cancer is achieved either by avoiding a causative exposure or by using an agent that prevents the development of the malignant process. Primary prevention includes reductions in behavioral or lifestyle risks (e.g., avoidance of tobacco exposure; use of sunscreen; adherence to a low-fat, high-fiber diet), avoidance of occupational or environmental risks, and chemoprevention (Table 56-2).

The main *behavioral and lifestyle risk factors* targeted for the primary prevention of cancer include tobacco, alcohol, dietary factors, and physical activity (see Table 56-2). Tobacco is the single greatest contributor to cancer incidence and mortality worldwide, and this burden is prevent-

Table 56-1 Probability of Developing Cancer by Age Group and Sex, United States, 2003-2005

	Lifetime	Ages 40-59 Years	Ages 60-79 Years
All Sites

Female	6%	0.7%	4%
Colorectal Cancer			
Male	6%	1%	4%
Female	5%	0.7%	3%
Breast Cancer			
Female	14%	4%	7%
Prostate Cancer			
Male	16%	2%	13%

Table 56-2 Major Targets of Primary Prevention of Cancer

Behavioral Targets	Associated Cancers
Tobacco	Lung, bronchus, esophagus, head and neck, stomach, pancreas, kidney, bladder, cervical
High alcohol consumption	Liver, rectum, breast, oral cavity, pharynx, larynx, esophagus
Obesity, high dietary fat	Colon, breast, endometrium, kidney, pancreas, esophagus, prostate
Low dietary fiber	Colon
Sedentary lifestyle	Colon, breast
Other Agents and Exposures	
Human papillomavirus 16 and 18	Cervical
Hepatitis B and C viruses	Liver and hepatocellular cancers
Asbestos	Mesothelioma and other types of lung cancer
Radon	Lung
Ultraviolet radiation	Melanoma, basal and squamous cell carcinomas
Ionizing radiation	Leukemia, thyroid, lung, breast

able. More than 1 million people die from tobacco-induced cancers globally each year, and tobacco accounts for one third of all cancer diagnoses in the United States. Cigarette smokers have a 20-fold risk for developing cancer compared with nonsmokers, with smoking being the single largest cause of lung cancer. Smoking and chewing tobacco are major risk factors for head, neck, mouth, and esophageal cancers. Second-hand smoke exposure increases the risk for lung cancer in nonsmokers. Significant investments in tobacco prevention and control at the local, state, and national levels have led to a decline in smoking prevalence in the United States through both smoking cessation and

primary prevention among youth. Tobacco use, however, continues to be high (especially among men) and has been increasing in a number of countries.

High consumption of alcohol is a significant risk factor for liver, rectal, and breast cancers. Alcohol abuse, especially among smokers, is associated with squamous cell cancers of the oral cavity, pharynx, larynx, and esophagus. Epidemiologic studies suggest that the increased cancer risk is associated with all type of alcoholic beverages.

Diet and body weight appear to play a role in cancer etiology, although it is difficult in epidemiologic studies to isolate specific dietary components (e.g., fat, total calories, fiber content, nutrient deficiencies) and to sort out the role of diet versus weight, obesity, distribution of adipose tissue, or sedentary lifestyle. Dietary fat and obesity are associated with colon and breast cancers, but the exact nature of the relationship is still under investigation. Central or visceral adiposity in both men and women is associated with increased incidence and mortality from a number of cancers, including endometrium, breast in postmenopausal women, kidney, gallbladder, pancreas, esophagus, colon, and prostate. Sufficient dietary intake of fruits and vegetables reduces the risk for gastric and esophageal cancers. Low dietary fiber is strongly associated with colon cancer in epidemiologic studies; however, interventions to increase fiber intake have not shown a reduction in colon adenomas in clinical trials.

There is strong evidence from epidemiologic studies that 30 to 60 minutes per day of moderate to vigorous physical activity reduces the risk for colon and breast cancer. The evidence is suggestive but mixed for prostate, lung, and endometrial cancers. Potential mechanisms for a link between physical activity and cancer prevention are enhanced immune function, reduced body fat, and hormonal changes.

Reducing exposure to certain infectious agents and chronic inflammation can contribute to the primary prevention of cancer. Viral agents are a prominent cause of human cancers. Chronic hepatitis B and C viral infections have been linked with the development of liver cancer. Evidence suggests that hepatitis B vaccination can reduce the incidence of hepatocellular cancer. Human papillomaviruses 16 and 18 have been linked with cervical cancer, with vaccines against these virus strains and those causing genital warts both on the market and in development (see Chapter 57). Other viral agents implicated in cancer include the Epstein-Barr virus (nasopharyngeal cancer and Burkitt lymphoma) and human T-cell leukemia virus type I (HTLV-1). Chronic inflammation as the result of exposure to a specific chemical or microbial agent or ultraviolet or ionizing radiation may promote carcinogenesis susceptibility through a number of mechanisms. For example, chronic infection with the bacterium *Helicobacter pylori* can cause certain gastric lymphomas and gastric adenocarcinoma.

Various pharmacologic agents have been associated with an increased risk for specific cancers. Unopposed estrogen use in postmenopausal women increases the risk for endometrial cancer, although rates drop significantly when combined estrogen-progesterone therapy is substituted. Synthetic estrogens such as diethylstilbestrol (DES), which was given to mothers during pregnancy, may result in the development of vaginal cancer in their offspring.

In regard to occupation and environmental exposures, asbestos is the most common cause of occupational cancer

Table 56-3 Cancer Chemopreventive Agents

Cancer	Chemopreventive Agent
Breast cancer	Selective estrogen receptor modulators (e.g., tamoxifen, raloxifene) Statin drugs
Ovarian cancer	Oral contraceptives
Colon cancer	Folic acid Nonsteroidal anti-inflammatory agents Statin drugs
Melanoma	Topical sunscreens
Prostate cancer	Lycopene Statin drugs
Cervical cancer	Human papillomavirus vaccine
Liver cancer	Hepatitis B vaccine

because of its link with the development of mesothelioma and other types of lung cancer. Radon exposure is the second leading cause of lung cancer, although there is a strong interaction between smoking and radon such that most radon-induced lung cancers are among smokers. Several other chemical compounds have been linked to human cancers including benzene (leukemia), benzidine (bladder), arsenic, soot and coal tars (lung and skin), and wood dusts (nasal). Carcinogens have been identified in air and water pollution as well. However, quantification of the association of these pollutants with development of cancer has proved difficult. Exposure to ionizing radiation, either accidental or therapeutic, is associated with an increased risk for leukemia as well as a variety of solid tumors. Exposure to ultraviolet radiation from the sun is a major cause of melanoma and basal and squamous cell carcinomas.

Chemopreventive agents are drugs, vaccines, or micronutrients (e.g., minerals, vitamins) used to prevent the development of cancer. Many agents have been shown through epidemiologic studies and randomized controlled trials to prevent some common types of cancer (Table 56-3). Chemopreventive agents usually have side effects and associated costs, and most are considered for people at high risk for developing the disease. The vaccine directed against specific strains of the human papillomavirus (HPV), offers the strong promise of preventing cervical cancer.

SECONDARY PREVENTION

Secondary prevention of cancer is achieved with screening tests to detect disease in asymptomatic patients at early stages of the disease progression. Proven cancer screening tests include mammography to detect breast cancer, Papanicolaou (Pap) smears to detect cervical dysplasia or cancer, and colonoscopy to detect polyps or colon cancer (Table 56-4). Screening tests do not prevent disease and are not diagnostic on their own. Instead, they identify patients who need additional diagnostic tests and may need treatment, with the intent of catching the disease at an earlier and thus more treatable stage. For most types of cancers, no effective screening tests exist.

For screening to be recommended for a disease, certain criteria must be met: (1) the disease must have a long asymptomatic (preclinical) phase, during which time intervention is likely to be beneficial, (2) an effective intervention

Table 56-4 Cancer Screening Tests with Demonstrated Early Detection Benefit

Cancer	Screening Recommendations for People at Average Risk
Breast	Screening mammography every 1-2 yr starting at age 40 yr Annual clinical breast examination (in conjunction with mammography)
Cervical	Papanicolaou smear screens every 1-3 yr for women with a cervix Begin within 3 years of onset of sexual activity but no later than age 21 yr
Colon	Tests that detect polyps and cancer: Flexible sigmoidoscopy every 5 yr Colonoscopy every 10 yr Virtual colonoscopy (computed tomographic colonography) every 5 yr Double-contrast barium enema every 5 yr Tests that detect cancer: Fecal occult blood test every year Fecal immunochemical test every year

must be available, (3) early treatment must reduce morbidity and mortality and be more effective than later treatment, and (4) the test should be highly sensitive and specific, and safe.

The *sensitivity* of a screening test is the likelihood of a positive test result in a person with the disease. A 100% sensitive test is never negative in a person who has the disease; that is, it has a 0% false-negative rate. The *specificity* of a test is the likelihood of a negative test result in a person who does not have the disease. A 100% specific test is never positive in a person without the disease and has a 0% false-positive rate. The *positive predictive value* of a test is the likelihood that a person with a positive test result has the disease, and the *negative predictive value* of a test is the likelihood that a person with a negative test result does not have the disease. Both values depend on the sensitivity and specificity of the test and the prevalence of the disease in the population screened.

Two main types of bias may occur in studies of screening effectiveness: (1) lead-time bias and (2) length-time bias. *Lead time* is the time between detection of disease by screening and the actual appearance of symptomatic disease. For rapidly progressive diseases with a short asymptomatic period, such as pancreatic cancer, treatment of disease detected by screening does not alter the outcome. Diagnosing the disease earlier with screening may make it appear that the patient lived longer, but the survival of the patient from the onset of disease is not altered. *Length-time bias* occurs when subsets of the cancer under study have different growth rates. Screening is more likely to detect cancers that grow slowly because of the greater prevalence of asymptomatic people with slow-growing tumors than with fast-growing tumors. Thus patients with cancer that is detected with screening appear to have longer survival as a result of screening, when in fact the longer course of their disease results from the behavior of the tumor itself. Randomized controlled trials are needed to address both lead time and length time bias. These trials, however, require large numbers

of participants and years to complete, and are vulnerable to biases including “contamination” (i.e., screening among participants randomized to the nonscreening arm of the study).

Screening tests have risks and benefits. False-negative results miss the diagnosis, and the patient does not benefit from having had the screening test. False-positive results are expensive, inconvenient, may have health risks, and can cause the patient to be labeled with a disease that is not truly present. Screening tests also have monetary costs. For mass screening to be recommended, the screening test should be cost-effective across the entire age spectrum being recommended for routine screening.

Genetic Screening for Inherited Susceptibility to Cancer

DNA testing is available to test for inherited susceptibility to several types of cancer. In general, this testing is reserved for people with a strong family history of the disease (Table 56-5). If a mutation is found in an affected family member, other family members can be tested to assess their risk for developing the disease. Most genes associated with a predisposition to cancer are large, and mutations can occur anywhere within the gene.

Patients having genetic testing should receive counseling before and after the test to ensure that they know the test limitations, the prevention options available if the test result is positive, and the risks associated with having a positive test result. The potential side effects of prevention measures, psychosocial issues, and the impact of genetic testing on the family should all be fully discussed with patients before testing. Patients who receive a negative test result must understand that their risk for cancer is not zero but is similar to that of the general population, and the possibility of guilt over not being affected should also be explored.

Table 56-5 Hereditary Cancer Syndromes for which Genetic Testing Is Available

Cancer and Involved Genes	Prevention Measures
Breast: <i>BRCA-1, BRCA-2</i> <i>PTEN, STK-11, TP53</i>	Prophylactic mastectomy Selective estrogen receptor modulators (tamoxifen, raloxifene) Lifestyle measures Increased intensity of screening, including breast MRI
Lobular breast cancer and gastric cancer <i>CDH-1</i> (E-cadherin)	Prophylactic gastrectomy Prophylactic mastectomy Increased intensity of screening, including breast MRI Selective estrogen receptor modulators (tamoxifen, raloxifene)
Ovarian: <i>BRCA-1, BRCA-2</i>	Prophylactic oophorectomy Oral contraceptives
Colon: Familial adenomatous Polyposis (FAP) <i>APC</i> Hereditary nonpolyposis Colon cancer (HNPCC) <i>MLH-1, MSH-2</i> <i>MSH-6, PMS-2</i> <i>MYH</i> -associated polyposis <i>MYH</i>	Prophylactic colectomy Nonsteroidal anti-inflammatory drugs Lifestyle measures Lifestyle measures Nonsteroidal anti-inflammatory drugs Increased surveillance Prophylactic total abdominal hysterectomy and oophorectomy Lifestyle measures Nonsteroidal anti-inflammatory drugs Prophylactic colectomy
Uterine: <i>PTEN, MLH-1, MSH-2, MSH-6, PMS-2</i>	Prophylactic hysterectomy Increased surveillance

FAP, familial adenomatous polyposis; HNPCC, hereditary nonpolyposis colorectal cancer; MRI, magnetic resonance imaging; MYH, mutY homologue.

Prospectus for the Future

Advances in molecular epidemiology are poised to make significant contributions to both cancer epidemiology and prevention. Epigenetic modifications, or changes in gene expression that are stable between cell divisions but do not change the nucleotide sequence, are increasingly recognized as playing an important role in the tumorigenic process. Increased understanding of epigenetic processes (DNA methylation, histone modification, and chromatin remodeling) holds great promise for increasing understanding of gene-environment interactions, and for the future development and testing of new diagnostic and treatment technologies. In addition, the use of new technologies and biomarkers (e.g., epigenomics, proteomics, and metabonomics) will become very useful for longitudinal epidemiologic studies of cancer risk, susceptibility, etiology, and prevention and early detection. An example of a promising application is the recognition of genetic polymorphisms that identify smokers at a particularly high risk for lung cancer. Patients found to be at high risk

would be candidates for screening or chemoprevention-based clinical trials.

At the population level, developing cost-effective strategies through which to disseminate behavioral, screening, vaccine, and chemoprevention measures to those at highest risk is critical to realizing the full potential of such prevention measures. Answers regarding the efficacy of several cancer screening tests (including prostate-specific antigen screening for prostate cancer and computed tomography screening for lung cancer) are forthcoming from studies currently underway. For screening tests with proven benefits, public health interventions and policy remain challenged with optimal utilization. Mammography use has leveled off and even declined in some populations, and colon cancer screening remains underused. Although tobacco control efforts have had a great impact, cigarette smoking remains the number one preventable cause of morbidity and mortality worldwide.

Solid Tumors

Robert F. Todd III and Jennifer J. Griggs

Lung Cancer

Lung cancer is a devastating malignant disease. Although the rate of increase of new lung cancers has leveled off, lung cancer remains the leading cause of cancer-related death in the world.

EPIDEMIOLOGY

Apart from nonmelanomatous skin cancer, lung cancer is now the most common malignant disease in the United States. More than 215,000 new cases of lung cancer are estimated to have occurred in 2008, and more than 161,840 deaths occur each year from lung cancer.

Tobacco smoke accounts for more than 90% of all lung cancers. One metabolite of cigarette smoke, benzopyrene diolepoxide, binds to areas near the *TP53* suppressor gene. This finding provides a link between the genetics of lung cancer and the epidemiologic association between smoking and cancer. Second-hand smoke is also associated with a higher risk for lung cancer than in the general population. A nonsmoking spouse of a smoker has a relative risk for lung cancer of 1.5 to 2 compared with nonexposed control individuals.

In addition to cigarette smoke, household exposure to radon seeping through the ground into enclosed spaces, as well as asbestos exposure, increase cancer risk. Cigarette smoking enhances the risk for cancer from both these toxic exposures. Although chest radiographs and computed tomographic (CT) screening of high-risk individuals may detect cancers at early stages of the disease, the value of systematic screening to reduce lung cancer mortality has not been proved.

PATHOLOGY

The two major types of lung cancer are *non-small cell lung cancer* (NSCLC) and *small cell lung cancer* (SCLC). NSCLC comprises several histologic subtypes, including squamous cell carcinomas, adenocarcinomas, and large cell tumors.

Squamous cell carcinoma usually exhibits a centrally located endobronchial lesion and is the subtype most commonly associated with paraneoplastic hypercalcemia. *Adenocarcinomas* are the most common lung cancers and are the type most often diagnosed in nonsmokers. Adenocarcinomas often exhibit a peripheral lung nodule. *Bronchioalveolar lung cancer* is a histologic variant of adenocarcinoma, characterized by multiple nodules and noninvasive growth along the peripheral airways of the lung. Sputum production with this subtype can be prolific. *Large cell tumors* are the least common; some have histologic features of neuroendocrine tumors. Although differences are noted in the clinical presentation of various subtypes, the natural history and response to conventional treatment are similar. However, with the advent of newer, molecularly targeted therapies, differences in response among the histologic subtypes are being observed.

SCLC is significantly linked to cigarette smoke exposure. The cell of origin is derived from the neuroendocrine family, which probably explains its proclivity to cause paraneoplastic syndromes such as the syndrome of inappropriate antidiuretic hormone production (SIADH) and Cushing syndrome. SCLC nearly always exhibits a large, central tumor with mediastinal involvement.

GENETICS

Many genetic abnormalities are associated with lung cancer. Representative examples include chromosomal deletions (loss of 3p alleles in most SCLCs and about half of NSCLCs), oncogene amplification (e.g., *K-ras*, *c-erbB-1*, and *c-erbB-2* in NSCLC), tumor suppressor gene loss or mutation (e.g., *p53* and *Rb*), and telomerase activation. Changes in the expression of lung cancer-associated molecular markers may have prognostic or therapeutic significance and may represent potential targets of novel therapy.

CLINICAL PRESENTATION

Signs and symptoms of all types of lung cancer commonly include cough, hemoptysis, chest pain, radiographic

Table 57-1 Staging Work-Up for Lung Cancer

Tumor	Staging Tests
Non-small cell lung cancer	Computed tomographic scans of chest through adrenal glands Bronchoscopy and mediastinoscopy if enlarged lymph nodes Positron-emission tomography if considering resection
Small cell lung cancer	Computed tomographic scans of chest, abdomen, and head Bone scan Positron-emission tomographic scan may also be useful for detecting cancer outside the chest

evidence of a mass or pneumonia, and weight loss in the chronic smoker. About 60% to 70% of patients with SCLC exhibit metastatic disease. Common metastatic sites include the brain, liver, skeleton, adrenal glands, and bone marrow. SCLC may also cause the superior vena cava syndrome as well as paraneoplastic syndromes. NSCLC exhibits metastatic disease in 35% to 40% of patients at the time of diagnosis, most often in the liver, lung, bone, and adrenal glands. NSCLC is associated with paraneoplastic syndromes such as pulmonary hypertrophic osteoarthropathy and hypercalcemia.

STAGING

Table 57-1 describes the tests usually required for a thorough work-up of the patient with lung cancer. Because treatment substantially differs between NSCLC and SCLC, the testing strategies are discussed separately.

Non-Small Cell Lung Cancer

The goals of staging for NSCLC are to find patients who may be cured by resection. Therefore, attention to the mediastinum, a common site of lymph node spread, and a search for metastatic disease are both performed as soon as possible after diagnosis. Testing usually begins with a CT scan extending through the liver and adrenal glands, common sites of metastases. Bronchoscopy or fine-needle aspiration is frequently used to make the histologic diagnosis. Patients with NSCLC who have enlarged mediastinal lymph nodes should undergo mediastinoscopy or bronchoscopic transbronchial biopsy to determine resectability (mediastinal nodes are rarely resectable). If an adrenal gland is enlarged, biopsy of the adrenal gland should be performed. In patients with resectable disease, surgical treatment may offer a chance for cure. Positron-emission tomography (PET) is a useful test during the work-up of the patient with NSCLC, but positive findings require pathologic or more precise radiologic corroboration before deciding against lung cancer surgery.

Small Cell Lung Cancer

The goal of staging in SCLC is to determine which patients have limited-stage disease (about 30% to 40% of SCLC patients at the time of diagnosis) who can be potentially cured by the administration of combined chemoradiotherapy, compared with patients with extensive-stage metastatic

Table 57-2 Staging System for Lung Cancer

Stage	Criteria
Non-Small Cell Lung Cancer	
IA	Tumor size is ≤ 3 cm and located more than 2 cm from the carina. No lymph nodes are involved.
IB	Tumor size is > 3 cm, ≤ 7 cm, and located more than 2 cm from the carina. No lymph nodes are involved.
IIA	Tumor size is ≤ 7 cm and located more than 2 cm from carina. Peribronchial and/or hilar nodes may be involved.
IIB	Tumor size is ≤ 7 cm located more than 2 cm from carina with peribronchial and/or hilar nodes involved; or tumor size > 7 cm (or satellite tumors within the same lobe) with invasion of chest wall, diaphragm, mediastinal pleura, pericardium, or located less than 2 cm from the carina, without lymph node involvement.
IIIA	Any size tumor is present and may have invaded chest wall, carina, heart, great vessels, trachea, and esophagus. Tumor may involve ipsilateral peribronchial, hilar, mediastinal, and/or subcarinal nodes.
IIIB	Any size tumor is present and may have invaded any structure. Nodal involvement is always present and may extend to contralateral mediastinum or supraclavicular or scalene area.
IV	Metastases are present (including a malignant pleural effusion).
Small Cell Lung Cancer	
Limited	Tumor is confined to one lung. Nodes may involve contralateral lung, but all cancer must be encompassed in one radiation portal.
Extensive	Metastatic disease is present or disease is not limited to one radiation field.

disease who cannot be cured but who can enjoy significant palliation with extension of survival as a result of chemotherapy. Limited-stage SCLC is defined as regional intrathoracic disease that can be encompassed within a single radiation field. Conversely, extensive disease represents locally advanced or widely metastatic disease that extends beyond a reasonable radiation field. Because common sites of metastatic disease include brain, liver, bone, and adrenal glands, diagnostic tests are performed to target these areas.

The staging system for each type of lung cancer is shown in Table 57-2. For the patient with NSCLC, tumor size, proximity to central structures, and location of lymph nodes are the most important features. Because surgery is rarely performed for the patient with SCLC, nodal detail is seldom obtained. The regional extent of the cancer and the ability to encompass the involved areas within a single radiation field determine treatment planning (Table 57-3).

TREATMENT

Non-Small Cell Lung Cancer

Because complete removal of the tumor provides the best chance for long-term survival, the focus of the primary treat-

Table 57-3 Treatment and Outcomes for Lung Cancer

Tumor	Standard Treatment by Stage	Outcome
Non-small cell lung cancer	Early stages: surgery only (I); surgery followed by adjuvant chemotherapy (II, IIIA) Later stage (unresectable): Combined chemotherapy and radiation or chemotherapy alone	Early stages: patients with stage II lung cancer have a 40%-50% survival rate with surgery and adjuvant chemotherapy Late stage: patients with stage IV lung cancer have 1-yr survival rate near 20% with chemotherapy
Small cell lung cancer	Limited: cisplatin-based chemotherapy with concurrent chest radiation Prophylactic cranial radiation is considered Extensive: chemotherapy palliates symptoms and prolongs survival but is not curative	Limited: 20%-30% 5-yr survival rate Extensive: median survival rate is 10 mo with treatment

ment for the patient with NSCLC should begin with an assessment of resectability. Resectability depends on the anatomic location of the tumor as well as the patient's medical condition and pulmonary reserve. In general terms, the risk for pneumonectomy is small if the patient has a forced expiratory volume in 1 second greater than 2 L, carbon dioxide diffusing capacity of more than 60%, a maximal voluntary ventilation of more than 50% of predicted values, or the ability to walk up three flights of stairs. Lesser resections (e.g., lobectomy) may require less stringent criteria. Occasionally, patients with severe obstructive disease cannot undergo a curative procedure because they lack pulmonary reserve.

Patients with stage I and II tumors (localized lesions or involvement limited to hilar lymph nodes) should undergo surgical treatment. Peripheral tumors are removed by lobectomy; more central tumors, if resectable, may require pneumonectomy. Stage III tumors may be operable in some patients, particularly if they are treated with chemotherapy and radiation therapy (i.e., neoadjuvant therapy) before resection. In patients with significant mediastinal lymph node involvement detected during tumor resection or at the time of mediastinoscopy, the chance of long-term survival is less than 20% even with surgical treatment. Although postoperative radiation therapy is seldom useful, recent reports show a survival benefit when patients with stages II and IIIA undergo adjuvant chemotherapy. Chemotherapy using a variety of agents combined with cisplatin or carboplatin improves survival after surgery by about 5%.

Almost 80% of lung cancers are unresectable. If the tumor cannot be resected and has not spread to distant organs (stages IIIA and IIIB), chemotherapy is administered concurrently with radiation. This treatment leads to better median survival and 5-year disease-free survival rates than with radiation alone, but combined therapy for unresectable disease should be reserved for patients with good functional status. Aggressive treatment is much less effective (due to unacceptable toxicity) in patients who have lost more than 5% of their body weight or who are active less than 50% of the day. The median survival for patients with locally advanced, unresectable lung cancer who are candidates for combined modality therapy is now 15 to 18 months, and nearly 20% achieve a 5-year disease-free survival.

Patients with metastatic disease may benefit from chemotherapy. The most active agents are platinum derivatives

such as cisplatin and carboplatin, taxanes such as paclitaxel and docetaxel, gemcitabine, vinorelbine, irinotecan, and pemetrexed. About 20% to 30% of patients achieve a greater than 50% reduction in their tumor volume after chemotherapy. For patients with advanced-stage lung cancer (stages IIIB with pleural effusion and IV), chemotherapy improves survival from an average of 8.5 to 11 months; quality-of-life studies show that chemotherapy delays symptoms and reduces their severity compared with no treatment. New agents that target neoplastic angiogenesis such as bevacizumab or the epidermal growth factor receptor antagonists such as erlotinib and cetuximab have shown therapeutic benefit either as single agents (e.g., erlotinib) or, more commonly, in combination with chemotherapy (bevacizumab) for these cancers.

Small Cell Lung Cancer

Patients with limited-stage SCLC are treated with curative intent with combined (concurrent) modality chemotherapy and radiotherapy. It is common practice to treat these patients with four to six cycles of chemotherapy (most commonly with cisplatin or carboplatin and etoposide) along with radiation therapy delivered to a radiation field encompassing the intrathoracic disease. About 50% to 60% of patients experience a complete response, and another 20% to 30% have a partial shrinkage of their cancer. Because 50% to 60% of patients with SCLC will ultimately develop brain metastases, prophylactic cranial radiation should be considered for those patients who have a complete response in the lung to primary chemoradiotherapy. About 20% to 30% of treated patients with limited-stage SCLC are alive and free of disease 3 years after diagnosis, and a proportion of these individuals are cured. Although patients with extensive-stage SCLC cannot be cured with existing therapy, chemotherapy can cause rapid tumor shrinkage with resolution of symptoms resulting in significant prolongation of life compared with supportive care alone.

Recurrent Lung Cancer

Both NSCLC and SCLC have high relapse rates. The use of second-line chemotherapy for these patients may palliate symptoms, but its use is not curative. Although these cancers may respond to subsequent agents such as docetaxel, pemetrexed, and erlotinib (NSCLC) or the camptothecins, the taxanes, and oral etoposide (SCLC), the use of these drugs should be limited to patients with good performance status, preferably on a clinical trial.

Head and Neck Cancers

EPIDEMIOLOGY AND NATURAL HISTORY

Most cancers of the head and neck, including cancers of the larynx, oral cavity, oropharynx, and sinuses, are squamous cell carcinomas. In 2008, an estimated 35,310 new cases were diagnosed, and 7590 deaths occurred. Tobacco use, alcohol consumption, and poor oral hygiene have all been linked to the development of cancers of the head and neck. Nasopharyngeal cancers are associated with Epstein-Barr viral infection. Infection with human papillomavirus (HPV), in particular HPV-16, is now an established risk factor for oropharyngeal cancer.

The major determinant of prognosis is the tumor burden, or the thickness of the tumor, and the presence or absence of regional lymph node involvement. The cure rate with small tumors is as high as 75% to 95% with radiation therapy or surgery. Continued use of tobacco after a diagnosis of a head and neck cancer is associated with a poor prognosis. People who have had cancer of the head and neck are at high risk for having a primary lung or esophageal cancer.

SYMPTOMS

Symptoms of cancers of the head and neck are related to the location of the tumor. For example, supraglottic laryngeal cancers cause pain with swallowing and a change in voice quality. Cancers of the oral cavity may exhibit a mass under the tongue or red or white patches in the mouth. Bleeding in the mouth or ill-fitting dentures may also be symptoms of cancer in the oral cavity. Symptoms of cancers of the sinus include sinusitis that does not resolve with appropriate treatment. Ear pain may be present with cancers of the oropharynx or hypopharynx.

DIAGNOSIS

Diagnosis of head and neck cancers require histologic confirmation with biopsy. Magnetic resonance imaging (MRI) or a CT scan of the head and neck is performed to determine a precise estimate of the extent of the tumor. Thorough examination of the entire aerodigestive tract with endoscopy will demonstrate a synchronous second primary tumor, for example, in the esophagus, in up to 15% of patients. Staging of the tumor is based on clinical and radiographic assessment.

TREATMENT

Small tumors that have not spread to regional lymph nodes are treated with radiation or surgery. Primary radiation therapy may allow preservation of organ function of, for example, the larynx, with surgical resection used in the case of recurrence. Locally advanced disease is treated with a combination of surgery and radiation therapy (with or without chemotherapy), or with a combination of radiation therapy and cisplatin-containing chemotherapy regimens. Most relapses occur within 2 to 3 years after therapy. Close surveillance is therefore warranted. Good-performance status patients with locally advanced, unresectable disease

may also derive palliative benefit from combined modality chemotherapy (or cetuximab) and radiotherapy.

Gastrointestinal Cancers

Cancers of the gastrointestinal tract are among the most common tumors, with more than 271,000 new cases occurring in 2008. Advances in the treatment of colorectal cancer have improved survival and quality of life for patients with these diseases. Table 57-4 outlines the common signs and symptoms, treatments, and prognosis of gastrointestinal tumors.

ESOPHAGEAL CANCER

Epidemiology and Natural History

The two types of esophageal cancer are squamous cell and adenocarcinoma. *Squamous cell cancers* are most common in the cervical and thoracic esophagus, and *adenocarcinomas* commonly occur in the lower esophagus down to the gastroesophageal junction. Squamous cell cancers are more common in African Americans and are associated with predisposing factors that include smoking, caustic injury, achalasia, and alcohol intake. Squamous cell cancers are associated with other tobacco-related cancers in the upper airways and digestive tract. The rate of adenocarcinoma is increasing; this increase is related in part to Barrett esophagus, an adenomatous metaplasia of the distal esophagus often caused by gastroesophageal reflux disease, but other factors are likely. Almost 25% of patients with severe Barrett esophagus eventually develop esophageal adenocarcinoma. The most useful intervention for patients with Barrett esophagus is frequent endoscopic screening and biopsy; pharmacologic treatment of acid reflux disease does not prevent neoplastic transformation.

Symptoms

The most common symptom of esophageal cancer is dysphagia. As the lumen of the esophagus narrows, the patient loses normal swallowing capacity and has a sensation that solid food becomes “stuck.” Eventually, the patient may be unable to swallow liquids. Patients commonly become afraid to eat because of frequent regurgitation at mealtime, resulting in significant weight loss.

Diagnosis

An upper gastrointestinal radiographic series or endoscopy will demonstrate an esophageal lesion, which should then undergo biopsy. The most effective staging tool is endoscopic ultrasonography, an accurate tool in assessing local depth of penetration and lymph node metastases. CT and positron-emission tomographic (PET) scanning are also required to ensure that the tumor has not already metastasized to the chest or liver, the two most common sites of spread.

Treatment

The most common treatment of esophageal cancer is surgery. Resection of the involved esophagus includes a wide margin

Table 57-4 Gastrointestinal Cancers

Tumor Site	Common Findings	Standard Treatments	Expected Outcome
Esophageal	Dysphagia, chest pain, weight loss	Early stage: neoadjuvant chemoradiotherapy and surgery Later stages: combination chemotherapy and radiation therapy and/or surgery	Stage II/III stage: about 30% 5-yr survival Average survival for metastatic disease is <9 mo
Gastric	Pain, supraclavicular adenopathy, vomiting, melena	Stage I: surgery alone Stage II and III: surgery if possible, followed by chemotherapy and/or radiation Metastatic disease: chemotherapy alone	Early stage: >90% 5-yr survival Positive nodal involvement: 20%-75% 5-yr survival for tumors <2 cm
Hepatocellular	Elevated α -fetoprotein; pain or change in liver function test	Resection for early lesions Unresectable: chemoembolization or tyrosine kinase inhibitor therapy for palliation	Always fatal in later stages of disease
Pancreas	Weight loss, boring midline pain through back, jaundice	Early stage: Whipple procedure and/or radiation therapy Late stage: chemotherapy with radiation or chemotherapy alone	Resectable: median survival 10-20 mo Radical surgery: 25% with negative nodal involvement and 10% with positive nodal involvement may be cured by surgery Unresectable: median survival 4-6 mo
Colon, rectal	Abdominal pain, occult or overt bleeding in stool, change in bowel habits	Early stage: resection alone If nodal involvement, add chemotherapy Chemotherapy and radiation therapy before and after surgery for patients with rectal cancers	Early stage: >70% at 5 yr Nodal involvement: 50%-70% at 5 yr Metastatic: median 14-24 mo
Anal	Constipation, bleeding, rectal pain and urgency	Early stage: chemotherapy with radiation therapy Later stage: abdominoperineal resection	Localized: 70% at 5 yr

on either side. The stomach is then pulled up to join the remainder of the esophagus. Alternatively, part of the intestine may be transposed to the chest to create another digestive pathway. About 10% to 30% of patients with stage II disease who are treated by surgical resection alone are alive and free of cancer 5 years after diagnosis. The results of recent studies indicate that administration of chemoradiotherapy before surgical resection (“neoadjuvant chemoradiotherapy”) may offer survival benefit over surgery alone. If surgical treatment is not possible, either because the cancer is technically unresectable or the patient is medically unfit for surgery, the standard of care for these patients is to provide chemotherapy and radiation. This approach may cure 20% to 30% of patients. Whether the outcomes of combined chemotherapy and radiation are as favorable as surgical resection alone is not clear.

For patients with metastatic esophageal cancer, systemic chemotherapy using platinum-based combination regimens are effective in palliation and extending survival. For patients with severe dysphagia that does not resolve with radiation or surgery, endoscopic placement of a metal or plastic stent may permit adequate nutrition and resumption of a normal lifestyle.

GASTRIC CANCER

Epidemiology and Natural History

Gastric cancer rates are highest in developing countries that use smoked meats and meats high in nitrates. Other predis-

posing conditions include pernicious anemia, achlorhydria, gastric ulcers, and prior gastric surgery. Except for cancers of the gastroesophageal junction, gastric cancer rates have decreased in the United States (21,500 new cases occurring in 2008). A recognized risk factor for gastric cancer is infection with *Helicobacter pylori*. Whether early treatment of *H. pylori* infection changes the rate of cancer in infected populations is not clear.

Diagnosis

Patients with gastric cancer commonly experience abdominal pain, early satiety, anemia, hematemesis, weakness, and weight loss. Frequently, the cancer has already involved local lymph nodes by the time the diagnosis is made. Physical examination may show a gastric mass, an umbilical node (Sister Mary Joseph node), or a left supraclavicular node (Virchow node). Pathologic analysis shows an adenocarcinoma that can be localized or spread throughout the gastric lining (*linitis plastica*). Required staging includes a CT scan to search for obvious nodal or metastatic involvement of the liver, upper gastrointestinal endoscopic examination, and endoscopic ultrasonography to determine depth of invasion and biopsy abnormal lymph nodes.

Treatment

Gastric cancer is most often treated surgically. When the tumor and all relevant lymph nodes have been removed, patients have a 20% to 60% chance of a 5-year survival, depending on the pathologic stage. If gastric cancer recurs,

the most common sites are local extension or hematogenous spread through the portal vein to the liver. Patients undergoing a complete resection for gastric cancer benefit from the addition of 5-fluorouracil (5-FU) and leucovorin chemotherapy and postoperative radiation therapy. This combination improves median survival by about 15 months compared with no adjuvant therapy. Patients with metastatic gastric cancer may elect chemotherapy to palliate symptoms. Active agents include platinum compounds, fluoropyrimidines, anthracyclines, taxanes, and irinotecan. Combination chemotherapy provides a 20% to 40% response rate and may extend survival.

COLORECTAL CANCER

Epidemiology and Natural History

About 1 in 20 people in the United States will be diagnosed with colon cancer (lifetime risk is 6%). An estimated 148,700 new cases were diagnosed in 2008, and in the same year, nearly 50,000 deaths occurred. Known predisposing factors are a history of ulcerative colitis and a strong family history of colon cancer. Several mutations, whether inherited or spontaneous, play a major role in the predisposition to colon cancer (see Chapter 55, Fig. 55-1 and Table 55-2). For example, familial polyposis is transmitted in an autosomal dominant manner. Individuals have mutations in the *APC* gene, which may be associated with periampullary and thyroid cancers or non-neoplastic growth such as osteomas, sebaceous cysts, and gastric polyps. Hereditary nonpolyposis colorectal cancer (HNPCC) is a more common autosomal disorder associated with microsatellite instability and mutations in *hMSH-2*, *hMLH-1*, *PMS-1*, *PMS-2*, and *hMSH-6*. Patients with HNPCC usually have colon or endometrial cancer when younger than 50 years and have first-degree relatives with colon cancer or other HNPCC-related cancers derived from the stomach, ovary, small bowel, biliary tract, ureter, or renal pelvis.

Whether the predisposing risk for colon cancer is genetically transmitted or sporadically acquired, a clear relationship exists between adenomatous polyps and the later development of colon cancer. Because the removal of polyps is probably the most important way to prevent the development of invasive colon cancer, the most reliable way to reduce colon and rectal cancer mortality is to perform regular screening. Colonoscopy is the most commonly used screening test. Studies using sigmoidoscopy and regular fecal occult blood testing also show reductions in the incidence and mortality of colorectal cancer. Patients with a proven mutation (Gardner syndrome, HNPCC) or a strong family history (familial adenomatous polyposis), and those who acquire other diseases associated with colorectal cancer, such as ulcerative colitis, should begin colonoscopy earlier than suggested for the general population. For patients with familial adenomatous polyposis, screening should start in the teenage years. For patients with HNPCC, screening for colon cancer should start 10 years before the age of diagnosis in the youngest family member with colorectal cancer. Research efforts are underway in the primary prevention of colorectal cancers using interventions such as diet, daily aspirin, cyclo-oxygenase-2 inhibitors, calcium and vitamin D supplementation, and other chemopreventive agents to reduce cancer incidence. Enthusiasm for promoting a high-

fiber diet to reduce the risk for colon cancer has waned. Lifestyle changes are still considered important—fresh fruits and vegetables, regular exercise, fewer than two red meat servings per week—based on epidemiologic association.

Symptoms

Rectal bleeding commonly occurs with colon and rectal cancers. Patients with left-sided colon lesions often complain of a change in stool color or caliber or pelvic pain and transient bloating. Right-sided lesions may become friable and may result in occult bleeding. Occasionally, patients with colon and rectal cancers are asymptomatic until the tumor totally obstructs the bowel or perforates the peritoneal cavity. Colon and rectal cancers tend to spread hematogenously to the lungs and liver. Rectal cancer is more likely than colon cancer to recur locally because it is more difficult to get a wide margin of normal tissue and lymph nodes within the tight confines of the pelvis.

Diagnosis

The work-up for colon cancer requires measurement of serum carcinoembryonic antigen (CEA), an abdominal-pelvic CT scan, a chest radiograph, and endoscopic imaging of the colon to ensure that all polyps and cancers are removed near the time of the primary operation. Table 57-5 describes the staging system for colon and rectal cancers.

Treatment

In patients with stages I, II, and III colon cancer, surgical resection of the primary carcinoma along with any regional lymph node metastases is routinely performed; multiagent, adjuvant chemotherapy is recommended for all patients with stage III cancer (which reduces the rate of recurrence by about 40%) and for selected high-risk individuals with stage II cancer. For patients with rectal cancer, either primary resection (which may require colostomy) or neoadjuvant chemoradiotherapy is performed. Because of the higher likelihood of local recurrence in rectal cancer, any lesion that invades the muscle or lymph nodes is also treated with radiation therapy (if not given before surgery) and adjuvant chemotherapy. Surgical resection of the primary lesion in patients with advanced (stage IV) colorectal cancer

Table 57-5 Staging for Colon and Rectal Cancer

Stage	Tumor Size	Nodal Status	Metastases
0	In situ	No	No
I	Invades mucosa only	No	No
II	May invade muscularis or through serosa	No	No
III	Any size tumor or any level of invasion	Yes	No
IV	Any size or depth	Positive nodal involvement present or absent	Yes

may be recommended to palliate or avoid symptoms of obstruction, bleeding, and pain.

Significant advances have been made in the use of chemotherapy for colorectal cancer. Regimens proved successful in prolonging survival for colon cancer include 5-FU with leucovorin or its oral analogue, capecitabine, alone. The addition of oxaliplatin to 5-FU–based adjuvant therapy has recently been shown to further improve survival after surgery. In the setting of metastatic cancer, infusions of chemotherapy with FOLFOX (5-FU, leucovorin, oxaliplatin), or FOLFIRI (5-FU, leucovorin, irinotecan) with the addition of antibodies targeting the vascular endothelial growth factor (VEGF; bevacizumab) or the epidermal growth factor receptor (cetuximab) prolong median survival beyond 20 months, almost twice the survival expected in the early 1990s. Despite improvements in survival, metastatic colon and rectal cancers are incurable unless the metastatic lesions can be surgically resected.

ANAL CARCINOMA

Anal cancers are increasing in frequency (currently about 5000 new cases per year). Persons infected with HPV and HIV are more likely to develop anal cancer. Patients with anal cancer usually experience rectal bleeding or complain of rectal fullness.

Combined chemotherapy with 5-FU and mitomycin and radiation therapy make up the standard approach to a patient with localized anal cancer. Results with combined therapy are superior to those with surgery, with the additional benefit of sparing the anal sphincter. Abdominoperineal resection is reserved for patients in whom chemoradiotherapy fails.

PANCREATIC CANCER

Epidemiology and Natural History

Pancreatic cancer, which is diagnosed in more than 37,000 people living in the U.S. each year, is strongly associated with cigarette smoking. A small proportion of pancreatic cancers are inherited from mutations in the *p16* and *BRCA-2* genes. Epithelial pancreatic cancer is an adenocarcinoma with an extremely high mortality rate because it is usually diagnosed when the tumor is beyond the capability of surgical resection. A less common type of pancreatic cancer, islet cell carcinoma, originates in the endocrine cells. Symptoms related to secretion of peptides such as gastrin, vasointestinal polypeptide, and insulin characterize these tumors.

Symptoms

The most common presentation of epithelial pancreatic cancer is abdominal pain accompanied by rapid weight loss. Characteristically, the pain is located in the periumbilical region and pierces or stabs through to the back. The pain is often explained by the frequent invasion of the celiac plexus deep in the retroperitoneum. Other symptoms of pancreatic cancer are the recent onset of diabetes, intestinal angina reflecting encasement of the superior mesenteric artery, a palpable gallbladder (Courvoisier sign), and jaundice from blockage of the distal common bile duct. Migrating thrombophlebitis (Trousseau sign) is a paraneoplastic complication of pancreatic adenocarcinoma. The tumor

marker CA-19-9 is elevated in up to 75% of patients with pancreatic cancer.

Treatment

The only curative treatment for pancreatic cancer is pancreaticoduodenectomy (Whipple procedure), an extensive operation requiring three anastomoses that carries a high mortality rate in centers with less experience with the procedure. The 5-year survival for surgically treated patients with localized pancreatic cancer is 25% for node-negative cancer but only 10% when lymph nodes are involved. Accordingly, it has become standard practice to offer adjuvant chemoradiotherapy or gemcitabine chemotherapy alone, which may provide a survival advantage. Patients with unresectable disease may benefit from local radiation therapy with concurrent 5-FU; more than 30% of patients treated with this combination have some improvement in their symptoms. Alternatively, gemcitabine-based chemotherapy alone may have palliative benefit. When patients have progressive or metastatic disease, the use of palliative chemotherapy with weekly gemcitabine has been shown to improve quality of life and survival to a small degree (5.7 months with gemcitabine, 4.4 months without gemcitabine, or 20% 1-year survival versus 5%). Recent meta-analyses suggest that certain gemcitabine-based chemotherapy combinations offer limited survival advantage over gemcitabine alone.

HEPATOCELLULAR CARCINOMA

Although uncommon in the United States (about 21,000 new cases per year), hepatocellular carcinoma (HCC) is one of the most common cancers throughout the world; more than 1 million cases are diagnosed each year. The common causes of HCC are chronic viral hepatitis (both B and C) and cirrhosis related to alcohol use or hemochromatosis. Although this approach is unproved, considerable interest exists in screening patients who are at extremely high risk with serial measurement for α -fetoprotein (AFP) levels. AFP levels are commonly elevated even in early-stage HCC.

Treatment of early-stage HCC is surgery. Cure rates are more than 75% for patients with tumors smaller than 2 cm. Patients with severe cirrhosis and who have small liver cancers may benefit from liver transplantation. Chemoembolization may provide palliative benefit for patients with unresectable tumors, but conventional cytotoxic chemotherapy is generally ineffective. However, recent findings suggest that molecularly targeted tyrosine kinase inhibitors such as sorafenib offer a survival advantage over supportive care.

Breast Cancer

EPIDEMIOLOGY

Breast cancer is the most common nonskin cancer in women and the second leading cause of cancer death (after lung cancer) among women in the United States. In 2008, an estimated 182,460 women were diagnosed with invasive breast cancer, and more than 40,000 died from breast cancer. Breast cancer in men is rare.

Risk factors for breast cancer include older age, a family history of breast cancer, early menarche, late menopause,

first-term pregnancy after age 25 years, nulliparity, prolonged use of exogenous estrogen, and postmenopausal obesity. Exposure to ionizing radiation, as is used in the treatment of Hodgkin disease, also increases the risk for breast cancer. Only 5% to 10% of patients with breast cancer are associated with the breast cancer-susceptibility genes, *BRCA-1* and *BRCA-2*. Patients with multiple affected family members or those with a personal or family history of male breast cancer, bilateral breast cancer, or ovarian cancer should be offered genetic counseling and genetic testing for *BRCA-1* and *BRCA-2*. Mammographic screening in both average- and high-risk populations has been shown to reduce breast cancer mortality.

PATHOLOGY

Most breast cancers are infiltrating ductal adenocarcinomas. A smaller proportion of breast cancers are infiltrating lobular adenocarcinomas. Tubular and mucinous carcinomas, which are a subtype of infiltrating ductal cancers, are associated with a better prognosis. The estrogen and progesterone receptor status of the primary tumor should be assessed in all cases of invasive breast cancer. The oncogene *HER-2/neu* (human epidermal growth factor receptor) is important in defining prognosis and treatment. Tumors that are negative for the estrogen and progesterone receptor and for overamplification of the *HER-2* oncogene (i.e., the so-called *triple-negative* tumors) are associated with a poorer prognosis. Such tumors are characteristic of those that develop in women who have the *BRCA-1* breast cancer susceptibility gene. Ductal carcinoma in situ (DCIS), also called *intraductal carcinoma*, is increasing in frequency, most likely because of increased mammographic screening.

CLINICAL PRESENTATION

Breast cancer is most often diagnosed through screening mammography or after a patient or her physician notices a palpable mass. Fewer than 10% of women have metastatic disease at diagnosis. Recurrent breast cancer most commonly exhibits metastases in the bone, liver, lung, and central nervous system, but breast cancer can recur in any organ of the body. Women with a history of breast cancer are also at increased risk for breast cancer in the contralateral breast. Inflammatory breast cancer is a clinical diagnosis in a woman with breast induration and erythema, often without a palpable mass. The skin findings are due to tumor emboli in the dermal lymphatics; skin biopsy is negative for cancer in 50% of patients.

STAGING

Breast cancer staging requires removal of the primary tumor and ipsilateral axillary lymph node assessment. Women with tumors larger than 5 cm and those with positive axillary lymph node involvement may have additional radiographic tests, including a chest radiograph, bone scan, and CT scan of the abdomen. Patients with smaller tumors and negative lymph node involvement do not need these tests unless they exhibit symptoms (e.g., skeletal pain) suggestive of metastatic involvement.

TREATMENT

For women with small breast tumors, breast-conserving therapy with lumpectomy followed by radiation therapy is standard therapy. Women with large tumors or with two or more tumors in separate quadrants of the breast should undergo mastectomy. Some women who are candidates for breast-conserving therapy choose to have a mastectomy, with or without breast reconstruction. Women who have had previous radiation to the breast, either for a previous breast cancer or other malignancies, are generally treated with mastectomy. Chemotherapy administered before surgical treatment (*primary* or *neoadjuvant chemotherapy*) may allow breast conservation in women with large tumors who would otherwise not be able to undergo a lumpectomy. Preoperative hormone therapy can be considered in frail patients with hormone receptor–positive tumors, but hormone therapy does not replace surgical treatment for most patients. Adjuvant therapy with chemotherapy and hormonal therapy improves relapse-free and overall survival rates in premenopausal and postmenopausal women who are at high risk for metastatic relapse. The monoclonal antibody trastuzumab, directed at the *HER-2* pathway, improves disease-free survival in patients with tumors that have overamplification (or high levels of overexpression) of the *HER-2* oncogene.

Treatment decisions in women with metastatic disease are based on the hormone receptor status, sites of disease, presence and severity of symptoms, time since initial diagnosis, and previous treatments. The monoclonal antibody trastuzumab may be used in combination with chemotherapy, hormonal therapy, or as a single agent. Life expectancy is longer in women with hormone-responsive disease and with lymph node or bone metastases, rather than liver, lung, or central nervous system metastases. Patients with metastatic breast cancer may live for many years, often responding to hormonal therapy for years before requiring chemotherapy for disease control. Many chemotherapeutic agents (singly or in combination), including the anthracyclines, taxanes, alkylating agents, fluoropyrimidines, vinca alkaloids, gemcitabine, and epithilones, demonstrate activity against breast cancer. Bisphosphonates, such as zoledronate and pamidronate, are given intravenously to decrease the pain associated with bone metastases and the risk for fracture in women with skeletal metastases.

DCIS is treated with either lumpectomy followed by radiation therapy or mastectomy. Women with multifocal or palpable DCIS should have assessment of lymph node status because a small but measurable proportion will have positive lymph node involvement that suggests the presence of invasive cancer. In these patients, systemic treatment is identical to that given to women with a clearly invasive breast primary tumor.

Prophylactic bilateral mastectomy is offered to women with the *BRCA-1* or *BRCA-2* breast cancer susceptibility genes. An alternative approach is close clinical surveillance, including monthly self-examination, frequent examination by a physician, and regular mammography or MRI. Oophorectomy or antiestrogen therapy can be used to decrease the risk for breast cancer in these women and in other women at high risk for the disease (see Chapter 56).

Table 57-6 Genitourinary Cancers

Tumor Site	Common Findings	Standard Treatments	Expected Outcomes
Testicle	Testicular swelling, pain, back pain Cough with metastatic presentation	Inguinal (not scrotal) orchiectomy Node-positive seminoma: radiation therapy Node-positive NSGCT: RPLND or chemotherapy	Early-stage seminoma: >90% 5-yr survival Stage III NSGCT: about 75% 5-yr survival Poor-risk tumors: <50%
Prostate	Elevated prostate-specific antigen, decreased urinary stream Bone pain with metastatic presentation	Early-stage: prostatectomy, radiation therapy, or watchful waiting Treatment recommendations depend on age, likelihood of spread, and tumor grade Later-stage tumors: hormone therapy, radiation therapy and/or chemotherapy	Early-stage: about 80%-90% 5-yr survival with surgery and radiation Stages C and D2: worse prognosis, time to relapse is variable
Bladder	Hematuria, cystitis	Superficial cancers: cystoscopic resection, biopsy, and intravesical chemotherapy Muscle invasion: neoadjuvant chemotherapy and cystectomy or bladder-sparing chemotherapy and radiation	Ten to 30% of superficial tumors progress to invasive cancer Muscle invasive disease: 50%-80% 5-yr survival; <40% of patients with positive nodal involvement live 5 yr
Renal cell	Hematuria, abdominal pain, and flank mass	Early-stage: radical nephrectomy Advanced or metastatic disease: high-dose IL-2, α -interferon, VEGF, or mTOR inhibitors	Confined to organ: 74%-100% 5-yr survival; Metastatic disease: 16%-32% 5-yr survival

IL-2, interleukin-2; mTOR, mammalian target of rapamycin; NSGCT, nonseminomatous germ cell tumor; RPLND, retroperitoneal lymph node dissection; VEGF, vascular endothelial growth factor.

Genitourinary Cancers

See Table 57-6 for a summary of genitourinary cancers.

PROSTATE CANCER AND TESTICULAR CANCER

These cancers are addressed in Chapter 72.

BLADDER CANCER

Epidemiology and Natural History

About 68,000 patients are diagnosed with bladder cancer each year in the United States. The disease is much less common in women than in men. About one fifth of affected patients will die of their disease. The most important risk factor is cigarette smoking, which accounts for at least two thirds of all cases. Other risk factors include exposure to polycyclic hydrocarbons in the dye, rubber, and paint industries, as well as long-term exposure to cyclophosphamide and phenacetin and chronic infection with *Schistosoma haematobium*.

Urothelial (transitional cell) carcinoma is the most common histologic type of bladder cancer. These tumors can occur anywhere urothelial lining exists, from the renal pelvis through the bladder and urethra. Squamous cell cancers, adenocarcinomas, and small cell carcinomas of the bladder and renal pelvis are less common and account for only 10% of all tumors in this region.

Symptoms

The most common presentation is gross or microscopic hematuria. About 30% of patients with bladder cancers experience symptoms of bladder irritation or spasms. When this cancer extends beyond the confines of the bladder, the

symptoms relate to compression of local structures and may include leg swelling, pelvic pain, and compression of the nerves in the pelvic plexus.

Diagnosis

Bladder cancers are divided into superficial, invasive, and metastatic tumors. The evaluation of bladder cancer requires direct imaging and biopsy to determine the level of tumor invasion. Depth of invasion correlates with prognosis and determines the type of treatment required. Therefore, cystoscopy is the most important diagnostic tool. In patients at high occupational risk for developing the disease, urine cytologic examination may be helpful in the absence of symptoms that require cystoscopy. Furthermore, an intravenous pyelogram may be needed if cystoscopy does not localize a tumor in the bladder or ureters.

The most important determinant of prognosis and treatment is whether the tumor has invaded the muscular wall of the bladder. Because the relationship between the depth of invasion detected by cystoscopy and that detected by cystectomy is only 50%, other tools such as a CT scan, MRI, and a bone scan are important to help define the presence of invasion, nodal involvement, or metastasis. Histologic grade is important because low-grade tumors rarely invade muscle, whereas high-grade cancers do so frequently.

Treatment

Superficial low-grade tumors are treated by transurethral resection of the bladder (TURB). Cystoscopy is performed every 3 months to assess response and perform resections when required. For frequent relapses or when superficial cancer involves most of the surface of the bladder, intravesical therapy is recommended. For these patients, immunomodulators such as bacille Calmette-Guérin (BCG) vaccine or interferon or chemotherapeutic agents such as thiotepa

or mitoxantrone are instilled in the bladder through a Foley catheter, allowed to dwell for a short time, and then voided. This process is repeated every week for 6 weeks and is followed by cystoscopy to assess response.

Tumors that invade the muscle require more aggressive surgical treatment. If the tumor has invaded muscle but is not through the bladder wall, the standard approach is neoadjuvant chemotherapy followed by radical cystectomy. In this procedure, the bladder is removed along with the prostate, seminal vesicles, and proximal urethra in men; in women, a hysterectomy is performed along with a bilateral salpingo-oophorectomy and partial removal of the anterior vaginal wall. Because the bladder is removed, a pouch is created from the small bowel, often called an *ileal conduit*, to store and expel urine. In selected patients, an orthotopic neobladder connected to the native urethra can be constructed. Not all patients with tumors that invade the bladder wall require removal of the bladder. Bladder preservation and a combination of TURB followed or preceded by chemotherapy and radiation may be considered for patients with localized tumors away from the trigone or for those who are unable to tolerate aggressive surgery, although the outcomes of this approach may not be equivalent to radical cystectomy. Chemotherapy after surgery is recommended when bladder cancer is found in lymph nodes or when patients have metastatic disease. Patients with metastatic disease frequently respond to combination chemotherapy containing cisplatin or other agents such as gemcitabine and a taxane, but the tumor invariably relapses.

RENAL CELL CARCINOMA

Epidemiology and Natural History

Renal cell carcinoma, one of the least common tumors of the genitourinary system, accounts for about 3% of all cancers (an estimated 68,810 new cases in 2008). Some relationship exists between kidney cancer and exposure to cadmium, perhaps in cigarette smoke. Renal cell carcinoma occurs commonly in von Hippel-Lindau disease, in which synchronous, bilateral renal carcinomas occasionally occur. Abnormalities of the long arm of chromosome 3 are observed in more than 90% of patients. Most renal cell carcinomas are adenocarcinomas; a subtype called *clear cell carcinoma* represents more than 75% of all the tumors removed.

The natural history of kidney cancers is variable. Some tumors progress relentlessly and are refractory to all interventions whereas some patients can have spontaneous regression of metastases.

Symptoms

The classic presentation, consisting of hematuria, flank pain, and an abdominal mass, is observed in only 10% of patients. More often, hematuria alone or persistent back pain prompts the patient to seek attention. Many renal cell carcinomas are found during a CT scan performed for unrelated reasons. Occasionally, bilateral lower extremity edema occurs when the tumor has completely occluded the inferior vena cava. Renal cell carcinoma is also associated with unusual paraneoplastic syndromes, including fever, polycythemia from erythropoietin production, and hypercalcemia from ectopic production of parathyroid hormone (PTH).

Diagnosis

The most common tool to diagnose renal cell carcinoma is CT scanning of the abdomen. A large, dense, contrast-enhancing mass occupies a substantial amount of one kidney and is frequently accompanied by nodal or venous involvement. An MRI or direct injection of dye is recommended to assess inferior vena cava involvement. Because renal cell carcinoma commonly spreads to lungs and liver, a CT evaluation of the chest should be included in the staging procedures.

Treatment

Resection is the most common treatment for cancer limited to the kidney. Surgical treatment may be possible even if parts of the renal vein and vena cava are involved.

Renal cell carcinoma is notably resistant to chemotherapy and radiation. However, renal tumors may respond to biologic response modifiers such as interleukin-2 (IL-2) in about 10% to 15% of patients. Occasionally, IL-2 induces a complete response. Similar dramatic events have spontaneously occurred. Clinical trials have suggested that nonmyeloablative allogeneic bone marrow transplantation may be effective in some patients with renal cell cancer refractory to other conventional immunotherapy, but the usefulness of this approach is limited by its toxicity and by availability of a suitable donor. New agents that target the VEGF pathway (and other tyrosine kinase-dependent receptors), such as bevacizumab, sunitinib, and sorafenib, and the mTOR inhibitor temsirolimus have recently shown significant promise in extending the progression-free survival of patients who are not eligible for high-dose IL-2 therapy.

OVARIAN CANCER

Epidemiology

Ovarian cancer occurs in 1 in 60 women in the United States. More than 21,650 cases are expected to be diagnosed in the United States in 2008, with an estimated 15,520 deaths. As with most cancers, the incidence of ovarian cancer increases with age. Other risk factors include nulliparity, estrogen replacement (without progestin) therapy, obesity, and a family history of ovarian cancer. Ovarian cancer is more common in women who have one of the breast cancer susceptibility genes (see Chapter 56) and Lynch syndrome. Exposure to talc may increase the risk for ovarian cancer. Use of oral contraceptives decreases the risk for ovarian cancer, as do more than one pregnancy, breastfeeding, tubal ligation, and hysterectomy.

Pathology

Most malignant ovarian tumors arise from celomic epithelium. Tumors can arise in any part of the peritoneal cavity; thus, prophylactic oophorectomy reduces but does not eliminate the risk for ovarian cancer. Epithelial ovarian tumors are classified histologically as benign, malignant, or borderline. The most common histologic types of ovarian cancer are serous, mucinous, and endometrioid. Stromal tumors, most often granulosa cell tumors, and germ cell tumors account for fewer than 15% of ovarian tumors. Cancers from sites such as the breast and gastrointestinal tract can metastasize to the ovaries.

Clinical Presentation

Symptoms of early ovarian cancer include vague pelvic or abdominal pain, early satiety, and indigestion, but the symptoms are nonspecific; most patients with ovarian cancer are not diagnosed until the disease is advanced. No effective screening tests exist for ovarian cancer, although transvaginal ultrasound and the tumor marker CA-125 may be helpful in high-risk women with an affected first-degree relative and in women who carry a breast cancer susceptibility gene. Advanced ovarian cancer often causes abdominal swelling and pain, intestinal obstruction, and vaginal bleeding.

Staging and Treatment

Ovarian cancer is surgically staged with a total abdominal hysterectomy and bilateral salpingo-oophorectomy, omentectomy, lymph node sampling, and peritoneal biopsies. Stage I disease involves only the ovaries; stage II disease involves extension to the uterus, fallopian tubes, and pelvic structures; and peritoneal spread outside the pelvis, or retroperitoneal and inguinal lymph node involvement, is stage III disease. Many patients have clearly visible peritoneal tumor implants; however, in those who do not, representative biopsy specimens from all areas of the peritoneum, omentum, and retroperitoneal lymph nodes should be removed for microscopic examination. Disease outside the abdomen and in the liver parenchyma is stage IV disease. Patients with malignant pleural effusions also have stage IV disease.

The mainstay of treatment for ovarian cancer is surgery. Women whose total residual disease after surgery is less than 2 cm in diameter have an improved prognosis compared with women who have greater amounts of residual disease; thus, every effort should be made to debulk the patient to minimal residual disease.

Combination chemotherapy with paclitaxel and carboplatin is administered postoperatively to women with most stages of epithelial ovarian cancer, with the notable exception of those women with grade 1, stage IA or IB disease. If first-line therapy fails, additional chemotherapy is undertaken with a variety of agents whose response rate is affected by time since completion of first-line therapy. Platinum-resistant disease is almost universally fatal in a short time. Pleural effusions can be palliated with chemotherapy.

ENDOMETRIAL CANCER

Epidemiology

Endometrial cancer is the fourth most common malignant disease among women in the United States; more than 40,000 cases are diagnosed each year, leading to an estimated 7470 deaths in 2008. The tumor is usually found with early-stage disease and is usually curable, with 5-year survival rates higher than 80%. Those with localized disease at diagnosis have a 95% 5-year survival rate. Risk factors for endometrial cancer include increasing age, late menopause, nulliparity, obesity, and Lynch syndrome. Women who are treated with estrogen without concomitant progesterone or with tamoxifen and those who do not ovulate are also at increased risk for the disease. Most endometrial cancers are endometrioid adenocarcinomas.

Clinical Presentation

Most women with endometrial carcinoma have abnormal uterine bleeding. Even minimal postmenopausal bleeding should prompt an evaluation for endometrial cancer. Advanced disease can cause urinary symptoms or back or pelvic pain.

Staging and Treatment

Staging is achieved by surgical exploration. Most endometrial cancers are stage I, with invasion into less than half the uterine wall. More advanced tumors involve the cervix, vagina, pelvic or periaortic lymph nodes, bladder, and rectal mucosa. Metastases outside the pelvis (stage IV disease) are less commonly observed in patients with endometrioid pathology. However, more aggressive histologic subtypes, such as uterine papillary serous tumors and carcinosarcomas, are more likely to present with extrapelvic disease and to spread similarly to ovarian cancers.

Treatment of endometrial cancer consists of total hysterectomy, bilateral salpingo-oophorectomy, pelvic and para-aortic lymph node dissections, and peritoneal washings for histologic examination. Omentectomy is performed in patients with high-grade tumors. Radiation therapy is given to women with histologically high-grade tumors and those with deep myometrial involvement. Chemotherapy is added to the adjuvant treatment of women with stage III disease and to most stages of disease with more aggressive subtypes. Women with progressive or metastatic disease are treated with megestrol acetate, chemotherapy, or palliative radiation therapy.

CERVICAL CANCER

Because of widespread screening for cervical cancer with the Papanicolaou (Pap) smear, the incidence of invasive cervical cancer and mortality from cervical cancer have continued to decline in the United States. An estimated 11,000 cases of cervical cancer were diagnosed in 2008 with an estimated 3870 women dying of the disease. Cervical cancer and its precursor, cervical intraepithelial neoplasia, are more common in women with HIV infection and those infected with HPV subtypes 16, 18, 31, 33, and 35. Smoking, high parity, immunosuppression, and the long-term use of oral contraceptives may affect the persistence of HPV infection and the progression to cervical cancer. The cervical cancer vaccine directed against HPV offers promise of preventing cervical cancer worldwide when administered to women before the onset of sexual activity and before the acquisition of HPV infection (see Chapter 56). Most women with cervical intraepithelial neoplasia or cervical cancer are asymptomatic and are found to have the disease by Pap smear. Vaginal bleeding, postcoital bleeding, vaginal discharge, and pelvic pain may occur in women with invasive disease. Signs and symptoms of advanced disease are local pelvic involvement, including leg edema, or back and leg pain. Metastatic disease is rare.

Biopsy of the cervix confirms the diagnosis of cervical cancer in a woman with an abnormal Pap smear or a cervical lesion. Some women may need a cone biopsy if the colposcopy-directed biopsy is inconclusive, does not confirm invasive disease, or shows cervical dysplasia, or if the sample is

inadequate. The use of other staging tests depends on the extent of local involvement, as determined by pelvic and rectal examination.

Treatment of cervical cancer depends on the stage of the disease. Cone biopsy may be sufficient in women with minimal microscopic invasion into the cervix who desire fertility. Women with more advanced disease that is still confined to the cervix can undergo radical hysterectomy with lymph node dissection, radiation with chemosensitization, or radical trachelectomy (in select cases of women still desiring fertility options). Combination chemotherapy with cisplatin and radiation therapy is recommended for women with locally advanced disease. Those with widely metastatic disease are treated with chemotherapy with or without palliative radiation therapy. A paclitaxel and cisplatin regimen is now the preferred treatment of recurrent, metastatic disease that is not amenable to radiation or pelvic exenteration.

Skin Cancer

BASAL CELL AND SQUAMOUS CELL CARCINOMA

Epidemiology and Natural History

Basal cell and squamous cell carcinomas are the most common cancers of the skin (in excess of one million unreported cases per year in the United States). Mortality from these cancers is exceedingly low, however, accounting for less than 0.1% of cancer deaths. Both types of cancer are more common on parts of the body exposed to sun and in people with light complexions. Although the most significant risk factor is exposure to ultraviolet radiation in sunlight, patients with immunosuppressive disorders (e.g., recipients of organ transplantation) or AIDS, as well as those with genetic disorders such as xeroderma pigmentosum, have a rate of skin cancer incidence that is many times higher than the rate of the general population. Unlike basal cell cancers, which rarely metastasize, squamous cell cancers can spread to regional lymph nodes. Thorough examination of regional lymph nodes is therefore necessary in patients with squamous cell cancer, particularly with squamous cell cancers of the lips, ears, and perianal and genital regions.

Treatment

Treatment options for basal cell and squamous cell cancers include surgical excision, radiation therapy, and cryosurgery. Topical fluorouracil may be used for treatment of superficial basal cell carcinomas or in situ squamous cell carcinomas. Dermatologists use Mohs micrographic surgery, which is a technique that examines serial frozen sections to achieve negative margins on each tumor border. This specialized approach offers the highest local control rates and is indicated for tumors with ill-defined borders and for those occurring in areas where maximal preservation of unaffected tissues is desirable, such as the eyes, nose, and genitalia.

MELANOMA

Epidemiology

The incidence of melanoma is increasing at a rate of 4% per year in the United States. Each year, more than 60,000 new

cases are diagnosed, and more than 8000 deaths occur. Incidence rates increase with age and are 10-fold higher in white persons than in black individuals. Melanoma risk factors are similar to those of basal cell and squamous cell skin cancers (see previous discussion) but also include a genetic component, such as a personal history of dysplastic nevi and a family history of melanoma.

Pathology

Most melanomas are superficial-spreading melanomas. The antigenic markers S-100 and homatropine methylbromide (HMB-45) can be used to confirm the diagnosis of undifferentiated melanomas, although S-100 is nonspecific and HMB-45 is not 100% sensitive. Ulceration indicates a worse prognosis.

Clinical Presentation

Patients with melanoma most often report a change in a pigmented skin lesion on a sun-exposed surface. Characteristic changes include *asymmetry*, *border irregularities*, *color variation*, *diameter* more than 6 mm, and *enlargement* (the ABCDE system). Although 90% of melanomas arise in the skin, melanomas can arise from any area where melanocytes reside, including the choroid of the eye. About 5% of melanomas arise from unknown primary sites. Melanoma can present with metastatic disease in lymph nodes, lung, bone, liver, or brain.

Staging

Melanoma is staged according to the thickness of the primary tumor, as measured both in millimeters of the tumor and in depth of invasion into the skin. The tumor thickness is the single most important prognostic factor. Even without nodal involvement, a melanoma more than 4 mm thick on the trunk has more than a 50% chance of distant metastasis. Sentinel lymph node analysis is indicated in patients with high-stage melanomas.

Treatment

Surgical excision with wide margins is required for cure of primary cutaneous lesions. The location and thickness of the lesion determine the optimal surgical margin. Locally recurrent lesions are surgically resected if possible; radiation therapy is given if surgical resection is not possible. In patients with regional lymph node involvement, adjuvant immunotherapy with 12 months of interferon- α may improve relapse-free survival rates. Many patients have severe side effects with interferon- α , such as myalgias and fever, and elect to discontinue treatment early.

When metastatic melanomas recur, the best treatment is high-dose IL-2. Although 5% to 10% of patients receiving this treatment may become long-term survivors, the toxicity of this approach precludes most patients from receiving it. In such patients, lower-dose interleukin treatments, oral temozolomide, intravenous dacarbazine, or multiagent chemotherapy (often administered with biologic agents like IL-2 and interferon) may be offered but are not curative. Radiation therapy is used to treat metastases to the brain, spinal cord, and bone, but melanoma is relatively resistant to radiation therapy.

Cancer of Unknown Primary

About 5% of people with cancer have metastatic disease in the absence of an identifiable primary tumor. Cancer of unknown primary most commonly exhibits disease in the bone, liver, lungs, or lymph nodes. Detailed pathologic examination, aided by immunohistochemical stains, electron microscopy, and chromosomal analysis, will usually distinguish between lymphomas and carcinomas. Such a distinction is important to make because lymphomas tend to be more responsive to therapy, and treatment of lymphomas differs from that of carcinomas. In patients with *adenocarcinoma of unknown primary origin*, limited radiographic examination, such as CT scans of the chest and abdomen, may help identify the site of the primary tumor. Other features of the metastatic disease may be revealing as well. For example, bone metastases are common in prostate and breast cancers, axillary lymphadenopathy is commonly seen in a woman with breast cancer, and liver metastases frequently occur in patients with lung, colon, and pancreatic cancers. Most tumor markers are nonspecific; therefore, reliance on a tumor marker alone in identifying a primary source of the cancer is not recommended. However, an elevated tumor marker level may provide supporting evidence for a primary cancer if risk factors for the tumor are present and the clinical pattern of spread is consistent.

Treatment of cancer of unknown primary is geared at palliation of symptoms with surgery, radiation therapy, combination chemotherapy with a broad spectrum of activity (active against a variety of cancers), or hormonal therapy (if the tumor is thought to be from an endocrine-responsive primary source such as prostate or breast cancer). Some people with cancer of unknown primary, such as people with

only lymph node involvement, may live free of disease for many years and may be considered cured.

Metastases from Solid Tumors

Most patients who die from cancer generally die from metastatic spread of the primary tumor to distant sites. The process of invasion and metastasis requires each of the following steps: (1) development of the tumor's own vascular supply through angiogenesis, (2) tumor cell invasion through the host tissue basement membrane, (3) tumor embolization through either the lymphatic system or the bloodstream (hematogenous spread), (4) arrest and invasion into the basement membrane of the distant organ, (5) reestablishment of blood vessels to sustain growth of the metastatic cells, and (6) proliferation within the target organ. The processes of invasion and metastasis are highly selective, with only 0.01% of circulating cells forming a metastatic focus.

Advances in cancer therapeutics, such as the use of antibodies to the angiogenic molecule VEGF receptor, are targeted at disrupting neovascularization within malignant tumors or at interfering with tumor cell proliferation. The hope is that targeted therapies used alone or with cytotoxic chemotherapy will improve outcome while minimizing the toxicity to normal tissues (see Chapters 55 and 59).

Surgery for metastatic disease is generally reserved for palliation of symptoms because surgical resection is usually not curative and is associated with morbidity. In selected patients with metastatic colon cancer to the liver or lung, resection of the metastatic disease may offer a chance for cure.

Prospectus for the Future

Advances in our understanding of cancer causation and epidemiology, disease staging, tumor heterogeneity, and tumor and patient factors involved in response to treatment will all increase our ability to prevent and treat cancer. For example, polymorphisms in drug-metabolizing enzymes may explain differences in response to chemotherapy and survival among women with breast cancer. Similarly, microarray technology, which allows analysis of hundreds of genes involved in cell proliferation, can elucidate pathways of resistance to treatment and allow for more precise selection of cytotoxic therapy. The

emerging concept of "cancer stem cells"—a small subpopulation of malignant cells capable of self-renewal that give rise to the bulk of more differentiated epithelial cancers—offers hope for the development of targeted therapies that attack this critical subset of tumor cells. Advances in imaging techniques may allow for detection of minimal residual disease, identifying patients who are likely to benefit from additional treatment. Finally, the increasing interest in measuring and improving quality of care will expand the reach of cancer therapies, improving cancer-specific outcomes at the population level.

Complications of Cancer and Cancer Treatment

Alok A. Khorana and Jennifer J. Griggs

Cancer patients can experience a variety of medical problems related either to the cancer itself or to anti-cancer therapies. These can include the so-called paraneoplastic syndromes, which occur in cancer patients but cannot be directly attributed to invasion or metastases from the tumor. The management of these various cancer complications requires a multidisciplinary approach.

Cancer-Associated Thrombosis

SIGNIFICANCE

Cancer patients are at increased risk for both venous and arterial thrombotic events, the second leading cause of death. Venous events include deep vein thrombosis (DVT) and pulmonary embolism (PE), together called venous thromboembolism (VTE). Arterial events include stroke and myocardial infarction. VTE can occur in up to one fifth of cancer patients and is associated with decreased survival. The hypercoagulable state in patients with cancer is the result of the activation of the coagulation system by neoplastic cells. Certain cancers, such as pancreas, stomach, lung, and lymphoma, are particularly associated with VTE. Cancer chemotherapy further increases the risk for VTE, as does tamoxifen, which is commonly used in the treatment of breast cancer (see Chapter 57). Other risk factors associated with VTE include central venous catheters, obesity, prior history of VTE, and use of erythropoiesis-stimulating agents. Recent studies have suggested that elevated platelet and leukocyte counts, tissue factor levels, and P-selectin levels may be predictive of VTE. A risk model for VTE has recently been proposed.

CLINICAL PRESENTATION

The suspicion for VTE should be high in patients with cancer who present with dyspnea, cough, wheezing, chest pain, tachycardia, upper abdominal pain, or leg swelling. Even in

patients who are ambulatory or on adequate anticoagulation, VTE should remain a consideration. The evaluation of patients with possible VTE is described in Chapter 54. Incidental PE may be identified on imaging studies conducted for staging of cancer, but these continue to be associated with adverse outcomes for cancer patients and should be treated appropriately.

TREATMENT

VTE can be effectively prevented with the use of prophylaxis in the hospitalized cancer patient. Unfractionated heparin, low-molecular-weight heparins (LMWHs), and fondaparinux have all been shown to be effective. Unfortunately, use of thromboprophylaxis continues to be low worldwide and requires a concerted systems-based approach. Cancer patients with established VTE should be treated with anticoagulation. In these patients, oral anticoagulation with warfarin is complicated by interactions with chemotherapeutic agents, variable nutrition status, and relative resistance. LMWHs given for up to 6 months are more effective than warfarin for preventing recurrent VTE in this setting and represent the preferred approach. Vena caval interruption using filters should be considered only in the presence of a clear contraindication to anticoagulation or after failure of LMWH anticoagulation. Chapter 54 addresses the use of anticoagulation therapy.

Febrile Neutropenia

SIGNIFICANCE

Febrile neutropenia (FN) is a common complication of chemotherapy and is defined as a blood neutrophil count lower than $0.5 \times 10^9/L$ with body temperature higher than $101^\circ F$. The risk for infectious complications depends on the severity and duration of neutropenia. FN is associated with increased hospitalization rates, use of broad-spectrum antibiotics, interruption of chemotherapy, increased morbidity, worsened quality of life, and increased mortality.

TREATMENT

Most patients with FN are initially managed in the hospital setting with broad-spectrum antibiotics while awaiting culture data. Antibiotic therapy can subsequently be tailored based on identification of organisms. Myeloid growth factors may be used to hasten neutrophil recovery. Highly selected low-risk patients may be managed in the outpatient setting. The incidence of FN can be reduced with the use of prophylactic growth factors (with or without prophylactic antibiotics) or chemotherapy dose reductions or delay.

Spinal Cord Compression

SIGNIFICANCE

After brain metastases, spinal cord compression is the most common neurologic complication of cancer. About 20,000 patients develop spinal cord compression each year, and most of these patients already have a known diagnosis of a malignant disease. Lung and breast cancers cause about 20% of patients to develop spinal cord compression. Lymphoma, sarcoma, multiple myeloma, and prostate and renal cell cancers each account for 6% to 7% of the patients with spinal cord compression. In only 10% of patients is spinal cord compression the first manifestation of cancer. Although the risk for spinal cord compression in a patient with cancer is only 1%, the effects can be devastating. Early recognition of symptoms and intervention usually prevent a complete loss of motor function.

Most compressive tumors occur at the anterior aspect of the spinal cord. Tumor cells disseminate through the bloodstream to the bone marrow, where they multiply within the vertebral body and eventually extend posteriorly. Tumors cause necrosis and demyelination of predominantly the lateral and posterior white-matter columns. This observation suggests that the obstruction of venous outflow is the cause of the congestion, edema, and hemorrhage within the spinal cord.

CLINICAL PRESENTATION

About 70% of cases of spinal cord compression are thoracic, 20% are lumbosacral, and 10% occur in the cervical region. In 50% of patients, only one vertebral body is involved; in 25% of people, contiguous vertebral bodies are involved. In the remaining patients, multiple noncontiguous vertebral bodies are involved. Most patients complain of back pain that is constant, dull, aching, and progressive. Sneezing, coughing, or neck flexion often exacerbates the pain. In contrast to the pain associated with disk herniation, the pain is usually worse when the patient is in the supine position. Radicular pain may be constant or intermittent and usually localizes to the level of the compression. Bilateral bandlike pain is more common with thoracic disease, whereas unilateral radicular pain is more common with lumbosacral lesions.

Neurologic signs develop insidiously: (1) weakness, particularly exhibiting difficulty with proximal leg function, which causes difficulty in climbing stairs and occurs in about 80% of patients; (2) paresthesias; (3) ataxia, which is the

result of proprioceptive impairment; and (4) autonomic dysfunction, including loss of bowel and bladder function. Weakness, sensory loss, ataxia, and autonomic dysfunction can all progress rapidly and may lead to paraplegia if treatment is not rapidly instituted.

DIAGNOSIS

Physical examination usually suggests the diagnosis and may help identify the level of spinal cord involvement. Radiologic tests should initially focus on the suspected area of involvement but should also include a thorough evaluation of the entire spine. The rapidity and severity of symptoms and signs determine how quickly diagnostic tests should be performed.

Plain radiographs are abnormal in 70% of patients with spinal cord compression. Among patients with pain, more than 80% will have abnormal radiographs. Typical radiographic findings include destruction of the pedicle and vertebral body collapse. Magnetic resonance imaging and computed tomography (CT) provide more information than do plain radiographs, and CT scans are superior in evaluating vertebral stability and bone destruction in patients undergoing surgical decompression.

TREATMENT

Loss of ambulation or sphincter function before treatment predicts a poor response to treatment. Goals of treatment are to prevent loss of neurologic function, palliate pain, prevent local recurrence, and preserve spinal stability.

Corticosteroids should be administered immediately. An intravenous bolus of dexamethasone 10 mg, with subsequent doses of 4 to 24 mg every 6 hours, is recommended for most patients. In highly selected patients with a single area of metastatic epidural spinal cord compression, immediate and direct decompressive surgical resection followed by radiation therapy is superior to radiation therapy alone. In patients with multiple sites of spinal cord compression and in those with highly radiosensitive cancers (e.g., lymphoma, multiple myeloma, germ cell tumors), radiation therapy is preferred. Surgical treatment is clearly needed in patients with spinal instability, in those without a histologic diagnosis, and in those who again develop epidural compression after or during radiation therapy.

Superior Vena Cava Syndrome

SIGNIFICANCE

The superior vena cava (SVC) syndrome is the result of obstruction of blood flow caused by compression or invasion of the SVC. The SVC is a thin-walled, low-pressure vessel surrounded by rigid structures that make it vulnerable to metastatic disease in adjacent lymph nodes. The SVC collateral vessels, including the azygos vein and the internal mammary, paraspinous, lateral thoracic, and esophageal veins, lessen the obstruction of flow. The azygos vein is the most important of these collateral vessels; SVC obstruction below the level of the azygos vein is not well tolerated.

Cancer is the cause of SVC syndrome in 65% of patients. Lung cancer is responsible for 80% of these cases, and lymphoma, breast cancer, and germ cell tumors account for most of the others. Nonmalignant causes include mediastinal fibrosis (e.g., histoplasmosis) and thrombosis of central venous catheters and pacemakers.

CLINICAL FINDINGS

Symptoms begin insidiously and are often worse on bending, stooping, or lying down. Symptoms include dyspnea, occurring in 60% to 70% of patients, and facial fullness, which occurs in 50% of patients. Cough, arm swelling, chest pain, and dysphagia may occur. Physical findings include venous distention of the neck and chest wall (60%), facial edema (50%), plethora and cyanosis (each in 20% of patients), and arm edema (10%).

DIAGNOSIS AND TREATMENT

Chest radiography shows mediastinal widening in two thirds of these patients and a pleural effusion in one fourth. A right hilar mass is observed in up to 15% of patients. CT scans can demonstrate the size, shape, and location of a mass; the extent of obstruction; and options for biopsy. Venography is not routinely obtained, but it may show patency of an SVC initially thought to be completely obstructed.

Treatment of the SVC syndrome requires a histologic diagnosis of the tumor before radiation or chemotherapy. Radiation to an occlusive mass can alter the tumor enough to preclude identification of the tumor type. Biopsy of a palpable supraclavicular or cervical node, thoracentesis, sputum cytologic analysis, mediastinoscopy, thoracoscopy, and percutaneous needle biopsy of the obstructing tumor are options for diagnosis.

The goals of treatment are to alleviate the obstruction and to attempt a cure. SVC occlusion does not change the prognosis of the underlying tumor. Small cell lung cancer, lymphoma, and germ cell tumors are best treated with chemotherapy alone or chemotherapy combined with radiation therapy.

Intravascular stents may successfully relieve a venous obstruction, even in patients with SVC thrombus. Percutaneous placement of stents should be considered in patients with severe symptoms requiring urgent relief because this can be done even before tissue diagnosis. Corticosteroids may improve symptoms in patients with cancers that respond to the cytolytic effects of steroids, such as breast cancer, lymphoma, and, occasionally, germ cell tumors. Corticosteroids are not effective in relieving symptoms in patients with lung cancer.

Hypercalcemia

SIGNIFICANCE

Hypercalcemia occurs with all types of cancer but most commonly in multiple myeloma and breast cancer. In patients with extensive osteolytic bone disease, the secretion of the parathyroid hormone–related polypeptide by the tumor, along with other cytokines such as transforming growth factor, interleukin-6, and tumor necrosis factor, causes hypercalcemia. The possibility of hypercalcemia should be

considered in all patients with cancer who exhibit a change in mental status.

CLINICAL FINDINGS

The symptoms of hypercalcemia depend less on the absolute serum calcium level than on the time course over which the hypercalcemia develops. Common symptoms are constipation, polydipsia, polyuria, fatigue, nausea, vomiting, and bradycardia. Most patients with hypercalcemia have volume depletion. Patients are often confused and may be obtunded. Muscle stretch reflexes are often hyperactive.

TREATMENT

Treatment of hypercalcemia uses two strategies: increasing urinary calcium excretion and decreasing bone resorption (Table 58-1). Drugs such as thiazide diuretics, those that decrease renal blood flow (e.g., histamine blockers, nonsteroidal anti-inflammatory drugs), calcium-containing drugs, and vitamins A and D should be stopped immediately.

Fluid replacement at a rate of 300 to 400 mL per hour for 3 to 4 hours should be given with frequent monitoring of electrolytes. Such rapid fluid replacement should be seen as rehydration rather than as primary therapy. Drugs that decrease bone resorption should be administered as soon as the patient is rehydrated. Bisphosphonates are the most commonly used antiresorptive drugs; pamidronate, at a dose of 60 to 90 mg, is administered over 2 to 4 hours. The major side effects of pamidronate are fever and myalgias. Finally, furosemide, which inhibits calcium absorption in the thick ascending loop of Henle, is a useful calciuretic agent.

Gallium nitrate is a more potent inhibitor of bone resorption and induces normocalcemia in 70% to 90% of patients. Calcitonin, at a dose of 6 to 8 U/kg intramuscularly every 6 hours for 48 hours, is a weak hypocalcemic agent but has a rapid onset of action. Calcitonin can be used concurrently with pamidronate and gallium. Corticosteroids can be used to treat hypercalcemia caused by hematologic malignancies; patients with breast cancer occasionally respond to steroids.

Patients can be treated as outpatients if (1) the serum calcium concentration is less than 12 mg/dL, (2) they have

Table 58-1 Management of Hypercalcemia

Outpatient Management of Hypercalcemia

Preferably administer therapy for hypercalcemia with cytotoxic therapy (e.g., chemotherapy, radiation therapy)
Provide clear instructions about oral intake of fluids
Avoid thiazide diuretics; furosemide is acceptable
Administer pamidronate once a week
Administer gallium nitrate subcutaneously daily to minimize rebound hypercalcemia after acute normalization

Inpatient Management of Hypercalcemia

Administer intravenous fluids immediately
Administer antiresorptive therapy once good urine output is established
Administer pamidronate twice every 48-72 hr
Administer gallium nitrate (5-day infusion)
Cross over to another therapy if no response occurs
Administer calcitonin for the comatose patient or for the patient with cardiac irritability
Administer mithramycin for nonresponding patients only
Consider dialysis in patients with renal insufficiency

Table 58-2 Paraneoplastic Syndromes

Syndrome	Associated Tumors	Mechanism
Ectopic ACTH production	Small cell lung cancer, pancreatic cancer, pheochromocytoma	Tumor secretion of ACTH precursor
SIADH	Lung cancer, head and neck tumors, brain tumors	Ectopic production of antidiuretic hormone
Cerebellar degeneration and peripheral neuropathy	Lung, ovarian, breast cancers, lymphoma (especially Hodgkin disease)	Autoantibodies, including antibodies to Purkinje cells (anti-YO antibodies and anti-Hu antibodies)
Opsoclonus-myoclonus	Lung cancer Neuroblastoma (in children)	No consistent findings; some patients have anti-HU antibodies
Lambert-Eaton myasthenic syndrome	Small cell lung cancer	Antibody production against calcium channels in presynaptic nerve terminal
Erythrocytosis	Renal cell carcinoma, hepatoma	Tumor production of erythropoietin
Thrombophlebitis	Pancreatic cancer, adenocarcinomas	Uncertain

ACTH, adrenocorticotropic hormone; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

no significant nausea and only mild constipation, (3) they are able to take fluids orally, (4) mentation is intact, (5) creatinine levels are normal, (6) they have a stable cardiac rhythm, and (7) a companion is available to observe them. Immediate inpatient management is indicated in all other situations.

Unless the underlying malignant disease is treated, hypercalcemia will persist or recur. Appropriate management of hypercalcemia therefore requires an attempt to control the cancer itself. Hypercalcemia that responds poorly to the previously discussed measures indicates a poor prognosis.

In patients with metastatic breast cancer undergoing effective treatment, hypercalcemia can develop as part of a treatment flare. Typically, such a response is characterized by bone pain and hypercalcemia, sometimes severe, occurring within 2 to 6 weeks of starting a new therapy. If symptoms are due to successful treatment, resolution typically occurs within 12 weeks. Technetium imaging with a bone scan may show greater activity than at baseline and may even demonstrate new bone lesions.

Paraneoplastic Syndromes

Tumors have disease manifestations through immunologic and metabolic factors that are not the direct result of invasion by neoplastic cells. These *paraneoplastic syndromes* may appear before the diagnosis of cancer is made. Because detection and treatment of the underlying malignant disease may improve the syndrome and occasionally may facilitate cure of the cancer, recognition of paraneoplastic syndromes is important.

Several of the paraneoplastic syndromes are the result of autoantibodies produced in response to the tumor, whereas others are the result of the hormonal production of ectopic peptide by the tumor. Tumor cells may also secrete hormones that are structurally distinct from the normal hormone; some of these are less active biologically than the normal hormone. The most common paraneoplastic syndrome is humoral hypercalcemia of malignancy, a condition usually caused by secretion by the tumor of the parathyroid hormone–related polypeptide. Table 58-2 lists the endocrinologic, neurologic, and hematologic paraneoplastic syndromes. Cutaneous syndromes, such as necrotizing

Table 58-3 Examples of Long-Term Complications of Cancer Treatment

Treatment	Examples of Long-Term Complications
Surgery	Loss of vocal function after laryngectomy for laryngeal cancer Malabsorption after bowel resection Erectile dysfunction and incontinence after radical prostatectomy Premature menopause after oophorectomy Postmastectomy pain and upper extremity lymphedema
Radiation therapy	Pulmonary fibrosis after mediastinal or lung radiation Esophageal stricture after esophageal radiation Secondary malignancies (e.g., breast cancer after radiation therapy for Hodgkin disease) Chronic breast fibrosis after breast radiation Neurocognitive deficits after whole-brain radiation Loss of salivary gland function after radiation for cancers of the head and neck Premature atherosclerosis after mediastinal radiation
Chemotherapy	Cardiac dysfunction from prolonged exposure to anthracycline treatments Peripheral neuropathy from taxanes, cisplatin, and vinca alkaloids Ototoxicity from cisplatin Pulmonary toxicity from bleomycin Secondary leukemia from cyclophosphamide and etoposide Premature menopause
Hormonal therapy	Endometrial cancer from tamoxifen Thromboembolic events related to tamoxifen Loss of bone mineral density related to aromatase inhibitors and luteinizing hormone–releasing hormone agonists

migratory erythema and dermatomyositis, and gastrointestinal syndromes can also occur.

Long-Term Effects of Cancer and Cancer Treatment

People who have been successfully treated for cancer may experience long-term effects of the cancer and its treatment. Surgery, chemotherapy, radiation therapy, hormonal therapy, and biologic therapies can all have adverse effects that persist long after disease control, remission, or cure is achieved. Such long-term sequelae of cancer treatments are

increasingly important as the number of cancer survivors increases and as the indications for chemotherapy and radiation broaden. Table 58-3 lists some of the long-term physical complications of cancer therapies.

In addition to the physical effects of cancer treatments, people who have survived cancer face a number of other issues, such as psychological consequences, persistent concerns about cancer recurrence, sexual dysfunction, and employment and insurance discrimination. Although most people can expect to return to their previous activities, most survivors report being affected in at least one of these areas. The impact of cancer on the family, including parents and siblings, partner, and children, persists long after cancer treatment is complete. Most people who have had cancer indicate that the disease and its treatment are life-changing events.

Prospectus for the Future

Advances in the management of cancer are likely to decrease the risk for catastrophic and permanent complications of cancer treatment. Selection of patients who are likely to reap the survival benefits of treatment will decrease the numbers of

patients living with the long-term effects of treatment. Similarly, identifying patients at high risk for complications, such as venous thromboembolism, will lead to prevention strategies for those most likely to benefit from such strategies.

Principles of Cancer Therapy

Alok A. Khorana and Barbara A. Burtness

The treatment of cancer is in the midst of a quiet revolution. Chemotherapy continues to be the mainstay of systemic treatment, but the explosion of knowledge regarding cancer biology has allowed research efforts to focus on the development of more specific “targeted” agents. The annual number of new drugs approved for cancer treatment has increased several-fold since the 1990s. In addition, there are now nearly 400 anticancer agents in clinical trials, more than for any other class of medicine. Surgery and radiation therapy techniques continue to be refined, and these are safe and effective treatments for localized cancers. Despite these advances, cancer is still the second-leading cause of death in the United States, and considerable resources are devoted to the palliative care of cancer patients. The treatment of cancer involves multiple disciplines and requires that surgeons and medical and radiation oncologists work in an integrated fashion to deliver the best possible care to the patient. This chapter reviews the principles of surgical, radiation, and medical approaches to cancer at various points during its natural history. Prerequisites to starting treatment, such as diagnosis and staging, as well as supportive care interventions that can improve the safety of cancer treatments, are also discussed.

Diagnosis and Staging

Definitive treatment for cancer must not commence without a histologic diagnosis except under urgent circumstances. This typically involves an invasive biopsy that obtains sufficient material to evaluate morphology, invasiveness of the tumor, and expression of various molecular markers using immunohistochemistry. Noninvasive tests, such as radiologic imaging, are generally not accepted as substitutes for tissue diagnosis. There are occasional exceptions, such as elevated α -fetoprotein levels along with imaging evidence, which can be used to make a diagnosis of hepatocellular carcinoma.

Once the diagnosis of cancer has been made, the next step is to systematically determine the extent of tumor

spread, a process called *staging*. Tumor staging can be clinical or pathologic. Staging for some of the solid tumors is described in Chapter 57. *Clinical staging* involves physical examination, and imaging studies including computed tomography scans, whole-body positron-emission tomography scans, radionuclide scans, or a combination thereof. The choice of studies for particular tumors is based on our knowledge of their propensity to spread to particular organs. *Pathologic staging* is more definitive and follows the tumor-node-metastasis (TNM) method developed by the American Joint Committee on Cancer and the International Union against Cancer. This system requires a careful evaluation of the primary resection specimen for three measurements: (1) the size and extent of invasion of the primary tumor (the T score), (2) the number and location of histologically involved regional lymph nodes (the N score), and (3) the presence or absence of distant metastases (the M score). The M score is based on information derived from both clinical and pathologic staging. TNM scores are then grouped into categories of stages from I through IV, reflecting an increasing burden of disease. The final TNM stage has both prognostic and therapeutic implications. For instance, a resected colon cancer that invades the muscularis propria, involves 2 of 16 lymph nodes, but has no evidence of distant metastases is staged as a T2 N1 M0 (stage III) colon cancer. The likelihood of tumor recurrence is 40% to 50%, and the patient is recommended to undergo 6 months of chemotherapy after surgery. On the other hand, if no lymph nodes are involved (T2 N0 M0, stage I), the likelihood of recurrence is less than 10%, and no chemotherapy is recommended.

Biomarkers provide additional prognostic information, such as the absence of hormone receptors or expression of *HER-2* in breast cancer, which are indicative of a poor prognosis. Such markers can also be predictive; for example, presence of *HER-2/neu* predicts for response to trastuzumab, and presence of hormone receptors predicts for response to tamoxifen. Prognostic and predictive biomarkers are available for different cancers, but these are not standardized, and most biomarkers have not been integrated into formal staging. Gene expression signatures that provide prognostic

information beyond that already available from formal staging have been identified for certain cancers. A 21-gene signature is commonly used for clinical decision making regarding adjuvant therapy in patients with node-negative, estrogen receptor–positive breast cancer. For certain tumors, measurement of serum levels of tumor markers, such as carcinoembryonic antigen in colon cancer or α -fetoprotein in testicular and liver cancers, can also be of prognostic importance.

An evaluation of the patient's major organ function and other illnesses must also be conducted before treatment can commence. In addition, when the intent of treatment is palliative and not curative, the patient's functional ability, termed *performance status*, must be assessed. This can be done using various history-based methods, such as the Eastern Cooperative Oncology Group or Karnofsky scales. Patients with poor performance status or significant comorbid conditions may not derive a benefit from chemotherapy and are at greater risk for significant adverse events.

Principles of Cancer Surgery

The surgeon is involved in the cancer patient's care at various times: preventing cancer by removal of precancerous lesions or of organs at high risk for cancer (e.g., bilateral mastectomy in those with hereditary defects that can lead to breast cancer); making the diagnosis of cancer by biopsy; providing definitive treatment by removing the primary tumor; assisting in staging by sampling lymph nodes; reconstructing the limb or organ sacrificed; and, finally, providing palliative treatment of cancer (e.g., intestinal bypass for obstruction, cord decompression, or orthopedic procedures to prevent or treat pathologic fractures). Invasive biopsies and certain minor surgical procedures, such as inserting permanent intravenous access devices or temporary feeding tubes, are increasingly being performed by interventional radiologists rather than surgeons.

When cancer is localized, surgery is the most effective curative treatment available. The intent is to completely remove the tumor, regional lymph nodes, and adjacent involved tissue, with a safe margin of normal tissue. At surgery, the tumor is isolated and almost never opened during the procedure. Refinements in cancer surgery include an increasing use of laparoscopic procedures in selected cancers and the identification of a sentinel lymph node by injecting a dye during surgery and foregoing a full lymph node dissection if the sentinel node is uninvolved by cancer.

Principles of Radiation Therapy

More than half of all cancer patients receive radiation therapy at some point during the course of their disease. Radiation therapy can be used as definitive treatment, either alone or in combination with chemotherapy. Unlike surgery, locoregional treatment with radiation can preserve organ structure and function, thereby resulting in enhanced quality of life for patients. For example, use of radiation with chemother-

apy for treatment of localized laryngeal cancer has similar outcomes compared with surgery but allows preservation of the larynx. Radiation therapy is also effective in the palliative setting in relieving many symptoms of advanced cancer, particularly pain.

Ionizing radiation damages cellular DNA directly or indirectly through free radical intermediates. Cells are most susceptible to radiation during the M and G₂ phases of the cell cycle. The aim of radiation therapy is to deliver the highest dose possible to the tumor with minimal toxicity to adjacent normal tissues. Dividing the total planned radiation dose into small daily fractions takes advantage of the difference in repair capability between normal and malignant tissue and improves the tolerance of normal tissue. The biologic effects of radiation can be modified by numerous factors, including the amount of oxygen in the irradiated tissue and the use of chemotherapy for sensitizing tissue to radiation.

The goals of treatment planning for radiation therapy is to precisely define the dose and volume irradiated. The dose of radiation is measured in units of absorbed dose, Gray (Gy), which has replaced the older unit rad (1 Gy = 100 rad). Conventional radiation treatments deliver 1.8 to 2 Gy per day, 5 days per week, over 5 to 6 weeks. For palliative treatment, higher doses per fraction are used to deliver an effective dose over a shorter period of time.

Ionizing radiation can be administered as external-beam therapy using a linear accelerator to generate electrons or high energy x-rays. Electrons have a limited depth of penetration and are useful for superficial tumors. High energy x-rays deliver the radiation deep in the body while reducing the dose to the skin as they enter. Brachytherapy uses radioactive sources to deliver ionizing radiation (gamma rays) directly to the tumor. An example of this is implantation of iodine-125 seeds into the prostate as definitive therapy for early prostate cancer. Current approaches to improving radiation therapy include the use of advanced technology that allows delivery of a higher dose of radiation to specific areas of the tumor and sparing of normal tissue (conformal and intensity-modulated radiation therapy).

Normal tissue response to radiation therapy can be acute or late (Table 59-1). Acute effects occur within days to weeks of irradiation and are seen primarily in rapidly proliferating tissues such as skin and gastrointestinal mucosa. The severity depends on the total dose, but the damage can usually be repaired. Late effects, such as necrosis, fibrosis, or organ failure appear months or years after irradiation and are dependent on fraction size. Another late complication of radiation therapy is the development of secondary malignancies. This has been documented after radiation for breast cancer and Hodgkin disease.

Principles of Medical Therapy

The term *chemotherapy* refers to the use of cytotoxic agents, singly or in combination, for the systemic treatment of cancer. Most such agents are general antiproliferative agents that are more effective against rapidly growing tumors and have significant adverse effects on normal tissues that also

Table 59-1 Acute and Late Effects of Radiation Therapy

Organ	Acute	Late	Dose (Gy) Associated with Adverse Effects
Bone marrow	Aplasia	Leukemia, myelodysplasia	25
Spinal cord	None	Myelopathy	45
Heart	None	Pericarditis, cardiomyopathy, coronary artery disease	45
Rectum	Diarrhea, tenesmus	Stricture, obstruction	60
Eye	Conjunctivitis	Retinopathy	55
Lung	Pneumonitis	Chronic pneumonitis	25

Table 59-2 Commonly Used Chemotherapy Agents

Drug	Cancers Treated	Specific Class/ Mechanism of Action	Common Side Effects
A. Cell Cycle Specific			
5-Fluorouracil	Colorectal and other gastrointestinal, head and neck, breast	Antimetabolite, inhibits thymidylate synthase	Myelosuppression, mucositis, diarrhea
Gemcitabine	Pancreas, lung, breast, bladder	Antimetabolite, deoxycytidine analogue	Myelosuppression, N/V
Methotrexate	ALL, choriocarcinoma, breast, bladder, head and neck, lymphoma	Antimetabolite, folic acid antagonist	Myelosuppression, mucositis, acute renal failure
Doxorubicin	Breast, lung, NHL	Anthracycline, intercalates into DNA	Myelosuppression, N/V, mucositis, cardiomyopathy
Irinotecan	Colorectal, lung	Camptothecin, topoisomerase I inhibitor	Myelosuppression, diarrhea
Paclitaxel	Breast, lung, Kaposi sarcoma, ovarian	Plant alkaloid, inhibits microtubule formation	Myelosuppression, hypersensitivity reaction, sensory neuropathy
Vincristine	ALL, lymphomas, myeloma, sarcoma	Plant alkaloid, disrupts microtubule assembly	Peripheral neuropathy, constipation
B. Cell Cycle Nonspecific			
Cyclophosphamide	Breast, NHL, CLL, sarcoma	Alkylating agent, cross-links DNA	Myelosuppression, hemorrhagic cystitis, N/V, alopecia
Cisplatin	Lung, bladder, ovarian, testicular, cervical, head and neck	Alkylating agent, cross-links DNA	Nephrotoxicity, N/V, myelosuppression, sensory neuropathy

ALL, acute lymphoblastic leukemia, CLL, chronic lymphocytic leukemia; NHL, non-Hodgkin lymphoma; N/V, nausea and vomiting.

divide rapidly, such as bone marrow and digestive tract mucosa. Newer agents, including monoclonal antibodies and signal transduction inhibitors, are directed against targets that are relatively specific to tumor cells and therefore have less toxicity. These drugs are classified separately from chemotherapy as *targeted therapy* agents.

MECHANISMS OF CHEMOTHERAPY

Chemotherapeutic agents can be cell cycle specific or cell cycle nonspecific. Cell cycle nonspecific agents have a greater effect on cells traversing the cell cycle but also affect non-cycling cells whereas cell cycle-specific agents affect only cycling cells. Chemotherapy agents are further classified according to their mechanism of action into alkylating agents, antimetabolites, antitumor antibiotics, and mitotic spindle inhibitors. Commonly used chemotherapy agents and their mechanisms of action, major indications, and common side effects are described in Table 59-2. A prominent side effect of most chemotherapy agents is bone marrow suppression. This, in turn, can lead to infections from neu-

tropenia and life-threatening bleeding from thrombocytopenia. For most drugs, treatment schedules have been developed whereby successive doses are given every 3 to 4 weeks. This interval between successive doses, called a *cycle* of chemotherapy, allows recovery of blood counts and other side effects before administration of the next dose. The concept of *dose intensity* is also important. Cellular killing with chemotherapy follows first-order kinetics: a given dose of drug kills only a fraction of tumor cells. The dose-response curve for chemotherapy drugs is steep. Thus, the greater the dose administered, the greater the kill: a 2-fold increase in dose can lead to a 10-fold increase in tumor cell kill. Unfortunately, this also means that dose reductions could impact on the eventual cure rate. Arbitrary reductions in doses of chemotherapy to spare patients toxicity should be avoided. Shortening the duration of cycles of chemotherapy using growth factor support, a “dose-dense” approach, has been shown to improve survival in selected patients when compared to traditional chemotherapy for breast cancer.

With rare exceptions, single chemotherapy agents cannot cure cancer. Combination chemotherapy regimens have

therefore been developed for a variety of cancers. Combination therapy provides maximal cell kill, broader coverage of resistant cells, and may prevent or slow the development of resistant cells. Drugs used in a combination are chosen based on known efficacy as a single agent but with differing mechanisms of action and nonoverlapping toxicity profiles. These regimens are commonly referred to by acronyms, such as CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) for lymphoma or FOLFOX (5-fluorouracil, leucovorin, and oxaliplatin) for colon cancer.

INDICATIONS FOR CHEMOTHERAPY

Chemotherapy is used in localized or advanced cancers for a variety of indications (Table 59-3). *Adjuvant* chemotherapy refers to its use after the primary tumor has been resected. Here, chemotherapy is directed against presumed systemic micrometastases in patients believed to be at high-risk for recurrence. In the example of stage III colon cancer cited previously, 6 months of adjuvant chemotherapy after colonic resection can reduce the patient's likelihood of developing recurrent cancer from 50% to 25%. Adjuvant chemotherapy has been shown to increase cure rates in breast and lung cancers as well. *Neoadjuvant* or *primary* chemotherapy refers to the use of chemotherapy before surgery, sometimes in combination with radiation therapy. If successful, neoadjuvant therapy can reduce the size of the tumor and consequently permit lesser surgery, for example, a lumpectomy instead of a mastectomy in breast cancer, or limb-sparing surgery instead of amputation in extremity sarcoma. In certain tumor sites, such as larynx or anal canal, neoadjuvant therapy can be so successful that it can lead to a complete obliteration of the tumor and avoid the need for surgery altogether. Chemotherapy is most often employed in the treatment of metastatic disease for which surgery or

radiation therapy is ineffective. In this setting, chemotherapy can be occasionally curative, such as in certain lymphomas or testicular cancers. Even when it is not curative, however, chemotherapy can often extend survival and improve cancer-related symptoms and the patient's quality of life.

EVALUATION OF RESPONSE

The efficacy of chemotherapy is gauged by various methods and has been granted its own vocabulary. In patients with metastatic disease, all known sites of disease are followed by physical examination and serial radiologic imaging. Responses are judged according to the internationally accepted Response Evaluation Criteria in Solid Tumors (RECIST) rules. Disappearance of all known lesions is called a *complete response*, whereas a 30% or greater reduction in long diameter is called a *partial response*. Appearance of new lesions or an increase in the size of known lesions by 20% is termed *progression* and implies failure of treatment. A tumor that is neither responding nor progressing is termed *stable disease*. The percentage of patients who experience a response is called the *response rate* to the agent or agents being given. New drugs are often evaluated on the basis of response rates. It is important for both patient and physician to realize, however, that a response does not imply cure. A drug with even a 100% response rate is not curative if all patients relapse within, say, 6 months. Therefore, the gold standard for measuring the efficacy of a drug is considered to be an improvement in *survival*, or its surrogate, *disease-free survival*—the time interval when no disease is present. The use of effective second-line therapies may minimize the survival differences between two treatments prescribed as initial therapy, and in this context, disease-free survival can serve as an important endpoint in evaluating new regimens. Increasingly, quality-of-life endpoints such as use of pain medications or analysis of patient-filled questionnaires are being used to assess efficacy of drugs given with palliative intent. In patients receiving adjuvant therapy, response rates cannot be measured because there is no clinically evident disease: disease-free and overall survival rates are the only endpoints of efficacy in this setting. Serial measurement of tumor markers can also be useful in identifying recurrence of cancer and monitoring response to therapy in patients with some cancers.

LIMITATIONS OF CHEMOTHERAPY

Despite the wide use of chemotherapy, it is now understood that it can be curative only under certain circumstances. Several reasons exist for the inability of standard doses of chemotherapy to cure cancer. First, tumor cell kinetics naturally protect against chemotherapy. When chemotherapy was initially developed, it was believed that tumors contained a very high percentage of cells traversing the cell cycle. However, we now know that most human tumors display gompertzian growth kinetics, that is, the rate of tumor cell doubling *slows* progressively as tumor size increases. Thus, the growth fraction of tumors is greatest when a tumor is clinically undetectable. However, when the patient is symptomatic and has clinically evident disease, the growth fraction of tumors is less than 5%. This partly explains why chemotherapy can be successful in the adjuvant setting (when the burden of disease is minimal), but rarely results

Table 59-3 Efficacy of Medical Therapy in Selected Cancers

Cure Possible in Advanced Setting

Testicular cancer
Acute leukemias: lymphocytic, promyelocytic, selected myelocytic
Lymphomas: Hodgkin, selected non-Hodgkin
Childhood solid tumors: rhabdomyosarcoma, Ewing sarcoma, Wilms tumor
Choriocarcinoma
Small cell lung cancer

Cure Possible in Adjuvant Setting

Breast cancer
Colorectal cancer
Osteosarcoma
Non-small cell lung cancer

Increased Survival and Palliation in Advanced Disease

Colorectal cancer
Breast cancer
Ovarian cancer
Head and neck cancer
Bladder cancer
Small cell lung cancer
Hepatocellular cancer
Renal cancer
Multiple myeloma

in cures in the metastatic setting. Second, cancer cells can be resistant to chemotherapy. One of the most important forms of resistance is intrinsic and is mediated by an evolutionarily conserved cell membrane efflux pump called *P-glycoprotein*. Resistance can also be acquired after a period of exposure to chemotherapy agents by a variety of mechanisms; for example, tumor cells can decrease the uptake of methotrexate by decreasing the expression of the folate transporter, or amplify expression of the target enzyme thymidylate synthase when treated with 5-fluorouracil. Finally, mutations in the *p53* gene are quite common in various cancers. The P53 protein causes cell-cycle arrest and mediates apoptosis when DNA damage occurs. In the absence of a functioning P53, cancer cells are protected from chemotherapy-induced apoptosis.

STEM CELL TRANSPLANTATION

One way of overcoming the limitations of chemotherapy is to increase the dose given to patients. A major obstacle to delivering higher doses, however, is the possibility of life-threatening complications that can result from bone marrow suppression. Stem cell transplantation is a procedure whereby patients are given myeloablative doses of chemotherapy (sometimes with radiation therapy) and then “rescued” with infusions of peripheral blood or bone marrow stem cells that reconstitute the ablated bone marrow. The source of stem cells can be patients themselves (*autologous* transplantation) or a human leukocyte antigen–matched related or unrelated donor (*allogeneic* transplantation). Stem cell transplantation has been shown to improve survival in selected patients with chronic myelogenous leukemia, relapsed Hodgkin and non-Hodgkin lymphoma, refractory acute myelogenous leukemia, and multiple myeloma. Allogeneic transplantations are more successful in inducing cures than autologous transplantations, owing to the immunologic response mounted by the donor cells, termed *graft-versus-malignancy* effect. Newer approaches to stem cell transplantation take advantage of this phenomenon by using lower, nonmyeloablative doses of chemotherapy and relying on the graft-versus-malignancy effect to achieve tumor remissions. However, allogeneic transplantations can only be offered to a minority of patients because of the limited availability of matched donors (particularly in ethnic minorities) and the inability of older patients and those with comorbid illnesses to tolerate this procedure. To increase the availability of donors, umbilical cord blood is increasingly being studied as a source of stem cells. The complications of stem cell transplantation are primarily related to the toxicity of chemotherapy and radiation therapy to vital organs, including lungs and liver. Long-term morbidity and mortality after allogeneic transplantation can result from *graft-versus-host disease* and from complications of immunosuppressive agents used to treat it.

TARGETED THERAPY

The limitations of chemotherapy, coupled with a greater understanding of cancer cell biology, led to the development of a new class of drugs that are directed against targets that are relatively specific to cancer cells. These targets include growth factors and signaling molecules that are essential for

proliferation of tumor cells, cell cycle proteins, regulators of apoptosis, and molecules that promote interactions between the tumor and host tissues, such as angiogenesis. Agents developed against these targets are also quite diverse and include monoclonal antibodies directed against cell surface antigens or growth factors, specific or multitargeted receptor tyrosine kinase inhibitors, specific pathway signal transduction inhibitors, antisense oligonucleotides, and gene therapies. Many of these agents are still in drug development. The usual side effects associated with chemotherapy such as myelosuppression, nausea and emesis, and alopecia are not observed with these drugs. However, other unique toxicities are seen. Commonly used targeted therapy agents, their mechanisms of action, major indications, and common side effects are described in Table 59-4.

The best-known targeted therapy agent is imatinib, which inhibits *bcr-abl*, the constitutively active fusion product arising from the Philadelphia chromosome of chronic myelogenous leukemia (CML) as well as *c-kit* (CD117), which is overexpressed in gastrointestinal stromal tumors (GIST) (Fig. 59-1). The daily oral administration of imatinib results in complete hematologic responses in more than 90% of patients in chronic-phase CML, and partial responses in more than 50% of patients with metastatic GIST. Although a major advance over traditional treatment for these malignancies, imatinib is not considered curative in most patients. Drug resistance to imatinib, in the form of a mutation in the kinase domain of *abl* that leads to poor binding of the drug, has been observed.

The success of imatinib as a single agent is unlikely to be replicated in many other malignancies, in which multiple redundant signaling pathways are dysregulated. Increasingly, tyrosine kinase inhibitors with multiple (as opposed to specific) targets are being studied. Sorafenib and sunitinib are two examples of such agents that inhibit various pathways, including vascular endothelial growth factor (VEGF), platelet-derived growth factor, and *c-KIT*. Initial studies have shown these drugs to be effective in renal and liver cancers. Furthermore, targeted therapy drugs can increase the efficacy of chemotherapy through various mechanisms. For instance, bevacizumab, an antiangiogenic agent directed against the proangiogenic VEGF increases both response rates and survival when combined with standard chemotherapy in advanced colon cancer. Similarly, the epidermal growth factor receptor (EGFR) antagonist cetuximab increases the efficacy of irinotecan-based chemotherapy in colon cancer and of definitive radiation therapy for oropharyngeal cancers. The availability of these agents has increased the number of drug combinations that can be used in particular cancers. Multiple combinations of chemotherapy and targeted therapy are now available for the treatment of advanced colon cancer. Correspondingly, median survival of patients with this disease has doubled. Another heartening aspect of targeted therapy agents has been (ironically) their broad applicability because many cancers utilize similar processes for growth and metastasis. For instance, bevacizumab may also be effective in lung and breast cancers.

Despite the excitement surrounding targeted therapy, much work is necessary to understand how and when these agents should be used. An example of how this might be done comes from recent research identifying specific molecular changes in EGFR, which are present in only 10% of lung

Table 59-4 Commonly Used Targeted Therapy Agents

Drug	Cancers Treated	Mechanism of Action	Common Side Effects
A. Monoclonal Antibodies			
Rituximab	NHL	Anti-CD-20	Infusional reaction, tumor lysis syndrome, skin reactions
Tositumomab	NHL	Anti-CD-20 radiolabeled with iodine-131	Infusional reaction, myelosuppression, infections
Bevacizumab	Colorectal, renal, lung, breast	Anti-VEGF	Hypertension, proteinuria, epistaxis, thromboembolism
Cetuximab, panitumumab	Colorectal	Anti-EGFR	Rash
Trastuzumab	Breast	Anti- <i>HER-2/neu</i>	Infusional reaction, congestive heart failure
B. Signal Transduction Inhibitors (Oral)			
Imatinib	CML, GIST	Inhibits <i>bcr-abl</i> and other receptor tyrosine kinases	N/V, diarrhea, fluid retention, myelosuppression
Erlotinib	Lung, pancreas	Anti-EGFR tyrosine kinase	Rash, diarrhea
Gefitinib	Lung	Anti-EGFR tyrosine kinase	Rash, hypertension, mild N/V
Sunitinib	Renal, GIST	VEGF, PDGF, <i>c-KIT</i>	Rash, diarrhea, fatigue
Sorafenib	Liver, renal	VEGF, PDGF, <i>c-KIT</i>	Hypertension, fatigue, diarrhea, hand-foot syndrome
Bortezomib	Lymphoma, myeloma	Proteasome inhibitor	Rash, N/V, neuropathy
C. Others			
Tretinoin (all- <i>trans</i> -retinoic-acid)	Acute promyelocytic leukemia	Differentiating agent	Vitamin A toxicity, retinoic acid syndrome, hyperlipidemia

CML, chronic myelogenous leukemia; EGFR, epidermal growth factor receptor; GIST, gastrointestinal stromal tumor; NHL, non-Hodgkin lymphoma; N/V, nausea and vomiting; VEGF, vascular endothelial growth factor.

Figure 59-1 Mechanism of action of *bcr-abl* and of its inhibition by imatinib. **A**, The *bcr-abl* oncoprotein with a molecule of adenosine triphosphate (ATP) in the kinase pocket. The substrate is activated by the phosphorylation of one of its tyrosine residues. It can then activate other downstream effector molecules. **B**, When imatinib occupies the kinase pocket, the action of *bcr-abl* is inhibited, preventing phosphorylation of its substrate. ADP, adenosine diphosphate. (Reproduced from Savage DG, Antman KH: Imatinib mesylate: A new oral targeted therapy. *N Engl J Med* 346:683-693, 2002).

cancer patients. Although gefitinib is ineffective in most lung cancer patients, advanced lung cancer patients with these activating EGFR mutations have an extremely high likelihood of response. Similarly, the EGFR antagonists cetuximab and panitumumab appear to be ineffective in patients with colorectal cancer whose tumors carry mutations in the *K-ras* gene.

ENDOCRINE THERAPY

Cancers originating from tissues that are regulated by hormones, such as breast and prostate, continue to be susceptible to hormonal control mechanisms even when metastatic. Endocrine therapy includes the use of both hormones and antihormonal agents that work as antagonists or partial agonists. Many patients with metastatic breast cancer express

hormone receptors (estrogen or progesterone) in tumor cells. More than 60% of these patients respond either to tamoxifen, an estrogen receptor modulator, or to aromatase inhibitors (letrozole, anastrozole, or exemestane), which inhibit adrenal steroid production. Similar responses are observed in men with metastatic prostate cancer treated with the luteinizing hormone–releasing hormone agonists leuprolide or goserelin, which decrease testosterone to castrate levels. In selected breast and prostate cancer patients, metastatic disease can be controlled for years with endocrine therapy only. Tamoxifen and the aromatase inhibitors are also highly effective in the adjuvant treatment of resected breast cancer. Furthermore, tamoxifen has been shown to reduce the incidence of breast cancer by 50% in healthy women at high-risk for developing breast cancer, making it a highly effective chemoprevention agent.

BIOLOGIC THERAPY

A diverse group of cytokines that use host immunomodulatory effects as their primary mechanism of action are classified as *biologic response modifiers* or *biologic agents*. Monoclonal antibodies are sometimes classified as biologic agents, although here they have been reviewed under targeted therapy. Interferons are used most commonly in chronic myelogenous leukemia, although they are not as successful as imatinib in inducing responses. Interferons are also used for the treatment of hairy cell leukemia, Kaposi sarcoma, and selected cases of melanoma and renal cell carcinoma. Interleukin-2 (IL-2) functions as a T-cell growth factor and induces lymphokine-activated and natural killer cell activity. IL-2 can induce responses in 10% to 20% of patients with metastatic melanoma or renal cell carcinoma. In a minority of these patients, responses are complete and last for years. However, IL-2 is associated with considerable toxicity, in particular, a capillary leak syndrome that leads to hypotension, edema, renal insufficiency, and even death.

Supportive Care

Supportive care interventions can improve the safety and tolerability of chemotherapeutic treatments. A diverse array of drugs is available for the treatment of chemotherapy-related side effects. Serotonin receptor antagonists and neurokinin-1 receptor antagonists, in combination with older antiemetic drugs, have made it possible to achieve complete control of chemotherapy-induced nausea and vomiting in nearly all settings. Erythropoietin and darbepoetin stimulate division and differentiation of erythroid precursors and are used for the treatment of chemotherapy-induced anemia. These agents are associated with increased thrombotic complications and, in some studies, with worse outcomes for cancer patients. Granulocyte-colony stimulating factor (filgrastim) and granulocyte-macrophage colony-stimulating factor (sargramostim) stimulate the proliferation and differentiation of myeloid progenitor cells and are used to shorten the duration of chemotherapy-induced neutropenia in patients with neutropenic fever. These agents are also used to mobilize and collect stem cells for transplantation. Filgrastim can also be used to shorten the duration of cycles of chemotherapy, permitting the dose-dense approach in adjuvant treatment of breast cancer discussed previously. Recombinant human keratinocyte growth factor (palifermin) helps protect against chemotherapy and radiation therapy–induced mucositis.

Palliative care is an integral part of the treatment of cancer, particularly in noncurative settings. Palliative aspects of treating cancer address not only physical symptoms, in particular pain syndromes, but also psychosocial and spiritual concerns. It is important to note that chemotherapy and radiation therapy are often employed with palliative intent and can improve quality of life. The oncologist usually provides palliative care along with active therapy for cancer, although end-of-life issues are more appropriately dealt with in a hospice setting.

Prospectus for the Future

Advances in cancer biology and the first wave of targeted therapy agents are just beginning to affect cancer mortality. Many changes in cancer drug development and use are necessary to achieve sustained improvement in cancer outcomes.

Drug Development

Currently, it can take up to \$1 billion and 10 years to develop a single new drug. Given the plethora of new agents and limited resources to test them, preclinical validation of drug targets must be improved. The use of RNAi technology as well as development of more sophisticated preclinical models will allow vetting of new agents before they enter clinical trials. More rational selection of patients based on an understanding of the drug target should also accelerate drug development. Many targeted therapies affect processes important for early tumor development, such as angiogenesis. The paradigm of cancer drug development therefore requires

change: instead of first testing drugs in patients with advanced and heavily pretreated disease, clinical trials should focus on early-stage cancers. Finally, optimizing clinical trial endpoints so that the efficacy of the drug can be discovered in real-time using biomarkers or functional imaging techniques (such as positron-emission tomography) will hasten the clinical trials process.

Rational Drug Therapy

The selection of agents to treat an individual patient is based primarily on histologic diagnosis and staging. Yet even within a given histologic classification and stage, there is enormous heterogeneity in tumor behavior. Molecular profiling of tumors using newly available genomic and proteomic technology will soon be incorporated into formal staging. This will permit rational, individualized therapy right at the bedside, rather than the one-size-fits-all approach currently being used.

Obesity

Osama Hamdy and Robert J. Smith

Definition and Assessment of Obesity

Obesity is usually defined as a body mass index (BMI) higher than 30 kg/m^2 (weight [kg]/(height [m])²). A person with a BMI of 25 to 29 is considered overweight. Severe obesity is defined as a BMI of more than 40. The old term *morbid obesity* refers to individuals weighing 45 kg more than desirable body weight (about 100 lb or about 60% above ideal body weight). There is increasing recognition of limitations to the interpretation of BMI, especially in individuals who are muscular or have a low BMI. Many clinicians prefer, at least conceptually, to define obesity not strictly by BMI but as an excess of body fat sufficient to confer risk. However, the BMI value is still useful for estimating overall health risks of obesity and comparing outcomes between clinical trials.

Population data in the United States indicate that adverse health consequences increase progressively with a BMI at or above 27 kg/m^2 . In considering the cardiometabolic risk of obesity, individuals who accumulate visceral fat and have higher waist circumferences are at much higher risk for cardiovascular disease than those with the same BMI or a similar percentage of body fat but lower waist circumferences. The National Cholesterol Education Program Adult Treatment Panel III (ATP III) has included a waist circumference greater than 40 inches (102 cm) in American men and 35 inches (88 cm) in American women among five criteria that define the cardiometabolic syndrome. As an alternative mode of assessment, central and probably visceral obesity is likely with a waist-to-hip circumference ratio greater than 1 in men and 0.6 in women. Dual-energy x-ray absorptiometry and abdominal computed tomography or magnetic resonance imaging can be used to quantify visceral obesity, but these measurements typically are used in research studies and are not routine in clinical care.

Epidemiology of Obesity

During the past 20 years, the prevalence of overweight and obesity has increased sharply for both adults and children in

the United States. Comparison of data from two National Health and Nutrition Examination Survey (NHANES) reports shows that among adults aged 20 to 74 years, the prevalence of obesity increased from 15% in the 1976-1980 survey to 32.9% in 2003-2004. According to the U.S. Centers for Disease Control and Prevention, after a quarter century of increases, obesity prevalence has stabilized, but levels are still high at 34% of U.S. adults older than 20 years in 2007. Because the adverse consequences of obesity develop over multiple years, it can be expected that the complications of obesity will continue to increase in prevalence. Overweight and obesity and their associated health problems have a significant economic impact on the U.S. health care system, accounting for about 9% of total medical expenditures. An epidemic of obesity and its complications similar to that in the United States is occurring throughout the world.

Pathogenesis of Obesity

Obesity exemplifies a genetic-environment interaction in which genetically prone individuals who lead a sedentary lifestyle and consume a larger amount of food are particularly at risk. Children of obese parents are 80% more likely to become obese through the combined effects of genetic and shared environmental factors.

In considering genetic factors, obesity may result from the effects of a single gene or the effects of multiple genes acting in concert. An example of a single gene defect is leptin deficiency. Leptin is a hormone produced in fat cells and is a potent inducer of satiety. Rare individuals with inactivating leptin mutations have been identified. They are characterized by increased food seeking and marked obesity, which can be substantially ameliorated by the administration of leptin. Mutations in a number of other genes that encode appetite regulatory proteins also have been identified as causes of obesity. However, these monogenic causes of obesity are rare, and the genes that contribute to common forms of human obesity have not yet been clearly identified. In addition to appetite regulation, there appears to be a heritable component associated with metabolic rate, spontaneous physical

Figure 60-1 Hormonal and neurogenic control of appetite and food intake. CCK, cholecystokinin; FA, fatty acid; GLP-1, glucagon-like peptide-1; PYY, peptide YY.

activity, and thermal responses to food. Polymorphisms in several candidate genes, including the melanocortin-4 receptor, the β_3 -adrenergic receptor, and peroxisome proliferator-activated receptor- $\gamma 2$ (PPAR- $\gamma 2$), have been linked in population studies to obesity. Genome-wide association scans recently have identified additional genes linked to obesity, and it is thought that genetic risk in most individuals derives from the synergistic or additive effects of multiple genes. Although the specific genetic factors still are not well understood, the heritability of obesity clearly is evident in twin and adoptee studies, in which obese individuals generally follow the weight pattern of their identical twins and biologic parents even when raised apart.

Many hormones, neurotransmitters, and neurogenic signals affect appetite and food intake, as shown in Figure 60-1. Endocannabinoids increase appetite, enhance nutrient absorption, and stimulate lipogenesis. Melanocortin hormone, through its effect on several receptors, modifies appetite. Multiple gut hormones play significant roles in inducing satiety, including glucagon-like peptide-1 (GLP-1), peptide YY (PYY), and cholecystokinin. Leptin and pancreatic amylin are other potent satiety hormones. On the other hand, ghrelin, which is secreted from the stomach fundus, functions as an orexigenic or hunger-inducing hormone.

Although the genetic determinants of obesity clearly are significant, it is important to recognize the equal influence of environmental and socioeconomic factors. Lower socioeconomic status, lower education level, cessation of smoking, and consumption of high glycemic index carbohydrates all are associated with increased prevalence of obesity. The current worldwide epidemic of obesity undoubtedly is

driven by changes in environmental and socioeconomic factors operating on a relatively stable background of genetic influences within a given population.

Pathogenesis of Obesity-Associated Risk

Recent evidence indicates that adipocytes in fat tissue function as an endocrine organ, producing secretory products with a major role in whole-body metabolism. The relationship of obesity to insulin resistance and endothelial dysfunction (the early stage of atherosclerosis) is mediated through the release of several hormones from adipose tissue. These hormones, designated adipocytokines or adipokines, include adiponectin, leptin, tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6), resistin, plasminogen activator inhibitor-1 (PAI-1), angiotensinogen, and monocyte chemoattractant protein-1 (MCP-1). Many of these factors have actions that are proinflammatory or alter blood coagulation. Their production is influenced by both the overall amount of adipose tissue and its distribution between central and peripheral body regions. The differences in adipokine gene expression between visceral and subcutaneous fat likely have an important role in the high cardiometabolic risk of visceral obesity.

Risks Associated with Obesity

Overweight and obese individuals are at increased risk for multiple clinical disorders. A partial list of obesity-related

conditions is provided in Table 60-1. Obese individuals often manifest more than one of these disorders, and such secondary consequences of obesity account for much of the morbidity and mortality of the obese state. The “metabolic syndrome” as defined by a National Cholesterol Education Program Expert Panel refers to a state of particularly high cardiometabolic risk that characterizes individuals with at least three of five individual risk factors: abdominal obesity (waist circumference >40 inches in men and >35 inches in women), glucose intolerance (fasting plasma glucose ≥ 100 mg/dL), hypertension ($\geq 130/\geq 85$ mm Hg), elevated plasma triglycerides (≥ 150 mg/dL), and low high-density lipoprotein (HDL) cholesterol (< 40 mg/dL in men and < 50 mg/dL in women). Even modest weight loss (7% to 10% of body weight) can result in substantial reduction in many if not all of these risks.

Treatment of Obesity

Current guidelines for treatment approaches to obesity are summarized in Table 60-2. The major options are lifestyle modification (diet and exercise), behavior modification, pharmacologic intervention, and bariatric surgery. In general, a combination of approaches is more effective than a single modality.

LIFESTYLE MODIFICATION

Managing overweight and obesity by lifestyle modification requires a multidisciplinary strategy and teamwork. Key

components include a structured dietary intervention and a physical activity program. Evidence-based dietary guidelines should be used to design individualized patient plans in consultation with a registered dietitian. As a general approach, daily caloric intake initially should be reduced by a modest 250 to 500 calories. Calories from carbohydrate should be decreased to about 40 percent of total calories, with a daily intake of no less than 130 g carbohydrate. Except in patients with renal impairment (creatinine clearance < 60 mL per minute) or significant microalbuminuria, protein may represent 20% to 30% of daily caloric intake to minimize lean mass loss during weight reduction. The remaining 30% of calories should come from fat. *Trans*-fats should be eliminated, and saturated fat should be reduced to 7% to 10% of total fat calories. Meal plans should also include increased soluble fiber (e.g., from fresh fruits and vegetables) and healthy carbohydrate consumption, especially foods with a low glycemic index. Caloric intake should be adjusted progressively as needed until weight loss is achieved. Underlying all these steps should be the goal of designing individualized plans that can be maintained over the long term. Many patients find it helpful to receive a structured dietary intervention that includes specific suggestions for daily meals. This may increase adherence and can be easier to follow than a list of general guidelines. Nutritionally complete meal replacement (e.g., in the form of shakes or bars) can be useful for some patients at the start of the weight reduction program.

Patients should meet with an exercise physiologist to construct an individualized plan that is responsive to their capabilities and lifestyle. A balanced exercise plan will incorporate a mix of cardiovascular, stretching, and strength exercises, and it should be graded to increase gradually in both duration and intensity. Patients can start with 10 to 20 minutes of daily stretching and aerobic exercise, with a gradual increase as tolerated. Any exercise should be preceded by a warm-up period to minimize injuries. Cardiovascular evaluation and oversight during implementation of exercise (e.g., through a cardiac rehabilitation program) should be considered based on individual risk. Current guidelines recommend an ultimate goal of 60 to 90 minutes of daily exercise, with a minimum of 150 to 175 minutes per week for weight loss benefits to be realized. Emphasis should be placed on moderate-intensity exercise, such as walking 20-minute miles, rather than strenuous exercise. Because patients who are not accustomed to exercising may find it difficult to incorporate physical activity into daily practice, it is also important to emphasize variety of exercises to avoid boredom.

Table 60-1 Clinical Conditions Associated with Obesity

Diabetes mellitus
Dyslipidemia
Hypertension
Ischemic heart disease
Stroke
Reproductive dysfunction
Cholelithiasis
Gastroesophageal reflux disease
Sleep apnea

Cancer (endometrial, breast, prostate)
Incontinence (women)

Table 60-2 Guide to Selecting Treatment Based on Body Mass Index

Treatment	Body Mass Index				
	25-26.9	27-29.9	30-34.9	35-39.9	≥ 40
Diet, physical activity, behavior therapy	Yes with comorbidities	Yes with comorbidities	Yes	Yes	Yes
Pharmacotherapy		Yes with comorbidities	Yes	Yes	Yes
Weight-loss surgery				Yes with comorbidities	Yes

“Yes” indicates that the treatment is indicated regardless of comorbidities.
Data from NIH/NHLBI/NAASO. October 2000, NIH Publication No. 00-4084.

BEHAVIOR MODIFICATION AND PATIENT EDUCATION

Cognitive-behavioral intervention and patient education are important components of successful weight loss programs. Whenever possible, cognitive-behavioral intervention should be conducted by an experienced psychologist. The fundamental principals of intervention should include behavioral goal setting, stimulus control techniques, cognitive restructuring, assertive communication skills, stress management, and relapse prevention. Cognitive behavioral support conducted in a group setting with weekly meetings is frequently successful. Patients should learn how to set realistic goals for weight loss over a specific period of time. They also should receive guidance and support in dealing with specific challenges, such as social eating, coping with craving, and managing relapses.

PHARMACOLOGIC OPTIONS

Three antiobesity drugs—sibutramine, orlistat, and phentermine—are approved for use in the United States. Only sibutramine and orlistat are approved for long-term use. Rimonabant, an endocannabinoid receptor antagonist, is used in many countries but has not been approved in the United States because of concern about its common psychiatric side effect of depression. A recent meta-analysis of 30 placebo-controlled trials of 1 to 4 years' duration has provided evidence for significant weight loss with sibutramine (4.2 kg average weight loss, 10 studies, 2623 participants), orlistat (2.9 kg, 16 studies, 10,631 participants), and rimonabant (4.7 kg, 4 studies, 6365 participants).

Sibutramine

Sibutramine is an oral serotonin- and noradrenaline-reuptake inhibitor that controls appetite by inducing satiety. Sibutramine-assisted weight loss has been accompanied by improved serum concentrations of triglycerides, but adverse effects of lowered concentrations of HDL cholesterol and increased blood pressure and pulse rate. It therefore is recommended that blood pressure be monitored during sibutramine treatment. There typically is a gradual rebound of weight gain on discontinuation of sibutramine.

Orlistat

Orlistat limits caloric intake through inhibition of the lipase-mediated breakdown of fat in the gastrointestinal tract. This typically decreases fat absorption by about 30% and increases fecal fat content. In addition to its weight loss effect, there is evidence that orlistat can decrease the incidence of diabetes, improve concentrations of total and low-density lipoprotein (LDL) cholesterol, and improve blood pressure and glycemic control in patients with diabetes. Conversely, HDL cholesterol may be slightly lowered by orlistat, and there is an increased risk for cholelithiasis. Most patients develop some degree of side effects that range from diarrhea, flatulence, oily stools, and fecal urgency to fecal incontinence (rare). Gastrointestinal side effects are usually proportional to the amount of fat intake. Possible deficiency of fat-soluble vitamins A, D, E, and K mandates their routine supplementation in patients on orlistat. The usual dose of orlistat is 120 mg before each meal. A 60-mg dose is currently available

over-the-counter. This dose is less effective but is associated with fewer adverse side effects.

Phentermine

Phentermine is approved for the short-term treatment of obesity. In addition to appetite suppression, it can cause elevated blood pressure, increased heart rate, and insomnia, owing to its sympathomimetic properties. Combining phentermine with tricyclic antidepressants or monoamine oxidase inhibitors may result in a marked increase in blood pressure and other serious side effects because of elevated serotonin levels.

BARIATRIC SURGERY

Bariatric surgery involves the use of one of several different techniques to modify the gastrointestinal tract in a manner that results in a decrease in calorie intake or absorption. The most common bariatric surgical procedures in the United States at present are Roux-en-Y gastric bypass (RYGB) and laparoscopic placement of an adjustable gastric band (LAGB) (Fig. 60-2). The number of bariatric procedures performed in the United States has increased about 15-fold over the past 10 years to nearly 200,000 in 2007. Bariatric surgery is indicated for individuals with a BMI of more than 40 kg/m² or with a BMI of more than 35 kg/m² plus high-risk comorbid conditions, such as severe sleep apnea, obesity-related cardiomyopathy, or uncontrolled type 2 diabetes. Bariatric surgery is not uniformly a low-risk procedure, and judicious patient selection and diligent perioperative care are mandatory. Contraindications include high operative risk (e.g., severe congestive heart failure or unstable angina), active substance abuse, and significant psychopathology.

LAGB is associated with substantially better maintenance of weight loss than lifestyle intervention alone and carries a very low operative mortality rate (0.1%). As a less invasive procedure than RYGB, it may be preferred in patients older than 55 years. LAGB is associated with significantly less loss of fat-free mass, but less excess weight loss than RYGB at 5 and 10 years. Complications associated with LAGB include band slippage, band erosion, balloon failure, port malposition, band and port infections, and esophageal dilation. Overall, complication and mortality rates are much lower for LAGB than those observed with RYGB.

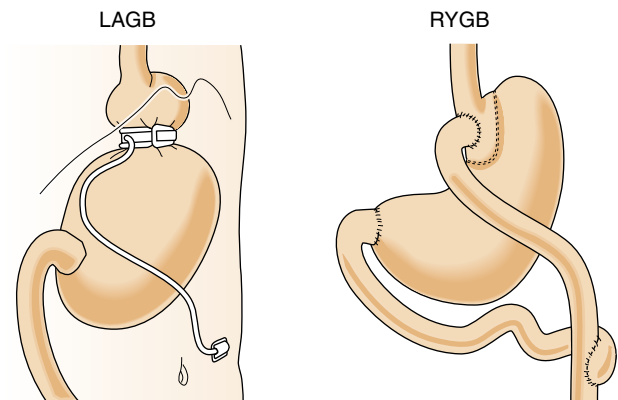

Figure 60-2 Common bariatric procedures. LAGB, laparoscopic adjustable gastric band; RYGB, Roux-en-Y gastric bypass.

RYGB is currently the most commonly performed bariatric procedure in the United States. In RYGB, the upper stomach is transected, creating a very small proximal gastric pouch with a capacity of 10 to 30 mL. The gastric pouch is anastomosed to a Roux-en-Y proximal jejunal segment, bypassing the remaining stomach, duodenum, and a small portion of jejunum. The operative mortality rate for RYGB is 0.5%. The resulting foregut bypass appears to have benefits beyond just calorie intake reduction and weight loss. These include improvement in the physiologic responses of gut hormones involved in glucose regulation and appetite control, such as ghrelin, GLP-1, and PYY. Mechanical improvements from decreased adiposity include less weight bearing by lower extremity joints and improved lung compliance and reduced fatty tissue around the neck, which relieves obstruction to breathing and sleep apnea.

A meta-analysis of 22,000 bariatric surgery patients demonstrated an average excess body weight loss of 61% accompanied by significant improvements in type 2 diabetes, hypertension, sleep apnea, and dyslipidemia. The beneficial effect of obesity surgery on type 2 diabetes is one of the most important outcomes, with resolution of diabetes in most patients (range, 40% to 100% of patients in various studies). Independent predictors of diabetes reversal following bariatric surgery include selection of RYGB as the bariatric procedure, a shorter duration of diabetes, and greater weight loss after surgery. Insulin-treated patients usually experience significant decreases in insulin requirements, and improvements in fasting blood glucose levels often occur before significant weight loss. Most type 2 diabetic patients are able to discontinue insulin therapy by 6 weeks after surgery, and euglycemia has been maintained up to 14 years after RYGB.

It is important to recognize that the altered gastrointestinal dynamics of gastric bypass surgery result in substantial risk for developing deficiencies of vitamins and minerals, including iron, calcium, vitamin B₁₂, vitamin D, and other

fat-soluble vitamins. Supplements of multivitamins, iron, and calcium should be provided postoperatively, and there should be periodic screening for acquired deficiencies. Inadequate protein intake and absorption may occur after RYGB and lead to protein malnutrition. An infrequent but serious complication of RYGB that recently has been recognized is hyperinsulinemic hypoglycemia, which appears to result from induced changes in pancreatic β -cell mass and insulin secretion. This requires careful diagnostic evaluation to confirm hyperinsulinemia and rule out insulinoma. Affected patients may be responsive to diet modifications (frequent, low carbohydrate feedings), but when symptoms are severe, patients may require partial or total pancreatectomy.

Prognosis

Although a small percentage of obese individuals are able to achieve and maintain weight loss for a long period after nonsurgical intervention, most regain weight over the following months or years. Weight regain even after bariatric surgery is not uncommon, with regain occurring typically after reaching maximum weight loss about 2 years after surgery. Weight reduction of 10% to 20% in an obese individual from any intervention results in a decrease in total and resting energy expenditure, and this may prevent further weight loss at a given level of reduced calorie intake. In considering the underlying causes of obesity, there currently is substantial support for the concept of a biologic set point or control mechanism that may target a body weight in the overweight or obese range. Whether the set point is determined by genetic or environmental factors, this concept lends support to the theory that behavior is not the sole determinant of obesity. Further understanding of the genetic and hormonal regulation of obesity and their roles in establishing a functional set point may help in creating long-lasting and effective treatment strategies.

Prospectus for the Future

- The fundamental behavioral, environmental, and genetic determinants of appetite, satiety, and obesity will be better understood.
- New medications will be developed that more effectively modulate appetite and satiety control mechanisms, likely with a greater emphasis on the use of multiple medications in combination.
- The environmental factors promoting obesity, including influences on food choice and total calorie intake, will be better understood and will need to be addressed as population-level determinants of obesity.

Anorexia Nervosa and Bulimia Nervosa

Michelle P. Warren

Anorexia nervosa is characterized by a classic triad of amenorrhea, weight loss, and psychiatric disturbance. The *Diagnostic and Statistical Manual of Mental Disorders* further defines criteria for anorexia as weighing less than 85% of ideal body weight and having missed at least 3 consecutive menstrual periods (Table 61-1). Anorexic patients are subdivided into those who just restrict food and those who purge. In addition, these patients may be hyperactive and exercise compulsively. There is a relatively high incidence of anorexia in athletes, particularly in groups in which there is an advantage to be thin, such as ballet dancers and gymnasts. Diabetic patients with anorexia nervosa may purposefully avoid good control in order to initiate weight loss. Bulimia nervosa is often related to previous anorectic behavior and is characterized by gorging followed by periods of severe food restriction. Unusual means are employed to lose weight, including vomiting and abuse of diuretics or laxatives. Weight may fluctuate, generally not to dangerously low levels, but many associated metabolic problems cause serious health issues. Bulimia is often associated with impulsive behavior, alcohol or drug use, promiscuity, and stealing or shoplifting.

Prevalence

The prevalence of these disorders has been increasing, with the lifetime prevalence of anorexia nervosa in women at 0.3% to 1%, and prevalence rates of 1% to 1.5% for bulimia in the United States. An even larger number of women (3% to 5%) have disordered eating that does not fulfill strict criteria for anorexia nervosa or bulimia nervosa, but instead meets criteria for an eating disorder “NOS” (not otherwise specified). All these conditions are much more common in women, with a ratio favoring females of 10:1 for anorexia. Although bulimia is more common in men than anorexia, most patients with this disorder are also women, with an incidence of 2% in female community-based samples and 4% to 13% in college-aged women. The physical consequences of extreme caloric restriction (<85% of ideal body

weight) or the metabolic insults resulting from overexercise or rarely bulimia include hypothalamic amenorrhea, low peak bone mass, bone loss, stress fractures, and infertility. The diagnostic criteria for anorexia nervosa and bulimia nervosa are summarized in Table 61-1.

Anorexia Nervosa

CLINICAL FEATURES

There is no blood test or specific physical finding that establishes the diagnosis of anorexia nervosa. Rather, the diagnosis is based on a symptom complex that includes severe weight loss and behavioral changes such as hyperactivity or preoccupation with food. There typically are perceptual changes with a distorted view of the body and generally an unreasonable concern about being too fat. Food intake may include large amounts of raw vegetables and diet soda, with avoidance of fat and meat. Most female patients present with amenorrhea, and this may be the first complaint to bring the patient to a physician. Constipation may be extreme, with bowel movements once a week and accompanying abdominal pain. Intolerance to cold is common, as are dry skin and hair loss. Lanugo-type hair may be present on the body. Hypercarotenemia may give a yellowish tinge to the skin. Petechiae, pedal edema, and acrocyanosis can occur. Bradycardia, hypotension, and hypothermia are common. Laboratory tests can be normal, but leukopenia accompanied by a relative lymphocytosis is common. Azotemia may develop secondary to dehydration; electrolyte abnormalities, including hyponatremia, hypokalemia, and hypophosphatemia, may occur; there may also be hypoglycemia. Typical endocrine abnormalities include hypothalamic amenorrhea characterized by low gonadotropins (especially luteinizing hormone) and also hypoestrogenism when amenorrhea is present. Low leptin and high ghrelin levels not infrequently are observed in anorexia nervosa. It is thought that these peptides, secreted by the adipose tissue and small bowel, respectively, serve as signals reflecting nutritional status and

Table 61-1 Diagnostic Features of Anorexia Nervosa and Bulimia Nervosa**Anorexia Nervosa**

- A. Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected)
- B. Intense fear of gaining weight or becoming fat, even though underweight
- C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight
- D. In postmenarchal females, amenorrhea (i.e., the absence of at least three consecutive menstrual cycles; a woman is considered to have amenorrhea if her periods occur only after hormone, e.g., estrogen, administration)

Bulimia Nervosa

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
 1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
 2. A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
- B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise
- C. Binge eating and inappropriate compensatory behaviors that occur, on average, at least twice a week for 3 months
- D. Self-evaluation unduly influenced by body shape and weight
- E. Disturbance that does not occur exclusively during episodes of anorexia nervosa

From American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. Washington, DC, American Psychiatric Association, 1994, pp 549-550.

in turn appropriateness for reproductive function. Low T_4 and T_3 with normal thyroid-stimulating hormone can occur, and serum cortisol levels may be high as a consequence of decreased clearance and prolonged half-life. Diurnal variation of cortisol still occurs, but at a higher set point. Insulin-like growth factor type I levels usually are low, and this may contribute to growth compromise in young patients. Numerous associated medical problems may occur, including hypoglycemia with coma, cardiac arrest, liver dysfunction, pancreatitis, and kidney stones. By far the most ubiquitous and persistent problem is osteoporosis, which may be accompanied by fractures (especially stress fractures in patients who exercise heavily). The fractures until recently were believed to be secondary to hypoestrogenism, but recent work indicates that the problem is nutritional in origin and will not reverse with estrogen or oral contraceptives.

TREATMENT AND PROGNOSIS

Patients with a body mass index of less than 18 should be evaluated by both a medical physician and a psychiatrist or

psychologist with experience in eating disorders. Patients who continue to lose weight, have complicating medical problems, or weigh less than 75% of ideal should be considered for inpatient treatment. Younger patients with intense family therapy can sometimes be managed as outpatients. Parenteral nutrition may be necessary in some patients to initiate weight gain and prevent severe medical problems. Because the mortality rate of anorexia nervosa is high (10%), the patient may need intensive monitoring in a specialized unit.

Most of the endocrine abnormalities resolve promptly with weight gain, but amenorrhea may take up to a year to resolve after recovery and may persist in up to 30% of patients. Osteoporosis and osteopenia will improve, and the occurrence of new fractures will decrease in proportion to BMI increases. Hormone replacement or oral contraceptives can be used if the amenorrhea persists. The return of menses is a hallmark of recovery, though this indicator will be lost in patients taking oral contraceptives. The recurrence rate of anorexia nervosa is high (up to 30%). In some patients, anorexia is chronic or, with partial improvement, takes the form of "eating disorder not otherwise specified." If infertility is an issue in weight-recovered patients, induction of ovulation often is successful with injectable gonadotropins or, in some cases with adequate estrogen secretion, oral clomiphene citrate. Ovulation has been induced by the administration of leptin in hypothalamic amenorrhea in an experimental protocol, and the administration of pulsatile gonadotropin-releasing hormone is effective but not currently available.

Bulimia Nervosa**CLINICAL FEATURES**

The purge-gorge syndrome of bulimia may occur alone, but more commonly the bulimic behavior evolves from a restrictive anorexia nervosa-type syndrome. Thus, the medical problems induced by purging and gorging may be superimposed on the clinical abnormalities associated with anorexia. Bulimia patients often are secretive about their behavior and thus may be difficult to diagnose in the absence of weight loss or menstrual irregularity. Problems resulting from bulimia include severe tooth decay, parotid enlargement, stomach rupture, metabolic alkalosis, carpopedal spasm, hypercarotenemia, subcutaneous emphysema, pneumomediastinum, and pancreatitis. Evidence exists for hormonal defects in gonadotropin-releasing hormone and cholecystokinin regulation. The incidence of menstrual irregularity is highly variable, and patients with bulimia may have anovulation with normal estrogen secretion. Body weight also is variable and generally normal. Most associated medical problems are due to the vomiting, although hypokalemia has been seen with diuretic abuse, and myopathic weakness and electrocardiographic abnormalities are from ipecac abuse.

TREATMENT AND PROGNOSIS

Bulimia is often associated with depression, drug and alcohol abuse, and antisocial behavior such as stealing and

promiscuity. All these problems need to be treated with appropriate psychiatric therapy as well as interventions to address drug dependency when it is present. Antidepressants have been used with variable success, and cognitive behav-

ioral therapy may be effective. Bulimia has a high rate of chronicity and relapse (30%), although risk for relapse declines after 4 years. Long-term therapy is usually required, and fortunately, mortality is low.

Prospectus for the Future

- Identification of the molecular mechanism of bone loss in anorexia nervosa, which could lead to appropriate pharmacologic intervention when there is resistance to weight gain and the occurrence of fractures
- Development of tests that better assess bone quality and identify patients at risk for fracture
- Identification of genes that predispose to anorexia and bulimia nervosa
- Development of pharmacologic interventions that better control bulimic behavior and prevent chronicity

Malnutrition, Nutritional Assessment, and Nutritional Support in Adult Patients

Thomas R. Ziegler

Malnutrition

Protein-energy malnutrition and depletion of specific micronutrients are common in adult patients with chronic illnesses and in those requiring hospitalization, with a typical prevalence of 20% to 40%. Illness-associated anorexia, gastrointestinal symptoms, depression or anxiety, and other morbidities often lead to decreased food intake. These factors, in addition to disrupted meal scheduling, frequently result in inadequate nutrient intake in hospitalized patients that may cause or worsen malnutrition. Some patients have abnormal nutrient losses due to diarrhea, vomiting, polyuria, wound drainage, and dialysis. Drugs, including corticosteroids, chemotherapeutic agents, antirejection drugs, and diuretics are associated with skeletal muscle breakdown, gastrointestinal injury, and electrolyte or water-soluble vitamin losses. Bedrest itself induces skeletal muscle wasting and impaired muscle protein synthesis. Stressful illnesses are associated with increased blood concentrations of catabolic hormones (cortisol, catecholamines, and glucagon), release of pro-inflammatory cytokines (interleukins [e.g., IL-1, IL-6, and IL-8]) and tumor necrosis factor- α [TNF- α], and the development of tissue resistance to anabolic hormones (insulin and insulin-like growth factor-I [IGF-I]). The combination of decreased nutrient intake and increased tissue nutrient losses, coupled with increased energy, protein, and micronutrient needs due to inflammation, infection, and cytokinemia, leads to the wasting and micronutrient depletion common in medical patients with acute and chronic illness. Significant loss of lean body mass or deficiency of specific vitamins and minerals is associated with weakness and fatigue, increased rates of infection, impaired wound healing, and delayed convalescence.

Nutritional Status

Accurate nutritional assessment is essential for detecting preexisting depletion of body protein, energy reserves, and micronutrients, identifying risk factors for malnutrition, and defining steps needed to prevent or reverse nutrient deficiencies and depletion of lean body mass. Blood concentrations of specific micronutrients (e.g., copper, thiamine, 25-hydroxyvitamin D, vitamin B₆, folate, and vitamin B₁₂) and electrolytes (e.g., magnesium, potassium, and phosphorus) are important to guide needs and repletion responses. Unfortunately, there is not a practical, simple test that can be used as an index of general protein-energy nutritional status. Therefore, nutritional assessment involves the consideration of multiple measures and determinants, as outlined in Table 62-1. Integration of this information ultimately provides reliable insight into whether patients are likely to have mild, moderate, or severe protein-energy malnutrition and depletion or deficiency of specific vitamins, minerals, or electrolytes. Patients with an involuntary body weight loss of 5% to 10% or more of their usual body weight in the previous few weeks or months and those weighing less than 90% of their ideal body weight (e.g., a body mass index (BMI) <18.5 kg/m²) should be carefully evaluated.

In hospitalized patients, especially those with severe illnesses, circulating concentrations of proteins (e.g., albumin, prealbumin, and transferrin) are generally quite low. These are not useful as protein nutritional status biomarkers, since they are markedly affected by non-nutritional factors, such as fluid status, capillary leak, iron status (transferrin), decreased hepatic synthesis, and increased clearance from the circulation. Because of its long circulating half-life (18 to 21 days), plasma albumin levels often remain low despite

adequate feeding and are slow to respond to nutritional repletion. Prealbumin has a much shorter circulating half-life than albumin (several days), and serial plasma prealbumin levels therefore can provide a rough indication of protein status in clinically stable outpatients.

Nutritional Requirements

Energy requirements can be estimated using indirect calorimetry or the Harris-Benedict equation to calculate basal energy expenditure (BEE) in kilocalories (kcal) per 24 hours:

$$\text{Males: BEE} = 66.5 + (13.8 \times \text{kg body weight}) + (5.0 \times \text{height in cm}) - (6.8 \times \text{age in years})$$

$$\text{Females: BEE} = 655 + (9.6 \times \text{kg body weight}) + (1.8 \times \text{height in cm}) - (4.7 \times \text{age in years})$$

The maintenance energy requirement is about 1.3 times BEE in ambulatory subjects. Caloric need for patients receiving specialized nutrition support can be estimated as 25 to 30 kcal/kg per day (using ideal body weight from standard tables). Lower amounts of calories typically are given in intensive care unit (ICU) patients (15 to 20 kcal/kg per day) to avoid complications of overfeeding. In obese subjects, adjusted body weight should be used in the calculation of energy and protein needs as defined by the following equation:

$$\text{Adjusted body weight} = (\text{current weight} - \text{ideal body weight}) \times 0.25 + \text{ideal body weight}$$

Guidelines for protein requirements in adult patients are given in Table 62-2. For most catabolic or malnourished patients requiring specialized feeding, a generally recommended protein dose is 1.5 g/kg per day in individuals with normal renal function. This is about twice the recommended dietary allowance (RDA) for healthy adults of 0.8 g/kg per day. The administered protein dose should be adjusted downward as a function of the degree and tempo of azotemia (in the absence of dialysis therapy) and hyperbilirubinemia (see Table 62-2).

Nutritional Support

Nutritional support beyond usual oral feeding should be considered when patients have evidence of protein-energy malnutrition or a clinical condition likely to result in malnutrition. Major indications for specialized oral or enteral nutrition (EN) and parenteral nutrition (PN) support are summarized in Table 62-3. Consultation with a multidisciplinary nutrition support team, if available, has been shown to reduce complications and costs, and to increase the appropriate use of EN and PN in hospital settings.

ORAL NUTRITION SUPPORT

Oral nutrition supplementation includes provision of balanced oral diets of usual foods supplemented with complete liquid or solid nutrient products. These may include protein

Table 62-1 Comprehensive Nutritional Assessment of Adult Medical Patients

- Review past medical and surgical history and current illness
- Obtain body weight loss history
- Estimate energy (calorie), protein, and micronutrient needs
- Determine dietary intake pattern in relation to nutrient needs
- Perform detailed physical examination (consider skeletal muscle wasting, skin lesions indicative of micronutrient deficiency)
- Evaluate gastrointestinal tract function
- Determine ambulatory and mental functional status
- Evaluate serial standard biochemical tests of organ function
- Consider consultation with multidisciplinary nutrition support team

Table 62-2 Estimated Protein Requirements in Adult Medical Patients

Clinical Condition	Protein Dose (g/kg/day)
Well-nourished with acute illness	1.2-1.5
Malnourished and/or severe catabolic stress	1.5-1.8
Postoperative	1.2-1.5
Hepatic failure	0.6-1.0 (based on estimated function)
Encephalopathy	0-0.6
Acute renal failure, not on renal replacement therapy	0.6-1.0 (based on estimated renal function/azotemia)
Renal failure, on renal replacement therapy	1.2-1.5

Table 62-3 Major Indications for Specialized Oral/Enteral or Parenteral Nutrition

- Evidence of moderate to severe protein or protein-energy malnutrition or deficiency of one or more essential micronutrients
- Involuntary loss of 5% to 10% or more of usual body weight
- Dietary food intake likely to be <50% of needs for more than 5 to 10 days
- Severe catabolic stress (e.g., intensive care unit care, serious infection, major operation), prolonged gastrointestinal dysfunction (>5-10 days), or intestinal failure (short bowel syndrome)
- Chronic obstructive lung disease, chronic infection, and other chronic inflammatory or catabolic disorders with documented poor nutrient intake and recent weight loss

supplements (e.g., hydrolyzed whey or casein powder that can be mixed with dietary beverages), high-potency multivitamin and mineral supplements, and specific micronutrients required to treat a diagnosed deficiency (e.g., zinc, copper, and vitamins B₆, B₁₂, and D). Several studies show

that convalescence is enhanced with addition of 1 to 2 cans per day of complete liquid nutrient supplements to meals following stress such as total hip replacement. It is prudent to place patients with significant illnesses who can tolerate oral medications on a potent oral multivitamin and mineral preparation, at least for several months, although this is not specifically evidence supported.

TUBE FEEDING (ENTERAL NUTRITION)

Patients with intact gastrointestinal (GI) function may be unable to consume adequate diet orally due to medical or surgical conditions. Although PN is commonly administered in these settings, this practice is not evidence based. Current guidelines strongly favor oral nutritional supplements or EN if specialized nutrition support is indicated in patients with a functional GI tract. From extensive data primarily derived from animal studies, EN is associated with improved gut barrier function, decreased infectious complications, less hypermetabolism, and decreased morbidity and mortality in catabolic models compared with PN.

When delivered in appropriate amounts, commercially available tube feedings provide complete nutrition for most patients, although some severely stressed patients and those with malabsorption may have special needs. The feedings can be delivered by conventional nasogastric tubes into the stomach, small-bore nasogastric or nasojejunal tubes, percutaneous gastrostomy or jejunostomy tubes, or percutaneous gastrojejunostomy tubes. Gastric feedings can be by either continuous or bolus feeds, whereas small bowel feeds must be by continuous slow infusion using an infusion pump to avoid diarrhea. Tube feedings should be initiated at a slow rate (e.g., 10 to 20 mL per hour) for 8 to 24 hours and slowly advanced to the goal rate at 8- to 24-hour intervals. If subcutaneous insulin is being given, standing orders should be in place to ensure provision of dextrose-containing intravenous fluids whenever tube feedings are stopped for more than 1 to 2 hours. In managing an EN regimen, it should be recognized that numerous studies have shown that patients commonly receive only 50% to 70% of prescribed tube feedings due to gastrointestinal intolerance or discontinuation for medical tests and procedures.

Most outpatients and hospitalized patients tolerate standard enteral formulas delivered by gastric or intestinal routes that provide between 1 and 1.5 kcal/mL. A large variety of enteral tube feeding products are available for clinical use. The specific product chosen should be based both on clinical conditions and underlying organ function, with the assistance of a dietitian or other nutrition support professional.

Diarrhea is common in hospital patients receiving tube feedings but is typically due to factors independent of the feeding, including administration of antibiotics, sorbitol-containing or hypertonic medications (e.g., acetaminophen elixir), and infections. Diarrhea due to tube feeding can occur as a result of rapid formula administration, underlying gut mucosal disease, or severe hypoalbuminemia with associated bowel wall edema. Use of a fiber-containing enteral formula is sometimes a useful maneuver to decrease diarrhea. Other complications of tube feeding include aspiration, discomfort or sinusitis with nasally placed feeding tubes, pharyngeal or esophageal mucosal erosion due to

local tube trauma, and entrance site leakage, skin breakdown, cellulitis, and pain with percutaneous feeding tubes. Metabolic complications of tube feeding include fluid imbalances, hyperglycemia, electrolyte abnormalities, azotemia, and occasionally refeeding syndrome. In general, if tube feedings are deemed to be required for more than 4 to 6 weeks, a percutaneous feeding tube should be placed.

Hospital patients receiving tube feedings should generally have blood glucose monitored at least daily, and blood electrolytes (including magnesium and phosphorus), renal function indices, and other blood chemistries at least weekly. There should be close monitoring of intake and output (including urine, stool, and drainage outputs), gastrointestinal tolerance, vital signs, physical findings, and changes in clinical course that may necessitate adjustments in the feeding regimen. When patients are able to consume oral food, tube feeding should be decreased incrementally and then discontinued when oral intake is clearly established (e.g., based on daily calorie counts by a dietitian).

PARENTERAL NUTRITION

PN support includes administration of complete nutrient mixtures, which contain dextrose, L-amino acids, lipid emulsion, electrolytes, vitamins, and minerals (plus certain medications as indicated, such as insulin or octreotide) by either peripheral or central vein. PN is lifesaving in patients with intestinal failure (e.g., short bowel syndrome). Unfortunately, in patient subgroups with lesser degrees of intestinal failure, only limited objective data from randomized, controlled studies are available on the efficacy of PN. Existing data indicate that PN benefits patients with preexisting moderate to severe malnutrition or with critical illness by decreasing overall morbidity and possibly mortality compared with patients receiving inadequate EN or hydration (intravenous dextrose) therapy alone.

The basic principle is to consider PN therapy in patients with a need for nutrition support who are unable to achieve adequate nutrient intake by the enteral route. Compared with PN, EN is less expensive, appears to better maintain intestinal mucosal structure and function, has fewer mechanical and metabolic complications, and is associated with reduced rates of nosocomial infections. Thus, the enteral route of feeding should be used and advanced whenever possible, and the amount of administered PN correspondingly reduced. Generally accepted indications for PN include (1) short bowel syndrome or other conditions causing intestinal failure that prohibit adequate intake or absorption of enteral nutrients (e.g., motility disorders, obstruction, severe ileus, severe inflammatory bowel disease), especially in patients with preexisting malnutrition; (2) inadequate enteral feeding (<50% of needs) that is likely to extend for 7 to 10 days due to an underlying illness; and (3) severe catabolic stress (e.g., requiring ICU care) with inadequate enteral nutrient intake likely to extend for 3 to 7 days or longer. In patients who meet these qualifications, PN is contraindicated if (1) the extra intravenous fluid required for PN cannot be tolerated; (2) there are severe electrolyte abnormalities or hyperglycemia on the planned day of PN initiation; (3) there is uncontrolled bloodstream infection or severe hemodynamic instability; or (4) placement of an intravenous line for PN poses undue risks.

PN can be delivered either as peripheral vein or central vein solutions. To diminish the risk for phlebitis, typical peripheral vein PN solutions provide low concentrations of dextrose (5%) and amino acids (<3.5%) with a large proportion of energy given as fat emulsion (50% to 60% of total calories). Because fluid restriction or organ dysfunction often precludes use of large fluid volumes, peripheral vein PN is generally not indicated in ICU patients. Intravenous lipid emulsions (typically added to PN as a 20% soybean oil-based solution) provide both essential linoleic and α -linolenic fatty acids and energy (10 kcal/g). The maximal recommended rate of fat emulsion infusion is about 1 g/kg per day. Most patients clear triglyceride from intravenous fat emulsion effectively from plasma, but it is important to monitor plasma triglyceride levels at baseline and then about weekly. Triglyceride levels should be maintained below 400 to 500 mg/dL to decrease risk for pancreatitis or compromised pulmonary diffusion capacity in patients with severe chronic obstructive lung disease.

Central venous administration of PN allows higher concentrations of dextrose and amino acids to be delivered as hypertonic solutions and thus decreases the amount of fat emulsion needed to reach caloric goals. Requirements for potassium, magnesium, and phosphorus are typically higher with central vein PN compared with peripheral vein PN owing to the increased dextrose provided (insulin-mediated intracellular electrolyte shift) and needs related to increased glucose metabolism and adenosine triphosphate (ATP) production. The higher concentrations of dextrose and amino acids allow most patients to achieve caloric and amino acid goals with only 1 to 1.5 L of PN per day. In central vein PN, initial orders typically provide 60% to 70% of non-amino acid calories as dextrose and 30% to 40% of non-amino acid calories as fat emulsion. These percentages are adjusted as indicated depending on blood glucose and triglyceride levels. Based on comprehensive data associating hyperglycemia with hospital morbidity and mortality, expert panels now recommend close blood glucose monitoring and control in ICU settings (goal of 80 mg/dL to 130 to 150 mg/dL). The dextrose amount in central vein PN should be reduced or regular insulin added to the PN bag, or both, to maintain blood glucose within the desired range. Separate intravenous insulin infusions should usually be used in acutely ill patients receiving central vein PN who develop hyperglycemia. Specific requirements for intravenous trace elements and vitamins have not been rigorously defined for patient subgroups, and therapy is directed at meeting published recommended doses that maintain blood levels in the normal range in most stable patients using standardized intravenous preparations.

The most common complication of peripheral vein PN is local phlebitis due to the catheter. Abnormalities in blood electrolytes can be corrected with adjustment of concentrations in the peripheral PN prescription. Hypertriglyceridemia typically responds well to lowering of the total PN lipid dose. Central vein PN is associated with a much higher rate of mechanical, metabolic, and infectious complications than peripheral vein PN. Mechanical complications include those related to insertion of the central venous catheter (e.g., pneumothorax, hemothorax, malposition of the catheter, and thrombosis). Infectious complications include catheter-related bloodstream infections and non-catheter-related

infections by bacteria and fungal species, which may in some cases be due to endogenous bacterial translocation from the gut lumen. The risk for these infections appears to be increased with use of non-subclavian vein central venous access (e.g., jugular, femoral veins) and multiple-use catheters with nondedicated PN infusion ports used for additional purposes such as blood drawing or medication administration. Poorly controlled blood glucose (>130 to 150 mg/dL) is not uncommon in patients requiring central vein PN, and this is associated with an increased risk for nosocomial infection. Risk factors for hyperglycemia include (1) poorly controlled blood glucose at PN initiation, (2) use of high dextrose concentrations (>10%) in the initial few days of PN administration or too rapid an increase in total dextrose load, (3) insufficient exogenous insulin administration, (4) inadequate monitoring of blood glucose responses to central vein PN administration, and (5) administration of corticosteroids and pressor agents such as norepinephrine (which stimulate gluconeogenesis and cause insulin resistance).

Overfeeding can induce severe metabolic complications, including carbon dioxide overproduction, azotemia, hyperglycemia, electrolyte alterations, and hepatic steatosis and injury (Table 62-4). Dextrose and lipid doses in PN should be advanced over several days after initiation, and blood glucose, electrolytes, triglycerides and organ function tests, intake and output measurements, and the clinical course must be closely monitored. Refeeding syndrome with central vein PN administration is relatively common in patients at risk, including those with preexisting malnutrition, electrolyte depletion, or alcoholism, or after prolonged periods of intravenous hydration therapy (e.g., 5% dextrose) without nutrition support, all of which are common in hospital patients. Refeeding syndrome is mediated by administration of excessive intravenous dextrose (>150 to 250 g, such as given in 1 L of PN with 15% to 25% dextrose). This markedly stimulates insulin release, which rapidly lowers blood potassium, magnesium, and especially phosphorus concen-

Table 62-4 Common Metabolic Complications of Parenteral Nutrition

Parenteral Nutrition Prescription Problem	Metabolic/Clinical Consequence
Excess kcal, CHO, fat	Abnormal liver function tests
Excess kcal, CHO, fat	Hepatic steatosis
Excess CHO	Hypercapnia
Excess fluid, kcal, CHO, fat	Respiratory insufficiency
Excess amino acids	Azotemia
Excess sodium and fluid	Sodium and fluid retention
Excess CHO, inadequate insulin	Hyperglycemia-mediated immune cell dysfunction, infection
Inadequate or excessive electrolytes	Abnormal blood electrolyte levels
Excess fluid, kcal, sodium, CHO, inadequate electrolytes	Cardiac failure, arrhythmias
Excess CHO, inadequate electrolytes, thiamine	Refeeding syndrome

CHO, carbohydrate; kcal, calories.

trations due to intracellular shift and utilization in carbohydrate metabolic pathways. Administration of high doses of carbohydrate also consumes thiamine, which is required as a cofactor for carbohydrate metabolism and can precipitate thiamine deficiency. Hyperinsulinemia tends to cause sodium and fluid retention at the level of the kidney. Together, fluid and sodium retention, the drop in electrolytes (which can cause arrhythmias), and hypermetabolism due to excessive calorie provision can result in heart failure, especially in patients with preexisting heart disease. Prevention of refeeding syndrome requires vigilance to identify patients at risk, use of initially low PN dextrose concentrations, provision of higher doses of potassium, magnesium, and phosphorus based on current blood levels and renal

function, and supplemental thiamine (100 mg per day for 3 to 5 days).

For patients in whom home PN is indicated, physicians should consult with social service professionals to identify appropriate home care companies and nutrition support professionals to assess intravenous line access, metabolic status, and the home PN order and to ensure follow-up care and monitoring of PN. It is important not to arrange for rapid hospital discharge in patients newly started on PN. Securing reliable venous access and monitoring of fluid and electrolyte status over a 2- to 3-day period is an important aspect of care for most patients started on PN and imperative in those with severe malnutrition and at risk for refeeding syndrome.

Prospectus for the Future

- Optimal levels for vitamins (e.g., vitamin D) and micronutrients will be better defined, thus making clearer the circumstances under which they should be measured and provided.
- Better evidence will be generated on target blood glucose levels that achieve optimal benefit compared with adverse consequences in hospitalized, acutely ill patients with various disorders.

Disorders of Lipid Metabolism

Geetha Gopalakrishnan and Robert J. Smith

Lipids such as free fatty acids (FFAs), cholesterol, and triglycerides are hydrophobic molecules that bind protein for transport. Nonesterified FFAs travel as anions complexed to albumin. Esterified complex lipids are transported in lipoprotein particles. Lipoproteins have a hydrophobic core (cholesteryl esters and triglycerides) and an amphiphilic surface monolayer (phospholipids, unesterified cholesterol, and apolipoproteins). Ultracentrifugation separates lipoproteins into five classes based on their density (Table 63-1). Proteins on the surface of lipoproteins, apolipoproteins (apo), activate enzymes and receptors that guide lipid metabolism. Defects in the synthesis and catabolism of lipoproteins result in dyslipidemia. Two classes of lipids, triglyceride and cholesterol, play a significant role in the pathogenesis of atherosclerosis and therefore are the focus of this chapter.

Lipid Metabolism

In the intestinal lumen, dietary triglycerides and cholesterol esters are hydrolyzed by pancreatic lipase to produce glycerol, FFAs, and free cholesterol. Formation of micelles enables the absorption of glycerol and FFAs into the intestinal cell. The transport of free cholesterol is mediated by a cholesterol gradient that exists between the lumen and intestinal cell. Within the cell, glycerol combines with three fatty acid chains to form triglycerides, and cholesterol is esterified to form cholesterol esters. Triglycerides (85% of chylomicron mass) and cholesterol esters are assembled with surface lipoproteins to form chylomicrons. After entering the circulation, chylomicrons acquire more surface apolipoproteins such as apo C-II and apo E from high-density lipoprotein (HDL) particles (Fig. 63-1). Apo C-II activates lipoprotein lipase (LPL) located on the capillary endothelium. LPL hydrolyzes the core chylomicron triglycerides to release FFAs, which function as an energy source. Excess fatty acids are stored in adipose tissue or used in hepatic lipoprotein synthesis. The triglyceride-poor chylomicron remnant is then cleared from the circulation by hepatic LDL receptors.

These receptors are activated by apo E located on the surface of chylomicrons.

Very-low-density lipoproteins (VLDL) are synthesized by the liver (see Fig. 63-1). FFA and cholesterol obtained from the circulation or synthesized by the liver are incorporated into VLDL particles. Any condition that increases the flux of FFA to the liver, such as poorly controlled diabetes, will increase VLDL production. The liver assembles triglycerides (55% of VLDL mass), cholesterol (20%), and surface apolipoproteins to form VLDL particles. Apo C-II on the VLDL surface activates LPL, which hydrolyzes the triglyceride core of VLDL particles to generate VLDL remnant or intermediate-density lipoprotein (IDL). The IDL, depleted of triglycerides (25%), can be cleared from the circulation by apo E-mediated LDL receptors or can be hydrolyzed further to form low-density lipoproteins (LDLs). LDLs are triglyceride-poor (5%) particles composed of cholesterol esters (60%) and apolipoproteins. Apo B-100 on the surface of LDL binds LDL receptors and facilitates LDL clearance from the circulation. Internalized LDL cholesterol is used to synthesize hormones, produce cell membranes, and store energy.

In the liver, LDL cholesterol is used to synthesize bile acids (see Fig. 63-1), which are secreted into the intestinal lumen along with free cholesterol. Bile acids help transport fat. About 50% of the cholesterol and 97% of the bile acid entering the lumen is reabsorbed back into the circulation. The reabsorbed cholesterol regulates cholesterol and LDL receptor synthesis.

Many cells in the body, including liver parenchymal cells, synthesize cholesterol (Fig. 63-2). Acetate is converted to 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA). HMG-CoA reductase converts HMG-CoA to mevalonic acid, which is then converted to cholesterol through a series of steps. HMG-CoA reductase is the rate-limiting step in the cholesterol synthesis pathway. Drugs that inhibit this enzyme decrease cholesterol biosynthesis and cellular cholesterol pools. Internalization of LDL particles into cells is regulated by negative feedback (see Fig. 63-2). A negative cholesterol balance increases the expression of LDL receptors and

Table 63-1 Properties of Lipoproteins

Lipoprotein Class	Density (g/mL)	Origin	Apolipoproteins	Lipid
Chylomicrons	<0.95	Intestine	C-II, E	TG (85%), cholesterol (10%)
VLDL	<1.006	Liver	B-100, C-II, E	TG (55%), cholesterol (20%)
IDL	1.006-1.019	VLDL catabolism	B-100, E	TG (25%), cholesterol (35%)
LDL	1.019-1.063	IDL catabolism	B-100	TG (5%), cholesterol (60%)
HDL	1.063-1.25	Liver, intestine	A-I, E	TG (5%), cholesterol (20%)

HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; TG, triglyceride; VLDL, very-low-density lipoprotein.

Figure 63-1 Normal metabolism of plasma lipoproteins (see text for details). B,E, membrane receptor for lipoproteins containing apo B and apo E (synonymous with the LDL receptor); apo, apolipoprotein; FFA, free (unesterified) fatty acids; FC, free (unesterified) cholesterol; HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LPL, lipoprotein lipase; VLDL, very-low-density lipoprotein.

subsequent uptake of cholesterol from the circulation. A positive cell cholesterol balance suppresses LDL receptor expression and decreases uptake of LDL cholesterol into cells. Circulating LDL particles then enter macrophages and other tissues through scavenger receptors. Scavenger receptors are not regulated; therefore, these cells accumulate excess intracellular cholesterol resulting in the formation of foam cells and atheromatous plaques.

The antiatherogenic effect of HDL is attributed to the removal of excess cholesterol from tissue sites and other lipoproteins. HDL is synthesized in the liver and intestine (see Fig. 63-1). Excess phospholipids, cholesterol, and apolipoproteins on remnant chylomicrons, VLDL, IDL, and LDL are transferred to HDL particles and thus increase HDL mass. Apo A-I, a surface lipoprotein on HDL particles, mobilizes cholesterol from intracellular pools and accepts cholesterol released during lipolysis of triglyceride-rich lipoproteins. It also activates lecithin:cholesterol acyltransferase (LCAT), an enzyme that esterifies cholesterol. These cholesterol esters then move from the hydrophilic HDL surface to the hydrophobic HDL core. Cholesterol ester transfer protein (CETP) transfers core HDL cholesterol esters to

other lipoproteins such as VLDL. These lipoproteins deliver cholesterol to peripheral sites for hormone and cell membrane synthesis.

Diagnostic and Therapeutic Approach to Dyslipidemia

Disorders of lipid metabolism result from genetic and acquired defects in the production and removal of lipoproteins. A total cholesterol, triglyceride, or LDL level above the 90th percentile or an HDL level below the 10th percentile for the general population defines dyslipidemia. Total cholesterol, triglyceride, and lipoprotein assessments must be made in the fasting state. Chylomicrons, which are present in plasma for up to 10 hours after a meal, otherwise confound these measurements. It is advisable to confirm dyslipidemia with two separate determinations. Total cholesterol, triglyceride, and HDL levels can be measured directly. VLDL and LDL levels are calculated. If the triglyceride level is

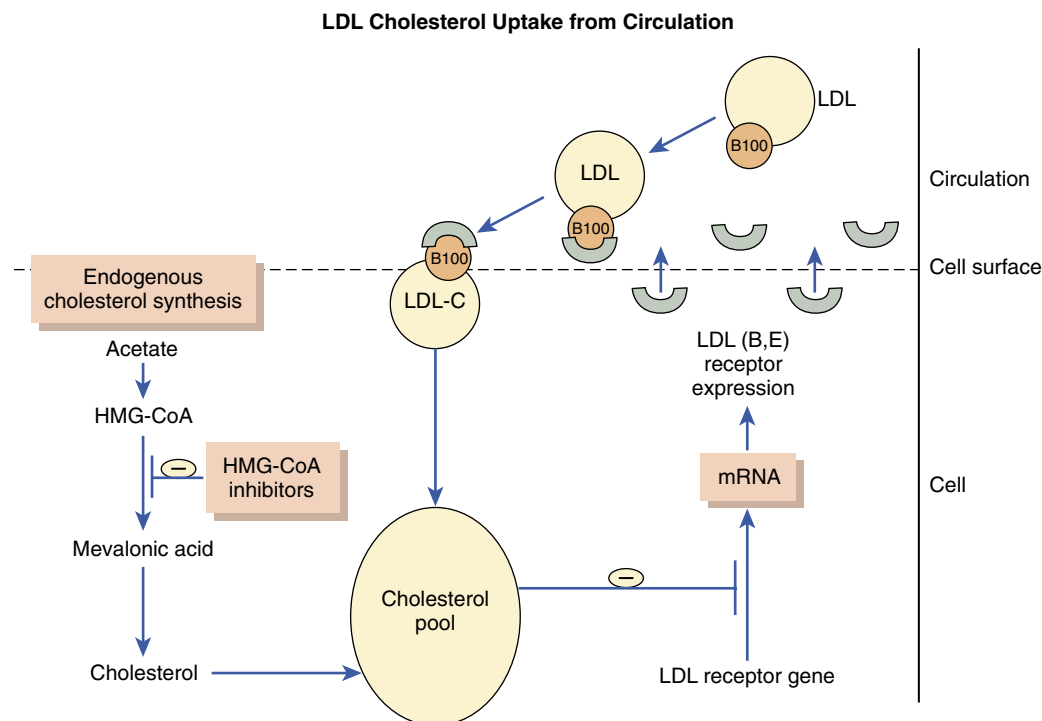

Figure 63-2 Regulation of low-density lipoprotein (LDL) receptor expression (see text for details). B,E, membrane receptor for lipoproteins containing apo B and apo E (synonymous with the LDL receptor); HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A; mRNA, messenger RNA.

less than 400 mg/dL, VLDL is calculated by dividing the triglyceride level by 5. LDL cholesterol is estimated by subtracting VLDL and HDL from the total cholesterol. VLDL and LDL cannot be determined if triglyceride levels are greater than 400 mg/dL. In this case, the lipoprotein abnormality can be identified by inspecting the serum. When the triglyceride level exceeds 350 mg/dL, the serum is cloudy. After refrigeration, a white surface layer depicts excess chylomicrons, whereas a dispersed opaque infranant reflects elevated VLDL.

The cost-effectiveness of screening and treating the general population for lipid disorders is continuously debated. Current guidelines do not recommend routine screening in children unless a lipoprotein abnormality or premature vascular disease is identified in a first-degree relative. A screening lipid panel is recommended for the general population at age 20 years, with fasting or nonfasting total cholesterol and HDL measurements as the initial screen (Table 63-2). If the total cholesterol value is greater than 200 mg/dL or the HDL value is less than 40 mg/dL, a repeat fasting lipid panel is required. If the total cholesterol value is less than 200 mg/dL and HDL is greater than 40 mg/dL, retesting is recommended every 5 years. Individuals with coronary heart disease (CHD), risk factors for CHD, or a CHD equivalent (symptomatic carotid artery disease, peripheral arterial disease, abdominal aortic aneurysm, or diabetes) should be screened more frequently based on risk assessment and LDL levels as shown in Table 63-2. CHD risk factors include age (men >45 years, women >55 years), family history of premature CHD (affected male first-degree relative <55 years or female first-degree relative <65 years), smoking, hypertension, and HDL less than 40 mg/dL. HDL greater than 60 mg/dL is cardioprotective. LDL treatment strategies are based on these risk indicators (Table 63-3).

Table 63-2 Recommendations for Screening*

1. Initial fasting lipid profile is recommended at age 20 years
2. Rescreen every 5 years if:
 - a. LDL <160 mg/dL in patients with 0-1 risk factor
 - b. LDL <130 mg/dL in patients with ≥ 2 risk factors
3. Rescreen every 1-2 years if:
 - a. LDL >160 mg/dL in patients with 0-1 risk factor
 - b. LDL >130 mg/dL in patients with ≥ 2 risk factors
 - c. LDL >100 mg/dL in patients with CHD or CHD risk equivalent

*Recommendations of the Adult Treatment Panel, National Cholesterol Education Program III, as modified in 2004. Coronary heart disease (CHD) risk factors include age (men >45 yr, women >55 yr), family history of premature CHD (male first-degree relative <55 yr, female first-degree relative <65 yr), smoking, hypertension, and high-density lipoprotein cholesterol (HDL) <40 mg/dL. Subtract a risk factor if HDL is >60 mg/dL. Coronary heart disease risk equivalents include symptomatic carotid artery disease, peripheral arterial disease, abdominal aortic aneurysm, and diabetes mellitus.
LDL, low-density lipoprotein cholesterol.

Treatment of elevated total and LDL cholesterol can slow the development and progression of CHD. Meta-analysis of primary and secondary prevention trials indicates that CHD mortality decreased by about 15% for every 10% reduction in serum cholesterol.

The impact of triglycerides on vascular disease is less clear. Metabolic factors such as diabetes and obesity are often associated with vascular disease and hypertriglyceridemia, and the atherogenic impact of these factors is difficult to separate from the effect of hypertriglyceridemia. However, in several population-based studies, abnormal triglyceride levels correlate with increased risk for CHD. Marked hypertriglyceridemia (>1000 mg/dL) is associated with the chylomicronemia

Table 63-3 Therapeutic Approach to Low-Density Lipoprotein Cholesterol Levels*

Risk Category	Treatment Goal: LDL (mg/dL)	Lifestyle Changes: LDL (mg/dL)	Drug Therapy: LDL (mg/dL)
≤One risk factor	<160	≥160	≥160-190
≥Two risk factors	<130	≥130	≥130-160
CAD or CAD risk equivalent	<100 (optional <70)	≥100	≥100-130

*Recommendations of the Adult Treatment Panel, National Cholesterol Education Program III, as modified in 2004. Coronary heart disease (CHD) risk factors include age (men >45 yr, women >55 yr), family history of premature CHD (male first-degree relative <55 yr, female first-degree relative <65 yr), smoking, hypertension, diabetes mellitus, and high-density lipoprotein cholesterol (HDL) <40 mg/dL. Subtract a risk factor if HDL is >60 mg/dL. Coronary heart disease (CHD) risk equivalents include symptomatic carotid artery disease, peripheral arterial disease, abdominal aortic aneurysm, and diabetes mellitus.

LDL, low-density lipoprotein cholesterol.

Table 63-4 Adult Treatment Panel III Nutrition Composition

Nutrient	Recommended Intake
Total fat	25%-35% of total calories
Saturated (<7%)	
Polyunsaturated (<10%)	
Monounsaturated (<20%)	
Carbohydrates	50%-60% of total calories
Protein	15% of total calories
Cholesterol	<200 mg/day
Fiber	20-30 g/day

syndrome, characterized by pancreatitis and xanthomas. A fasting lipid panel is required to diagnose hypertriglyceridemia. Triglyceride levels above 200 mg/dL are classified as abnormal. Borderline triglyceride levels range from 150 to 200 mg/dL, and normal values are less than 150 mg/dL. A diet and exercise program is recommended for all individuals with abnormal triglyceride levels. Pharmacologic treatment can be considered if fasting triglycerides are greater than 200 mg/dL, especially if individuals are at risk for CHD or pancreatitis. Low HDL (<40 mg/dL) can also increase the risk for CHD. In the Framingham Heart Study, every 5 mg/dL decrease in HDL increased the risk for myocardial infarction. Lifestyle modifications (e.g., exercise) can be prescribed to improve HDL levels.

Management of Dyslipidemia

Treatment is initiated after two abnormal lipid findings. Dietary modifications can reduce LDL cholesterol and triglyceride levels (Table 63-4). If *target goals* are not achieved, pharmacologic therapy is considered (Table 63-5). Treatment effect can be assessed after 1 to 2 months and additional agents prescribed if goals are not achieved with maximal drug dosing.

LIFESTYLE MODIFICATION

Lifestyle modification should be the initial step in the management of hyperlipidemia (see Table 63-4). Restricting dietary intake of fat from 45% to 25% of total calories has been shown to lower total cholesterol by about 15% and LDL cholesterol by 25%. Low-fat diets that limit saturated fat

content promote LDL receptor expression and increase the uptake of LDL cholesterol from the circulation. By contrast, saturated fat downregulates hepatic LDL receptors and increases circulating LDL. Unsaturated fats (poly and mono) generally do not have this effect and, therefore, are the preferred form of fat intake. However, polyunsaturated fats containing fatty acids with a *trans* rather than *cis* double bond configuration (*trans* fatty acids) increase plasma cholesterol levels similar to saturated fat.

Limiting the intake of saturated and *trans* unsaturated fatty acids requires appropriate calorie substitutions. Increasing carbohydrate content to achieve this goal can increase hepatic synthesis of triglyceride. Dietary substitution with soluble fibers (e.g., oat bran) has been recommended because these fibers have a limited effect on triglyceride levels. They also bind bile acids in the gut and thus decrease cholesterol levels. Other polyunsaturated fats such as omega-3 fatty acids are cardioprotective. They are abundant in fatty fish, flaxseed oil, canola oil, and nuts. They reduce VLDL production, inhibit platelet aggregation, and decrease CHD. Even two servings per week of fatty fish such as salmon can be beneficial.

Dietary fat increases the influx of triglyceride into plasma. LPL hydrolyzes the triglyceride core of chylomicrons and VLDL particles. This enzyme reaches kinetic saturation at triglyceride levels greater than 1000 mg/dL. At this point, any increase in triglyceride-rich lipoproteins results in an exaggerated increase in triglyceride levels. Therefore, dietary restriction of fat (<10%) is essential for the treatment of marked hypertriglyceridemia. Other factors such as carbohydrate and alcohol intake can also increase the synthesis of triglyceride. Therefore, restricting alcohol intake to one or two servings per week and adhering to a low-fat, high-fiber diet will improve hypertriglyceridemia.

Exercise has been shown to increase LPL activity. Even a single exercise session can reduce triglycerides and increase HDL. The impact of exercise on LDL is less clear. With low to moderate exercise regimens, clearance of VLDL particles increases LDL production. However, this effect is not seen with high-intensity exercise programs. A decrease in LDL cholesterol occurs with high-intensity exercise, and this effect is independent of weight loss.

PHARMACOTHERAPY

If diet and exercise modifications do not sustain a normal lipid profile, drug therapy is appropriate. Likely benefit needs to be balanced with potential adverse effects when

Table 63-5 Pharmacologic Agents Commonly Used for the Treatment of Hyperlipidemia

Drug Class	LDL	HDL	Triglycerides	Side Effects
HMG-CoA inhibitors	↓ 20%-60%	↑ 5%-10%	↓ 10%-30%	Liver toxicity, myositis, rhabdomyolysis, enhanced warfarin effect
Cholesterol absorption inhibitors	↓ 17%	No effect	No effect	Abnormal liver enzymes in combination with an HMG-CoA inhibitor, potential increase in cancer risk and cancer death
Bile acid sequestrants	↓ 15%-30%	Slight increase	No effect	Nausea, bloating, cramping, abnormal liver function, interference with the absorption of other drugs such as warfarin and thyroxine
Fibric acids	↓ 5%-20%	↑ 15%-35%	↓ 35%-50%	Nausea, cramping, myalgias, liver toxicity, enhanced warfarin effect
Nicotinic acid	↓ 10%-25%	↑ 15%-35%	↓ 25%-30%	Hepatotoxicity, hyperuricemia, hyperglycemia, flushing, pruritus, nausea, vomiting, diarrhea

↓, Decreased; ↑, increased; HMG-CoA, 3-hydroxy-3-methylglutaryl-coenzyme A.

determining drug therapy. Many patients require two or three agents to achieve adequate control.

HMG-CoA reductase is the rate-limiting enzyme involved in cholesterol biosynthesis. Inhibition of this enzyme decreases cellular cholesterol pools and subsequently increases uptake of LDL cholesterol from the circulation. HMG-CoA reductase inhibitors (e.g., lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, and rosuvastatin) increase cholesterol utilization, decrease VLDL synthesis, and increase HDL synthesis. As a result, lower LDL and triglyceride levels and higher HDL levels are noted with treatment. Meta-analysis of primary and secondary CHD prevention trials has shown reductions in all-cause and cardiovascular mortality rates with statin therapy. These agents limit progression and may even cause regression of coronary atherosclerosis. Therefore, they are first line in the management of abnormal LDL cholesterol. Elevated liver enzymes and muscle toxicity are potential dose-related complications. Myositis can occur with statins alone but is a higher risk when statins are used in combination with nicotinic acid or fibric acid derivatives. Some of these agents can also potentiate the effect of warfarin.

Cholesterol absorption inhibitors (e.g., ezetimibe) function by interfering with the transport of cholesterol at the intestinal brush border. They increase cholesterol utilization and decrease LDL cholesterol levels. Although there is a reduction in LDL cholesterol, improvements in cardiovascular events and mortality with treatment have not been confirmed. Ezetimibe can be used as a single agent or in combination with an HMG-CoA reductase inhibitor to lower LDL cholesterol levels. In combination, this agent can increase serum transaminase levels and potentially increase the risk for cancer and cancer death. The evidence linking ezetimibe to cancer risk is limited, and more studies are needed to confirm this association.

Drugs that interfere with the absorption of cholesterol from the intestinal lumen will increase cholesterol utilization and decrease circulating levels. Bile acid sequestrants (e.g., cholestyramine, colestipol, and colesevelam) bind bile acids in the intestinal lumen and increase fecal excretion. Subsequently, more LDL cholesterol is utilized by the liver to synthesize bile acids. The decrease in cellular cholesterol pools upregulates LDL receptors and decreases the amount of LDL in the circulation. Mild increases in HDL cholesterol are also noted with this agent as a result of increased intes-

tinal HDL formation. Treatment is associated with a reduction in the incidence of CHD. Bile acid sequestrants can be used alone for mild lipid dysfunction or combined with another lipid-lowering agent such as an HMG-CoA reductase inhibitor. Abnormal liver function and gastrointestinal symptoms (nausea, bloating, and cramping) are common side effects that limit the use of bile acid sequestrants. They can interfere with the absorption of other drugs such as warfarin and thyroxine; therefore, it is important to time the intake of such medications away from the bile acid sequestrant.

Fibric acid derivatives such as gemfibrozil and fenofibrate activate peroxisome proliferator-activated receptor alpha (PPARα) and increase FFA oxidation in muscle and liver. A consequent decrease in net hepatic lipogenesis leads to diminished VLDL and subsequent LDL production. Fibric acid derivatives also enhance LPL activity and HDL synthesis. As a result, treatment is usually associated with not only lower triglyceride and LDL levels but also higher HDL levels. An increase in LDL sometimes occurs with the initiation of fibric acid derivatives. This derives from increased VLDL conversion to LDL as a consequence of enhanced LPL activity. The impact of fibric acid derivatives on LDL levels needs to be balanced with their benefits. Reduced cardiovascular events have been demonstrated in a subset of individuals with high triglyceride (>200 mg/dL) and low HDL (<40 mg/dL) levels, but improvements in cardiovascular or all-cause mortality otherwise has not been confirmed with these agents. Liver toxicity and myositis are potential side effects of fibric acid derivatives, and these changes also interfere with the metabolism of warfarin, leading to a need for its dose adjustment.

Nicotinic acid has an antilipolytic effect and thus decreases the influx of FFA to the liver. As a result, hepatic VLDL synthesis and LDL production are reduced. Nicotinic acid also decreases HDL catabolism and prevents the transfer of cholesterol from HDL to VLDL particles. Lower triglyceride and LDL levels and higher HDL levels are noted with treatment. In addition, nicotinic acid stimulates tissue plasminogen activator and prevents thrombosis. It is the preferred agent for the reduction of lipoprotein(a) [Lp(a); discussed later in this chapter]. The cardioprotective effect of nicotinic acid may be linked to its effect on Lp(a) and HDL. Side effects include hepatotoxicity, hyperuricemia, hyperglycemia, and flushing.

Table 63-6 Secondary Causes of Hyperlipidemia

Clinical	Elevated Lipoprotein	Mechanism
Diabetes	Chylomicron, VLDL, LDL	Increase in VLDL production and decrease in VLDL/LDL clearance
Obesity	Chylomicron, VLDL, LDL	Increase in VLDL production and decrease in VLDL/LDL clearance
Lipodystrophy	VLDL	Increase in VLDL production
Hypothyroidism	LDL, VLDL	Decrease in LDL/LDL clearance
Estrogen	VLDL	Increase in VLDL production
Glucocorticoids	VLDL, LDL	Increase in VLDL production and conversion to LDL
Alcohol	VLDL	Increase in VLDL production
Nephrotic Syndrome	VLDL, LDL	Increase in VLDL production and conversion to LDL

LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

Specific Disorders of Lipid Metabolism

A number of specific disorders of overproduction or impaired removal of lipoproteins result in dyslipidemia. These disorders are often familial, but secondary causes also need to be considered. Comorbid conditions (diabetes, hypothyroidism), medications (estrogen, glucocorticoids, β blockers), and lifestyle factors (diet, alcohol) can increase the production and clearance of lipoproteins (Table 63-6). Addressing these factors can often normalize lipid levels. If abnormalities persist, evaluation of genetic causes and treatment with pharmacologic therapy should be considered.

FAMILIAL HYPERCHOLESTEROLEMIA

Mutations in the gene that encodes the LDL (apo B/E) receptor results in familial hypercholesterolemia (FH). Impairment in LDL receptor synthesis or function decreases the clearance of LDL and increases circulating LDL levels. Excess LDL then enters macrophages through scavenger receptors resulting in foam cell and cholesterol plaque formation. These plaques deposit in arteries (atheroma), skin or tendons (xanthoma), eyelids (xanthelasma), and iris (corneal arcus). The homozygous (HM) form of this autosomal dominant disorder is rare. Affected individuals present early in life with elevated total cholesterol (600 to 1000 mg/dL) and LDL (550 to 950 mg/dL). Triglyceride and HDL levels are normal. They develop CHD, aortic stenosis due to atherosclerosis of the aortic root, and tendon xanthomas. These xanthomas commonly involve the Achilles tendon and present as tenosynovitis. If untreated, patients with HM FH typically die from

myocardial infarction before age 20 years. The heterozygous (HZ) form of FH affects 1 in 500 individuals, with the partial receptor defect resulting in cells displaying half the normal number of fully functional LDL receptors. These individuals have lower elevated total cholesterol (>300 to 600 mg/dL) and LDL (250 to 500 mg/dL) levels than those with the HM form. Premature CHD (<45 years of age in men and <55 years of age in women) and tendon xanthomas are characteristic clinical findings.

Although FH can be established by identifying one of the many known gene mutations in the LDL receptor or by demonstrating diminished LDL receptor function, the diagnosis of FH usually is made on the basis of clinical features. Elevated total cholesterol (>300 mg/dL) and LDL (>250 mg/dL) in an individual with personal or family history of premature CHD and tendon xanthomas identifies individuals at risk for FH. Treatment requires a low-fat (<20% of total calories), low cholesterol (<100 mg per day) diet in combination with drug therapy. Usually FH patients require multiple agents to lower cholesterol levels to target range. Bile acid sequestrants are considered in younger individuals because of their limited side-effect profile, but more potent agents such as statins, cholesterol absorption inhibitors, and niacin are necessary in high-risk older individuals. In patients who do not tolerate medications or who have limited receptor function, ileal bypass surgery to decrease gastrointestinal absorption of bile acids or LDL apheresis to remove excess LDL can be considered.

FAMILIAL DEFECTIVE APOLIPOPROTEIN B-100

In this autosomal dominant disorder, a defect in the apo B-100 protein results in impaired binding of LDL particles to the LDL receptor. Most cases are linked to a single mutation (glutamine for arginine substitution) in the apo B-100 gene, but other mutations in the apo B-100 gene have also been identified in recent years. The disorder affects as many as 1 in 750 Caucasians with hypercholesterolemia. The clinical presentation is similar to FH, with elevated total cholesterol and LDL levels associated with premature CHD and tendon xanthomas. However, the HM and HZ clinical forms are milder than in FH because apo E-mediated clearance of remnant particles is still functional. Total cholesterol ranges from 350 to 550 mg/dL in HM and 200 to 350 mg/dL in HZ. DNA analysis can identify the apo B-100 gene mutation and confirm the diagnosis, but genetic diagnosis is not necessary to initiate therapy. A low-cholesterol, low-fat diet in combination with a statin, bile acid resin, or niacin is recommended to lower cholesterol levels to target ranges.

ELEVATED PLASMA LIPOPROTEIN(a)

Lp(a) is a specialized form of LDL assembled extracellularly from apolipoprotein(a) and LDL. Disulfide bridges link apo(a) to apo B-100 located on the surface of LDL particles. Apo(a) has sequence homologous with the fibrin-binding domains of plasminogen and, when present at elevated levels, interferes with fibrinolysis by competing with plasminogen. This leads to decreased thrombolysis and increased clot formation. Lp(a) also binds macrophages, promoting

foam cell formation and atherosclerotic plaques. Genetic predisposition, African American heritage, and conditions associated with elevated LDL levels such as FH influence serum Lp(a) levels. Screening should be considered in individuals with family or personal history of premature CHD without dyslipidemia or in individuals refractory to cholesterol lowering therapy. The diagnosis can be made by documenting an Lp(a) level of more than 30 mg/dL in a patient with premature CHD. The primary goal of therapy is to lower LDL levels with agents such as statins. If LDL goals cannot be achieved, then Lp(a)-lowering therapy with niacin can be considered. Niacin decreases Lp(a) by as much as 38%, and it also stimulates tissue plasminogen activator and prevents thrombosis.

POLYGENIC HYPERCHOLESTEROLEMIA

Hypercholesterolemia in most individuals is thought to reflect small influences of many different genes. The exact nature of these genetic defects is poorly defined, but apo E may play a role in the pathogenesis. Apo E4 on chylomicron and VLDL remnants has a high affinity for the LDL receptor. Elevated binding of apo E4-containing lipoproteins to LDL receptors may downregulate LDL receptor synthesis and increase circulating LDL levels. Environmental factors such as diet can influence chylomicron and VLDL production, resulting in downregulation of the LDL receptor in high apo E4 conditions. This leads to an increased propensity for CHD, and treatment with LDL-lowering agents is recommended based on risk factors (see Table 63-5).

FAMILIAL COMBINED HYPERLIPOPROTEINEMIA

Familial combined hyperlipoproteinemia (FCHL) is an autosomal dominant polygenic disorder affecting 1% to 2% of the population. Factors such as diet, glucose intolerance, and medications can influence the phenotypic presentation. In FCHL, excess VLDL is synthesized in the liver. VLDL is hydrolyzed by LPL to produce LDL. Mutations in the LPL gene affecting its expression or function can decrease the efficiency of VLDL catabolism. Dysfunction of LPL is noted in one third of patients with FCHL. Diminished LPL activity increases circulating VLDL triglyceride. Furthermore, fewer VLDL remnant particles are available for HDL synthesis. Therefore, FCHL needs to be considered in all patients with total cholesterol level higher than 250 mg/dL, triglycerides higher than 175 mg/dL, or HDL lower than 35 mg/dL. There are no definitive diagnostic tests, but family screening can help confirm the diagnosis. The phenotype of FCHL is variable, with individuals displaying high LDL cholesterol, high VLDL triglyceride, or both based on the genetic defect and environmental factors. Patients also typically have high apo B (>120 mg/dL) and a low LDL cholesterol-to-apo B-100 ratio (<1.2). They accumulate small dense LDL particles, which are thought to be atherogenic and contribute to premature coronary artery disease. Xanthomas or xanthelasmas are not a feature of this disorder. Affected individuals require a low-fat, low-cholesterol diet plus multiple lipid-lowering drugs to achieve target goals. Fibric acid derivatives, which hydrolyze the triglyceride core of VLDL particles and increase LDL production, are recommended for

treatment of the hypertriglyceridemia. Patients with FCHL often additionally require a statin or niacin to lower LDL cholesterol.

FAMILIAL DYSBETALIPOPROTEINEMIA

Apo E on the surface of lipoprotein particles binds LDL receptors and facilitates clearance of remnant particles from the circulation. The apo E2 allele has a lower affinity for LDL receptors than the E3 and E4 alleles. In individuals homozygous for apo E2, LPL hydrolyzes the triglyceride core, and the resulting cholesterol-rich lipoproteins (chylomicrons, VLDL, and IDL remnant particles) accumulate in the circulation. Expression of this phenotype usually requires a precipitating condition that increases lipoprotein production (e.g., diabetes, alcohol consumption) or decreases clearance (e.g., hypothyroidism). In addition to the more common autosomal recessive mutation of apo E described previously, several apo E mutations have been described that result in an autosomal dominant phenotype presenting in childhood and not requiring a secondary factor to express the phenotype. Premature CHD, peripheral vascular disease, and xanthomas involving the palmer crease are characteristic clinical features. Individuals with familial dysbetalipoproteinemia have elevated total cholesterol (300 to 400 mg/dL) and triglycerides (300 to 400 mg/dL). The ratio of total cholesterol to triglyceride in VLDL particles is elevated (>0.2), and the remnant VLDL (β -VLDL or IDL) particles can be detected with agarose gel electrophoresis. Definitive diagnosis requires genetic testing to identify apo E2 homozygosity or mutation. Treatment of coexisting conditions such as diabetes and hypothyroidism can normalize lipid levels in apo E2 homozygotes. If target levels are not achieved, dietary therapy and lipid-lowering drugs such as fibric acid derivatives and HMG-CoA reductase inhibitors should also be considered.

LIPOPROTEIN LIPASE DEFICIENCY

Mutations in the LPL gene resulting in deficiency of LPL synthesis or function lead to increased circulating chylomicron and VLDL particles and severe hypertriglyceridemia. Homozygous LPL deficiency is rare. It presents in childhood with triglycerides higher than 1000 mg/dL. Heterozygous LPL deficiency occurs in 2% to 4% of the population and usually requires a precipitating factor such as uncontrolled diabetes to manifest the phenotype. These individuals have moderate hypertriglyceridemia (250 to 750 mg/dL) that can increase to levels above 1000 mg/dL with secondary factors, such as insulin resistance or estrogen therapy. This can result in the chylomicronemia syndrome, characterized by marked hypertriglyceridemia (>1000 to 2000 mg/dL), pancreatitis, eruptive xanthomas, lipemia retinalis, and hepatosplenomegaly. Visual inspection demonstrates lipemic plasma. After refrigeration for 12 hours, a creamy top layer (increased chylomicrons) or turbid plasma infranatant (increased VLDL), or both, can be demonstrated. Documentation of diminished LPL activity confirms the diagnosis. A diet low in fat (<10% of total calories or <20 to 25 g per day) is the primary treatment. Secondary factors such as uncontrolled diabetes and alcohol use should be addressed, and VLDL-lowering agents (e.g., fibric acid

derivatives and niacin) may be needed to prevent severe hypertriglyceridemia.

APOLIPOPROTEIN C-II DEFICIENCY

Apo C-II is an activating cofactor for lipoprotein lipase. Deficiency of apo C-II is a rare autosomal recessive disorder that leads to increased chylomicrons and VLDL particles in the circulation, resulting in severe hypertriglyceridemia. Clinical manifestations are similar to LPL deficiency, including hypertriglyceridemia (>1000 mg/dL) and symptoms of pancreatitis, eruptive xanthomas, lipemia retinalis, and hepatosplenomegaly. Documenting the absence of apo C-II by plasma electrophoresis or demonstrating improvement in LPL activity with the addition of apo C-II confirms the diagnosis. Treatment of mild to moderate hypertriglyceridemia is similar to LPL deficiency. Recommendations include appropriate management of secondary factors such as diabetes and hypothyroidism, dietary fat restriction (<10% of calories), and drug therapy (e.g. fibric acid derivatives). For severe hypertriglyceridemia, plasma transfusion (with apo C-II) can be considered to lower triglyceride levels by activating LPL.

FAMILIAL HYPERTRIGLYCERIDEMIA

Familial hypertriglyceridemia is an autosomal dominant disorder characterized by overproduction of hepatic VLDL. The exact defect or mutation is unknown. Secondary factors that increase VLDL, such as diabetes, alcohol ingestion, and estrogen therapy, appear to exacerbate this condition. Low HDL associated with familial hypertriglyceridemia is related to increased catabolism. Individuals with this condition present with hypertriglyceridemia (200 to 500 mg/dL) and low HDL (<35 mg/dL). The decrease in HDL increases the risk for CHD. Secondary factors can exacerbate the problem by raising triglyceride levels above 1000 mg/dL and increasing the risk for pancreatitis and xanthomas. This diagnosis is considered in individuals with a family and personal history of hypertriglyceridemia, CHD, and normal LDL levels. A cloudy infranant noted after overnight refrigeration of plasma identifies a disorder of VLDL metabolism. Treatment starts with management of secondary factors that may exacerbate the condition. Dietary fat restriction (<10% of calories) and drug therapy with niacin and fibric acid derivatives should be initiated if target goals are not achieved.

Prospectus for the Future

- Target goals for LDL treatment are continuously debated. More aggressive LDL management may be recommended as more evidence supporting lower LDL levels becomes available.
- The long-term risks of various drugs will need to be balanced with the potential benefit of achieving treatment goals. Further studies evaluating potential complications will guide therapeutic decisions. The potential cancer risk associated with ezetimibe will need to be clarified.
- Disorders of lipid metabolism result from defects in the production and removal of lipoproteins. A better understanding of these defects may lead to the development of drug therapy aimed at specific genetic mutations or enzyme dysfunction.
- Development of agents targeting HDL metabolism may play a role in CHD prevention.

Disorders of Metals and Metalloproteins

David G. Brooks

Wilson Disease

Wilson disease, or hepatolenticular degeneration, is the result of the defective excretion of copper. Accumulation of this metal produces damage to multiple organs, with the liver and brain prominently affected. Wilson disease is an autosomal recessive genetic disorder that affects people worldwide with a frequency approximating 1 in 30,000.

NORMAL COPPER METABOLISM

Copper is an essential dietary trace element. A balance of dietary intake and hepatobiliary excretion meets physiologic requirements. Humans ingest 1 to 5 mg/day, and an adult body contains 100 to 150 mg copper. Copper is absorbed in the proximal small intestine. The liver, which is the main organ for copper homeostasis, rapidly takes up absorbed copper. The liver plays important roles in transport, storage, and excretion of copper. Copper is normally excreted into bile canaliculi in a regulated fashion that is dependent on copper concentration in hepatocytes. Up to 95% of plasma copper is bound to ceruloplasmin, an abundant plasma protein produced by the liver. The putative role of ceruloplasmin as a copper transporter to extrahepatic tissues has been called into question by the absence of copper deficiency in aceruloplasminemia, a genetic disease featuring the absence of apoceruloplasmin. Rather, ceruloplasmin is more likely to play a critical role in recycling iron, highlighting an interaction of iron and copper homeostasis.

PATHOGENESIS

Mutations in patients with Wilson disease occur in a gene, *ATP7B*, which encodes a copper-transporting adenosine triphosphatase (ATPase). This protein transports copper across cell membranes and is essential for exporting copper from hepatocytes into the bile canaliculi. Wilson disease protein also transports cytosolic copper into membrane-bound compartments of hepatocytes containing newly synthesized apoceruloplasmin. In the absence of *ATP7B* transporter,

copper is not transported, and apoceruloplasmin is secreted into the blood, where it has a rapid turnover. Thus, low plasma ceruloplasmin levels are a helpful diagnostic sign of Wilson disease (Table 64-1). Copper accumulates slowly in liver (see Table 64-1) and later in other organs. High levels of copper are a risk factor for generating reactive oxygen species, which contribute to end-organ damage. Liver dysfunction, the most common presentation in childhood, usually appears after 6 years of age but has been reported as young as 3 years of age. Presentations vary from acute hemolysis or fulminant liver failure to chronic, progressive liver failure or neuropsychiatric disease. Most patients have liver biopsy evidence of some cirrhosis resulting from copper-mediated damage. Hepatocellular carcinoma occurs rarely but has been reported in men long after treatment was initiated so that surveillance is indicated. Neurologic symptoms, in particular as a result of basal ganglia dysfunction, are the initial presentation in up to 40% to 50% of patients. Parkinsonian symptoms predominate with dystonia, choreoathetosis, and tremor. A minority of patients experience psychiatric symptoms, including personality change, depression, or cognitive impairment, all of which indicate that the cerebral cortex is affected by copper deposition. Associated findings include *hemolytic anemia* (negative Coombs test) and kidney damage (*nephrolithiasis* and *Fanconi syndrome* with amino aciduria and glucosuria). Cardiac dysrhythmia, osteoporosis, rhabdomyolysis, arthralgia, and endocrine dysfunction have also been reported.

DIAGNOSIS

A combination of laboratory tests strongly supports the diagnosis of Wilson disease (see Table 64-1). About 95% of patients have a low ceruloplasmin level (<0.2 g/L), with some having normal levels because ceruloplasmin is an acute-phase reactant that is high during inflammation such as fulminant liver failure. Serum copper is slightly decreased and non-ceruloplasmin-bound serum copper is usually elevated. A significant increase in urinary copper excretion (>100 mcg per 24 hours) is almost always present, which

Table 64-1 Diagnostic Copper Testing in Wilson Disease

Test	Levels in Healthy Persons	Levels in Wilson Disease
Liver copper content (mcg Cu/g dry weight)	10-50	100-2000
Serum ceruloplasmin (mg/dL)	20-45	0-20
Serum copper (mcg/dL)	70-160	25-70
Urinary copper (mcg/day)	3-35	100-1000

should increase further with chelator therapy. Liver biopsy often reveals micronodular cirrhosis with nodular regeneration, copper deposition, and elevated copper content (>250 mcg/g dry weight), which remains the gold standard of diagnosis. Sunflower cataracts and Kayser-Fleischer rings, which are yellow-brown to green deposits at the periphery of the cornea, strongly support the diagnosis. Magnetic resonance imaging (MRI) of basal ganglia may show degeneration or evidence suggestive of copper deposition. Genetic testing is available; however, hundreds of mutations are known, which means that only specialized laboratories offer this service. In defined ethnic groups, identifying genetic mutations that confirm Wilson disease may be practical and have important genetic counseling implications for family members. For example, the H1069Q mutation is found in up to 50% of Caucasian patients and, when present in the homozygous state, is reported to predict later onset disease with a higher frequency of neurologic complications.

TREATMENT

Wilson disease is a treatable genetic disorder. Therefore, this diagnosis is an important consideration in anyone with unexplained hemolysis or liver, basal ganglia, or psychiatric signs or symptoms. The goal of therapy is to reduce total-body copper burden without inducing copper deficiency. The mainstays of therapy to induce negative copper balance are chelation to remove excess copper already in the body and inhibiting absorption of dietary copper. Two copper chelators are approved for clinical use: trientine (Syprine) and D-penicillamine (Cuprimine). Historically, penicillamine was the treatment of choice. However, 10% to 20% of patients develop side effects of this therapy that can be treatment limiting and severe, including bone marrow aplasia. For D-penicillamine, treatment can be initiated with 1 to 3 g per day divided into two to four doses, although titrating the dose up from 250 to 500 mg per day may improve tolerance. Pyridoxine (vitamin B₆) should be supplemented while taking penicillamine. Twenty-four hour urine copper excretion should increase from 1 to 5 mg per day with symptomatic improvement on average after 4 months of therapy. Complete blood counts and urinary protein are important to monitor during penicillamine therapy. Further, under no circumstances should D-penicillamine be abruptly stopped; doing so increases the risk for acute hepatic decompensation. Trientine is reported to have a lower incidence of side effects than penicillamine. It can be started at 1200 to 1800 mg per day divided into three doses but reduced to 900

to 1200 mg per day for maintenance therapy. Both chelators should be given before or after but not with food. Copper reduction therapies should be expected to take 6 to 8 weeks to begin to show evidence of efficacy and may require a couple years to reach maximal effect.

A novel dietary strategy, high-dose zinc (150 mg per day divided in three doses), can significantly decrease copper absorption. Zinc inhibits net copper absorption by inducing the small intestine to produce the copper-chelating protein, metallothionein. Metallothionein-bound copper is sloughed with small intestinal absorptive cells. Zinc can cause dyspepsia, and changing the formulation (acetate, sulfate, or gluconate) may improve this side effect. As an essential nutrient, zinc is generally well tolerated and is increasingly appreciated as a cornerstone of therapy in Wilson disease. Starting acutely ill patients on combination therapy with chelator and zinc is indicated, whereas maintenance therapy with zinc alone is possible after an acute “de-coppering” stage. Monitoring 24-hour urine copper during therapy is important to ensure compliance. The level should reach 3 to 8 μmol per day, which is about 200 to 500 mcg copper per day lost in urine. With zinc supplementation, the goal is to reach 24-hour urinary copper below 2 μmol per day, whereas concurrent quantitation of urinary zinc monitors compliance with oral zinc therapy. It is important to monitor blood non-ceruloplasmin-bound copper for the target range of 50 to 150 mcg/L during therapy, so that overtreatment does not result in copper deficiency and secondary sideroblastic anemia and hemosiderosis. Supplementation with the antioxidant vitamin E taken with meals or N-acetyl cysteine may offset some of the organ damage induced by reactive oxygen species. A diet low in copper minimizing shellfish, nuts, mushrooms, and chocolate can be an adjunct to therapy. Urinalysis and blood counts should be followed closely during penicillamine therapy. Giving a test dose of penicillamine is important because it triggers hypersensitivity reactions strong enough to prevent its use in up to 10% of patients. Fever, lymphadenopathy, cytopenias, lupus erythematosus-like reactions, and nephrotic syndrome can result. Trientine is an alternative treatment for those with hypersensitivity reactions to penicillamine. Liver transplantation, even from living related donors who carry a single defective gene for Wilson disease, has been a successful treatment for those with progressive liver failure.

Hemochromatosis

Hemochromatosis is the condition of excessive iron storage causing dysfunction of a characteristic pattern of organs. It is important for physicians to detect hemochromatosis because it is a fatal disease that is entirely preventable if diagnosed early. Hemochromatosis may be primary, or it may develop secondary to multiple transfusions, when it is sometimes referred to as *hemosiderosis*. The primary form, which is known as *hereditary hemochromatosis* (HH), is the focus of this section.

NORMAL IRON METABOLISM

The adult male body contains 4 g of iron, over half of which is in the form of hemoglobin. To meet the daily iron require-

Table 64-2 Iron Indices in Healthy Persons and in Patients with Symptomatic Hemochromatosis

Index	Levels in Healthy Persons	Levels in Hemochromatosis
Plasma iron (mcg/dL)	50-150	180-300
Total iron-binding capacity (mcg/dL)	250-375	200-300
Percent transferrin saturation	20-40	80-100
Serum ferritin (ng/mL)	10-200	900-6000
Urinary iron after 0.5 g desferrioxamine	0-2	9-23
Liver iron (mcg/100 mg dry weight)	30-140	600-1800

ment for erythropoiesis, iron is recycled from the reticulo-endothelial system. Iron is absorbed in the duodenum, and the efficiency of absorption is tightly regulated. Thus, the duodenum responds to bodily iron requirements and can significantly increase absorption of iron in response to iron deficiency. Iron is not actively excreted, although about 1 mg of iron is lost daily through sloughed cells. Iron loss is significantly increased by menstrual bleeding and pregnancy; hence, women are less susceptible to HH than men. These losses are offset by absorption of 1 to 3 mg of iron daily in normal individuals (and abnormally high iron absorption in patients with hemochromatosis).

The liver is critical for iron storage and transport (as well as pathology of HH). Iron stored in *ferritin* protein in the liver is less prone to form reactive oxygen species. Ferritin secretion from the liver is positively correlated with hepatic iron stores. Hepatocytes secrete the iron bound to the transport protein (apo) transferrin, which circulates about 20% to 40% saturated with iron (Table 64-2). Transferrin-bound iron is the major source of iron for extrahepatic tissues that have transferrin receptors. After transferrin receptor-mediated endocytosis, iron may be released in the acidic environment of an intracellular vesicle (endosome), and transferrin is recycled to be released at the cell surface.

Recent discovery of *hepcidin*, a polypeptide hormone, has shed new light on iron physiology. Hepcidin is produced by the liver in response to iron stores and is believed to signal the need for iron absorption to the duodenum and reticulo-endothelial system. Hecpidin may be upregulated in anemia of chronic disease causing abnormal iron distribution and absorption.

PATHOGENESIS OF HEREDITARY HEMOCHROMATOSIS

Four types of hereditary hemochromatosis are known. The genetic bases of these disorders are known in three of the four types, and all defective gene products have a role in cellular iron trafficking. In two of the types, the defective genes encode ferritin or transferrin receptors. In the third type, which is the common form of hereditary hemochro-

matosis, discovery of the gene has generated new insight into the basis of iron homeostasis. Only the common form of hereditary hemochromatosis is discussed in this chapter.

The common form of hereditary hemochromatosis is the result of defects in a gene and protein called HFE, hence the name HFE-linked hemochromatosis. This gene is near the major histocompatibility complex (MHC) locus on chromosome 6, in keeping with the longstanding observation that certain MHC isotypes (e.g., human leukocyte-associated antigen [HLA-A3]) are co-inherited with hemochromatosis. The HFE protein is an MHC class I-like molecule that requires association with β_2 -microglobulin to function. In the absence of either HFE or β_2 -microglobulin, mice develop iron overload reminiscent of human hemochromatosis. HFE binds tightly to the transferrin receptor and regulates its affinity for transferrin ligand. More than 85% of hemochromatosis in patients of northern European ancestry is attributable to two specific HFE mutations that interfere with its function. The most common mutation in patients results in the substitution of tyrosine for the normal cysteine at position 282 (C282Y). This mutation is most concentrated in people of northern European ancestry, a finding that accounts for the Caucasian predilection for HH. The C282Y mutation is found in 1 in 10 Caucasians in the United States. By mendelian genetics, 1 in 400 Caucasians carries two of these mutations. However, the observed prevalence of hemochromatosis associated with end-organ damage is at least an order of magnitude less common than this genetic prevalence. In Australia, 28% of male and 1.4% of female homozygotes for C282Y mutation developed iron overload disease, indicating that a minority of individuals with two mutations will develop HH. Put another way, the positive predictive value of a genetic test is low. This phenomenon, called *reduced penetrance*, explains why genetic testing has limited utility as a screening tool for this disorder. However, testing for C282Y or another common mutant allele, H63D, is useful in patients with iron overload to confirm the diagnosis of hemochromatosis and for counseling family members of a confirmed case.

The essential defect in hereditary hemochromatosis is increased absorption of dietary iron. A slight increase in the efficiency of iron absorption, coupled with the inability to excrete iron, leads to increasing hepatic iron storage as a function of time. With increasing iron stores, the liver secretes more ferritin, and serum transferrin becomes increasingly saturated with iron. Initially, a patient may have general signs such as fatigue. Later, signs of liver disease, such as increased serum transaminases, are apparent. Liver biopsy shows increased iron stores in hepatocytes with sparing of Kupffer cells; a specimen should be analyzed to quantitate the amount of iron. High iron stores can lead to a generation of toxic reactive oxygen species, fibrosis, cirrhosis, hepatocellular carcinoma, and death.

The earliest symptoms of hemochromatosis include fatigue, lethargy, arthralgia, and right upper quadrant discomfort. As the capacity of liver to store iron safely is exceeded, particularly after transferrin saturation reaches 100%, iron is deposited in other tissues. Deposition in the synovium produces iron-induced arthritis, which is particularly evident in the second and third metacarpophalangeal joints. In the pancreatic islets, β cells are damaged, with decreased insulin secretion culminating in diabetes mellitus.

Iron can cause restrictive cardiomyopathy and a predisposition to conduction system abnormalities, resulting in arrhythmias. Hypogonadism, secondary to hypopituitarism, can result in impotence, menstrual irregularities, or premature menopause. Discoloration of the skin, often a gray-brown color referred to as *bronzing*, is characteristic of late hemochromatosis. The classic triad of *bronze diabetes with liver failure* is a late manifestation that is rarely observed today. Physicians should strive to recognize the early, more general symptoms of fatigue and arthralgia because treatment can prevent permanent organ damage.

DIAGNOSIS

In its earliest stages, hyperferritinemia and transferrin saturation above 50% are the only signs of hemochromatosis (see Table 64-2). Serum ferritin levels above 200 ng/mL in women or 300 ng/mL in men are frequently used to define iron overload. Transferrin saturation is calculated as serum iron \div total iron-binding capacity (TIBC). Modern laboratory measurements are usually of serum transferrin, and the TIBC is calculated as $1.4 \times$ serum transferrin. If these values are marginally elevated on a random sample, a repeat measure on a fasting blood sample is indicated. If the transferrin saturation is maintained greater than 50%, evaluation for liver disease is indicated. Serum ferritin greater than 1000 ng/mL has been reported to carry a significantly increased risk for cirrhosis. As the disease progresses, hepatomegaly with abnormal liver function tests may develop. Liver biopsy is the only method to ascertain whether fibrosis is present and to prove increased hepatic iron content (see Table 64-2), the gold standard for the diagnosis of HH. A useful diagnostic test of iron overload is the concept of “mobilizable iron” defined as the mass of iron that can be safely removed by phlebotomy without inducing anemia. A unit of blood is estimated to contain 250 mg iron from a man and 200 mg from a woman. If a prospective patient can donate more than 8 to 10 U or 2 g of iron in less than a year without anemia, they have iron overload. Genetic testing in an individual with elevated serum iron indices can confirm the diagnosis of hemochromatosis. MRI has potential for detecting hepatic iron overload, and future research will be aimed at making this noninvasive test more quantitative.

TREATMENT

Symptomatic patients without treatment have a 5-year survival rate of 10%. Early diagnosis is crucial in hemochromatosis because treatment may prevent serious complications such as cirrhosis and hepatocellular carcinoma. Established arthritis, hypogonadism, and liver fibrosis remain resistant to treatment, although proper treatment will slow progression. Therapy consists of phlebotomy to remove iron from the body; this can increase the 10-year survival rate to 75% in patients with cirrhosis. Because the source of excess iron is dietary, removing iron supplements from the diet of a patient with hemochromatosis is imperative. Because vitamin C aids absorption of iron, recommending avoidance of vitamin C supplements is prudent. Iron is typically limiting for erythropoiesis so that blood can be removed at more frequent intervals from patients with hemochroma-

tosis than from normal individuals. Patients with severe iron loading can tolerate weekly or biweekly phlebotomy without anemia for months. A running total of units of blood removed and corresponding hemoglobin should be maintained. Serum iron indices should be checked periodically during phlebotomy therapy. Goals include maintaining ferritin below 50 ng/mL and transferrin saturation below 30%. After these goals have been reached, maintenance phlebotomy 2 to 5 times each year is required to prevent reaccumulation of iron. It is important for patients with evidence of liver disease to avoid other hepatotoxins such as alcohol.

SCREENING

As a common, genetic disease associated with well-tolerated preventive and treatment measures, HH has been a frequent topic of discussion about screening. Repeated investigation of the issue has led to the conclusion that widespread public health screening is not justified at this time. However, screening within targeted populations should be considered. These include males of Northern European ancestry, individuals with a positive family history of iron overload, and patients with unexplained related conditions such as fatigue, arthralgia, diabetes, liver disease, cardiomyopathy, and hypogonadism. Serum ferritin and transferrin saturation are an appropriate initial screening test. If elevated, the algorithm outlined earlier under “Diagnosis” should be followed. As previously discussed, genetic testing should not be used to screen patients with unknown liver disease because it has limited positive predictive value, and the existing genetic tests do not detect all causes of HH particularly outside Caucasian ethnic backgrounds.

Porphyrias

Porphyria is the name given to a group of genetic or acquired diseases associated with deficient synthesis of heme. Heme is an essential cofactor for the structure and function of hemoglobin and proteins such as cytochrome P-450. Bone marrow produces more than 80% of body heme at a steady state to support erythropoiesis. Liver produces about 15% of total heme, but its synthesis can be increased 10-fold. For example, heme synthesis will be induced by ingestion of a drug that relies on a heme-containing enzyme for detoxification. This induction of hepatic heme synthesis underlies the important observation that certain drugs trigger porphyria attacks (Table 64-3). Porphyrias result from partial deficiency of one of seven enzymes involved in biosynthesis of heme (Fig. 64-1). Attacks of porphyria are associated with the accumulation of the biochemical intermediates in the heme synthesis pathway that precede the deficient enzyme (see Fig. 64-1). Some of these intermediates are toxic and can lead to the observable sign of dark, reddish urine. The two major classes of porphyria, bone marrow and hepatic, derive from the organ accounting for the overproduction of heme synthesis intermediates (Table 64-4).

Four of the five hepatic porphyrias have acute onset of neurovisceral pain as a result of the accumulation of early intermediates of heme synthesis such as δ -aminolevulinic acid (ALA) and porphobilinogen (see Fig. 64-1). Named

acute for their hallmark abrupt presentation (and sometimes resolution), these porphyrias also have chronic features, including pain, neuropathy, and depression. Excess porphyrins, produced in bone marrow porphyrias, deposit in skin and absorb light, which confers photosensitivity and results

in cutaneous manifestations such as blistering of sun-exposed skin. This section describes three porphyrias that are the most common and encompass the cardinal biochemical and clinical features of these disorders.

Table 64-3 Partial List of Drugs Precipitating Attacks of Acute Intermittent Porphyria

Barbiturates
Carbamazepine
Chlorpropamide
Chlordiazepoxide
Danazol

Griseofulvin
Meprobamate
Oral contraceptives
Phenytoin
Progestins
Pyrazinamide
Sulfonamide antibiotics
Theophylline
Tolbutamide
Valproic acid

ACUTE INTERMITTENT PORPHYRIA

Acute intermittent porphyria (AIP) is an autosomal dominant disorder due to half or less normal activity of porphobilinogen (PBG) deaminase. Under most circumstances, half-normal activity of this enzyme is sufficient to prevent porphyria; indeed, up to 90% of people with half-normal enzyme activity never experience attacks. PBG deaminase is the third enzyme in the pathway of heme biosynthesis (see Fig. 64-1). When it is limiting, there is accumulation of the two intermediates of the pathway before this enzyme (ALA and PBG) (see Fig. 64-1). A high urinary PBG level during an attack is a critical diagnostic feature, although the level is often normal between attacks. Finding deficient PBG deaminase enzyme activity in red blood cells confirms the diagnosis.

As the names *acute* and *intermittent* imply, acute attacks punctuate prolonged well periods in patients with AIP. The acute presentation of AIP can be dramatic and life-threatening. Abdominal pain, largely thought to be the result of neurotoxicity, is present in more than 90% of patients with acute attacks. Abdominal pain may be severe enough to prompt surgical evaluation for an acute abdomen and can be associated with nausea, vomiting, and bowel dysmotility. Neuropathy is evidenced by decreased sensation or muscle weakness that may involve cranial and respiratory nerves.

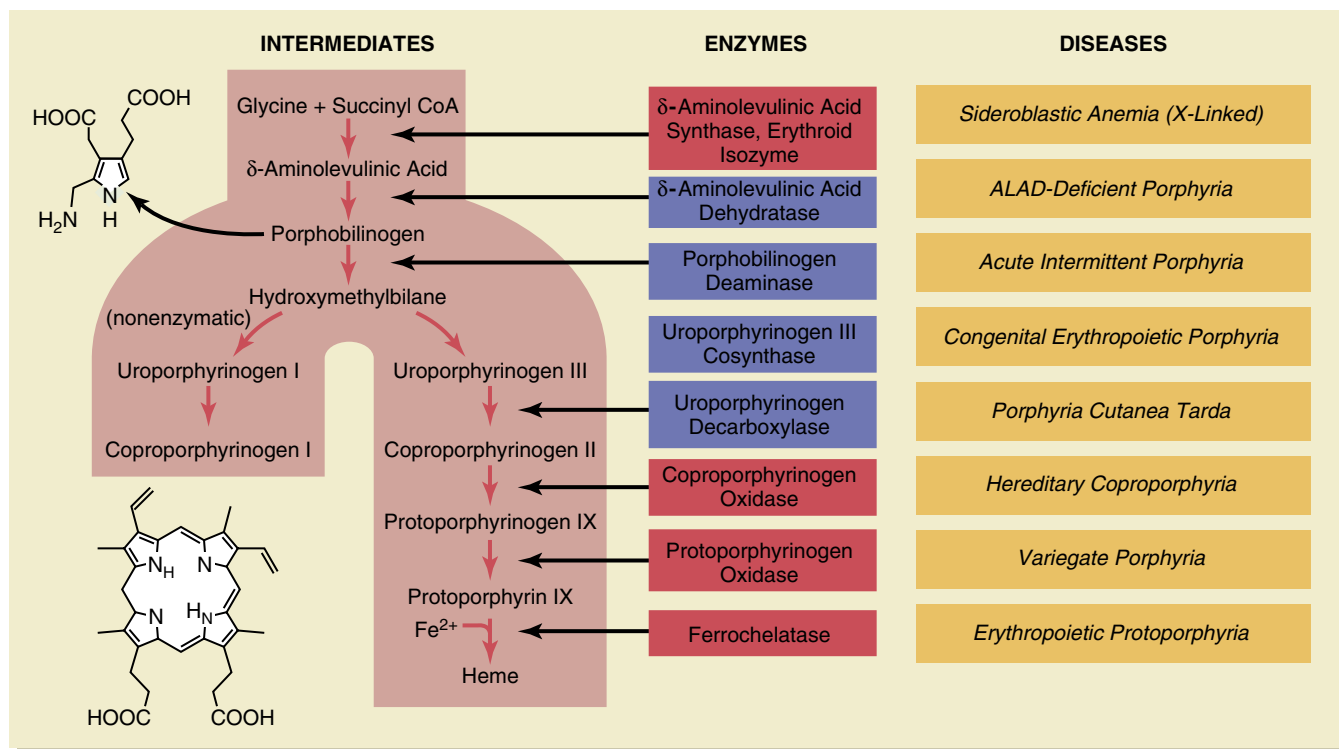

Figure 64-1 The heme biosynthetic pathway and the major diseases of porphyrin metabolism. The initial and last three enzymes (*in red*) are mitochondrial, and the other four (*in blue*) are cytosolic. X-linked sideroblastic anemia is not classically considered a porphyria. ALAD, aminolevulinic acid dehydratase. (From Anderson KE: The porphyrias. In Goldman L, Bennett JC [eds]: Cecil Textbook of Medicine, 21st ed. Philadelphia, WB Saunders, 2000, p 1124.)

Table 64-4 Porphyrins Grouped by Organ Source of Excess Heme Precursors

Organ Source	Porphyria	Prevalence	Neurologic Symptoms	Skin Drug Photosensitivity	Inducible
Liver	ALA dehydratase porphyria	Very rare	+	–	+
	Acute intermittent porphyria	5-10/100,000	+	–	+
	Porphyria cutanea tarda	Uncertain, but most common porphyria	+	+	+
	Hereditary coproporphyria	Rare	+	+	+
	Variagate porphyria	Not rare	+	+	+
Bone marrow	Congenital erythropoietic porphyria	Rare	–	+	–
	Erythropoietic protoporphyria	Several hundred known worldwide	–	+	–

ALA, δ -aminolevulinic acid.

Sympathetic tone is high with hypertension and tachycardia. Central nervous system manifestations include anxiety, paranoia, depression, and seizures, which may result in part from hyponatremia due to inappropriate secretion of antidiuretic hormone.

Most patients suffer their initial attack after puberty. Triggers of attacks include drugs, particularly those that induce the mitochondrial cytochrome P-450 system such as barbiturates, carbamazepine, and sulfonamides (see Table 64-3). Caloric restriction, fasting, surgery, states of high progesterone, infections, and in particular the interaction of more than one of these triggers have precipitated attacks.

DIAGNOSIS AND TREATMENT OF ACUTE PORPHYRIAS

A high index of suspicion is important for diagnosing porphyrias because of the nonspecific nature of presenting complaints. The most common feature is abdominal pain, followed by pain elsewhere, paresis, nausea, vomiting, constipation, mental symptoms, and excess sympathetic tone. A single urine PBG level should be promptly sent and, if elevated in an adult with above symptoms, consideration should be given to starting treatment. The urine specimen should be saved in the dark and cold without preservatives so that ALA and total porphyrins can be quantitated if the PBG proves to be elevated. Plasma and fecal porphyrins plus erythrocyte PBC deaminase level should be sent to confirm the diagnosis of AIP.

Treatment of patients with acute porphyria starts with prevention. Adequate caloric intake, particularly carbohydrates, and avoidance of triggers such as alcohol, offending drugs, and caloric restriction are important. Narcotics are safe to control pain, and β -adrenergic blockers can be used to control tachycardia and hypertension. Intravenous formulations of heme, such as hematin, are effective in reducing the duration and severity of attacks, perhaps by blunting the induction of heme biosynthesis and thereby abrogating further accumulation of toxic intermediates (e.g., PBG, ALA). Indeed, prompt institution of intravenous hematin therapy is pivotal because rare episodes of acute porphyria are life-threatening or associated with permanent neurologic impairment such as paresis.

PORPHYRIA CUTANEA TARDA

Porphyria cutanea tarda (PCT) is the most common porphyria and shows the cardinal feature of bullous involvement of sun-exposed skin. This results from accumulation of uroporphyrinogen and related heme-synthetic intermediates, which absorb light and confer photosensitivity. PCT is due to decreased activity of the hepatic enzyme uroporphyrinogen decarboxylase. More than 75% of patients have type I or *sporadic* disease, in which the family history is negative for affected relatives, and there is no mutation in the gene (*UROD*) encoding the enzyme. Triggers of attacks include supplemental estrogen, alcohol, iron overload, hepatitis C virus (HCV), and AIDS. Many patients with iron overload and symptomatic PCT are carriers of mutations in the hereditary hemochromatosis gene (*HFE*). Most other cases of PCT occur in people heterozygous for a mutation in *UROD*, so-called type II disease. In these patients, the same triggers as noted for AIP can elicit symptomatic PCT.

PCT typically begins in early adulthood with subacute appearance of fragile skin and includes vesicles and bullae, grayish skin discoloration, and hypertrichosis of the face. There is a complicated relationship between liver disease and PCT: liver involvement may be a cause, effect, or comorbid factor for PCT. There may be mild transaminase elevations, iron overload, HCV infection, liver cirrhosis, hepatoma, and hepatocellular carcinoma.

Diagnosis of PCT includes skin and family histories, consideration of recently started medicines, and plasma fluorescence for characteristic porphyrin peaks. Increased porphyrins in plasma, urine, and feces are required to attribute clinical manifestations to PCT. Up to 100-fold elevated uroporphyrins can be found in urine of symptomatic patients. A low level of *UROD* activity is found in about 25% of patients with inherited PCT. Mutation screening of the *UROD* gene may be the only way to detect asymptomatic family members of so-called type III patients who appear to only manifest deficiency of this enzyme in liver.

Avoiding and minimizing liver toxins such as alcohol and excess iron is a mainstay of therapy. Treatment includes avoiding triggers or removing any excess iron by phlebotomy and chloroquine, or sometimes both of these measures. It is important to lower the burden of porphyrins, and chlo-

roquine is useful by forming a complex with porphyrin that has improved excretion. Chloroquine is given at low dose (125 mg and no more than 250 mg twice weekly), with up to 2 months required for demonstrable biochemical improvement and 1 year for remission. Dialysis does not remove plasma porphyrins, and this contributes to an increased incidence of type I PCT in end-stage renal failure patients. PCT in the setting of dialysis is a therapeutic challenge because chloroquine does not work; low-volume phlebotomy and desferrioxamine, an iron chelator, have been tried.

ERYTHROPOIETIC PORPHYRIA

Erythropoietic porphyria (EPP) results from deficiency of the last enzyme in heme biosynthesis, ferrochelatase. As a result of this late block in the pathway, large amounts of protoporphyrin accumulate (see Fig. 64-1) and produce serious cutaneous damage through a photodynamic reaction as observed in patients with PCT. A brief exposure to sunlight can produce burning, redness, and edema suggestive of angio-

edema developing within hours and resolving over several days after sun exposure. Vesicles and bullae are less common than in patients with PCT. Unlike PCT, manifestations of EPP typically occur in childhood and can even have severe congenital forms. A reddish urine in diapers is sometimes the initial clue in congenital forms. About one fourth of EPP patients will have liver involvement, with gallstones found in up to 10% of patients.

A massive increase in erythrocyte protoporphyrin levels is the diagnostic hallmark of EPP, so much so that fluorescent red blood cells can sometimes be visualized on a blood smear. Fecal protoporphyrins are usually elevated in symptomatic patients, whereas high urinary protoporphyrins are not as elevated and may indicate hepatic involvement. Avoidance of sun or use of potent sunscreens is the mainstay of prevention. Avoiding alcohol and drugs known to induce heme synthesis can be helpful. β -carotene is a useful adjunct therapy that may limit oxidative damage to sun-exposed skin, although it takes weeks to fully penetrate the skin where it has its effect. Liver transplantation has been performed for severe liver disease.

Prospectus for the Future

- Identification of factors that will protect a person with a deleterious genotype from developing hemochromatosis, Wilson disease, or a porphyria. Development of drugs and other therapeutic approaches will be based on this knowledge.
- Effective screening strategies will be expanded, based on biochemical indices for hemochromatosis, with more people entering therapy at earlier stages of the disease.

Hypothalamic-Pituitary Axis

Vivien S. Herman-Bonert

Anatomy and Physiology

The pituitary gland, weighing 500 to 900 mg, lies at the base of the skull in the sella turcica within the sphenoid bone. The cavernous sinus borders laterally on the pituitary gland. The optic chiasm courses over the superior aspect. Two thirds of the pituitary gland is composed of the anterior lobe, and one third is the posterior lobe.

The anterior pituitary gland receives a rich vascular supply, largely from the hypothalamus via a hypothalamic-pituitary portal circulation. Hypothalamic stimulatory and inhibitory hormones are directly transported via the hypothalamic-pituitary portal circulation to specific cells of the anterior pituitary gland, where they regulate synthesis and secretion of pituitary trophic hormones (Fig. 65-1; **Web Figs. 65-1 and 65-2**).

A specific pituitary cell type secretes each of the anterior pituitary hormones: adrenocorticotropic hormone (ACTH), growth hormone (GH), prolactin (PRL), and thyroid-stimulating hormone (TSH). In addition, the same cell secretes the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Arginine vasopressin (AVP), also known as *antidiuretic hormone* (ADH), is synthesized in the hypothalamus and transported through the pituitary stalk to the posterior lobe of the pituitary gland (Table 65-1), where it is stored and available to be secreted when stimulated. Oxytocin is also stored and secreted by the posterior pituitary lobe.

Pituitary Tumors

Each of the five pituitary cell types, either singly or in combination, can give rise to benign pituitary adenomas, which secrete hormones characteristic of the particular cell type. Prolactinomas are the most common secretory pituitary tumors. Isolated reports of pituitary carcinomas with distant metastases have been described.

The earliest clinical manifestations of pituitary tumors are usually the characteristic signs and symptoms caused by the hormone hypersecretion. Subsequently, if the tumor is large, local manifestations of tumor enlargement may develop. Pressure on surrounding structures can cause signs and symptoms of large pituitary adenomas (secretory or nonsecretory). Headache is a frequent symptom. If the tumor extends into the suprasellar space, the optic chiasm may be compressed, which classically results in bitemporal hemianopia. Lateral extension into the cavernous sinus can result in ophthalmoplegia, diplopia, or ptosis as a result of dysfunction of the third, fourth, and sixth cranial nerves. Compression of surrounding normal pituitary tissue by an enlarging tumor mass can cause hyposecretion of one or several pituitary trophic hormones, resulting in signs and symptoms of hypopituitarism. Destructive pituitary lesions result in hormone loss, which follows a particular pattern: initially GH secretion is reduced, followed by LH and FSH, then TSH, and lastly ACTH.

The presence of a pituitary tumor is confirmed by pituitary magnetic resonance imaging (MRI) (**Web Fig. 65-3**). The contrast agent gadolinium is used to help differentiate small pituitary lesions from normal anterior pituitary tissue. Microadenomas are defined as pituitary lesions less than 10 mm in diameter. Macroadenomas are pituitary lesions more than 10 mm in diameter. They may cause significant deviation of the pituitary stalk to the opposite side. Adenomas exceeding 15 mm frequently have suprasellar extension with compression and displacement of the optic chiasm. An MRI may also show lateral extension of large adenomas into the cavernous sinus. A primary congenital defect or herniation of the arachnoid membrane through an incompetent diaphragma sella, either after pituitary surgery or radiation, can cause empty sella syndrome, the most common cause of an enlarged sella.

Endocrine evaluation should precede imaging studies because about 10% to 20% of the normal population harbors

nonfunctional asymptomatic pituitary microadenomas that are incidentally detected by MRI (Table 65-2).

Disorders of Anterior Pituitary Hormones

GROWTH HORMONE

GH is a 191–amino acid peptide with a molecular weight of 22,000 Da. Secretion is stimulated by the 40– and 44–amino acid hypothalamic growth hormone–releasing hormone (GHRH) and inhibited by the hypothalamic tetradecapeptide somatostatin. These hypothalamic factors bind to pituitary somatotroph cells and regulate GH secretion. GH binds to receptors in the liver and induces secretion of insulin-like growth factor I (IGF-I), which circulates

in the blood bound to binding proteins (BPs), the most important of which is IGF-BP3. IGF-I mediates most of the growth-promoting effects of GH. GH also affects carbohydrate metabolism.

Evaluation of Growth Hormone Reserve

Provocative tests that stimulate the somatotroph are necessary to assess GH deficiency (GHD) because basal GH levels are frequently very low even in normal individuals. Insulin-induced hypoglycemia (insulin tolerance test [ITT]) is the gold standard test for assessing GH reserve. Insulin (0.05 to 0.15 U/kg) is administered intravenously to reduce the patient’s blood glucose levels to 50% of initial blood glucose or to 40 mg/dL with serial sampling of serum GH and glucose. Hypoglycemia is a potent stimulus for GH secretion, and a normal response is a peak GH level in excess of 5 ng/mL at 60 minutes in adults and 10 ng/mL in children. Combined infusion of GHRH and arginine is as sensitive and specific as insulin-induced hypoglycemia in stimulating GH secretion in adulthood and is recommended in elderly patients and in patients with ischemic heart disease or seizures. Alternate tests validated for the evaluation of adult GHD include glucagon and arginine plus growth hormone–releasing peptide (GHRP) stimulation tests.

A single GH stimulation test is sufficient for the diagnosis of adult GHD. However, patients with a low serum IGF level and three or more pituitary hormone deficiencies have more than a 97% chance of having GHD and do not need to undergo GH stimulation testing. The GH cutoff for the diagnosis of GHD varies with age, body mass index, and the GH stimulation test employed. IGF-I levels can be used as a screening test for GH deficiency because GH regulates IGF-I levels. GH deficiency is associated with low IGF-I and low IGF-BP3. A low serum IGF-I level is suggestive of GHD; however, a normal IGF-I level does not rule out GHD.

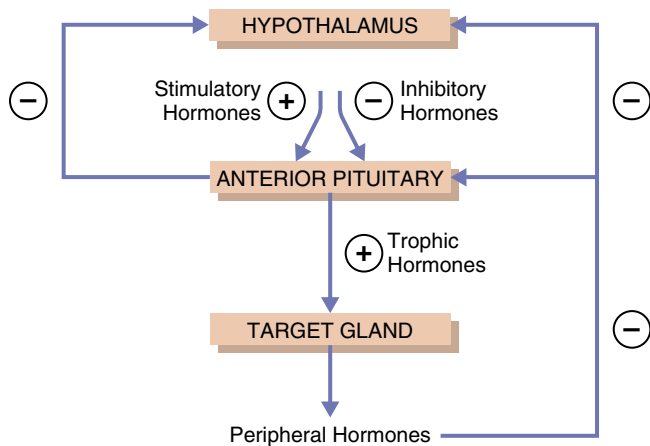

Figure 65-1 Feedback control of the hypothalamic-pituitary target gland axis.

Table 65-1 Pituitary–Target Organ Hormone Axis

Hypothalamic Hormone	Pituitary Target Cell	Pituitary Hormone Affected	Peripheral Target Gland	Peripheral Hormone Affected
Stimulatory				
<i>Anterior Lobe of Pituitary Gland</i>

Table 65-2 Screening Tests for Pituitary Disorders

Disorder	Tests
Pituitary Tumor	
Acromegaly	IGF-I OGTT: Measure BS and GH (0, 60, 120 min)
Prolactinoma	Basal serum prolactin
ACTH-secreting tumor	24-hr urine-free cortisol and creatinine level 1 mg overnight dexamethasone suppression test 2 mg and 8 mg dexamethasone suppression tests Serum ACTH Dexamethasone-CRH test Bilateral inferior petrosal sinus sampling
TSH-secreting tumor	Serum TSH, TFT
Gonadotropin-secreting tumor	FSH, LH, α subunit
Hypopituitarism	
Growth hormone deficiency	IGF-I GH provocative test: ITT Arginine-GHRH
Gonadotropin deficiency	Women: basal estradiol, LH, FSH Men: testosterone (total; free), LH, FSH
TSH Deficiency	Serum TSH, free T ₄
ACTH Deficiency	ACTH Provocative test: ITT Metyrapone test Cortrosyn-stimulation test (1 mcg and 250 mcg)

ACTH, adrenocorticotropic hormone; BS, blood sugar; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone–releasing hormone; IGF-I, insulin-like growth factor I; ITT, insulin tolerance test; LH, luteinizing hormone; OGTT, oral glucose tolerance test; T₄, thyroxine; TSH, thyroid-stimulating hormone; TFT, thyroid function test.

Evaluation of Growth Hormone Hypersecretion

GH is secreted in a pulsatile manner, and thus dynamic GH testing is more valuable than the measurement of a single random GH level. Moreover, cirrhosis, starvation, anxiety, type 1 diabetes mellitus, and acute illness can be associated with GH hypersecretion. However, measurement of serum IGF-I is a useful indicator of GH hypersecretion because this level does not fluctuate throughout the day. IGF-I levels are elevated in almost all patients with GH hypersecretion. A simple and specific dynamic test for GH hypersecretion is the administration of oral glucose, in which 100 g of glucose administered orally suppresses GH levels to less than 1 ng/mL after 120 minutes in healthy individuals. In patients with acromegaly, GH levels may increase, remain unchanged, or decrease (however, not below 1 ng/mL) after an oral glucose load. If no pituitary mass is detected, an extrapituitary source of ectopic GH or GHRH should be sought through imaging studies of the chest and abdomen.

Adult Growth Hormone Deficiency

GH deficiency during infancy and childhood is exhibited as growth retardation, short stature, and fasting hypoglycemia. Adult GH deficiency manifests as increased abdominal adiposity, reduced muscle strength and exercise capacity, decreased lean body mass and increased fat mass, reduced bone mineral density, glucose intolerance and insulin resistance, abnormal lipid profile, and impaired psychosocial well-being. Adult GH deficiency is frequently accompanied by other symptoms of panhypopituitarism.

Treatment

GH is administered in adulthood as a subcutaneous daily injection (0.1 to 0.3 mg per day). GH replacement therapy in adults decreases fat mass, increases lean body mass and bone mineral density, and is associated with improved cardiovascular risk factors (e.g., lipid profile, waist-to-hip ratio, central obesity).

Acromegaly and Gigantism

In childhood, GH hypersecretion leads to gigantism; in adults whose long bone epiphyses are fused, GH excess causes acromegaly with local overgrowth of bone in the acral areas. GH hypersecretion is almost always caused by a GH-secreting pituitary adenoma. About 70% of patients with acromegaly have macroadenomas. Ectopic GHRH secretion can occur with pancreatic islet cell tumors and bronchial or intestinal carcinoids. Ectopic GH secretion occurs rarely with pancreas, breast, and lung tumors. Both ectopic GH and GHRH are clinically exhibited with acromegaly but are extremely rare.

Clinical Features

The clinical features of acromegaly are insidious, and it may take several years for the disfiguring features to be diagnosed. Untreated, acromegaly causes increased rates of morbidity and mortality late in the course of the disorder. The most classic clinical feature is acral enlargement, exhibited as a widening of the hands and feet and a coarsening of the facial features; the frontal sinuses enlarge, leading to prominent supraorbital ridges, and the mandible grows downward and forward, resulting in prognathism and wide spacing of the teeth. Ring, glove, and shoe sizes increase as a result of soft tissue and bony enlargement of hands and feet (**Web Fig. 65-4**). The bony and soft tissue changes are accompanied by endocrine, metabolic, and systemic manifestations (Table 65-3).

Treatment

Trans-sphenoidal microsurgery is the initial therapy of choice, resulting in rapid reduction of GH levels with a low rate of surgical morbidity. Cure rates are proportional to preoperative tumor size with a 90% success rate for patients with microadenomas. Radiotherapy is an effective method of reducing GH hypersecretion; however, it may take as long as 20 years for GH levels to fall after radiotherapy, and the incidence of hypopituitarism is high. Medical management involves the use of drugs that decrease GH secretion from the pituitary tumor (somatostatin analogues, dopamine agonists) or block the peripheral action of GH at the hepatic receptor (GH receptor antagonists). Octreotide acetate, a

Table 65-3 Clinical Features of Acromegaly

Change	Manifestations
Somatic Changes	
Acral changes	Enlarged hands and feet
Musculoskeletal changes	Arthralgias Prognathism Malocclusion Carpal tunnel syndrome Proximal myopathy
Skin changes	Sweating
Colon changes	Polyps Carcinoma
Cardiovascular symptoms	Cardiomegaly Hypertension
Visceromegaly	Tongue Thyroid Liver
Endocrine-Metabolic Changes	
Reproduction	Menstrual abnormalities Galactorrhea Decreased libido
Carbohydrate metabolism	Impaired glucose tolerance Diabetes mellitus
Lipids	Hypertriglyceridemia

long-acting somatostatin analogue, is effective in reducing GH and IGF-I levels to normal in 40% to 65% of patients and shrinks tumor mass in about 50% of cases. A long-acting, slow-releasing depot preparation of octreotide administered once monthly is as effective as short-acting subcutaneous octreotide preparations. Side effects of octreotide include diarrhea, abdominal cramps, flatulence, and gallstone formation. Bromocriptine, a dopamine agonist, is effective in suppressing GH in only a minority of patients with acromegaly. The GH receptor antagonist, pegvisomant, binds to the GH receptor on the hepatic surface and thus blocks the normal physiologic action of GH. The mechanism of normal GH action at the liver involves binding of the GH to its hepatic receptor, followed by receptor dimerization, which then activates signaling pathways that result in IGF-I generation. Pegvisomant blocks GH receptor dimerization and subsequent IGF-1 generation and normalizes IGF-1 levels in 97% of patients with acromegaly. Liver function tests and pituitary adenoma size must be monitored on a long-term basis.

PROLACTIN

Prolactin (PRL), a 198–amino acid, 22,000–Da polypeptide, is synthesized and secreted by pituitary lactotrophs. Hypothalamic dopamine provides predominantly inhibitory control of PRL secretion, allowing only a low basal rate of secretion. Thyrotropin-releasing hormone (TRH) and vasoactive intestinal polypeptide are putative PRL-releasing factors. PRL secretion is episodic. Estrogens increase basal and stimulated PRL secretion; glucocorticoids and TSH blunt TRH-induced PRL secretion. PRL levels increase during pregnancy. After childbirth, PRL stimulates milk production. However, elevated PRL levels are not needed to maintain lactation, and basal PRL secretion falls as the infant's suckling reflex maintains lactation.

Prolactinomas

Microprolactinomas are more common in women, whereas macroadenomas occur more frequently in men. PRL inhibits pulsatile gonadotropin secretion and suppresses the midcycle LH surge with consequent menstrual irregularities. Hyperprolactinemia in women can cause hypogonadotropic hypogonadism, resulting in estrogen deficiency. In men who have hyperprolactinemia, testosterone levels are usually suppressed.

Clinical Features

Prolactinomas are often recognized earlier in women, who have menstrual irregularities and infertility, as opposed to men, who exhibit decreased libido and erectile dysfunction.

About 90% of women who have hyperprolactinemia have amenorrhea, galactorrhea, or infertility. If the prolactinoma occurs in adolescents before the onset of menarche, they may have primary amenorrhea. Prolactinomas account for 15% to 20% of secondary amenorrhea. Anovulation is associated with infertility. Galactorrhea may not be clinically obvious and may be discovered only during breast examination.

Estrogen deficiency may cause osteopenia, vaginal dryness, hot flashes, and irritability. PRL stimulates adrenal androgen production, and androgen excess can result in weight gain and hirsutism. Hyperprolactinemia may be associated with anxiety and depression.

Men usually exhibit a loss of libido and erectile dysfunction as a result of hypogonadism. These symptoms are often attributed to causes other than prolactinoma, which results in frequent delay in diagnosis until visual impairment, headache, and hypopituitarism develop.

Diagnosis

Several physiologic conditions (e.g., pregnancy, stress, nipple stimulation), as well as certain medications (e.g., phenothiazines, methyl dopa, cimetidine, metoclopramide) and pathologic states (e.g., hypothyroidism, chronic renal failure, chest wall lesions), increase PRL secretion. These conditions may be associated with mildly elevated PRL levels; however, basal PRL levels in excess of 200 ng/mL usually imply prolactinoma. MRI confirms the diagnosis of prolactinoma.

Treatment

Medical management with a dopamine agonist (e.g., bromocriptine, cabergoline) restores gonadal function and fertility in most patients. Dopamine agonists cause tumor shrinkage in a significant number of patients with macroadenomas. Side effects of dopamine agonists, which occur more frequently with bromocriptine than cabergoline, include dizziness, nausea, vomiting, nasal stuffiness, and orthostatic hypotension. Cabergoline-related cardiac valvulopathy was recently reported in patients with Parkinson disease receiving doses of cabergoline far greater than used for the treatment of prolactinoma. However, valvulopathy is of concern in young patients requiring long-term dopamine agonist therapy, and bromocriptine, if tolerable, is the preferred therapy, until well-controlled prospective clinical studies are available. Trans-sphenoidal surgery is indicated in patients who are intolerant or resistant to medical treatment.

THYROID-STIMULATING HORMONE

TSH, a 28,000-Da glycoprotein hormone, is synthesized and secreted by the pituitary thyrotroph cells. TSH secretion is stimulated by the hypothalamic tripeptide TRH. The inhibitory effect of hypothalamic somatostatin augments the negative feedback inhibition of TSH secretion by peripheral thyroid hormones. TSH attaches to receptors on the thyroid gland and activates adenyl cyclase, stimulating iodine uptake and the synthesis and release of the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3). T_4 and T_3 , in turn, exert negative feedback inhibition on pituitary TSH and hypothalamic TRH secretion.

Evaluation of TSH Secretion

TSH is measured by ultrasensitive assays (immunoradiometric assays), which can accurately distinguish low, normal, and high TSH levels. The ultrasensitive TSH assay has largely replaced the need for any further tests. The presence of low circulating TSH levels in the presence of low thyroid hormone levels differentiates secondary (central) hypothyroidism as a result of hypothalamic-pituitary dysfunction from primary hypothyroidism, which manifests low thyroid hormone levels, with concomitant high TSH levels.

TSH Deficiency

TSH deficiency causes thyroid gland involution, hypofunction, and clinical hypothyroidism. Clinical features of hypothyroidism include lethargy, constipation, cold intolerance, bradycardia, weight gain, poor appetite, dry skin, and delayed relaxation time of peripheral reflexes.

Treatment

Patients with central hypothyroidism are treated with thyroxine. Measuring the serum FT4 level, which should be in the mid to normal range, assesses the adequacy of thyroid replacement. TSH levels are low to normal in central hypopituitarism; thus, TSH levels cannot be used to monitor thyroid hormone replacement dosage in secondary hypothyroidism.

Thyrotropin-Secreting Pituitary Tumors

Thyrotropin-secreting pituitary tumors are extremely rare, exhibiting hyperthyroidism, goiter, and inappropriately elevated (or normal) TSH levels in the presence of elevated serum thyroid hormone levels. TSH-secreting tumors are usually plurihormonal, secreting GH, PRL, and the glycoprotein hormone α subunit, as well as TSH. These tumors are often resistant to removal, which necessitates several surgical procedures or radiotherapy. Octreotide acetate, a somatostatin analogue, has been found to be useful in decreasing TSH secretion in patients with these tumors and has been shown to shrink the tumor in some cases. Iodine-131 thyroid ablation or thyroid surgery may be needed to control thyrotoxicosis.

ADRENOCORTICOTROPIC HORMONE

ACTH, a 39-amino acid peptide, is synthesized as part of a larger 241-amino acid precursor molecule, pro-opiomelanocortin, which is subsequently cleaved enzymatically into β -lipotropin (β -LPH), ACTH, joining peptide,

and an amino-terminal peptide in the anterior lobe of the pituitary gland. ACTH is then cleaved into β -melanocyte-stimulating hormone and corticotropin-like peptide (ACTH [18-39]), whereas β -LPH is split into LPH and β -endorphin.

Hypothalamic corticotropin-releasing hormone (CRH) and to a lesser extent ADH stimulate ACTH secretion by pituitary corticotroph cells. ACTH stimulates cortisol synthesis and secretion from the adrenal gland. Cortisol exerts a negative feedback on ACTH and CRH secretion. ACTH is secreted in pulses and is under circadian control, reaching maximal levels in the last hours before awakening, followed by a steady decline to a nadir in the evening. Both psychological and physical stresses increase ACTH and cortisol secretion, whereas glucocorticoids inhibit ACTH secretion as well as CRH and ADH synthesis and release. ACTH also maintains adrenal size by increasing protein synthesis.

Evaluation of ACTH Secretion

Excess ACTH secretion results in hypercortisolemia, which may be caused by an ACTH-secreting pituitary adenoma (Cushing disease) or by ectopic ACTH secretion. ACTH deficiency results in adrenocortical insufficiency, with decreased secretion of cortisol. Aldosterone secretion is largely regulated by the renin-angiotensin axis; therefore, aldosterone secretion remains intact (see Chapter 67).

Basal ACTH Levels

Random basal ACTH measurements are unreliable because of the short plasma half-life and pulsatile secretion of the hormone. Interpretation of plasma ACTH levels requires concomitant assessment of plasma cortisol levels. Because ACTH regulates cortisol secretion, plasma cortisol levels better reflect hypothalamic-pituitary-adrenal function. An 8:00 AM cortisol less than 3 mcg/dL suggests adrenal insufficiency. ACTH levels can be used to differentiate primary from secondary adrenal insufficiency. Plasma ACTH levels are normal to high in adrenal insufficiency because of a primary adrenal disorder and are low to absent in adrenal insufficiency secondary to hypothalamic-pituitary hypofunction (see Chapter 67).

Evaluation of ACTH Reserve

To assess the adequacy of ACTH reserve under conditions of stress, provocative testing is performed. The insulin-induced hypoglycemia test previously described as a stimulus for pituitary GH release also stimulates the hypothalamic-pituitary-adrenal axis. A peak cortisol level of at least 18 mcg/dL confirms normal ACTH reserve. Insulin-induced hypoglycemia is the most reliable test of the ACTH secretory response to stress. The test is contraindicated in older patients and in patients with cerebrovascular disorders, seizure disorders, or cardiovascular disease. Metyrapone (30 mg/kg orally at midnight) inhibits the 11- β -hydroxylase enzyme in the adrenal gland, which converts 11-deoxycortisol to cortisol. Low cortisol stimulates CRH and ACTH. An 11-deoxycortisol level greater than 7 mg/dL, with a simultaneous serum cortisol level less than 5 mcg/dL, the morning after metyrapone administration, indicates an adequate response. If compromised adrenal function is suggested, the ITT and metyrapone tests are potentially hazardous, and a physician should closely monitor patients.

Prolonged ACTH deficiency results in adrenal atrophy, and thus ACTH status can be assessed indirectly by measuring adrenal cortisol reserve. Cortrosyn-stimulation testing correlates well with the ITT. About 250 mcg cosyntropin (Cortrosyn; synthetic ACTH [1-24]) administered intravenously or intramuscularly results in a peak cortisol level of more than 20 mcg/dL within 60 minutes in normal individuals. An inadequate response implies either impaired pituitary ACTH secretion or primary adrenal failure. Numerous recent studies suggest that low-dose (1 mcg) ACTH stimulation provides a more sensitive test than the supraphysiologic 250-mcg dose.

Evaluation of ACTH Hypersecretion

Pituitary corticotroph adenomas in Cushing disease or ectopic ACTH-secreting tumors result in ACTH hypersecretion and hypercortisolemia.

Initially, a diagnosis of hypercortisolemia must first be confirmed by measuring 24-hour urinary-free cortisol levels, midnight plasma or salivary cortisol levels, or lack of suppression of an 8:00 AM serum cortisol after 1 mg of dexamethasone administered at 11:00 PM on the evening before (1 mg overnight dexamethasone suppression).

After confirming Cushing syndrome and hypercortisolemia, plasma ACTH levels are measured to differentiate between ACTH-dependent Cushing syndrome (pituitary or ectopic ACTH secretion) and ACTH-independent Cushing syndrome (adrenal adenoma or hyperplasia). This differential diagnosis is discussed in Chapter 67.

ACTH Deficiency

ACTH deficiency results in adrenal failure, causing lethargy, weakness, nausea, vomiting, dehydration, orthostatic hypotension, coma, and, if untreated, death.

Treatment

Patients with adrenal insufficiency should be treated with hydrocortisone, 15 to 25 mg per day in two or three divided doses; cortisone acetate, 25 to 37.5 mg per day; or prednisone, 5 to 7.5 mg per day. The dose should be increased 5- to 10-fold in times of stress. Stress doses of steroid should be administered if the patient undergoes surgery with rapid tapering of the dose postoperatively. The dose of steroid should be doubled when the patient has minor illnesses.

Mineralocorticoid replacement is not required with central adrenal insufficiency because the renin-aldosterone system is intact.

ACTH-Secreting Pituitary Tumors

ACTH-secreting pituitary tumors result in hypercortisolemia associated with obesity, moon facies, cervicodorsal dysplasia, striae, thinning of the skin, hirsutism, hypertension, menstrual irregularities, glucose intolerance, mood changes, proximal myopathy, and osteopenia (Fig. 65-2). The differential diagnosis of hypercortisolemia is discussed in Chapter 67.

Figure 65-2 Clinical features of Cushing syndrome. **A**, Centripetal and some generalized obesity and dorsal kyphosis in a 30-year-old woman with Cushing disease. **B**, Same woman as shown in **A**, depicting moon facies, plethora, hirsutism, and enlarged supraclavicular fat pads. **C**, Facial rounding, hirsutism, and acne in a 14-year-old girl with Cushing disease. **D**, Central and generalized obesity and moon facies in a 14-year-old boy with Cushing disease. **E**, **F**, Typical centripetal obesity with livid abdominal striae observed in a 41-year-old woman (**E**) and a 40-year-old man (**F**) with Cushing disease. **G**, Striae in a 24-year-old patient with congenital adrenal hyperplasia treated with excessive doses of dexamethasone as replacement therapy. **H**, Typical bruising and thin skin of a patient with Cushing disease. In this case, the bruising has occurred without obvious injury. (From Larsen PR, Kronenberg H, Melmed S, et al: *Williams Textbook of Endocrinology*, 10th ed. Philadelphia, WB Saunders, 2003.)

Treatment

Treatment modalities used to control ACTH hypersecretion in Cushing disease include trans-sphenoidal resection, radiation therapy, and medical therapy. Drugs that block steroid synthesis include ketoconazole, metyrapone and aminoglutethimide, mifepristone, and trilostane.

Treatment of ectopic ACTH syndrome is designed to remove the ectopic tumor if possible.

GONADOTROPINS (LUTEINIZING HORMONE AND FOLLICLE-STIMULATING HORMONE)

Gonadotroph secretion of LH and FSH is regulated by hypothalamic gonadotropin-releasing hormone (GnRH), a 10–amino acid peptide secreted in a pulsatile manner. Gonadal steroids (estrogen and testosterone) and peptides (inhibin and activin) regulate negative feedback inhibition. Basal LH and FSH are secreted in a pulsatile manner, concordantly with the pulsatile release of GnRH. GnRH release determines the onset of puberty and generates the midcycle gonadotropin surges necessary for ovulation. Gonadal steroids exert both positive and negative feedback effects on gonadotroph secretion. In addition, the gonadal polypeptide inhibin, produced by ovarian granulosa cells and testicular Sertoli cells, negatively inhibits FSH secretion, whereas activins stimulate FSH secretion. LH and FSH bind to receptors in the ovaries and testes and stimulate sex steroid secretion (predominantly LH) as well as gametogenesis (predominantly FSH). LH stimulates gonadal steroid secretion by testicular Leydig cells and by the ovarian follicles. In women, the ovulatory LH surge results in rupture of the follicle and then luteinization. FSH stimulates Sertoli cell spermatogenesis in men and follicular development in women.

Evaluation of Hypothalamic-Pituitary-Gonadal Axis

LH and FSH levels vary with age, and with the menstrual cycle in women. Prepubertal gonadotropin levels are low, and postmenopausal women have elevated levels. Male FSH and LH levels are pulsatile but fluctuate less than those in women. During the follicular phase of the menstrual cycle, LH levels rise steadily, with a midcycle spike that stimulates ovulation. FSH rises during the early follicular phase, falls in the late follicular phase, and peaks at midcycle, concurrent with the LH surge. Both LH and FSH levels fall after ovulation.

Basal testosterone and FSH levels are measured in men. Low basal testosterone and FSH levels, indicative of hypogonadism, are confirmed by measuring three pooled samples drawn 20 minutes apart, which compensates for the normal pulsatile gonadotropin secretion.

Gonadotropin and sex steroid estimation in women is more complex. However, women with regular menstrual cycles and a documented normal luteal-phase serum progesterone concentration are unlikely to have significant gonadotropin dysfunction. In women with amenorrhea, measurement of serum LH, FSH, estradiol, PRL, and human chorionic gonadotropin (hCG) can differentiate among (1) primary ovarian failure, with elevated FSH and LH levels and normal PRL levels; (2) hyperprolactinemia, with elevated PRL and normal to low follicular-phase LH, FSH, and estradiol levels; and (3) pregnancy, with a positive hCG, normal to high PRL, normal LH, and high estradiol.

Gonadotropin deficiency is best diagnosed by concurrent measurement of serum gonadotropins and gonadal steroid concentrations. Low or normal FSH and LH levels in the presence of a low testosterone level (in men) or a low estradiol level (in women) confirm the diagnosis of gonadotropin deficiency. Low levels of gonadal steroids in the presence of elevated gonadotropin levels suggest primary gonadal failure.

Gonadotropin Deficiency

Central hypogonadism during childhood results in failure to enter normal puberty. Girls have delayed breast development, scant pubic and axillary hair, and primary amenorrhea. In boys, the phallus and testes remain small, and body hair is sparse. Sex steroids are required for closure of the epiphyses of the long bones; thus, in isolated gonadotropin deficiency, growth continues (as GH is intact) because epiphyseal fusion fails, resulting in tall adolescents with eunuchoid proportions (upper segment-to-lower segment ratio < 1:1). In adult women, hypogonadism is exhibited as breast atrophy, loss of pubic and axillary hair, and secondary amenorrhea. Hypogonadal men develop testicular atrophy, decreased libido, erectile dysfunction, decreased muscle mass and bone mineral density, loss of body hair, and elevated low-density lipoprotein (LDL) cholesterol levels.

Treatment

Androgen replacement therapy is recommended in men with central hypogonadism. Testosterone can be administered as an intramuscular injection (testosterone enanthate, 200 to 300 mg every 2 or 3 weeks) or as a transdermal patch (2.5 to 5 mg per day) or gel (2.5 to 10 mg per day). Adequate replacement results in a mid-normal serum testosterone level.

Premenopausal women with central hypogonadism should receive estrogen replacement therapy, and, if they have a uterus, they should receive progesterone either continuously or cyclically to protect the uterine lining. Estrogen-progesterone replacement recommendations for postmenopausal hypopituitary women are the same as for postmenopausal women without hypopituitarism.

Gonadotropin-Secreting Pituitary Tumors

Gonadotropin-secreting pituitary tumors are rare and have been reported mainly in men. Most tumors are large at the time of presentation and hypersecrete only FSH. Patients usually have signs and symptoms of local pressure, such as visual impairment. Patients may also exhibit hypogonadism with low or normal testosterone levels or low or normal sperm counts. This results from inhibitory effects of chronically high levels of gonadotropins (LH and FSH) on the testicles. In rare cases, excess LH may stimulate testosterone levels.

Surgical removal of gonadotropin-secreting adenomas is the usual primary treatment; however, patients may require subsequent radiotherapy.

Hypothalamic Dysfunction

In children and young adults, craniopharyngioma is the most frequent cause of hypothalamic dysfunction. Primary central nervous system tumors, pinealomas, and dermoid and epidermoid tumors also cause hypothalamic dysfunction in adulthood. Clinical manifestations of tumors that can cause hypothalamic dysfunction include visual loss, symptoms of raised intracranial pressure (headache and vomiting), hypopituitarism (including growth failure), and diabetes insipidus. Hypothalamic disturbances include disorders of thirst (e.g., polydipsia, polyuria, dehydration), appetite (e.g., hyperphagia, obesity), temperature regulation, and consciousness (e.g., somnolence, emotional lability). Diabetes insipidus is a common manifestation of hypothalamic lesions but rarely occurs with primary pituitary lesions. An MRI can confirm the diagnosis. Because hypopituitarism occurs frequently with hypothalamic lesions, anterior pituitary function should be assessed.

Craniopharyngioma is treated by surgical resection and may require subsequent radiotherapy. Biopsy of other types of hypothalamic tumors is usually required for histologic diagnosis before surgical resection because some, such as dysgerminoma, may be radiosensitive.

Hypopituitarism

Hypopituitarism results from diminished secretion of one or more pituitary hormones. The syndrome results either from anterior pituitary gland destruction or dysfunction secondary to deficient hypothalamic stimulatory-inhibitory factors that normally regulate pituitary function. Congenital or acquired lesions can also cause hypopituitarism (Table 65-4). Pituitary insufficiency is usually a slow, insidious disorder. Pituitary lesions may result in single or multiple hormone losses.

DIAGNOSIS

The diagnosis of pituitary hormone deficiency has been previously discussed in relation to the individual hormones.

TREATMENT

Patients with panhypopituitarism must have adequate replacement of growth hormone, T_4 , glucocorticoids, and appropriate sex steroids. Children with short stature resulting from GH deficiency should receive GH replacement therapy. The safety and efficacy of GH replacement therapy for adults who develop GH deficiency is being evaluated. Testosterone therapy in men restores libido and potency, growth of body hair, and muscle strength. Estrogen replacement therapy in women maintains secondary sex characteristics and prevents hot flashes. Both testosterone and estrogen may protect bone from osteoporosis. Hypogonadotropic female patients may require ovulation induction and in vitro fertilization to treat infertility. In patients with combined TSH and ACTH deficiency, glucocorticoids should be replaced before T_4 because T_4 may aggravate adrenal insufficiency and may precipitate acute adrenal failure.

Table 65-4 Causes of Hypopituitarism

Type of Disorder	Cause
Congenital	Septo-optic dysplasia Prader-Willi syndrome Laurence-Moon-Biedl syndrome Isolated anterior pituitary hormone-releasing factor deficiency
Tumors	Pituitary tumors Secretory adenomas Nonsecretory adenomas Hypothalamic tumors Craniopharyngioma Hamartoma Pinealoma Dermoid Epidermoid Glioma Lymphoma Meningioma Metastatic cancers
Infiltrative	Hemochromatosis Langerhans cell histiocytosis Sarcoidosis Metastatic carcinoma (breast and bronchus) Amyloidosis
Infectious	Tuberculosis Mycoses Syphilis
Physical trauma	Cranial trauma and hemorrhage Ionizing radiation Stalk section Surgery
Vascular	Postpartum pituitary necrosis (Sheehan syndrome) Pituitary apoplexy Carotid aneurysm

Posterior Pituitary Gland

The posterior pituitary gland secretes ADH and oxytocin. These hormones are synthesized in the hypothalamic nuclei in neuronal cell bodies that extend from the hypothalamus to the posterior pituitary. ADH binds to receptors on the renal tubule, increasing the water permeability of the luminal membrane of the collecting duct epithelium, thus facilitating reabsorption of water and concentration of the urine. Maximal ADH effect results in a small volume of concentrated urine with a high osmolarity (as high as 1200 mOsm/kg). Deficiency of ADH results in a large volume of very dilute urine (as low as 100 mOsm/kg). In addition to the renal tubular effects, ADH also binds to peripheral arteriolar receptors, causing vasoconstriction and resultant increase in blood pressure. However, a countereffect to the hypertensive effect of ADH is that ADH also causes bradycardia and the inhibition of sympathetic nerve activity.

Deficiency of ADH or insensitivity of the kidneys to ADH results in diabetes insipidus, which is exhibited as polyuria and polydipsia. Inappropriate secretion of ADH in excess amounts results in the syndrome of inappropriate antidiuretic hormone production (SIADH) and causes a hyponatremic state.

Oxytocin causes uterine smooth muscle contraction.

DIABETES INSIPIDUS

Vasopressin deficiency occurs with posterior pituitary dysfunction and leads to diabetes insipidus with polyuria, polydipsia, and nocturia. Diabetes insipidus can be of a central (neurogenic) origin where the posterior lobe of the pituitary fails to secrete adequate amounts of ADH; or it can be of nephrogenic origin, caused by failure of the kidney to respond to adequate amounts of circulating ADH. Regardless of the cause, patients are polyuric, secreting large volumes of dilute urine. This causes cellular and extracellular dehydration, stimulating thirst, which results in polydipsia. The causes of central diabetes insipidus are entirely different from those of nephrogenic diabetes insipidus (Table 65-5).

Differential Diagnosis

Diabetes insipidus (central or nephrogenic) must be distinguished from primary polydipsia, a compulsive disorder of thirst in which patients drink in excess of 5 to 10 L per day of water, resulting in decreased ADH secretion and subsequent diuresis. One possible distinguishing clinical feature is that patients with diabetes insipidus prefer cold beverages. Several tests can be performed to confirm the diagnosis of diabetes insipidus and differentiate the syndrome from primary polydipsia. Initially, random simultaneous samples of plasma and urine for evaluation of sodium and osmolarity are obtained. In diabetes insipidus (central or nephrogenic), inappropriate diuresis results in a urine osmolarity that is less than that of plasma osmolarity. Plasma osmolarity may be elevated, depending on the patient's state of hydration. However, in primary polydipsia, both plasma and urine are dilute.

Table 65-5 Causes of Diabetes Insipidus

Central Diabetes Insipidus

- Idiopathic
- Familial
- Hypophysectomy
- Infiltration of hypothalamus and posterior pituitary
 - Langerhans cell histiocytosis
 - Granulomas
- Infection
- Tumors (intrasellar and suprasellar)
- Autoimmune

Nephrogenic Diabetes Insipidus

- Idiopathic
- Familial
 - V₂ receptor gene mutation
 - Aquaporin-2 gene mutation
- Chronic renal disease (e.g., chronic pyelonephritis, polycystic kidney disease, or medullary cystic disease)
- Hypokalemia
- Hypercalcemia
- Sickle cell anemia
- Drugs
 - Lithium
 - Fluoride
 - Demeclocycline
 - Colchicine

The primary test used to differentiate the causes of polyuria is the water deprivation test (**Web Fig. 65-5**). The patient is denied fluids for 12 to 18 hours, and body weight, blood pressure, urine volume, urine specific gravity, and plasma and urine osmolarity are measured every 2 hours. Careful supervision is required because patients with diabetes insipidus may become rapidly dehydrated and hypotensive if denied access to water, in which case the test is stopped. A normal response is a decrease in urine output to 0.5 mL per minute, as well as an increase in urine concentration to greater than that of plasma. Patients with diabetes insipidus (either central or nephrogenic) maintain a high urine output, which continues to be dilute (specific gravity 1.005) despite water deprivation. In patients with primary polydipsia, urine osmolarity increases to values greater than plasma osmolarity. Water deprivation is continued until the urine osmolarity plateaus (an hourly increase of <30 mOsm/kg for 3 successive hours). At that point, 5 units of aqueous vasopressin are administered subcutaneously, and the urine osmolarity is measured after 1 hour. In patients with complete central diabetes insipidus, urine osmolarity increases above plasma osmolarity, whereas in nephrogenic diabetes insipidus, the urine osmolarity increases less than 50% in response to ADH. Patients with partial central diabetes insipidus also show an increase in urine osmolarity, but it is less than 50%, whereas patients with primary polydipsia have increases of less than 10%. ADH levels should be measured during the water deprivation test. Patients with nephrogenic diabetes insipidus have normal or increased levels of ADH during water deprivation, in contrast to those with complete central diabetes insipidus, who have suppressed levels. Patients with partial central diabetes insipidus show a smaller than normal increase in plasma ADH during water deprivation. Patients should be cautioned not to drink large amounts of fluid until the effects of the aqueous vasopressin have worn off (4 to 8 hours) to avoid symptomatic hyponatremia.

Treatment

Central Diabetes Insipidus

Desmopressin acetate (DDAVP), a synthetic analogue of ADH, is usually administered intranasally or orally in the treatment of diabetes insipidus. Frequency of administration is determined by the severity of the disease. Adequacy of replacement is monitored by regular measurement of serum sodium and urine output.

Nephrogenic Diabetes Insipidus

As far as possible, the underlying disease process should be reversed. Specific treatment of nephrogenic diabetes insipidus is designed to maintain a state of mild sodium depletion with reduction in the solute load on the kidneys and subsequent increased proximal tubular reabsorption. Diuretics coupled with dietary salt restriction can be used to achieve this goal.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE PRODUCTION

See Chapter 28.

Prospectus for the Future

- U.S. Food and Drug Administration approval and clinical use of several novel therapies for secretory pituitary tumors (e.g., somatostatin receptor subtype and selective analogue therapy, universal somatostatin receptor ligand for acromegaly)
- Long-term studies to define indications, safety, and efficacy of GH replacement therapy in adulthood
- Development of novel methods of GH administration including long-acting depot and intranasal preparations
- Clear understanding of the relative roles of surgery, radiation therapy, and novel medical therapies for the treatment of pituitary tumors
- Definition of the role of primary medical therapy in the treatment algorithms for pituitary tumors
- Controlled, prospective clinical studies to evaluate the long-term effects of low-dose dopamine agonist therapy on cardiac valve integrity

Thyroid Gland

Vivien S. Herman-Bonert and Theodore C. Friedman

The thyroid gland secretes thyroxine (T_4) and triiodothyronine (T_3), both of which modulate energy utilization and heat production and facilitate growth. The gland consists of two lateral lobes joined by an isthmus. The weight of the adult gland is 10 to 20 g. Microscopically, the thyroid is composed of several follicles that contain colloid surrounded by a single layer of thyroid epithelium. The follicular cells synthesize thyroglobulin, which is then stored as colloid. Biosynthesis of T_4 and T_3 occurs by iodination of tyrosine molecules in thyroglobulin.

Thyroid Hormone Physiology

THYROID HORMONE SYNTHESIS

Dietary iodine is essential for synthesis of thyroid hormones. Iodine, after conversion to iodide in the stomach, is rapidly absorbed from the gastrointestinal tract and distributed in the extracellular fluids. After active transport from the bloodstream across the follicular cell basement membrane, iodide is enzymatically oxidized by thyroid peroxidase, which also mediates the iodination of the tyrosine residues in thyroglobulin to form monoiodotyrosine and diiodotyrosine. The iodotyrosine molecules couple to form T_4 (3,5,3',5-tetraiodothyronine) or T_3 (3,5,3-triiodothyronine). Once iodinated, thyroglobulin containing newly formed T_4 and T_3 is stored in the follicles. Secretion of free T_4 and T_3 into the circulation occurs after proteolytic digestion of thyroglobulin, which is stimulated by thyroid-stimulating hormone (TSH). Deiodination of monoiodotyrosine and diiodotyrosine by iodotyrosine deiodinase releases iodine, which then reenters the thyroid iodine pool (**Web Fig. 66-1**).

THYROID HORMONE TRANSPORT

T_4 and T_3 are tightly bound to serum carrier proteins: thyroxine-binding globulin (TBG), thyroxine-binding prealbumin,

and albumin. The unbound or free fractions are the biologically active fractions and represent only 0.04% of the total T_4 and 0.4% of the total T_3 .

PERIPHERAL METABOLISM OF THYROID HORMONES

The normal thyroid gland secretes T_4 , T_3 , and reverse T_3 , a biologically inactive form of T_3 . Most of the circulating T_3 is derived from 5'-deiodination of circulating T_4 in the peripheral tissues. Deiodination of T_4 can occur at the outer ring (5'-deiodination), producing T_3 (3,5,3'-triiodothyronine), or at the inner ring, producing reverse T_3 (3,3,5'-triiodothyronine).

CONTROL OF THYROID FUNCTION

Hypothalamic thyrotropin-releasing hormone (TRH) is transported through the hypothalamic-hypophysial portal system to the thyrotrophs of the anterior pituitary gland, stimulating synthesis and release of TSH (Fig. 66-1). TSH, in turn, increases thyroidal iodide uptake and iodination of thyroglobulin, releases T_3 and T_4 from the thyroid gland by increasing hydrolysis of thyroglobulin, and stimulates thyroid cell growth. Hypersecretion of TSH results in thyroid enlargement (goiter). Circulating T_3 exerts negative feedback inhibition of TRH and TSH release.

PHYSIOLOGIC EFFECTS OF THYROID HORMONES

Thyroid hormones increase basal metabolic rate by increasing oxygen consumption and heat production in several body tissues. Thyroid hormones also have specific effects on several organ systems (Table 66-1). These effects are exaggerated in hyperthyroidism and lacking in hypothyroidism, accounting for the well-recognized signs and symptoms of these two disorders.

Figure 66-1 Hypothalamic-pituitary-thyroid axis. T₃, triiodothyronine; T₄, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

Table 66-1 Physiologic Effects of Thyroid Hormone

Cardiovascular Effects

Increased heart rate and cardiac output

Gastrointestinal Effects

Increased gut motility

Skeletal Effects

Increased bone turnover and resorption

Pulmonary Effects

Maintenance of normal hypoxic and hypercapnic drive in the respiratory center

Neuromuscular Effects

Increased muscle protein turnover and increased speed of muscle contraction and relaxation

Lipids and Carbohydrate Metabolism Effects

Increased hepatic gluconeogenesis and glycogenolysis, as well as intestinal glucose absorption
Increased cholesterol synthesis and degradation
Increased lipolysis

Sympathetic Nervous System Effects

Increased numbers of β -adrenergic receptors in the heart, skeletal muscle, lymphocytes, and adipose cells
Decreased cardiac α -adrenergic receptors
Increased catecholamine sensitivity

Hematopoietic Effects

Increased red blood cell 2,3-diphosphoglycerate, facilitating oxygen dissociation from hemoglobin with increased oxygen available to tissues

Thyroid Evaluation

Thyroid gland function and structure can be evaluated by (1) determining serum thyroid hormone levels, (2) imaging thyroid gland size and architecture, (3) measuring thyroid autoantibodies, and (4) performing a thyroid gland biopsy by fine-needle aspiration (FNA).

TESTS OF SERUM THYROID HORMONE LEVELS

Total serum T₄ and T₃ measure the total amount of hormone bound to thyroid-binding proteins by radioimmunoassay. Total T₄ and total T₃ levels are elevated in hyperthyroidism and are low in hypothyroidism. Increase in TBG (as with pregnancy or estrogen therapy) increases the total T₄ and T₃ without actual hyperthyroidism. Similarly, total T₄ and T₃ are low despite euthyroidism in conditions associated with low thyroid-binding proteins (e.g., congenital decrease, protein-losing enteropathy, cirrhosis, nephrotic syndrome). Thus, further tests to assess the free hormone level that reflects biologic activity must be performed. Free T₄ level is usually measured directly or by dialysis or ultrafiltration.

Serum TSH is measured by a third-generation immunometric assay, which uses at least two different monoclonal antibodies against different regions of the TSH molecule, resulting in accurate discrimination between normal TSH levels and levels below the normal range. Thus, the TSH assay can diagnose clinical hyperthyroidism (elevated free T₄ and suppressed TSH) and subclinical hyperthyroidism (normal free T₄ and suppressed TSH). In primary (thyroidal) hypothyroidism, serum TSH is supranormal because of diminished feedback inhibition. The TSH is usually low but may be normal in secondary (pituitary) or tertiary (hypothalamic) hypothyroidism.

Serum thyroglobulin measurements are useful in the follow-up of patients with papillary or follicular carcinoma. After thyroidectomy and iodine-131 (¹³¹I) ablation therapy, thyroglobulin levels should be less than 0.5 mcg/L while the patient is on suppressive levothyroxine treatment. Levels in excess of this value indicate the possibility of persistent or metastatic disease.

Calcitonin is produced by the C-cells of the thyroid and has a minor role in calcium homeostasis. Calcitonin measurements are invaluable in the diagnosis of medullary carcinoma of the thyroid and for monitoring the effects of therapy for this entity.

THYROID IMAGING

Technetium-99m (^{99m}Tc) pertechnetate is concentrated in the thyroid gland and can be scanned with a gamma camera, yielding information about the size and shape of the gland and the location of the functional activity in the gland (thyroid scan). The thyroid scan is often performed in conjunction with a quantitative assessment of radioactive iodine uptake by the thyroid with ¹²³I, which quantitates thyroid uptake. Functioning thyroid nodules are called *warm* or *hot* nodules; *cold* nodules are nonfunctioning. Malignancy is usually associated with a cold nodule; 16% of surgically removed cold nodules are malignant.

Thyroid ultrasound evaluation is useful in the differentiation of solid nodules from cystic nodules. It also may be used to guide the clinician during FNA of a nodule (**Web Fig. 66-2**).

THYROID ANTIBODIES

Autoantibodies to several different antigenic components in the thyroid gland, including thyroglobulin (TgAb), thyroid

peroxidase (TPO Ab, formerly called *antimicrosomal antibodies*), and the TSH receptor, can be measured in the serum. A strongly positive test for TPO Ab indicates autoimmune thyroid disease. Elevated thyroid receptor–stimulating antibody occurs in Graves disease (see the discussion under “Pathogenesis” later in this chapter).

THYROID BIOPSY

FNA of a nodule to obtain thyroid cells for cytologic evaluation is the best way to differentiate benign from malignant disease. FNA requires adequate tissue samples and interpretation by an experienced cytologist.

Hyperthyroidism

Thyrotoxicosis is the clinical syndrome that results from elevated circulating thyroid hormones. Clinical manifestations of thyrotoxicosis are due to the direct physiologic effects of the thyroid hormones as well as to the increased sensitivity to catecholamines. Tachycardia, tremor, stare, sweating, and lid lag are all due to catecholamine hypersensitivity.

SIGNS AND SYMPTOMS

Table 66-2 lists the signs and symptoms of hyperthyroidism. Thyrotoxic crisis, or *thyroid storm*, is a life-threatening complication of hyperthyroidism that can be precipitated by surgery, radioactive iodine therapy, or severe stress (e.g., uncontrolled diabetes mellitus, myocardial infarction, acute infection). Patients develop fever, flushing, sweating, significant tachycardia, atrial fibrillation, and cardiac failure. Significant agitation, restlessness, delirium, and coma frequently occur. Gastrointestinal manifestations may include nausea, vomiting, and diarrhea. Hyperpyrexia out of proportion to other clinical findings is the hallmark of thyroid storm.

DIFFERENTIAL DIAGNOSIS

Thyrotoxicosis usually reflects excess secretion of thyroid hormones resulting from Graves disease, toxic adenoma,

multinodular goiter, or thyroiditis (Table 66-3 and Fig. 66-2). However, it may be the result of excessive ingestion of thyroid hormone or, rarely, thyroid hormone production from an ectopic site as observed in struma ovarii.

GRAVES DISEASE

Graves disease, the most common cause of thyrotoxicosis, is an autoimmune disease that is more common in women, with a peak age incidence of 20 to 40 years. One or more of the following features are present: (1) goiter; (2)

Table 66-3 Causes of Thyrotoxicosis

Common Causes
Graves disease
Toxic adenoma (solitary)
Toxic multinodular goiter
Less Common Causes
Subacute thyroiditis (de Quervain or granulomatous thyroiditis)
Hashimoto thyroiditis with transient hyperthyroid phase
Thyrotoxicosis factitia
Postpartum (probably variant of silent thyroiditis)
Rare Causes
Struma ovarii
Metastatic thyroid carcinoma
Hydatidiform mole
Thyroid-stimulating hormone-secreting pituitary tumor

Table 66-2 Signs and Symptoms of Hyperthyroidism

Symptoms
Nervousness
Heat intolerance
Fatigue and weakness
Palpitations
Increased appetite
Weight loss
Oligomenorrhea
Signs
Tachycardia
Atrial fibrillation
Wide pulse pressure
Brisk reflexes
Fine tremor
Proximal limb-girdle myopathy
Chemosis

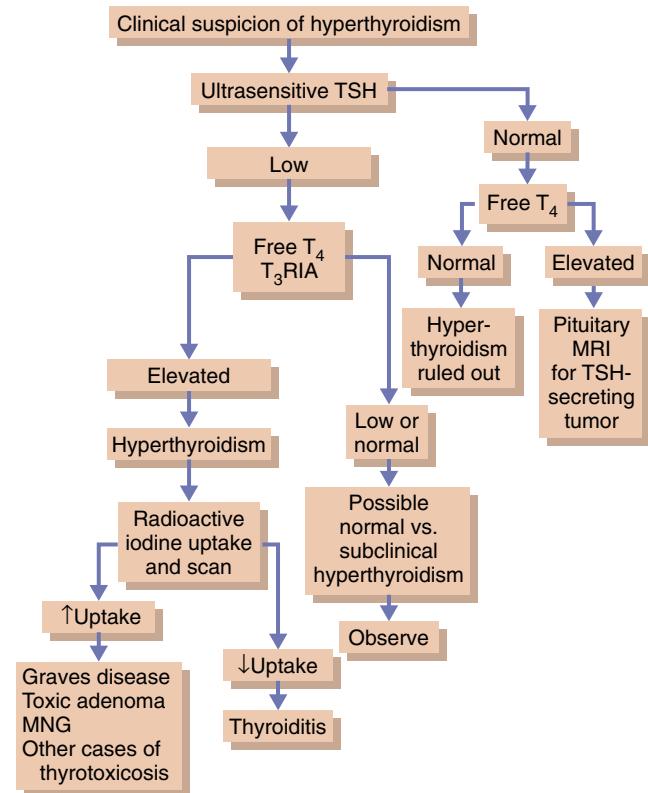

Figure 66-2 Algorithm for differential diagnosis of hyperthyroidism. MNG, multinodular goiter; MRI, magnetic resonance imaging; T₃RIA, triiodothyronine radioimmunoassay; T₄, thyroxine; TSH, thyroid-stimulating hormone.

thyrotoxicosis; (3) eye disease ranging from tearing to proptosis, extraocular muscle paralysis, and loss of sight as a result of optic nerve involvement; and (4) thyroid dermopathy, usually observed as significant skin thickening without pitting in a pretibial distribution (pretibial myxedema).

Pathogenesis

Thyrotoxicosis in Graves disease is due to the overproduction of an antibody that binds to the TSH receptor. These thyroid-stimulating immunoglobulins increase thyroid cell growth and thyroid hormone secretion. Ophthalmopathy is due to inflammatory infiltration of the extraocular eye muscles by lymphocytes, with mucopolysaccharide deposition. The inflammatory reaction that contributes to the eye signs in Graves disease may be caused by lymphocytes sensitized to antigens common to the orbital muscles and thyroid.

Clinical Features

The common manifestations of thyrotoxicosis (see Table 66-2) are characteristic features of younger patients with Graves disease. In addition, patients may exhibit a diffuse goiter or the eye signs characteristic of Graves disease. Older patients often do not have the florid clinical features of thyrotoxicosis, and the condition termed *apathetic hyperthyroidism* is exhibited as flat affect, emotional lability, weight loss, muscle weakness, congestive heart failure, and atrial fibrillation resistant to standard therapy.

Eye signs of Graves disease may be either a nonspecific manifestation of hyperthyroidism from any cause (e.g., thyroid stare) or may result from Graves disease as a result of a specific inflammatory infiltrate of the orbital tissues leading to periorbital edema, conjunctival congestion and swelling, proptosis, extraocular muscle weakness, or optic nerve damage with visual impairment (**Web Fig. 66-3**).

Pretibial myxedema (thyroid dermopathy) occurs in 2% to 3% of patients with Graves disease and exhibits a thickening of the skin over the lower tibia without pitting. Onycholysis, characterized by separation of the fingernails from their beds, often occurs in patients with Graves disease. Thyroid acropachy, or clubbing, may also occur in Graves disease.

Laboratory Findings

Elevated T_4 and/or T_3 and a suppressed TSH confirm the clinical diagnosis of thyrotoxicosis. Thyroid-stimulating immunoglobulin is usually elevated and may be useful in patients with eye signs who do not have other characteristic clinical features. Increased uptake of ^{123}I differentiates Graves disease from early subacute or Hashimoto thyroiditis, in which uptake is low in the presence of hyperthyroidism. Magnetic resonance imaging or ultrasonography of the orbit usually shows orbital muscle enlargement, whether or not clinical signs of ophthalmopathy are observed.

Treatment

Three treatment modalities are used to control the hyperthyroidism of Graves disease. They are antithyroid drugs, radioactive iodine, and surgery.

Antithyroid Drugs

The thiocarbamide drugs propylthiouracil, methimazole, and carbimazole block thyroid hormone synthesis by inhib-

iting thyroid peroxidase. Propylthiouracil also partially inhibits peripheral conversion of T_4 to T_3 . Medical therapy must be administered for a prolonged period (1 to 2 years) until the disease undergoes spontaneous remission. On cessation of medication, 40% to 50% of patients remain in remission, and the patients who experience relapse usually then undergo definitive surgery or radioactive iodine treatment. Side effects of the thiocarbamide regimen include pruritus and rash (in about 5% of patients), cholestatic jaundice, acute arthralgias, and, rarely, agranulocytosis (in 0.5% of patients). Patients must be instructed to discontinue the medication and consult a physician if they develop fever or sore throat because these symptoms may indicate agranulocytosis. At the onset of treatment during the acute phase of thyrotoxicosis, β -adrenergic blocking drugs help alleviate tachycardia, hypertension, and atrial fibrillation. As the thyroid hormone levels return to normal, treatment with β blockers is tapered.

Radioactive Iodine

In terms of cost, efficacy, ease, and short-term side effects, radioactive iodine has benefits that exceed both surgery and antithyroid drugs; however, most patients become hypothyroid following its use. ^{131}I is often the treatment of choice in adults with Graves disease. It is contraindicated in women who are pregnant, but it does not increase the risk for birth defects in offspring conceived after ^{131}I therapy. Patients with severe thyrotoxicosis, very large glands, or underlying heart disease should be rendered euthyroid with antithyroid medication before receiving radioactive iodine because ^{131}I treatment can cause a release of preformed thyroid hormone from the thyroid gland into the circulation; this release can precipitate cardiac arrhythmias and exacerbate symptoms of thyrotoxicosis. After administering radioactive iodine, the thyroid gland shrinks, and patients become euthyroid over a period of 6 weeks to 3 months. About 80% of patients become hypothyroid after radioactive iodine treatment. Serum-free T_4 and TSH levels should be monitored and replacement with levothyroxine instituted if hypothyroidism occurs. Hypothyroidism always occurs after surgical total thyroidectomy, frequently after subtotal thyroidectomy, and in a smaller percentage of patients after antithyroid medication, mandating lifelong monitoring of all patients with Graves disease.

Surgery

Either subtotal or total thyroidectomy is the treatment of choice for patients with very large glands and obstructive symptoms or multinodular glands, or for patients desiring pregnancy within the next year. It is essential that the surgeon be experienced in thyroid surgery. Preoperatively, patients receive 6 weeks of treatment with antithyroid drugs to ensure that they are euthyroid at the time of surgery. Two weeks before surgery, oral-saturated solution of potassium iodide is administered daily to decrease the vascularity of the gland. Permanent hypoparathyroidism and recurrent laryngeal nerve palsy occur postoperatively in less than 2% of patients.

TOXIC ADENOMA

Solitary toxic nodules, which are usually benign, occur more frequently in older patients. Clinical manifestations are

those of thyrotoxicosis. Physical examination shows a distinct solitary nodule. Laboratory investigation shows suppressed TSH and significantly elevated T_3 levels, often with only moderately elevated T_4 . Thyroid scan shows a hot nodule of the affected lobe with complete suppression of the unaffected lobe. Solitary toxic nodules are treated with radioactive iodine. However, unilateral lobectomy after the administration of antithyroid drugs to render the patient euthyroid may be required for large nodules.

TOXIC MULTINODULAR GOITER

Toxic multinodular goiter occurs in older patients with long-standing multinodular goiter, especially in patients from iodine-deficient regions who are exposed to increased dietary iodine or receive iodine-containing radiocontrast dyes. The presenting clinical features are frequently tachycardia, heart failure, and arrhythmias.

Physical examination shows a multinodular goiter. The diagnosis is confirmed by laboratory features of suppressed TSH, elevated T_3 and T_4 , and a thyroid scan with multiple functioning nodules. The treatment of choice is often ^{131}I ablation. It is especially effective in patients with small glands and a high radioactive uptake.

SUBCLINICAL HYPERTHYROIDISM

In subclinical hyperthyroidism, T_4 and T_3 levels are normal with a suppressed TSH. The causes of this condition include early presentation of all forms of hyperthyroidism, including Graves disease, toxic adenoma, and toxic multinodular goiter. Because these patients, especially those who are older, are at an increased risk for developing cardiac dysrhythmias, many patients with a persistently suppressed TSH should be treated with thiocarbamide drugs or radioactive iodine. A decreased bone mineral density is another indication for treatment.

THYROIDITIS

Thyroiditis may be classified as acute, subacute, or chronic. Although thyroiditis may eventually result in clinical hypothyroidism, the initial presentation is often that of hyperthyroidism as a result of acute release of T_4 and T_3 . Hyperthyroidism caused by thyroiditis can be readily differentiated from other causes of hyperthyroidism by suppressed uptake of radioactive iodine, reflecting decreased hormone production by damaged cells.

A rare disorder, acute suppurative thyroiditis, exhibits high fever, a redness of the overlying skin, and thyroid gland tenderness; it may be confused with subacute thyroiditis. If blood cultures are negative, needle aspiration should identify the organism. Intensive antibiotic treatment and, occasionally, incision and drainage are required.

Subacute Thyroiditis

Subacute thyroiditis (de Quervain or granulomatous thyroiditis) is an acute inflammatory disorder of the thyroid gland, probably secondary to viral infection, which resolves completely in 90% of cases. Patients with subacute thyroiditis complain of fever and anterior neck pain. The patient may have symptoms and signs of hyperthyroidism. The

classic feature on physical examination is an exquisitely tender thyroid gland. Laboratory findings vary with the course of the disease. Initially, the patient may be symptomatically thyrotoxic with elevated serum T_4 , depressed serum TSH, and low radioactive iodine uptake on scan. Subsequently, the thyroid status will fluctuate through euthyroid and hypothyroid phases and may return to euthyroidism. An increase in radioactive iodine uptake on the scan reflects recovery of the gland. Treatment usually includes nonsteroidal anti-inflammatory drugs, but a short course of prednisone may be required if pain and fever are severe. During the hypothyroid phase, replacement therapy with levothyroxine may be indicated.

Postpartum thyroiditis resembles subacute thyroiditis in its clinical course. It usually occurs within the first 6 months after delivery and goes through the triphasic course of hyperthyroidism, hypothyroidism, and then euthyroidism, or it may develop with only hypothyroidism. Some patients have an underlying chronic thyroiditis.

Chronic Thyroiditis

Chronic thyroiditis (Hashimoto or lymphocytic thyroiditis) from destruction of normal thyroidal architecture by lymphocytic infiltration results in hypothyroidism and goiter. Riedel struma is probably a variant of Hashimoto thyroiditis, characterized by extensive thyroid fibrosis resulting in a rock-hard thyroid mass. Hashimoto thyroiditis is more common in women and is the most common cause of goiter and hypothyroidism in the United States. Occasionally, patients with Hashimoto thyroiditis may have transient hyperthyroidism with low radioactive iodine uptake, owing to the release of T_4 and T_3 into the circulation. Chronic thyroiditis can be differentiated from subacute thyroiditis in that the gland is nontender to palpation and antithyroid antibodies are present in high titer. Early in the disease, TgAb is significantly elevated, but it may disappear later. TPO Ab is usually present early and generally remains present for years. Radioactive iodine uptake may be high, normal, or low. Serum T_3 and T_4 levels are either normal or low; when low, the TSH is elevated. FNA of the thyroid shows lymphocytes and Hürthle cells (enlarged basophilic follicular cells). Hypothyroidism and significant glandular enlargement (goiter) are indications for levothyroxine therapy. Adequate doses of levothyroxine are administered to normalize TSH levels and shrink the goiter.

Thyrotoxicosis Factitia

Thyrotoxicosis factitia exhibits typical features of thyrotoxicosis from ingestion of excessive amounts of thyroxine, often in an attempt to lose weight. Serum T_3 and T_4 levels are elevated and TSH is suppressed, as is the serum thyroglobulin concentration. Radioactive iodine uptake is absent. Patients may require psychotherapy.

Rare Causes of Thyrotoxicosis

Struma ovarii occurs when an ovarian teratoma contains thyroid tissue, which secretes thyroid hormone. A body scan

confirms the diagnosis by demonstrating uptake of radioactive iodine in the pelvis.

Hydatidiform mole is due to proliferation and swelling of the trophoblast during pregnancy, with excess production of chorionic gonadotropin, which has intrinsic TSH-like activity. The hyperthyroidism remits with surgical and medical treatment of the molar pregnancy.

Hypothyroidism

Hypothyroidism is a clinical syndrome caused by deficiency of thyroid hormones. In infants and children, hypothyroidism causes retardation of growth and development and may result in permanent motor and mental retardation. Congenital causes of hypothyroidism include agenesis (complete absence of thyroid tissue), dysgenesis (ectopic or lingual thyroid gland), hypoplastic thyroid, thyroid dysmorphogenesis, and congenital pituitary diseases. Adult-onset hypothyroidism results in a slowing of metabolic processes and is reversible with treatment. Hypothyroidism is usually primary (thyroid failure), but it may be secondary (hypothalamic or pituitary deficiency) or the result of resistance at the thyroid hormone receptor (Table 66-4). In adults, autoimmune thyroiditis (Hashimoto thyroiditis) is the most common cause of hypothyroidism. This condition may be isolated or part

of the polyglandular failure syndrome type II (Schmidt syndrome), which also includes insulin-dependent diabetes mellitus, adrenal insufficiency, pernicious anemia, vitiligo, gonadal failure, hypophysitis, celiac disease, myasthenia gravis, and primary biliary cirrhosis. Iatrogenic causes of hypothyroidism include ^{131}I therapy, thyroidectomy, and treatment with lithium or amiodarone. Iodine deficiency or excess can also cause hypothyroidism.

CLINICAL MANIFESTATIONS

The clinical presentation of hypothyroidism (Table 66-5) depends on the age of onset and severity of thyroid deficiency. Infants with congenital hypothyroidism (also called *cretinism*) may exhibit feeding problems, hypotonia, inactivity, an open posterior fontanelle, and edematous face and hands. Mental retardation, short stature, and delayed puberty occur if treatment is delayed.

Hypothyroidism in adults usually develops insidiously. Patients often complain of fatigue, lethargy, and gradual weight gain for years before the diagnosis is established. A delayed relaxation phase of deep tendon reflexes (*hung-up reflexes*) is a valuable clinical sign characteristic of severe hypothyroidism. Subcutaneous infiltration by mucopolysaccharides, which bind water, causes the edema (termed *myxedema*) and is responsible for the thickened features and puffy appearance of patients with severe hypothyroidism (Web Fig. 66-4).

Severe untreated hypothyroidism can result in myxedema coma, characterized by hypothermia, extreme weakness, stupor, hypoventilation, hypoglycemia, and hyponatremia, and is often precipitated by cold exposure, infection, or psychoactive drugs.

LABORATORY TESTS

Laboratory abnormalities in patients with primary hypothyroidism include elevated serum TSH and low total and free T_4 . A low or low-normal morning serum TSH in the setting of hypothalamic or pituitary dysfunction characterizes secondary hypothyroidism. Often, the serum total and free T_4 levels are at the lower limits of normal.

Hypothyroidism is often associated with hypercholesterolemia and elevated creatine phosphokinase skeletal muscle (MM) fraction (the fraction representative of skeletal muscle). Anemia is usually normocytic, normochromic but may be macrocytic (vitamin B₁₂ deficiency resulting from associated pernicious anemia) or microcytic (caused by nutritional deficiencies or menstrual blood loss in women). Because TPO Ab is usually positive in Hashimoto thyroiditis, the major cause of hypothyroidism in adults, its measurement is helpful in deciding whether L-thyroxine treatment is appropriate in patients with subclinical hypothyroidism (discussed later).

DIFFERENTIAL DIAGNOSIS

Because the initial manifestations of hypothyroidism are subtle, the early diagnosis of hypothyroidism demands a high index of suggestion in patients with one or more of the signs or symptoms (see Table 66-5). Early symptoms that are often overlooked include menstrual irregularities (usually menorrhagia), arthralgias, and myalgias.

Laboratory diagnosis may be complicated by the finding of a low total T₄ in euthyroid states associated with low TBG, such as nephrotic syndrome, cirrhosis, or TBG deficiency. TSH and free T₄ levels are normal in these instances. A low total T₄ may also be found with nonthyroidal illness (*euthyroid sick syndrome*), a condition occurring in acutely ill patients. In such patients, total and occasionally free T₄ levels are low, and the serum TSH level is usually normal but may be mildly elevated. This condition may be differentiated from primary hypothyroidism by absence of a goiter, negative antithyroid antibodies, and elevated serum reverse T₃ levels as well as by clinical presentation. The thyroid hormone levels return to normal with resolution of the acute illness, and the patients do not require levothyroxine therapy.

TREATMENT

Patients with hypothyroidism should be initially treated with synthetic levothyroxine. Although T₃ is the more bioactive thyroid hormone, peripheral tissues convert T₄ to T₃ to maintain physiologic levels of the latter. Thus, administration of levothyroxine results in bioavailable T₃ and T₄. Levothyroxine has a half-life of 8 days; consequently, it needs to be given only once a day. The average replacement dose of levothyroxine for adults is 75 to 150 µg per day. In healthy adults, 1.6 µg/kg per day is an appropriate starting dose. In some older patients and patients with cardiac disease, levothyroxine should be increased gradually, starting at 25 µg daily and increasing this dose by 25 µg every 2 weeks, although most patients can safely be started on a full replacement dose. The therapeutic response to levothyroxine therapy should be monitored clinically and with serum TSH levels, which should be measured 6 weeks after a dose adjustment. TSH levels between 0.5 and 2 mU/L are optimal. Patients with secondary hypothyroidism (pituitary or hypothalamic dysfunction) should be treated with levothyroxine until their free T₄ is in the mid-normal range because TSH measurements are not useful to guide therapy in this condition.

In patients with myxedema coma, 300 to 400 mg of levothyroxine is administered intravenously as a loading dose,

followed by 50 mg daily and hydrocortisone (100 mg intravenously 3 times a day) and intravenous fluids. Steroids should be given before thyroxine in autoimmune conditions. The underlying precipitating event should be corrected. Respiratory assistance and treatment of hypothermia with warming blankets may be required. Although myxedema coma carries a high mortality rate despite appropriate treatment, many patients improve in 1 to 3 days.

Subclinical Hypothyroidism

In subclinical hypothyroidism, T₄ and T₃ levels are normal or low normal, with a mildly elevated TSH. Some of these patients will develop overt hypothyroidism. The decision about when to treat patients with a mildly elevated TSH is controversial; it is frequently recommended that patients should be treated with levothyroxine if they have a TSH greater than 5 mU/L on two occasions and either positive anti-TPO Ab test results or a goiter. If the patient does not have an appreciable goiter and has negative anti-TPO Ab results, the patient should be treated with levothyroxine only if he or she has a TSH greater than 10 mU/L on two occasions.

Goiter

Enlargement of the thyroid gland is called *goiter*. Patients with goiter may be euthyroid (simple goiter), hyperthyroid (toxic nodular goiter or Graves disease), or hypothyroid (nontoxic goiter or Hashimoto thyroiditis). Thyroid enlargement (often focal) may also be the result of a thyroid adenoma or carcinoma. In nontoxic goiter, inadequate thyroid hormone synthesis leads to TSH stimulation with resultant enlargement of the thyroid gland. Iodine deficiency (endemic goiter) was once the most common cause of nontoxic goiter. With the use of iodized salt, it is now almost nonexistent in North America.

Dietary goitrogens can cause goiter, and iodine is the most common goitrogen. Other goitrogens include lithium and vegetable products such as thioglucosides found in cabbage. Thyroid hormone biosynthetic defects can cause goiter associated with hypothyroidism or, with adequate compensation, euthyroidism.

A careful thyroid examination coupled with thyroid hormone tests can delineate the cause of the goiter. A smooth, symmetrical gland, often with a bruit, and hyperthyroidism are suggestive of Graves disease. A nodular thyroid gland with hypothyroidism and positive antithyroid antibodies is consistent with Hashimoto thyroiditis. A diffuse, smooth goiter with hypothyroidism and negative antithyroid antibodies may be indicative of iodine deficiency or a biosynthetic defect. Goiters may become very large, extend substernally, and cause dysphagia, respiratory distress, or hoarseness. An ultrasound evaluation or radioactive iodine scan delineates the thyroid gland, and a TSH level can determine the functional activity of the goiter.

Hypothyroid goiters are treated with thyroid hormone at a dose that normalizes TSH. Euthyroid goiters may be

treated with levothyroxine therapy; however, in most cases, especially with long-standing goiters, regression is unlikely. Surgery is indicated for nontoxic goiter only if obstructive symptoms develop or substantial substernal extension is present.

Solitary Thyroid Nodules

Thyroid nodules are common. They can be detected clinically in about 4% of the population and are found in about 50% of the population at autopsy. Benign thyroid nodules are usually follicular adenomas, colloid nodules, benign cysts, or nodular thyroiditis. Patients may have one prominent nodule on clinical examination, but thyroid ultrasound evaluation may reveal multiple nodules. Although most nodules are benign, a small percentage are malignant. In addition, most thyroid cancers are low-grade malignancies. History, physical examination, and laboratory tests can be helpful in differentiating benign from malignant lesions (Table 66-6). For example, lymph node involvement or hoarseness is strongly suggestive of a malignant tumor.

The major etiologic factor for thyroid cancer is childhood or adolescent exposure to head and neck radiation. Previ-

ously, radiation was used to treat an enlarged thymus, tonsillar disease, hemangioma, or acne. Recently, exposure to radiation from nuclear plants (e.g., Chernobyl, Ukraine) has contributed to an increased incidence of thyroid cancer. Patients with a history of irradiation should have a baseline thyroid ultrasound and their thyroid carefully palpated every 1 to 2 years.

A dominant nodule (>1–1.5 cm) or nodules with ultrasound features compatible with neoplasia should undergo FNA, which is a safe procedure that has reduced the need for surgical excision. An expert cytologist can identify most benign lesions (75% of all biopsies). In addition, malignant lesions (5% of biopsies), such as papillary, anaplastic, and medullary carcinoma, can be specifically identified. Follicular neoplasms, however, cannot be diagnosed as benign or malignant by FNA; a cytology report of follicular neoplasia, along with “suspicious” cytology, requires surgical excision. However, if the patient has a follicular lesion and a suppressed TSH, a thyroid scan should be performed because hot nodules are rarely malignant.

Although in the past benign thyroid nodules were treated with levothyroxine suppression, this is no longer recommended because it is uncommon for thyroid nodules to shrink substantially with levothyroxine.

Table 66-6 High-Risk Factors for Malignancy in a Thyroid Nodule

History

- Head and neck irradiation
- Exposure to nuclear radiation
- Rapid growth
- Recent onset
- Young age
- Male sex
- Familial incidence (medullary and about 5% of papillary)

Physical Examination

- Hard consistency of nodule
- Fixation of nodule
- Lymphadenopathy
- Vocal cord paralysis
- Distant metastasis

Laboratory and Imaging

- Elevated serum calcitonin
- Cold nodule on technetium scan
- Solid lesion with microcalcifications on ultrasonography

Thyroid Carcinoma

The types and characteristics of thyroid carcinomas are presented in Table 66-7. Papillary carcinoma is associated with local invasion and lymph node spread. Poor prognosis is associated with thyroid capsule invasion, size greater than 2.5 cm, age at onset older than 45 years, tall cell variant, and lymph node involvement. Follicular carcinoma is slightly more aggressive than papillary carcinoma and can spread by local invasion of lymph nodes or hematogenously to bone, brain, or lung. Many tumors show both papillary and follicular cell types. Patients may exhibit metastases before diagnosis of the primary thyroid lesion. Anaplastic carcinoma tends to occur in older individuals, is very aggressive, and rapidly causes pain, dysphagia, and hoarseness.

Medullary thyroid carcinoma is derived from calcitonin-producing parafollicular cells and is more malignant than papillary or follicular carcinoma. It is multifocal and spreads both locally and distally. It may be either sporadic or familial. When familial, it is inherited in an autosomal dominant

Table 66-7 Characteristics of Thyroid Cancers

Type of Cancer	Percentage of Thyroid Cancers	Age of Onset (yr)	Treatment	Prognosis
Papillary	80	40-80	Thyroidectomy, followed by radioactive iodine ablation	Good
Follicular	15	45-80	Thyroidectomy, followed by radioactive iodine ablation	Fair to good
Medullary	3	20-50	Thyroidectomy and central compartment lymph node dissection	Fair
Anaplastic	1	50-80	Isthmusectomy followed by palliative x-ray treatment	Poor
Lymphoma	1	25-70	X-ray therapy and/or chemotherapy	Fair

pattern and is part of multiple endocrine neoplasia type IIA (medullary carcinoma of the thyroid, pheochromocytoma, and hyperparathyroidism) or multiple endocrine neoplasia type IIB (medullary carcinoma of the thyroid, mucosal neuromas, intestinal ganglioneuromas, marfanoid habitus, and pheochromocytoma). Elevated basal serum calcitonin levels confirm the diagnosis. Evaluation for *RET* proto-oncogene mutations should be performed in patients with medullary carcinoma, and, if present, all first-degree relatives of the patients should be examined.

TREATMENT

Lobectomy may be performed for isolated papillary microcarcinoma. However, most papillary or follicular tumors require thyroidectomy with a central compartment lymph node dissection, as well as a modified neck dissection if evidence of lateral lymph node metastases is found. After surgery, patients with low-risk, small carcinomas may be administered doses of levothyroxine sufficient to keep the TSH level in the low-normal or slightly suppressed range and monitored with serum thyroglobulin determinations and neck ultrasound examinations. Patients with large lesions and those at high risk for persistence or metastatic disease should be treated with radioactive iodine. Sufficient levothyroxine is then administered to suppress serum TSH to subnormal levels. Frequent clinical and ultrasound neck examinations for masses should be accompanied by measurement of serum thyroglobulin levels. Thyroid cancer patients are considered to have no residual disease if neck ultrasound imaging studies are negative and there is no rise in serum thyroglobulin after TSH stimulation. Recurrence

and metastases are also evaluated by ^{131}I whole-body scans carried out under conditions of TSH stimulation, which increase ^{131}I uptake by the thyroid tissue. Elevated TSH levels can be achieved by withdrawal of thyroxine supplementation for 6 weeks. As an alternative, to avoid the resultant symptomatic hypothyroidism, recombinant human TSH can be administered while the patient remains on thyroid hormone replacement. A rise in serum thyroglobulin levels suggests recurrence of thyroid cancer. Local or metastatic lesions that take up ^{131}I (whole-body scan) can be treated with radioactive iodine after the patient has stopped thyroid hormone replacement, whereas those that do not take up ^{131}I can be treated with surgical excision or local x-ray therapy.

Medullary carcinoma of the thyroid requires total thyroidectomy with removal of the central lymph nodes in the neck. Completeness of the procedure is determined by measurement of serum calcitonin, which is also used in monitoring for recurrence.

Anaplastic carcinoma is treated with isthmusectomy to confirm the diagnosis and to prevent tracheal compression, followed by palliative x-ray treatment. Thyroid lymphomas are also treated with x-ray therapy or chemotherapy, or both.

The prognosis for well-differentiated thyroid carcinomas is good. The patient's age at the time of diagnosis and sex are the most important prognostic factors. Men older than 40 years of age and women older than 50 years of age have higher recurrence and death rates than do younger patients. The 5-year survival rate for invasive medullary carcinoma is 50%, whereas the mean survival for anaplastic carcinoma is 6 months.

Prospectus for the Future

- Use of recombinant TSH in combination with radioactive iodine to treat euthyroid goiters and recurrences and metastases of thyroid cancers
- Genetic identification of patients at risk for autoimmune thyroid disease
- Differentiation of benign from malignant follicular neoplasms on FNA tissue by immunogenetic methodology
- Development of effective targeted chemotherapies for thyroid cancer

Adrenal Gland

Theodore C. Friedman

Physiology

The adrenal glands (Fig. 67-1) lie at the superior pole of each kidney and are composed of two distinct regions: the cortex and the medulla. The adrenal cortex consists of three anatomic zones: the outer *zona glomerulosa*, which secretes the mineralocorticoid aldosterone; the intermediate *zona fasciculata*, which secretes cortisol; and the inner *zona reticularis*, which secretes adrenal androgens. The adrenal medulla, lying in the center of the adrenal gland, is functionally related to the sympathetic nervous system and secretes the catecholamines epinephrine and norepinephrine in response to stress.

The synthesis of all steroid hormones begins with cholesterol and is catalyzed by a series of regulated, enzyme-mediated reactions (Fig. 67-2). Glucocorticoids affect the metabolism, cardiovascular function, behavior, and inflammatory and immune response (Table 67-1). Cortisol, the natural human glucocorticoid, is secreted by the adrenal glands in response to ultradian, circadian, and stress-induced hormonal stimulation by adrenocorticotropic hormone (ACTH). Plasma cortisol has significant circadian rhythm; levels are highest in the morning. ACTH, a 39–amino acid neuropeptide, is part of the pro-opiomelanocortin (POMC) precursor molecule, which also contains β -endorphin, β -lipotropin, corticotropin-like intermediate-lobe peptide (CLIP), and various melanocyte-stimulating hormones (MSHs). The secretion of ACTH by the pituitary gland is regulated primarily by two hypothalamic polypeptides: the 41–amino acid corticotropin-releasing hormone (CRH) and the decapeptide vasopressin. Glucocorticoids exert negative feedback on CRH and ACTH secretion. The brain hypothalamic-pituitary-adrenal (HPA) axis (Fig. 67-3) interacts with and influences the function of the reproductive, growth, and thyroid axes at multiple levels, with major participation of glucocorticoids at all levels.

The renin-angiotensin-aldosterone system (Fig. 67-4) is the major regulator of aldosterone secretion. Renal juxtaglomerular cells secrete renin in response to a decrease in circulating volume or a reduction in renal perfusion pressure, or both. Renin is the rate-limiting enzyme that cleaves

the 60-kD angiotensinogen, synthesized by the liver, to the bioinactive decapeptide angiotensin I. Angiotensin I is rapidly converted to the octapeptide angiotensin II by angiotensin-converting enzyme in the lungs and other tissues. Angiotensin II is a potent vasopressor and stimulates aldosterone production but does not stimulate cortisol production. Angiotensin II is the predominant regulator of aldosterone secretion, but plasma potassium concentration, plasma volume, and ACTH levels also influence aldosterone secretion. ACTH also mediates the circadian

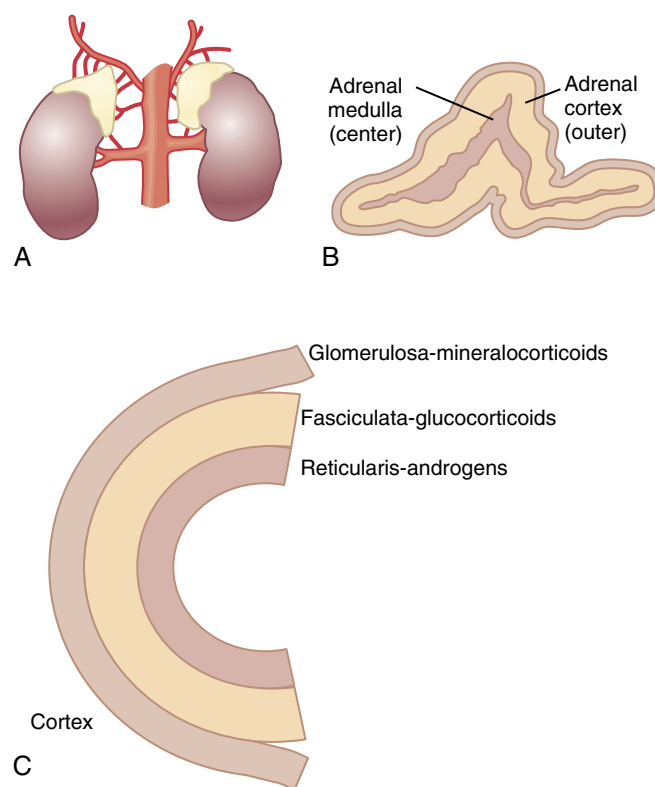

Figure 67-1 A, Anatomic location of the adrenal glands. B, Distribution of adrenal cortex and medulla. C, Zones of the adrenal cortex.

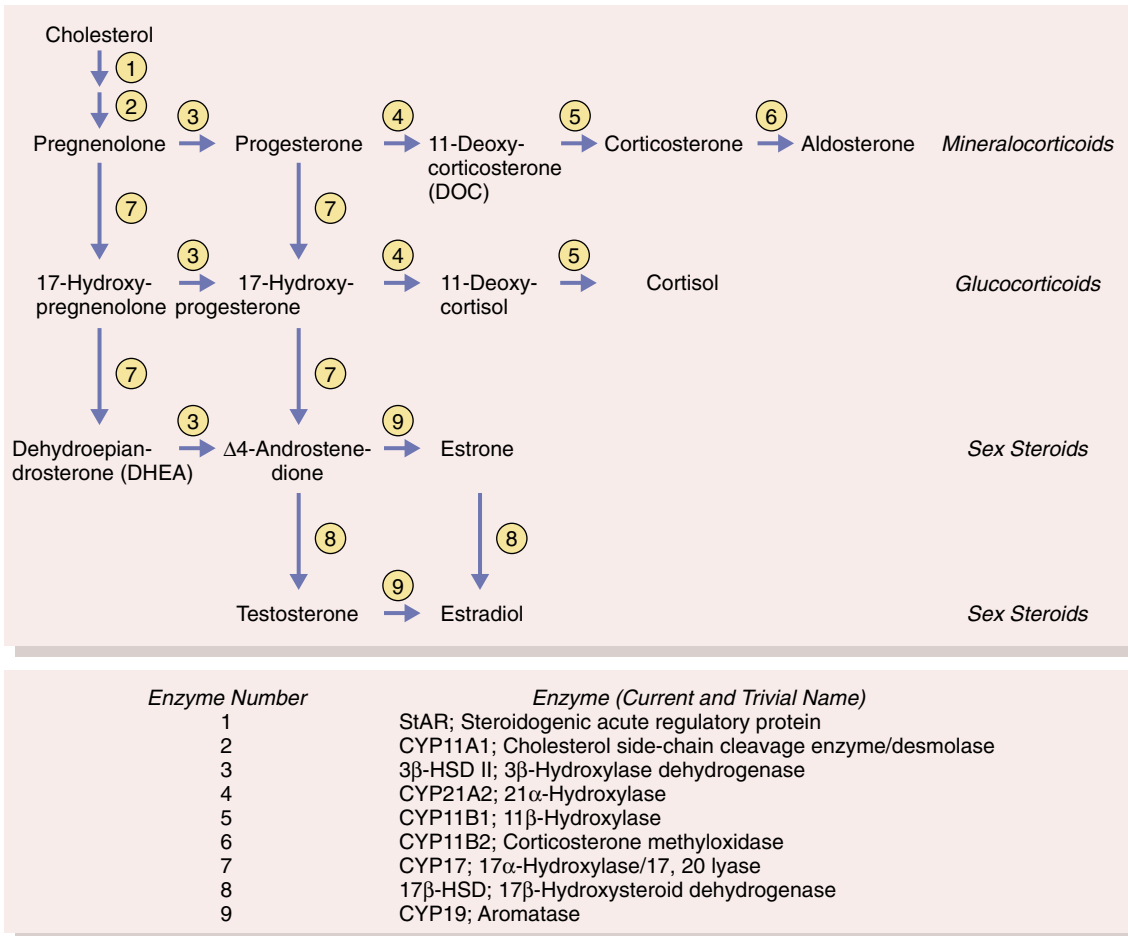

Figure 67-2 Pathways of steroid biosynthesis.

rhythm of aldosterone; as a result, the plasma concentration of aldosterone is highest in the morning. Aldosterone binds to the type I mineralocorticoid receptor. In contrast, cortisol binds to both the type I mineralocorticoid and type II glucocorticoid receptors, although the intracellular enzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD) type II, which catabolizes cortisol to inactive cortisone, limits the functional binding to the former receptor. The availability of cortisol to bind to the glucocorticoid receptor is modulated by 11 β -HSD type I, which interconverts cortisol and cortisone. Binding of aldosterone to the cytosol mineralocorticoid receptor leads to sodium (Na⁺) absorption and potassium (K⁺) and hydrogen (H⁺) secretion by the renal tubules. The resultant increase in plasma Na⁺ and decrease in plasma K⁺ provide a feedback mechanism for suppressing renin and, subsequently, aldosterone secretion.

About 5% of cortisol and 40% of aldosterone circulate in the free form; the remainder is bound to corticosteroid-binding globulin and albumin.

Adrenal androgen precursors include dehydroepiandrosterone (DHEA) and its sulfate and androstenedione. These are synthesized in the zona reticularis under the influence of ACTH and other adrenal androgen-stimulating factors. Although they have minimal intrinsic androgenic activity, they contribute to androgenicity by their peripheral conversion to testosterone and dihydrotestosterone. In men, excessive adrenal androgens have no clinical consequences;

however, peripheral conversion of excess adrenal androgen precursor secretion in women results in acne, hirsutism, and virilization. Because of gonadal production of androgens and estrogens and the secretion of norepinephrine by sympathetic ganglia, deficiencies of adrenal androgens and catecholamines are not clinically recognized.

Adrenal Insufficiency

Glucocorticoid insufficiency can be primary, resulting from the destruction or dysfunction of the adrenal cortex, or secondary, resulting from ACTH hyposecretion (Table 67-2). Autoimmune destruction of the adrenal glands (Addison disease) is the most common cause of primary adrenal insufficiency in the industrialized world, accounting for about 65% of cases. Usually both glucocorticoid and mineralocorticoid secretions are diminished in this condition and, if untreated, may be fatal. Isolated glucocorticoid or mineralocorticoid deficiency may also occur, and it is becoming apparent that mild adrenal insufficiency (similar to subclinical hypothyroidism, discussed in Chapter 66) should also be diagnosed and treated. Adrenal medulla function is usually spared. About 70% of patients with Addison disease have antiadrenal antibodies.

Tuberculosis used to be the most common cause of adrenal insufficiency. However, its incidence in the

Table 67-1 Actions of Glucocorticoids

Metabolic Homeostasis

Regulate blood glucose level (permissive effects on gluconeogenesis)
 Increase glycogen synthesis
 Raise insulin levels (permissive effects on lipolytic hormones)
 Increase catabolism, decrease anabolism (except fat), inhibit growth hormone axis
 Inhibit reproductive axis
 Stimulate mineralocorticoid receptor by cortisol

Connective Tissues

Cause loss of collagen and connective tissue

Calcium Homeostasis

Stimulate osteoclasts, inhibit osteoblasts
 Reduce intestinal calcium absorption, stimulate parathyroid hormone release, increase urinary calcium excretion, decrease reabsorption of phosphate

Cardiovascular Function

Increase cardiac output
 Increase vascular tone (permissive effects on pressor hormones)
 Increase sodium retention

Behavior and Cognitive Function**Immune System**

Increase intravascular leukocyte concentration
 Decrease migration of inflammatory cells to sites of injury
 Suppress immune system (thymolysis; suppression of cytokines, prostanoids, kinins, serotonin, histamine, collagenase, and plasminogen activator)

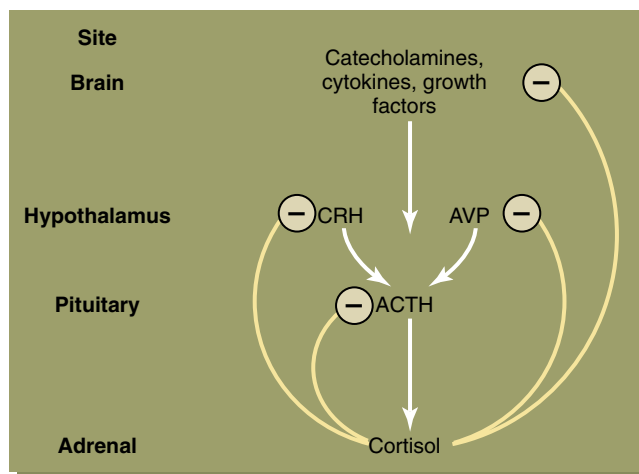

Figure 67-3 Brain hypothalamic-pituitary-adrenal axis. ACTH, adrenocorticotropic hormone; AVP, arginine vasopressin; CRH, corticotropin-releasing hormone.

industrialized world has decreased since the 1960s, and it now accounts for only 15% to 20% of patients with adrenal insufficiency; calcified adrenal glands can be observed in 50% of these patients. Rare causes of adrenal insufficiency are provided in Table 67-2. Many patients with HIV infection have decreased adrenal reserve without overt adrenal insufficiency.

Addison disease may be part of two distinct autoimmune polyglandular syndromes. The triad of hypoparathyroidism, adrenal insufficiency, and mucocutaneous candidiasis char-

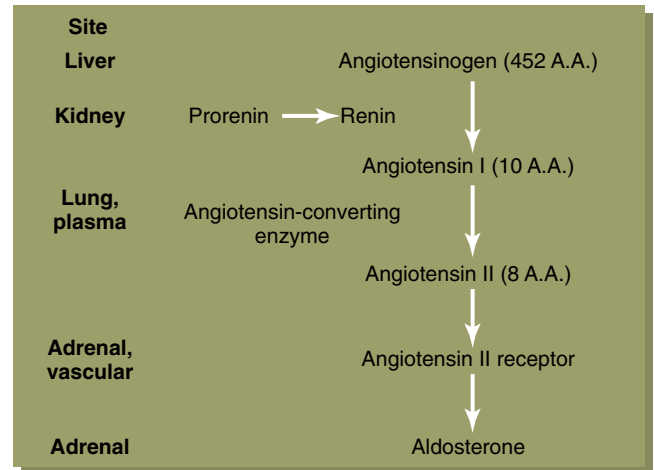

Figure 67-4 Renin-angiotensin-aldosterone axis. A.A., amino acids.

acterize type I polyglandular autoimmune syndrome, also termed *autoimmune polyendocrine-candidiasis-ectodermal dystrophy* or *autoimmune polyglandular failure syndrome*. Other, less common manifestations include hypothyroidism, gonadal failure, gastrointestinal malabsorption, insulin-dependent diabetes mellitus, alopecia areata and totalis, pernicious anemia, vitiligo, chronic active hepatitis, keratopathy, hypoplasia of dental enamel and nails, hypophysitis, asplenism, and cholelithiasis. This syndrome develops in childhood. Type II polyglandular autoimmune syndrome, also called *Schmidt syndrome*, is characterized by Addison disease, autoimmune thyroid disease (Graves disease or Hashimoto thyroiditis), and insulin-dependent diabetes mellitus. Other associated diseases include pernicious anemia, vitiligo, gonadal failure, hypophysitis, celiac disease, myasthenia gravis, primary biliary cirrhosis, Sjögren syndrome, lupus erythematosus, and Parkinson disease. This syndrome usually develops in adults.

Common manifestations of adrenal insufficiency are anorexia, weight loss, increasing fatigue, occasional vomiting, diarrhea, and salt craving. Muscle and joint pain, abdominal pain, and postural dizziness may also occur. Signs of increased pigmentation (initially most significantly on the extensor surfaces, palmar creases, and buccal mucosa) often occur secondary to the increased production of ACTH and other POMC-related peptides by the pituitary gland (**Web Fig. 67-1**). Laboratory abnormalities may include hyponatremia, hyperkalemia, mild metabolic acidosis, azotemia, hypercalcemia, anemia, lymphocytosis, and eosinophilia. Hypoglycemia may also occur, especially in children.

Acute adrenal insufficiency is a medical emergency, and treatment should not be delayed pending laboratory results. In a critically ill patient with hypovolemia, a plasma sample for cortisol, ACTH, aldosterone, and renin should be obtained, and then treatment with an intravenous bolus of 100 mg of hydrocortisone and parenteral saline administration should be initiated. A plasma cortisol concentration of more than 34 $\mu\text{g/dL}$ rules out the diagnosis of adrenal crisis, whereas a value of less than 20 $\mu\text{g/dL}$ in the setting of shock is consistent with adrenal insufficiency. A plasma cortisol value between 20 $\mu\text{g/dL}$ and 34 $\mu\text{g/dL}$ in the

ACTH, adrenocorticotropic hormone.

In a patient with chronic symptoms suggestive of adrenal insufficiency, a basal morning plasma cortisol measurement or a 1-hour cosyntropin test, or both, should be performed. In the later test, 0.25 mg ACTH (1-24) (cosyntropin) is given intravenously, and plasma cortisol is measured 0, 30, and 60 minutes later. A normal response is a plasma cortisol concentration higher than 20 μ g/dL at any time during the test. A patient with a basal morning plasma cortisol concentration of less than 5 μ g/dL and a stimulated cortisol concentration below 18 μ g/dL probably has evident adrenal insufficiency and should receive treatment. A basal plasma morning cortisol concentration between 10 and 18 μ g/dL in association with a stimulated cortisol concentration lower than 18 μ g/dL probably indicates impaired adrenal reserve and a requirement for receiving cortisol replacement under stress conditions (as described in a later discussion under "Treatment" in this chapter). Recently, a 1-mcg cosyntropin test to assess partial adrenal insufficiency has been described. This test may identify more patients who need cortisol replacement under stress conditions but should not be used to determine which patients need daily cortisol replacement.

Once the diagnosis of adrenal insufficiency is made, the distinction between primary and secondary adrenal insufficiency needs to be established. Secondary adrenal insufficiency results from inadequate stimulation of the adrenal cortex by ACTH. This can result from lesions anywhere along the hypothalamic-pituitary axis or as a sequela of prolonged suppression of the HPA axis by exogenous glucocorticoids. The presentation of secondary adrenal insufficiency is similar to that of primary adrenal insufficiency with a few important differences. Because ACTH and other POMC-related peptides are reduced in secondary adrenal insufficiency, hyperpigmentation does not occur. In addition, because mineralocorticoid levels are normal in secondary adrenal insufficiency, symptoms of salt craving, as well as the laboratory abnormalities of hyperkalemia and metabolic acidosis, are not present. However, hyponatremia is often observed as a result of increased secretion of the antidiuretic hormone (ADH) (resulting from volume depletion and ADH cosecretion with CRH), which accompanies glucocorticoid insufficiency, resulting in impaired water excretion. Because corticotropin is the most preserved of the pituitary hormones, a patient with secondary adrenal insufficiency caused by a pituitary lesion usually has symptoms or laboratory abnormalities consistent with hypothyroidism, hypogonadism, or growth hormone deficiency. To distinguish primary from secondary adrenal insufficiency, a basal morning plasma ACTH value and a standing (upright for at least 2 hours) serum aldosterone level and plasma renin activity should be measured. A plasma ACTH value of more than 20 pg/mL (normal value is 5 to 30 pg/mL) is consistent with primary adrenal insufficiency, whereas a value less than 20 pg/mL probably represents secondary adrenal insufficiency. An upright plasma renin activity of more than 3 ng/mL per hour in the setting of a suppressed aldosterone level is consistent with primary adrenal insufficiency, whereas a value less than 3 ng/mL per hour probably represents secondary adrenal insufficiency. The 1-hour cosyntropin test is suppressed in both secondary and primary adrenal insufficiency.

Secondary adrenal insufficiency occurs commonly after the discontinuation of glucocorticoids. Alternate-day

setting of a severely ill patient may indicate partial adrenal insufficiency. In severe illness, albumin and cortisol-binding globulin (CBG) are low, resulting in a low total but not free cortisol level; thus, a low total cortisol level may not be diagnostic of adrenal insufficiency in this setting.

glucocorticoid treatment, if feasible, results in less suppression of the HPA axis than does daily glucocorticoid therapy. The natural history of recovery from adrenal suppression is first a gradual increase in ACTH levels, followed by the normalization of plasma cortisol levels and then normalization of the cortisol response to ACTH. Complete recovery of the HPA axis can take up to 1 year, and the rate-limiting step appears to be recovery of the CRH neurons.

TREATMENT

After stabilization of acute adrenal insufficiency, patients with Addison disease require lifelong replacement therapy with both glucocorticoids and mineralocorticoids. Many patients are overtreated with glucocorticoids and undertreated with mineralocorticoids. Because overtreatment with glucocorticoids results in insidious weight gain and osteoporosis, the minimal cortisol dose tolerated without symptoms of glucocorticoid insufficiency (usually joint pain) is recommended. An initial regimen of 15 to 20 mg hydrocortisone first thing in the morning and 5 mg hydrocortisone at around 4:00 PM mimics the physiologic dose and is recommended. Whereas glucocorticoid replacement is fairly uniform in most patients, mineralocorticoid replacement varies greatly. The initial dose of the synthetic mineralocorticoid fludrocortisone should be 100 µg per day, and dosage should be adjusted to keep the standing plasma renin activity between 1 and 3 ng/mL per hour. A standing plasma renin activity higher than 3 ng/mL per hour, while the patient is taking the correct glucocorticoid dosage, is suggestive of undertreatment with fludrocortisone.

Under the stress of a minor illness (e.g., nausea, vomiting, fever higher than 100.5° F), the hydrocortisone dose should be doubled for as short a period as possible. The inability to ingest hydrocortisone pills may necessitate parenteral hydrocortisone administration. Patients undergoing a major stressful event (i.e., surgery necessitating general anesthesia, major trauma) should receive 150 to 300 mg parenteral hydrocortisone daily (in three divided doses) with a rapid taper to normal replacement during recovery. All patients should wear a medical information bracelet and should be instructed in the use of intramuscular emergency hydrocortisone injections.

Hyporeninemic Hypoaldosteronism

Mineralocorticoid deficiency can result from decreased renin secretion by the kidneys. Resultant hypoangiotensinemia leads to hypoaldosteronism with hyperkalemia and hyperchloremic metabolic acidosis. Plasma sodium concentration is usually normal, but total plasma volume is often deficient. Plasma renin and aldosterone levels are low and unresponsive to stimuli, including hypokalemia. Diabetes mellitus and chronic tubulointerstitial diseases of the kidney are the most common underlying conditions leading to the impairment of the juxtaglomerular apparatus. A subset of hyporeninemic hypoaldosteronism is caused by autonomic insufficiency and is a frequent cause of orthostatic hypotension. Stimuli such as upright posture or volume depletion,

mediated by baroreceptors, do not cause a normal renin response. Administration of pharmacologic agents such as nonsteroidal anti-inflammatory agents, angiotensin-converting enzyme inhibitors, and β-adrenergic antagonists can also produce conditions of hypoaldosteronism. Fludrocortisone and the α₁ agonist midodrine are effective in correcting the orthostatic hypotension and electrolyte abnormalities caused by hypoaldosteronism.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) refers to disorders of adrenal steroid biosynthesis that result in glucocorticoid and mineralocorticoid deficiencies. Because of deficient cortisol biosynthesis, a compensatory increase in ACTH occurs, inducing adrenal hyperplasia and overproduction of the steroids that precede blockage of enzyme production (see Fig. 67-2). Five major types of CAH exist, and the clinical manifestations of each type depend on which steroids are in excess and which are deficient. All these syndromes are transmitted in an autosomal recessive pattern. 21-Hydroxylase (CYP21) deficiency is the most common of these disorders and accounts for about 95% of patients of CAH. In this condition, there is a failure of 21-hydroxylation of 17-hydroxyprogesterone and progesterone to 11-deoxycortisol and 11-deoxycorticosterone, respectively, with deficient cortisol and aldosterone production. Cortisol deficiency leads to increased ACTH release, causing overproduction of 17-hydroxyprogesterone and progesterone. Increased ACTH production also leads to increased biosynthesis of androstenedione and DHEA, which can be converted to testosterone. Patients with 21-hydroxylase deficiencies can be divided into two clinical phenotypes: classic 21-hydroxylase deficiency, usually diagnosed at birth or during childhood, and late-onset 21-hydroxylase deficiency, which develops during or after puberty. Two thirds of the patients with classic 21-hydroxylase deficiency have various degrees of mineralocorticoid deficiency (salt-losing form); the remaining one third is not the salt-losing form (simple virilizing form). Both decreased aldosterone production and increased concentrations of precursors that are mineralocorticoid antagonists (progesterone and 17-hydroxyprogesterone) contribute to salt loss in the salt-losing form, in which the enzymatic block is more severe.

The most useful measurement for the diagnosis of classic 21-hydroxylase deficiency is that of plasma 17-hydroxyprogesterone. A value greater than 200 ng/dL is consistent with the diagnosis. Late-onset 21-hydroxylase deficiency represents an allelic variant of classic 21-hydroxylase deficiency and is characterized by a mild enzymatic defect. This deficiency is the most frequent autosomal recessive disorder in humans and is present especially in Ashkenazi Jews. The syndrome usually develops around the time of puberty with signs of virilization (hirsutism and acne) and amenorrhea or oligomenorrhea. This diagnosis should be considered in women with unexplained hirsutism and menstrual abnormalities or infertility. The diagnosis is made from the finding of an elevated level of plasma 17-hydroxyprogesterone (>1500 ng/dL) 30 minutes after administration of 0.25 mg of synthetic ACTH (1-24).

The aim of treatment for classic 21-hydroxylase deficiency is to replace glucocorticoids and mineralocorticoids, suppress ACTH and androgen overproduction, and allow for normal growth and sexual maturation in children. A proposed approach to treating classic 21-hydroxylase deficiency recommends physiologic replacement with hydrocortisone and fludrocortisone in all affected patients, including those with the simple virilizing form. The deleterious effects of excess androgens can then be prevented by the use of an antiandrogen agent (flutamide) and an aromatase inhibitor (testolactone) that blocks the conversion of testosterone to estrogen.

Although the traditional treatment for late-onset 21-hydroxylase deficiency is dexamethasone (0.5 mg per day), the use of an antiandrogen such as spironolactone (100 to 200 mg per day) or flutamide (125 mg per day) is probably more effective and has fewer side effects. Mineralocorticoid replacement is not needed in late-onset 21-hydroxylase deficiency.

11 β -Hydroxylase (CYP11B1) deficiency accounts for about 5% of the patients with CAH. In this syndrome, the conversions of 11-deoxycortisol to cortisol and 11-deoxycorticosterone to corticosterone (the precursor to aldosterone) are blocked. Affected patients usually have hypertension and hypokalemia because of increased amounts of precursors with mineralocorticoid activity. Virilization occurs, as with 21-hydroxylase deficiency, and a late-onset form exhibiting as androgen excess also occurs. The diagnosis is made from the finding of elevated plasma 11-deoxycortisol levels, either basally or after ACTH stimulation.

Rare forms of CAH are 3 β -HSD type II, 17 α -hydroxylase (CYP17), and steroidogenic acute regulatory protein deficiencies.

Syndromes of Adrenocortical Hyperfunction

Hypersecretion of the glucocorticoid hormone cortisol results in Cushing syndrome, a metabolic disorder affecting carbohydrate, protein, and lipid metabolism. Hypersecretion of mineralocorticoids such as aldosterone results in a syndrome of hypertension and electrolyte disturbances.

CUSHING SYNDROME

Pathophysiology

Increased production of cortisol is seen in both physiologic and pathologic states (Table 67-3). Physiologic hypercortisolism occurs in stress, during the last trimester of pregnancy, and in persons who regularly perform strenuous exercise. Pathologic conditions of elevated cortisol levels include exogenous or endogenous Cushing syndrome and several psychiatric states, including depression, alcoholism, anorexia nervosa, panic disorder, and alcohol or narcotic withdrawal.

Cushing syndrome may be caused by exogenous ACTH or glucocorticoid administration or by endogenous overproduction of these hormones. Endogenous Cushing syndrome

Edematous states (cirrhosis, nephrosis, congestive heart failure)

ACTH, adrenocorticotropin hormone; CRH, corticotropin-releasing hormone.

is either ACTH dependent or ACTH independent. ACTH dependency accounts for 85% of patients and includes pituitary sources of ACTH (Cushing disease), ectopic sources of ACTH, and, in rare instances, ectopic sources of CRH. Pituitary Cushing disease accounts for 80% of patients with ACTH-dependent Cushing syndrome. Ectopic secretion of ACTH occurs most commonly in patients with small cell

lung carcinoma. These patients are older, usually have a history of smoking, and primarily exhibit signs and symptoms of lung cancer rather than those of Cushing syndrome. Patients with the clinically apparent ectopic ACTH syndrome, in contrast, have mostly intrathoracic (lung and thymic) carcinoids. The remaining patients have pancreatic, adrenal, or thyroid tumors that secrete ACTH. ACTH-independent causes account for 15% of patients with Cushing syndrome and include adrenal adenomas, adrenal carcinomas, micronodular adrenal disease, and autonomous macronodular adrenal disease. The female-to-male ratio for noncancerous forms of Cushing syndrome is 4:1.

Clinical Manifestations

The clinical signs, symptoms, and common laboratory findings of hypercortisolism observed in patients with Cushing syndrome are listed in Table 67-4 (see also Fig. 65-2). Typically, the obesity is centripetal, with a wasting of the arms and legs, which is distinct from the generalized weight gain observed in idiopathic obesity. Rounding of the face (called *moon facies*) and a dorsocervical fat pad (*buffalo hump*) may occur in obesity that is not related to Cushing syndrome, whereas facial plethora and supraclavicular filling are more specific for Cushing syndrome. Patients with Cushing syndrome may have proximal muscle weakness; consequently, the physical finding of the inability to stand up from a squat or out of a car seat can be quite revealing. Sleep disturbances, mood swings, and other psychological abnormalities are frequently seen. Cognitive dysfunction and severe fatigue

are often found. Menstrual irregularities often precede other cushingoid symptoms in affected women. Patients of both sexes complain of a loss of libido, whereas affected men frequently complain of erectile dysfunction. Adult-onset acne or hirsutism in women should also suggest Cushing syndrome. The skin striae observed in patients with Cushing syndrome are violaceous (i.e., purple, dark red), with a width of at least 1 cm. Thinning of the skin on the top of the hands is a specific sign in younger adults with Cushing syndrome. Old pictures of patients are extremely helpful for evaluating the progression of the physical stigmata of Cushing syndrome.

Associated laboratory findings in Cushing syndrome include elevated plasma alkaline phosphatase levels, granulocytosis, thrombocytosis, hypercholesterolemia, hypertriglyceridemia, and glucose intolerance, diabetes mellitus, or both. Hypokalemia or alkalosis usually occurs in patients with severe hypercortisolism as a result of the ectopic ACTH syndrome.

Diagnosis

If the history and physical examination findings are suggestive of hypercortisolism, then the diagnosis of Cushing syndrome can usually be established by collecting urine for 24 hours and measuring urinary-free cortisol (UFC). UFC excretion reflects plasma-unbound cortisol that is filtered and excreted by the kidney. This test is extremely sensitive for the diagnosis of Cushing syndrome because in 90% of affected patients, the initial UFC level is greater than 50 μg per 24 hours when measured by high-pressure liquid chromatography (HPLC) or mass spectroscopy cortisol assays. Patients with Cushing disease usually have UFC levels between 50 and 200 μg per 24 hours, whereas patients with the ectopic ACTH syndrome and cortisol-secreting adrenal adenomas or carcinomas frequently have UFC levels greater than 200 μg per 24 hours (Fig. 67-5).

Cortisol is normally secreted in a diurnal manner; the plasma concentration is highest in the early morning (between 6:00 and 8:00 AM) and lowest around midnight. The normal 8:00 AM plasma cortisol level ranges between 8 and 25 $\mu\text{g}/\text{dL}$ and declines throughout the day. By 11:00 PM, the values are usually less than 5 $\mu\text{g}/\text{dL}$. Most patients with Cushing syndrome lack this diurnal variation. Thus, although their morning cortisol levels may be normal, their evening concentrations are significantly higher. Evening or night values greater than 50% of the morning values are consistent with Cushing syndrome. Measurement of random morning cortisol levels is not particularly helpful.

The overnight dexamethasone suppression test has been widely used as a screening test to evaluate patients who may have hypercortisolism. Dexamethasone, 1 mg, is given orally at 11:00 PM, and plasma cortisol is measured the following morning at 8:00 AM. A morning plasma cortisol level greater than 3 mcg/dL suggests hypercortisolism. This test produces a significant number of both false-positive and false-negative results, but is still recommended by the 2008 Endocrine Society consensus guidelines.

Because of the difficulty of obtaining nighttime plasma cortisol levels, measurement of late-night salivary cortisol has been developed to assess hypercortisolism. Late-night salivary cortisol reflects circulating free cortisol and can be obtained by the patient on one or more occasions and mailed

to a reference laboratory. This test appears to have a high degree of sensitivity and specificity for the diagnosis of Cushing syndrome. Growing evidence suggests that a large number of patients found to have Cushing syndrome have cortisol levels that are elevated on some occasions but not on all occasions. For this reason, multiple measurements of UFC or salivary cortisol may be needed to both diagnose and exclude Cushing syndrome, especially in subjects with suggestive signs and symptoms of hypercortisolism. Thus, both positive and negative tests of hypercortisolism need confirmation before proceeding to the differential diagnosis of Cushing syndrome.

Differential Diagnosis

Once the diagnosis of Cushing syndrome is established, the cause of the hypercortisolism needs to be ascertained, which is accomplished by biochemical studies that evaluate the feedback regulation of the HPA axis, by venous sampling techniques, and by imaging procedures. The initial approach is to measure basal ACTH levels that are normal or elevated in Cushing disease and the ectopic ACTH syndrome but are suppressed in primary adrenal Cushing syndrome. Patients with a suppressed ACTH level can proceed to adrenal imaging studies. To distinguish between Cushing disease and the ectopic ACTH syndrome, the high dose or 8-mg overnight dexamethasone suppression test, ovine CRH (oCRH) test, and bilateral simultaneous inferior petrosal sinus sampling are used.

In the dexamethasone suppression test (Liddle test), 0.5 mg of dexamethasone is given orally every 6 hours for 2 days, followed by 2 mg of dexamethasone every 6 hours for another 2 days. On the second day of the high dose of dexamethasone, UFC is suppressed to less than 10% of that of the baseline collection in patients with pituitary adenomas but not in patients with the ectopic ACTH syndrome or adrenal cortisol-secreting tumors. Although the Liddle test is often helpful in establishing the cause of Cushing syndrome, it has some disadvantages. The test requires accurate measurement of urine collections, often necessitating inpatient hospitalization. In about 50% of patients with bronchial carcinoids causing ectopic ACTH production, cortisol secretion is suppressible by high-dose dexamethasone, which yields a false-positive result. In addition, because patients with Cushing syndrome are often episodic secretors of corticosteroids, considerable variation in daily UFC excretion can occur, and false results can be obtained. Therefore, the Liddle test should be interpreted cautiously and other confirmatory tests should be performed before surgery is recommended.

An overnight high-dose dexamethasone suppression test is helpful in establishing the cause of Cushing syndrome. In this test a baseline 8:00 AM cortisol level is measured, and then 8 mg of dexamethasone is given orally at 11:00 PM. At 8:00 AM the following morning, a plasma cortisol measurement is obtained. Suppression, which would occur in patients with pituitary Cushing disease, is defined as a decrease in plasma cortisol to less than 50% of the baseline level. Few patients with bronchial carcinoid have been examined; as a result, the suppressibility of these tumors by high-dose overnight dexamethasone is not well established.

The oCRH test can also be used to establish the cause of Cushing syndrome. Pituitary corticotrophs of normal indi-

viduals and of patients with pituitary Cushing disease respond to oCRH by increasing the secretion of ACTH and therefore cortisol. Thus, the oCRH test cannot be used to distinguish normal persons from patients with pituitary Cushing disease. Patients with cortisol-secreting adrenal tumors have low or undetectable concentrations of ACTH that do not respond to the oCRH test. Patients with ectopic ACTH secretion have high basal ACTH levels that do not increase with the oCRH test. In patients with both the ectopic ACTH syndrome and primary adrenal hypercortisolism, cortisol levels do not change in response to the oCRH test. Discrepancies between the oCRH and dexamethasone tests necessitate further work-up to ascertain the diagnosis.

Bilateral inferior petrosal sinus sampling (BIPSS) is an accurate and safe procedure for distinguishing pituitary Cushing disease from the ectopic ACTH syndrome. Venous blood from the anterior lobe of the pituitary gland empties into the cavernous sinuses and then into the superior and inferior petrosal sinuses. Venous plasma samples for ACTH determination are obtained from both inferior petrosal sinuses, along with a simultaneous peripheral sample, both before and after intravenous bolus administration of CRH. In baseline measurements an ACTH concentration gradient of 1.6 or more between a sample from either of the petrosal sinuses and the peripheral sample is strongly suggestive of pituitary Cushing disease, whereas patients with the ectopic ACTH syndrome or adrenal adenomas have no ACTH gradient between their petrosal and peripheral samples. After CRH administration, a central-to-peripheral gradient of more than 3.2 is consistent with pituitary Cushing disease. The use of CRH has enabled complete distinction of pituitary Cushing disease from nonpituitary Cushing syndrome. An ACTH gradient ipsilateral to the side of the tumor is found in 70% to 80% of patients sampled. Although BIPSS requires an experienced radiologist in petrosal sinus sampling, this procedure is available at many tertiary care facilities.

Imaging of the pituitary gland by magnetic resonance imaging (MRI) with gadolinium is the preferred procedure for localizing a pituitary adenoma. In many centers, a *dynamic* MRI is performed, which visualizes the pituitary as the gadolinium enters and leaves the gland. This test detects about 60% to 90% of pituitary ACTH-secreting tumors and can detect many pituitary tumors as small as 2 mm in diameter. About 10% of normal individuals may have a nonfunctioning pituitary adenoma found on a pituitary MRI. It is therefore recommended that pituitary imaging not be the sole criterion for the diagnosis of pituitary Cushing disease.

Treatment

The preferred treatment for all forms of Cushing syndrome is appropriate surgery. Pituitary Cushing disease is best treated by trans-sphenoidal surgery. When the operation is performed by an experienced neurosurgeon, the cure rate is higher than 80%. Trans-sphenoidal surgery carries very low rates of morbidity and mortality. Growth hormone and androgen deficiency in both sexes are the most common complications of surgery. Other complications (e.g., meningitis, cerebrospinal fluid leakage, optic nerve damage, isolated thyrotropin deficiency) are uncommon. Patients who have failed initial pituitary surgery or have recurrent Cushing disease may be treated with either pituitary irradiation or

bilateral adrenalectomy. Irradiation has more long-term complications than trans-sphenoidal surgery and results in curing about 60% of patients, but it may take up to 5 years to render a person eucortisolemic. Panhypopituitarism eventually develops in almost all these patients; consequently, growth hormone, thyroid, gonadal, and even steroid replacement may be needed. A more appealing option for patients with Cushing disease who remain hypercortisolemic after pituitary surgery is bilateral adrenalectomy, followed by lifelong glucocorticoid and mineralocorticoid replacement therapy. About 10% of patients with Cushing disease who undergo bilateral adrenalectomy develop Nelson syndrome, which is an ACTH-secreting macroadenoma that often causes visual field deficits and hyperpigmentation. The incidence of Nelson syndrome is reduced if patients undergo pituitary irradiation.

In patients with the ectopic ACTH syndrome, it is hoped that the tumor is localized by appropriate scans and can be removed surgically. A unilateral adrenalectomy is the treatment of choice in patients with a cortisol-secreting adrenal adenoma. Patients with cortisol-secreting adrenal carcinomas initially should also be managed surgically; however, they have a poor prognosis, with only 20% surviving more than 1 year after diagnosis.

Medical treatment for hypercortisolism may be needed to prepare those patients for surgery who are undergoing or have undergone pituitary irradiation and are awaiting its effects or who are not surgical candidates or who elect not to have surgery. Ketoconazole, o,p'-DDD, metyrapone, aminoglutethimide, mifepristone, and trilostane are the most commonly used agents for adrenal blockade and can be used alone or in combination.

PRIMARY MINERALOCORTICOID EXCESS

Pathophysiology

Increased mineralocorticoid activity is exhibited by salt retention, hypertension, hypokalemia, and metabolic alkalosis. The causes of primary aldosteronism (see Table 67-3) are aldosterone-producing adenoma (75%), bilateral adrenal hyperplasia (25%), adrenal carcinoma (1%), and glucocorticoid-remediable hyperaldosteronism (<1%). The adrenal enzyme defects—11 β -HSD type II, 11 β -hydroxylase, and 17 α -hydroxylase deficiencies and apparent mineralocorticoid excess (from licorice or carbenoxolone ingestion, which inhibits 11 β -HSD type II, or from a congenital defect in this enzyme) are also states of functional mineralocorticoid overactivity. Secondary aldosteronism (see Table 67-3) results from an overactive renin-angiotensin system.

Primary aldosteronism is usually recognized during evaluation of hypertension or hypokalemia and represents a potentially curable form of hypertension. Up to 5% of patients with hypertension have primary aldosteronism. These patients are usually between the ages of 30 and 50 years, and the female-to-male ratio is 2:1.

Clinical Manifestations

Hypertension, hypokalemia, and metabolic alkalosis are the main clinical manifestations of hyperaldosteronism; most of the presenting symptoms are related to hypokalemia. Symptoms in patients with mild hypokalemia are fatigue, muscle weakness, nocturia, lassitude, and headaches. If more severe

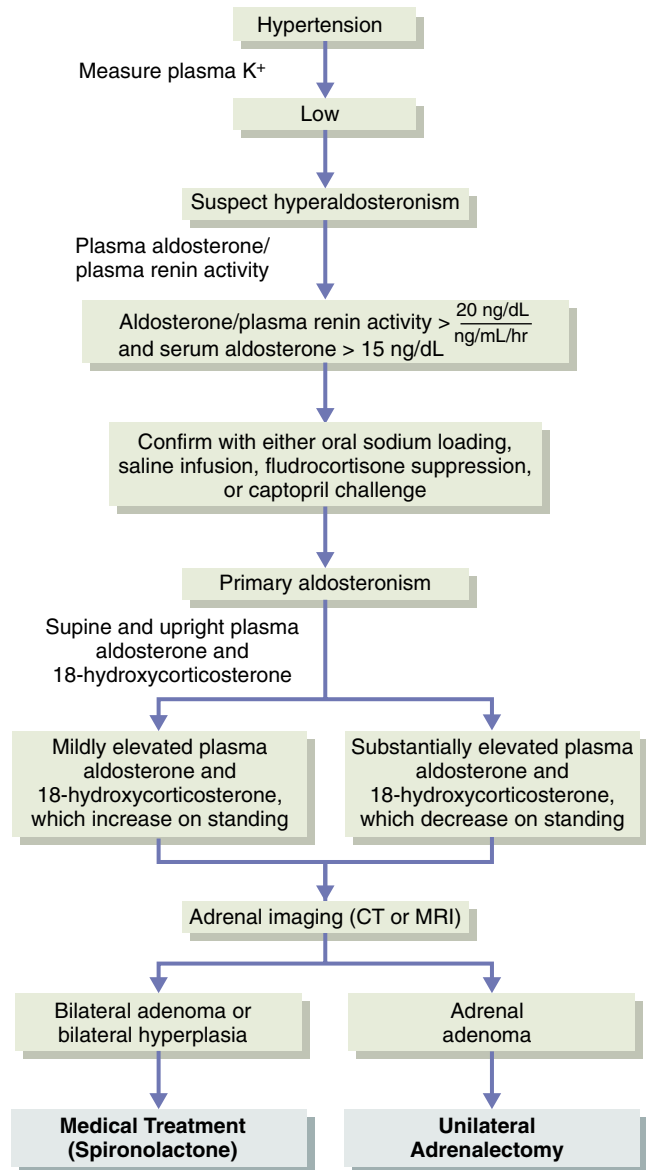

Figure 67-6 Flowchart for evaluating a patient with probable primary hyperaldosteronism. CT, computed tomography; MRI, magnetic resonance imaging.

hypokalemia exists, polydipsia, polyuria, paresthesias, and even intermittent paralysis and tetany can occur. Blood pressure can range from being minimally elevated to very high. A positive Trousseau or Chvostek sign may occur as a result of metabolic alkalosis.

Diagnosis and Treatment

Initially, hypokalemia in the presence of hypertension must be documented (Fig. 67-6). The patient must have adequate salt intake and discontinue diuretics before potassium measurement. If hypokalemia is found under these conditions and the patient is taking spironolactone, then it should be stopped, and a morning plasma aldosterone level and a plasma renin activity (PRA) should be measured. A serum aldosterone-to-PRA ratio greater than 20 ng/dL per hour and a serum aldosterone level greater than 15 ng/dL suggest the diagnosis of hyperaldosteronism. Following the finding of an elevated serum aldosterone/PRA ratio, confirmatory tests for hyperaldosteronism should be performed. These

include oral sodium loading, saline infusion, fludrocortisone suppression or captopril challenge.

Once the diagnosis of primary aldosteronism has been demonstrated, distinguishing between an aldosterone-producing adenoma and a bilateral hyperplasia is important because the former is treated with surgery and the latter is treated medically. In the initial test (a postural challenge), an 8:00 AM supine blood sample is drawn for plasma aldosterone, 18-hydrocorticosterone, renin, and cortisol measurement. The patient then stands for 2 hours, and an upright sample is drawn for measurement of the same hormones. A basal plasma aldosterone level of less than 20 ng/dL is usually found in patients with bilateral hyperplasia, and a value greater than 20 ng/dL suggests the diagnosis of adrenal adenoma. In bilateral hyperplasia, plasma aldosterone often increases as a result of the increase in renin in response to the upright position, whereas in adenoma, plasma aldosterone levels usually fall as a result of decreased stimulation by ACTH at 10:00 AM in comparison with ACTH stimulation at 8:00 AM. At 8:00 AM, a plasma 18-hydroxycorticosterone level of greater than 50 ng/dL that falls with upright posture occurs in most patients with an adenoma, whereas an 8:00 AM level less than 50 ng/dL that rises with upright posture occurs in most patients with bilateral hyperplasia.

A computed tomography (CT) scan of the adrenal glands should be performed to localize the tumor. The patient should undergo unilateral adrenalectomy if a discrete adenoma is observed in one adrenal gland, if the contralateral gland is normal, and if biochemical test results are consistent with an adenoma. Patients in whom biochemical study findings are consistent with an adenoma but CT results are consistent with bilateral disease should undergo adrenal venous sampling for aldosterone and cortisol measurement. Patients in whom biochemical and localization study findings are consistent with bilateral hyperplasia should be treated medically, usually with eplerenone or spironolactone. Those in whom biochemical study results are consistent with bilateral hyperplasia should also be evaluated for dexamethasone-suppressible hyperaldosteronism by receiving a trial of dexamethasone, which reverses the hyperaldosteronism in this rare autosomal dominant disorder.

Hyperaldosteronism and hypertension secondary to activation of the renin-angiotensin system can occur in patients with accelerated hypertension, in those with renovascular hypertension, in those receiving estrogen therapy, and rarely in patients with renin-secreting tumors. Hyperaldosteronism without hypertension occurs in patients with Bartter syndrome, sodium-wasting nephropathy, and renal tubular acidosis, as well as those who abuse diuretics or laxatives.

Adrenal Medullary Hyperfunction

The adrenal medulla synthesizes the catecholamines norepinephrine, epinephrine, and dopamine from the amino acid tyrosine. Norepinephrine, the major catecholamine produced by the adrenal medulla, has predominantly α -agonist actions, causing vasoconstriction. Epinephrine acts primarily on the β receptors, having positive inotropic and chronotropic effects on the heart, causing peripheral vasodilation and increasing plasma glucose concentrations in response to

hypoglycemia. The action of circulating dopamine is unclear. Whereas norepinephrine is synthesized in the central nervous system and sympathetic postganglionic neurons, epinephrine is synthesized almost entirely in the adrenal medulla. The adrenal medullary contribution to norepinephrine secretion is relatively small. Bilateral adrenalectomy results in only minimal changes in circulating norepinephrine levels, although epinephrine levels are dramatically reduced. Thus, hypofunction of the adrenal medulla has little physiologic effect, whereas hypersecretion of catecholamines produces the clinical syndrome of pheochromocytoma.

PHEOCHROMOCYTOMA

Pathophysiology

Although pheochromocytomas can occur in any sympathetic ganglion in the body, more than 90% of pheochromocytomas arise from the adrenal medulla. Most extra-adrenal tumors occur in the mediastinum or abdomen. Bilateral adrenal pheochromocytomas occur in about 5% of the cases and may occur as part of familial syndromes. Pheochromocytoma occurs as part of multiple endocrine neoplasia type IIA or IIB. The former (Sipple syndrome) is marked by medullary carcinoma of the thyroid, hyperparathyroidism, and pheochromocytoma; the latter is characterized by medullary carcinoma of the thyroid, mucosal neuromas, intestinal ganglioneuromas, marfanoid habitus, and pheochromocytoma. Pheochromocytomas are also associated with neurofibromatosis, cerebelloretinal hemangioblastosis (von Hippel-Lindau disease), and tuberous sclerosis.

Clinical Manifestations

Because most pheochromocytomas secrete norepinephrine as the principal catecholamine, hypertension (often paroxysmal) is the most common finding. Other symptoms include the triad of headache, palpitations, and sweating, as well as skin blanching, anxiety, nausea, fatigue, weight loss, and abdominal and chest pain. Emotional stress, exercise, anesthesia, abdominal pressure, or intake of tyramine-containing foods may precipitate these symptoms. Orthostatic hypotension can also occur. Wide fluctuations in blood pressure are characteristic, and the hypertension associated with pheochromocytoma usually does not respond to standard antihypertensive medicines. Cardiac abnormalities, as well as idiosyncratic reactions to medications, may also occur.

Diagnosis and Treatment

Although measurements of fractionated catecholamine and metanephrine levels in the urine are the most used screening tests, plasma-free metanephrine and normetanephrine levels are the best tests for confirming or excluding pheochromocytoma because the metabolism of catecholamines to free metanephrines is independent of catecholamine release and can be performed in the absence of hypertension and other symptoms. A plasma-free metanephrine level greater than 0.61 nmol/L and a plasma-free normetanephrine level greater than 0.31 nmol/L are consistent with the diagnosis of a pheochromocytoma. If the values are only mildly elevated, a clonidine suppression test could be performed. In this test, clonidine (0.3 mg) is given orally, and plasma catecholamines (including free metanephrine and nor-

metanephrine) are measured before and 3 hours after administration. In normal persons, catecholamine levels decrease into the normal range, whereas in patients with pheochromocytoma, levels are unchanged or increase. Once the diagnosis of pheochromocytoma is made, a CT scan of the adrenal glands should be performed. Most intra-adrenal pheochromocytomas are readily visible on this scan and enhance with contrast. If the CT scan is negative, then extra-adrenal pheochromocytomas can often be localized by iodine 131-labeled metaiodobenzylguanidine (¹³¹I-MIBG), positron emission tomography, octreotide scan, or abdominal MRI. Pheochromocytomas show a high signal intensity on T2-weighted images.

The treatment of pheochromocytoma is surgical if the lesion can be localized. Patients should undergo preoperative α blockade with phenoxybenzamine 1 to 2 weeks before surgery. β -Adrenergic antagonists should be used before or during surgery. About 5% to 10% of pheochromocytomas are malignant. ¹³¹I-MIBG or chemotherapy may be useful, but the prognosis is poor. α -Methyl-*p*-tyrosine, an inhibitor of tyrosine hydroxylase, the rate-limiting enzyme in catecholamine biosynthesis, may be used to decrease catecholamine secretion from the tumor.

INCIDENTAL ADRENAL MASS

Clinically inapparent adrenal masses are discovered inadvertently in the course of diagnostic testing or treatment for other clinical conditions that are not related to the suggestion of adrenal disease and thus are commonly known as *incidentalomas* (Web Fig. 67-2). Some of these tumors secrete a small amount of excess cortisol, leading to a condition called *subclinical Cushing syndrome*. A morning ACTH level and an overnight 1-mg dexamethasone test are recommended for patients with an adrenal incidentaloma. Patients with hypertension should also undergo measurement of serum potassium level, plasma aldosterone concentration or

plasma renin activity ratio, and urine or plasma-free metanephrines. Surgery should be considered in all patients with functional adrenal cortical tumors that are hormonally active or larger than 4 cm. Tumors not associated with hormonal secretion of less than 4 cm can be monitored with repeat imaging and hormonal assessment.

PRIMARY ADRENAL CANCER

Primary adrenal carcinomas are rare, with an incidence of 1 to 5 per million persons. The female-to-male ratio is 2.5:1, and the mean age of onset is 40 to 50 years. About 25% of patients have symptoms, including abdominal pain, weight loss, anorexia, and fever. At presentation, metastatic spread is evident in 75% of cases. In an incidentally discovered adrenal mass, large size is more likely to be malignant. For tumors that are larger than 6 cm, 25% of these are adrenocortical carcinomas, and resection is definitely recommended for tumors larger than 6 cm and often recommended for tumors greater than 4 cm. In patients who do not have a known cancer, most adrenal masses that turn out to be malignant are primary adrenocortical carcinomas, whereas in patients with a known malignancy, an adrenal mass is likely to be a metastasis in about 75% of patients. Eighty percent of primary adrenal carcinomas are functional, with glucocorticoid alone (45%) or glucocorticoid plus androgens (45%) being the most common hormones secreted.

The treatment of adrenocortical carcinomas is surgery; this includes removing the primary tumor with an adrenalectomy followed by resection of metastasis (usually lung or liver) as they are detected. These cancers are usually resistant to radiation and chemotherapy, but the adrenolytic compound, mitotane, has been shown to improve survival in patients with this tumor. Adrenocortical carcinomas carry a poor prognosis, with overall 5-year survival rates of less than 20%.

Prospectus for the Future

- Appreciation of the role tissue-specific, intracellular glucocorticoid excess plays in common diseases such as osteoporosis, depression, cardiovascular disease, diabetes, and hypertension
- Selective adrenal adenomectomy, sparing normal adrenal tissue
- Appreciation of the importance of mild (subclinical) adrenal insufficiency and excess

Male Reproductive Endocrinology

Glenn D. Braunstein

The testes are composed of Leydig (interstitial) cells that secrete testosterone and estradiol and the sperm-producing seminiferous tubules. They are regulated by the gonadotropin luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which are secreted by the anterior pituitary under the influence of the hypothalamic decapeptide gonadotropin-releasing hormone (GnRH) (Fig. 68-1). LH stimulates the Leydig cells to secrete testosterone, which feeds back in a negative fashion at the level of the pituitary and hypothalamus to inhibit further LH production. FSH stimulates sperm production through interaction with the Sertoli cells in the seminiferous tubules. Feedback inhibition of FSH is through gonadal steroids, as well as through inhibin, a glycoprotein produced by Sertoli cells.

Biochemical evaluation of the hypothalamic-pituitary-Leydig axis is carried out by the measurement of serum LH and testosterone concentrations, whereas a semen analysis and a serum FSH determination provide an assessment of the hypothalamic-pituitary-seminiferous tubular axis. The ability of the pituitary to release gonadotropins can be tested dynamically through GnRH stimulation, and the ability of the testes to secrete testosterone can be evaluated through injections of human chorionic gonadotropin (hCG), a glycoprotein hormone that has biologic activity similar to that of LH.

Hypogonadism

Either testosterone deficiency or defective spermatogenesis constitutes *hypogonadism*. Often both disorders coexist. The clinical manifestations of androgen deficiency depend on the time of onset and the degree of deficiency. Because testosterone is required for wolffian duct development into the epididymis, vas deferens, seminal vesicles, and ejaculatory ducts, as well as for virilization of the external genitalia through the major intracellular testosterone metabolite, dihydrotestosterone, early prenatal androgen deficiency leads to the formation of ambiguous genitalia and to male

pseudohermaphroditism. Androgen deficiency occurring later during gestation may result in micropenis or *cryptorchidism*, the unilateral or bilateral absence of testes in the scrotum resulting from the failure of normal testicular descent. During puberty, androgens are responsible for male sexual differentiation, which includes growth of the scrotum, epididymis, vas deferens, seminal vesicles, prostate, penis, skeletal muscle, and larynx. Additionally, androgens stimulate the growth of axillary, pubic, facial, and body hair, as well as increased sebaceous gland activity, and they are responsible through conversion to estrogens for the growth and fusion of the epiphyseal cartilaginous plates clinically seen as the *pubertal growth spurt*. Thus, prepubertal androgen deficiency leads to poor muscle development, decreased strength and endurance, a high-pitched voice, sparse axillary and pubic hair, and the absence of facial and body hair. The long bones of the lower extremities and arms may continue to grow under the influence of growth hormone, a condition leading to eunuchoid proportions in which the arm span exceeds the total height by 5 cm or more, and growth of the lower extremities is greater relative to total height. Postpubertal androgen deficiency may result in a decrease in libido, impotence, low energy, fine wrinkling around the corners of the eyes and mouth, and diminished facial and body hair.

Male hypogonadism may be classified into three categories according to the level of the defect (Table 68-1). Diseases directly affecting the testes result in *primary* or *hypogonadotropic hypogonadism*, characterized by oligospermia or azospermia and low testosterone levels but with elevations of LH and FSH because of a decrease of the negative feedback regulation on the pituitary and hypothalamus by androgens, estrogens, and inhibin. In contrast, hypogonadism from lesions in the hypothalamus or pituitary gives rise to *secondary* or *hypogonadotropic hypogonadism* because the low testosterone level or ineffective spermatogenesis is a result of inadequate stimulation of the testes by insufficient or inadequate concentrations of the gonadotropins. The third category of hypogonadism is the result of defects in androgen action.

Figure 68-1 Regulation of the hypothalamic-pituitary-testicular axis. +, Positive feedback; –, negative feedback; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

Table 68-1 Classification of Male Hypogonadism

Hypothalamic-Pituitary Disorders (Secondary Hypogonadism)

Panhypopituitarism
Isolated gonadotropin deficiency
Complex congenital syndromes
Hyperprolactinemia
Hypothalamic dysfunction

Gonadal Disorders (Primary Hypogonadism)

Klinefelter syndrome and associated chromosomal defects
Myotonic dystrophy
Cryptorchidism
Bilateral anorchia
Seminiferous tubular failure
Adult Leydig cell failure
Androgen biosynthesis enzyme deficiency

Defects in Androgen Action

Testicular feminization (complete androgen insensitivity)
Incomplete androgen insensitivity
5 α -reductase deficiency

HYPOTHALAMIC-PITUITARY DISORDERS

Panhypopituitarism occurs congenitally from structural defects or from inadequate production or the release of the hypothalamic-releasing factors. The condition may also be acquired through replacement by tumors, infarction from

vascular insufficiency, infiltrative disorders, autoimmune diseases, trauma, and infections.

Kallmann syndrome is a form of hypogonadotropic hypogonadism associated with problems in the ability to discriminate odors, either incompletely (*hyposmia*) or completely (*anosmia*). This syndrome results from a defect in the migration of the GnRH neurons from the olfactory placode into the hypothalamus. Thus, it represents a GnRH deficiency. Patients remain prepubertal, with small, rubbery testes, and they develop eunuchoidism (**Web Fig. 68-1**).

Hyperprolactinemia may result in hypogonadotropic hypogonadism because prolactin elevation inhibits normal GnRH release, decreases the effectiveness of LH at the Leydig cell level, and also inhibits some of the action of testosterone at the target organ level. Normalization of prolactin levels through withdrawal of an offending drug, by surgical removal of the pituitary adenoma, or with the use of dopamine agonists reverses this form of hypogonadism.

Weight loss or systemic illness in male patients can cause another form of secondary hypogonadism, *hypothalamic dysfunction*. This weight loss or illness induces a defect in the hypothalamic release of GnRH and results in low gonadotropin and testosterone levels. This condition is commonly observed in patients with cancer, AIDS, and chronic inflammatory processes.

PRIMARY GONADAL ABNORMALITIES

The most common congenital cause of primary testicular failure is *Klinefelter syndrome*, which occurs in about 1 of every 600 live male births and is usually caused by a maternal meiotic chromosomal nondisjunction that results in an XXY genotype. At puberty, clinical findings include the following: varying degrees of hypogonadism; gynecomastia; small, firm testes measuring less than 2 cm in the longest axis (normal testes measure 3.5 cm or greater); azoospermia; eunuchoid skeletal proportions; and elevations of FSH and LH (**Web Fig. 68-2**). Primary gonadal failure is also found in patients with another congenital condition, *myotonic dystrophy*, which is characterized by progressive weakness; atrophy of the facial, neck, hand, and lower extremity muscles; frontal baldness; and myotonia.

About 3% of full-term male infants have *cryptorchidism*, which spontaneously corrects during the first year of life in most of these children; consequently, by 1 year of age, the incidence of this condition is about 0.75%. When the testes are maintained in the intra-abdominal position, the increased temperature leads to defective spermatogenesis and oligospermia. Leydig cell function generally remains normal, and therefore adult testosterone levels are normal. *Bilateral anorchia*, also known as the vanishing testicle syndrome, is a rare condition in which the external genitalia are fully formed, thus indicating that ample quantities of testosterone and dihydrotestosterone were produced during early embryogenesis. However, the testicular tissue disappears before or shortly after birth, and the result is an empty scrotum. Differentiation from cryptorchidism can be made through an hCG stimulation test. Patients with cryptorchidism have an increase in serum testosterone after an injection of hCG, whereas patients with bilateral anorchia do not.

Acquired gonadal failure has numerous causes. The adult seminiferous tubules are susceptible to a variety of

injuries, and seminiferous tubular failure is found after infections such as mumps, gonococcal or lepromatous orchitis, irradiation, vascular injury, trauma, alcohol ingestion, and use of chemotherapeutic drugs, especially alkylating agents. The serum FSH concentrations may be normal or elevated, depending on the degree of damage to the seminiferous tubules. The Leydig cell compartment may also be damaged by these same conditions. In addition, some men experience a gradual decline in testicular function as they age, possibly because of microvascular insufficiency. The decreased testosterone production may clinically exhibit lowered libido and potency, emotional lability, fatigue, and vasomotor symptoms such as hot flushes. The serum LH concentration is usually elevated in this situation.

DEFECTS IN ANDROGEN ACTION

When either testosterone or its metabolite, dihydrotestosterone, binds to the androgen receptor in target cells, the receptor is activated and binds DNA with resulting stimulation of transcription, protein synthesis, and cell growth, which collectively constitutes androgen action. An absence of androgen receptors causes the syndrome of *testicular feminization*, a form of male pseudohermaphroditism. These genetic males have cryptorchid testes but appear to be phenotypic females. Because androgens are inactive during embryogenesis, the labial-scrotal folds fail to fuse, and a short vagina results. The fallopian tubes, uterus, and upper portion of the vagina are absent because the testes secrete müllerian duct inhibitory factor during early fetal development. At puberty, these patients have breast enlargement because the testes secrete a small amount of estradiol, and the peripheral tissues convert testosterone and adrenal androgens to estrogens. Axillary and pubic hair does not grow because androgen action is required for development. The serum testosterone concentrations are elevated as a result of continuous stimulation by LH, the concentrations of which are raised because of the inability of the testosterone to act in a negative feedback fashion at the hypothalamic level. Patients may have incomplete forms of androgen insensitivity caused by point mutations affecting the androgen receptor gene, and clinically these patients show varying degrees of male pseudohermaphroditism.

Patients who lack the 5α -reductase enzyme required to convert testosterone to dihydrotestosterone are born with a *bifid scrotum*, which reflects abnormal fusion of the labial-scrotal folds, and *hypospadias*, in which the urethral opening is in the perineal area or in the shaft of the penis. At puberty, androgen production is sufficient to partially overcome the defect; the scrotum, phallus, and muscle mass enlarge, and these patients appear to develop into physiologically normal men.

DIAGNOSIS

Figure 68-2 illustrates an algorithm for the laboratory evaluation of hypogonadism in a phenotypic man. Serum concentrations of LH, FSH, and testosterone should be obtained, and a semen analysis should be performed. A low testosterone level with low concentrations of gonadotropins indicates a hypothalamic-pituitary abnormality, which needs to be evaluated with serum prolactin determination

and radiographic examination. Elevated concentrations of gonadotropins with a normal or low testosterone level reflect a primary testicular abnormality. If no testes are palpable in the scrotum and careful *milking* of the patient's lower abdomen does not bring retractile testes into the scrotum, an hCG stimulation test should be performed. A rise in serum testosterone concentrations indicates the presence of functional testicular tissue, and a diagnosis of cryptorchidism can be made. An absence of a rise in testosterone levels suggests bilateral anorchia. Small, firm testes in the scrotum are highly suggestive of Klinefelter syndrome; this diagnosis needs to be confirmed with a chromosomal karyotype. Testes more than 3.5 cm in the longest diameter that are of normal consistency or are soft indicate postpubertal acquired primary hypogonadism. If the major abnormality is a deficient sperm count with or without an elevation of FSH, differentiation between a ductal problem and acquired primary hypogonadism must be made. When spermatozoa are present, at least the ducts emanating from one testicle are patent; this condition indicates an acquired testicular defect. If the patient has no sperm in the ejaculate, a primary testicular or ductal problem may cause this condition. The seminal vesicles secrete fructose into the seminal fluid. Therefore, the presence of fructose in the ejaculate should be followed by a testicular biopsy to determine whether the defect results from spermatogenic failure or from an obstruction of the ducts leading from the testes to the seminal vesicles. Absence of seminal fluid fructose indicates a congenital absence of the seminal vesicles and vas deferens.

MALE INFERTILITY

Infertility affects about 15% of couples, and male factors appear to be responsible in about 40% of cases. Female factors account for another 40%, whereas a couple factor is present in about 20% of cases. In addition to the defects in spermatogenesis that occur in patients with hypothalamic, pituitary, testicular, or androgen action disorders, hyperthyroidism, hypothyroidism, adrenal abnormalities, and systemic illnesses may also result in defective spermatogenesis, as can microdeletions of genetic material on the Y chromosome. Disorders of the vas deferens, seminal vesicles, and prostate may also lead to infertility, as can diseases affecting the bladder sphincter that may result in *retrograde ejaculation*, in which the sperm passes into the bladder rather than through the penis. Anatomic defects of the penis as observed in patients with hypospadias, poor coital technique, and the presence of antisperm antibodies in the male or female genital tract also are associated with infertility.

THERAPY FOR HYPOGONADISM AND INFERTILITY

Treatment of androgen deficiency in patients who have hypothalamic-pituitary or primary testicular abnormalities is best accomplished with exogenous testosterone administration, either through intramuscular injection of intermediate-acting testosterone esters or with transdermal testosterone patches or gel. Testosterone therapy increases libido, potency, muscle mass, strength, athletic endurance, and hair growth on the face and body. Side effects include

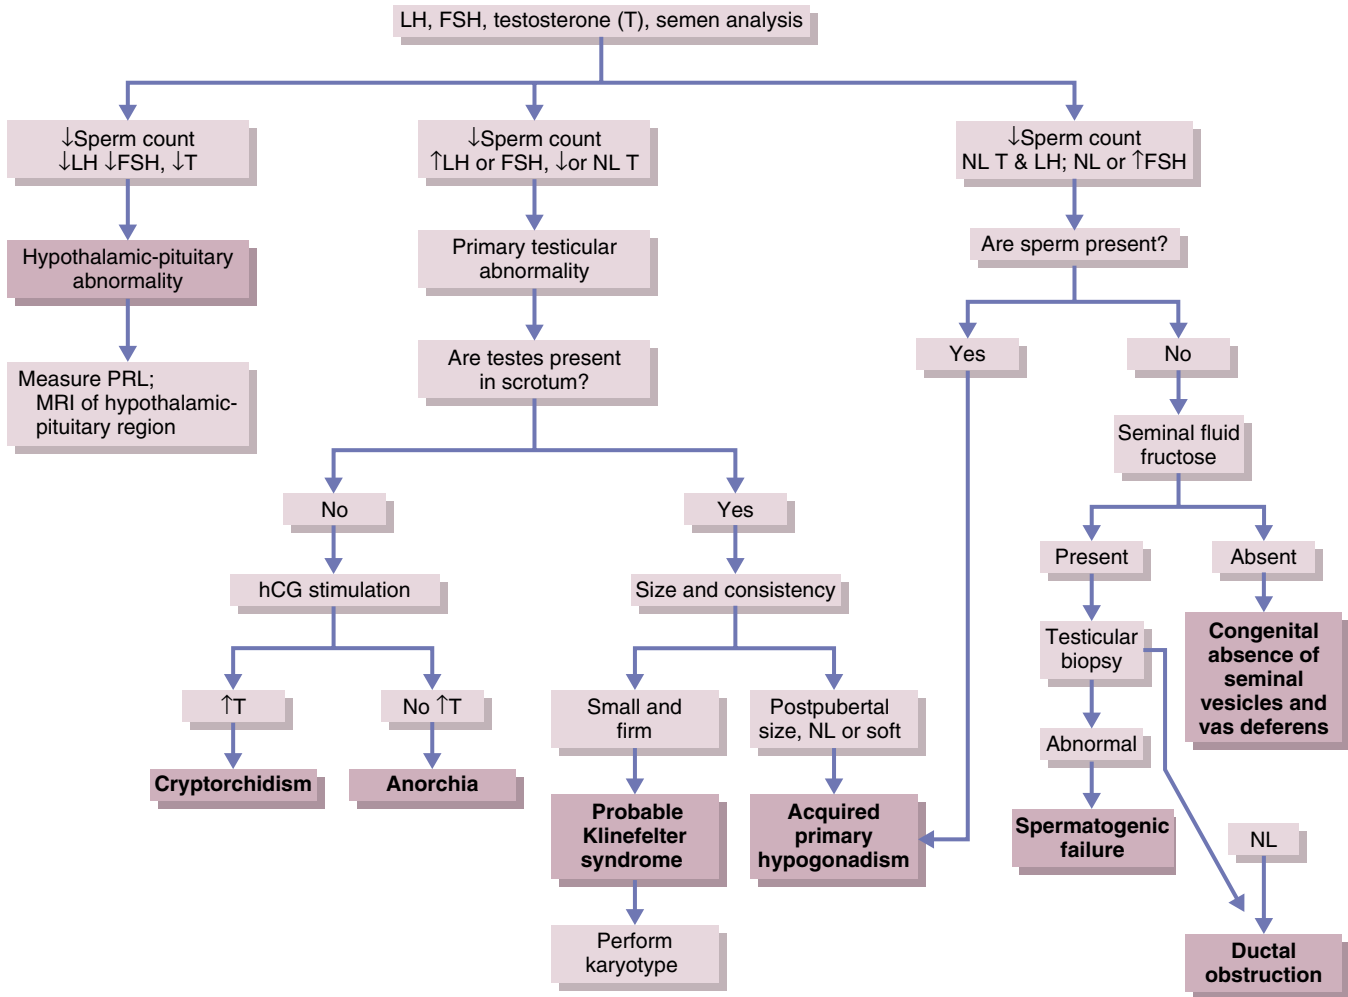

Figure 68-2 Laboratory evaluation of hypogonadism. ↑, Elevated; ↓, decreased or low; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; MRI, magnetic resonance imaging; NL, normal; PRL, prolactin.

acne, fluid retention, erythrocytosis, BPH, and, rarely, sleep apnea. This therapy is contraindicated in patients with cancer of the prostate.

If fertility is desired, patients with hypothalamic abnormalities may develop virilization and spermatogenesis with the use of GnRH given in a pulsatile fashion subcutaneously with an external pump. Direct stimulation of the testes in patients with hypothalamic or pituitary abnormalities may be accomplished with the use of exogenous gonadotropins, which increase testosterone and sperm production. If primary testicular failure is present and the patient has oligospermia, an attempt can be made to concentrate the sperm for intrauterine insemination or in vitro fertilization. If the azoospermia is due to ductal obstruction, repair of the obstruction may be undertaken, or aspiration of sperm from the epididymis may be accomplished for in vitro fertilization.

Gynecomastia

Gynecomastia refers to a benign enlargement of the male breast resulting from proliferation of the glandular

component. This common condition is found in as many as 70% of pubertal boys and in about one third of adults 50 to 80 years old. Estrogens stimulate and androgens inhibit breast glandular development. Thus, gynecomastia is the result of an imbalance between estrogen and androgen action at the breast tissue level. This condition may result from an absolute increase in free estrogens, a decrease in endogenous free androgens, androgen insensitivity of the tissues, or enhanced sensitivity of the breast tissue to estrogens. Table 68-2 lists the common conditions associated with gynecomastia.

Gynecomastia must be differentiated by mammogram from fatty enlargement of the breasts without glandular proliferation and other disorders of the breasts, especially breast carcinoma. *Male breast cancer* is usually seen as a unilateral, eccentric, hard or firm mass that is fixed to the underlying tissues. It may be associated with skin dimpling or retraction, as well as crusting of the nipple or nipple discharge. In contrast, gynecomastia occurs concentrically around the nipple and is not fixed to the underlying structures.

Painful and tender gynecomastia in a pubertal adolescent should be monitored with periodic examinations because, in most patients, pubertal gynecomastia disappears within 1

Idiopathic

year. Incidentally discovered, asymptomatic gynecomastia in an adult requires a careful assessment for the following: alcohol, drug, or medication use; liver, lung, or kidney dysfunction; and signs and symptoms of hypogonadism or hyperthyroidism. If these conditions are not present, only follow-up is required. In contrast, in an adult with recent onset of progressive painful gynecomastia, thyroid, liver, and renal function should be determined. If test results are normal, serum concentrations of hCG, LH, testosterone, and estradiol should be measured. Further evaluation should be carried out according to the scheme outlined in Figure 68-3.

Removal of the offending drug or correction of the underlying condition causing the gynecomastia may result in regression of the breast glandular tissue. If the gynecomastia persists, a trial of antiestrogens, such as tamoxifen, may be given for 3 months to see whether regression occurs. Gynecomastia that has been present for more than 1 year usually contains a fibrotic component that does not respond to medications. Therefore, correction usually requires surgical removal of the tissue.

Prospectus for the Future

- Prospective, randomized, double-blind studies that examine the risks and benefits of testosterone replacement in aging men with a low level of testosterone
- Improved definition of the molecular basis for unexplained infertility
- New genetic tools for evaluating the androgen receptor
- Improved gonadotropin assays to differentiate hypogonadotropic hypogonadism from the low serum gonadotropin concentrations found at times in normal men
- Elucidation of the roles of inhibin and leptin in gonadal function and fertility
- Improved definition of environmental toxins that affect testicular function

Definition

Diabetes mellitus comprises a heterogeneous group of metabolic diseases that are characterized by chronic hyperglycemia and disturbances in carbohydrate, lipid, and protein metabolism resulting from defects in insulin secretion, insulin action, or both. Fasting (chronic) and postprandial hyperglycemia are mainly responsible for the acute, short-term, and late complications, which affect all body organs and systems.

U.S. population statistics for 2007 show that the total prevalence of diabetes in all ages was an estimated 23.6 million people (8% of the population; 12.0 million men, 11.5 million women 20 years or older); 17.9 million diagnosed, 5.7 million undiagnosed, and 57 million with prediabetes. In people 20 years or older, the prevalence was 23.5 million (10.7%), and in those 60 years or older, the prevalence rose to 12.2 million (23.1% of all people in this age group). The incidence of diabetes in people 20 years or older was 1.6 million. The total cost of diabetes in the United States in 2007 was estimated to be \$174 billion (direct medical costs \$116 billion, and indirect costs \$58 billion), with a per capita annual health care cost of \$11,744, 3 times more than in people without diabetes. Diabetes, the sixth leading cause of death by disease in the United States, accounts for almost 18% of all deaths in people over 25 years of age, and it is the leading cause of end-stage renal disease (ESRD), new cases of blindness, and nontraumatic lower limb amputations in the United States. Cardiovascular disease is the major cause of diabetes-related death and is 2 to 5 times more common in patients with diabetes than in the general population. Life expectancy in middle-aged patients is reduced by 5 to 10 years. The prevalence of

diabetes worldwide is reaching pandemic proportions; currently, more than 150 million (300 million people by 2025), in large part because of increased obesity (65% of U.S. adults are overweight or obese), poor nutrition, and sedentary lifestyles in both adults and children.

Diagnosis

Presentation of patients with diabetes depends on the type of diabetes and the stage of the pathologic process. Patients with *type 1 diabetes mellitus* (T1DM) commonly present with classic acute symptoms of hyperglycemia: polydipsia, polyuria, weight loss, and, less frequently, polyphagia, blurred vision, and pruritus, 25% for the first time in diabetic ketoacidosis (DKA). In patients with *type 2 diabetes mellitus* (T2DM), the disease is often present for many years (average 4 to 7 years) before diagnosis, and as many as 50% have an established cardiovascular complication at the time of diagnosis. The symptoms are usually less acute than those in T1DM, and they may be accompanied by lethargy and fatigue in what was, until recently, a generally older population. With the current epidemic of obesity, there is a concomitant increase in the incidence and prevalence of T2DM in childhood and adolescence; 2 million adolescents (12 to 19 years of age) have *prediabetes*. Chronic hyperglycemia may be associated with impairment of growth, susceptibility to infections (e.g., balanitis, vaginitis), and slow wound healing. Risk factors for T2DM are listed in Table 69-1 and include sedentary lifestyle, poor nutrition, and overweight and obesity.

Diagnostic criteria for diabetes are listed in Table 69-2. Any of the three serum glucose measurements may be used for diagnosis and must be confirmed, on a subsequent day, by any one of the three. The diagnostic *fasting plasma glucose* (FPG) correlates with the 2-hour postchallenge glucose cut-point, resulting in fewer people with undiagnosed and misdiagnosed diabetes. These low cut-off diagnostic values identify critical levels at which the prevalence of microvascular complications increases dramatically, and set new levels for earlier and aggressive diabetes therapy, in an attempt to prevent these complications.

Although the *oral glucose tolerance test* (OGTT) remains the standard for diagnostic purposes, measurement of FPG by comparison, which is simpler, cheaper, equally accurate, faster to perform, more reproducible, and convenient, is used for routine diagnosis. Measurement of *glycosylated hemoglobin* (HbA_{1c}) is a useful tool for monitoring glycemic control and for making therapeutic decisions but is not recommended for diagnostic purposes. The OGTT is still used for diagnosing gestational diabetes (Table 69-3).

In the United States, estimates indicate that at least 57 million people have blood glucose levels greater than normal but less than those diagnostic for diabetes, a state referred to as *prediabetes*. These people are generally euglycemic and have abnormal glucose responses only when challenged with an OGTT. Depending on the diagnostic test, this group or metabolic stage is referred to as having either *impaired fasting glucose* (IFG) or *impaired glucose tolerance* (IGT) (see Table 69-2). This category of people may be considered to have *subclinical diabetes*, in a similar fashion to other subclinical hormone conditions (e.g., subclinical hypothyroid-

Table 69-1 Screening Criteria for Diabetes in Asymptomatic, High-Risk Adults

1. Testing for diabetes should be considered in all persons ≥ 45 years and, if normal, should be repeated at 3-year intervals.
2. Testing should be considered at a younger age (< 30 years) or performed more frequently in individuals who:
 - a. Are overweight (BMI > 25) or who have central obesity with normal BMI (18.5-24.9)
 - b. Have a habitually sedentary lifestyle
 - c. Have a first-degree relative with diabetes (i.e., parent or sibling, 45%-80% in T2DM, 5% in T1DM; equates to a 40% risk)
 - d. Are members of a high-risk ethnic population (e.g., African American, Latino, Hispanic American, Native American, Asian American, Pacific Islander)
 - e. Have delivered a baby weighing > 9 lb (4 kg), have experienced unexplained perinatal death, or have been diagnosed with gestational diabetes
 - f. Are hypertensive ($\geq 140/90$ mm Hg)
 - g. Have an HDL cholesterol level ≤ 35 mg/dL (0.9 mmol/L) and/or a triglyceride level ≥ 250 mg/dL (2.82 mmol/L)
 - h. Had, on previous testing, impaired glucose tolerance (plasma glucose ≥ 140 mg/dL [7.8 mmol/L] but < 200 mg/dL [11.1 mmol/L] during 2 hr after 75-g oral glucose tolerance test) or impaired fasting glucose (plasma glucose 100-125 mg/dL [5.6-6.9 mmol/L])
 - i. Have other clinical conditions associated with insulin resistance (e.g., PCOS, acanthosis nigricans [60%-90% in T2DM])
 - j. Have a history of vascular disease, particularly cardiovascular and cerebrovascular

BMI, body mass index (weight [kg]/height [m²]); HDL, high-density lipoprotein; PCOS, polycystic ovary syndrome; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

Adapted from the American Diabetes Association: Clinical Practice Recommendations 2008. *Diabetes Care* 31(Suppl 1), 2008.

ism or hyperthyroidism) or *preclinical* conditions (e.g., pre-hypertension). These people are at increased risk for developing T2DM (7% per year) and its complications, particularly cardiovascular (50% increased risk), and need to be identified for early counseling and treatment, which includes lifestyle modification with weight loss and increased physical activity. Obese patients younger than 60 years and at very high risk may benefit from the addition of metformin.

Screening for Diabetes

Screening for T1DM involves the measurement of autoantibody markers (antibodies to islet cells, insulin, glutamic acid decarboxylase, and tyrosine phosphatase). Several reasons mitigate against the routine screening of both healthy children in the general population and those at high risk for developing T1DM (siblings of patients with T1DM); these include lack of established cut-off values for immune markers, lack of consensus regarding effective therapy for patients with positive test results, and lack of cost-effectiveness.

Screening of certain high-risk populations for T2DM (see Table 69-1) is considered cost-effective. More than one third of people with T2DM are undiagnosed. Twenty-five to 33% of patients with T2DM have family members with diabetes. Because of the insidious nature of T2DM, patients have a

Table 69-2 Criteria for the Diagnosis of Diabetes Mellitus

Plasma Glucose	Normal	Impaired Fasting Glucose [§]	Impaired Glucose Tolerance [§]	Diabetes Mellitus
Fasting*	<100 (5.6)	≥100 and <126	—	≥126 (7.0)
2-hour postload	<140 (7.8)	—	≥140 and <200	≥200 (11.1)
Random [†]	—	—	—	≥200 with symptoms

*Fasting; no caloric intake for at least 8 hours.

[†]Random; refers to any time of day, unrelated to meals. The classic symptoms of hyperglycemia include polyuria, polydipsia, and weight loss.

[§]Prediabetes refers to impaired fasting glucose and/or impaired glucose tolerance.

The standard oral glucose tolerance test, defined by the World Health Organization, requires a 75-g anhydrous glucose load.

Numbers represent venous plasma glucose values in mg/dL. Numbers in parentheses represent venous plasma glucose values in mmol/L.

To definitively make the diagnosis of diabetes, these criteria should be confirmed on another day using any of the three tests.

Data from the American Diabetes Association: Clinical Practice Recommendations 2008. Diabetes Care 31(Suppl 1), 2008.

Table 69-3 Screening and Diagnostic Criteria for Gestational Diabetes Mellitus

Plasma Glucose	50-g Screening Test	75-g Diagnostic Test	100-g Diagnostic Test
Fasting	—	≥95	≥95 (5.3)
1 hr	≥140	≥180	≥180 (10.0)
2 hr	—	≥155	≥155 (8.6)
3 hr	—	—	≥140 (7.8)

50-g, 75-g, and 100-g refer to oral glucose loads.

Numbers represent venous plasma glucose values in mg/dL. Numbers in parentheses represent venous plasma glucose values in mmol/L.

Data from the American Diabetes Association: Clinical Practice Recommendations 2008. Diabetes Care 31(Suppl 1), 2008.

high risk for developing complications by the time of clinical diagnosis (see “Complications,” later in this chapter). Early diagnosis and treatment may reduce the burden of this disease, its complications (particularly microvascular and macrovascular disease), and associated comorbidities, such as dyslipidemia, hypertension, and obesity.

Gestational diabetes mellitus (GDM) refers to the presence of glucose intolerance that develops during pregnancy and usually returns to normal after delivery. GDM occurs in 2% to 5% of all pregnancies, but it may complicate as many as 14% in certain populations (see Table 69-1, criterion 2d) and accounts for about 90% of diabetes during pregnancy. If this condition is not diagnosed, or left untreated, the consequences for both mother and fetus may be severe. Screening for GDM is routinely performed between 24 and 28 weeks of gestation in women older than 25 years and in younger women who fulfill one or more of the criteria in Table 69-1 (2a through 2d and 2g). Women at high risk (obese, personal history of GDM, glycosuria, first-degree relative with diabetes) should be screened at their initial obstetric or prenatal visit. A positive screening test (plasma glucose ≥140 mg/dL [7.8 mmol/L] 1 hour after a 50-g glucose challenge administered to a nonfasting patient) dictates the need for diagnostic testing with a 3-hour, 100-g OGTT performed in the fasting state (≥8 hours without caloric intake). Meeting or exceeding any two or more of the plasma glucose values listed in Table 69-3 is diagnostic of GDM. Women with GDM should be reclassified 6 or more weeks postpartum (see Table 69-2). About 25% of lean women and up to 50% of obese women will go on to develop overt diabetes

(types 1 or 2), IFG, or IGT over a 20-year period. Pregnancy serves as a provocative test and not as a risk factor for the future development of diabetes.

Classification

Improved understanding of the origins and pathogenesis of diabetes has facilitated revision of the classification of diabetes mellitus (Table 69-4) from one based mainly on therapeutic considerations, such as insulin dependence or independence, to one based on etiology. Any patient with diabetes may require insulin therapy at some stage of the disease, irrespective of the classification.

TYPES 1 AND 2 DIABETES

The underlying pathologic process in most patients with T1DM (5% to 10% of people with diabetes) is autoimmune destruction of the pancreatic islet β cells with absolute loss of insulin secretion. The disease has strong human leukocyte antigen (HLA) associations and numerous antibody markers of immune destruction (Table 69-5). In a few patients with T1DM, the pathogenesis remains idiopathic. Patients with β -cell destruction or failure resulting from identifiable non-autoimmune causes are not included in this class. T2DM (90% to 95% of people with diabetes) results from variable combinations of insulin resistance and insulin secretory defects (β -cell dysfunction), with one or the other abnormality predominating in a given patient.

Distinguishing between T1DM and T2DM is not always a simple process. T2DM is diagnosed in children as young as 6 years and may account for as many as 25% to 33% of all new cases of diabetes diagnosed in adolescents 9 to 19 years of age, often associated with an increase in weight and parallel decrease in physical activity. These adolescents may even present in DKA before they ultimately achieve control of their disease with diet and oral antihyperglycemic agents. T1DM can also occur in elderly patients. This condition has been described as *latent autoimmune diabetes of adulthood* [LADA] (also known as late-onset autoimmune diabetes, or *type 1.5DM*) and may account for many insulin-requiring patients previously misclassified as T2DM. Patients with T1DM who later develop obesity, insulin resistance, and possibly metabolic syndrome and T2DM are said to have *double-double*, *hybrid*, or *type 3* diabetes.

Hyperglycemia, the metabolic hallmark of diabetes, changes in degree over time, which reflects the severity and

stage of the underlying pathologic process, which may progress, regress, or remain static, and the effectiveness of its treatment, but does not signal an alteration in the *nature* of the process.

Prediabetes is a condition (defined previously) that warrants close attention and treatment to prevent progression to T2DM and the significant cardiovascular diseases that develop in this prodromal period.

OTHER SPECIFIC TYPES OF DIABETES

These groups together account for 1% to 2% of patients with diabetes. Inheritance of *maturity-onset diabetes of the young*

(MODY types 1 to 5) is autosomal dominant, and hyperglycemia appears before the age of 25 years.

Within the small group of *genetic insulin-resistance states*, impaired insulin action is the result of either a defective insulin receptor molecule (type A insulin resistance, leprechaunism, or Rabson-Mendenhall syndrome) or abnormalities in postreceptor signal transduction pathways (lipoatrophic diabetes).

Destruction of the pancreas results in reduced insulin secretion, with subsequent development of diabetes.

Several *insulin counter-regulatory hormones* (glucagon, catecholamines, cortisol, and growth hormone) that antagonize insulin action and increase insulin resistance precipitate diabetes when they are produced in excess. Excess *aldosterone* production by a tumor, through induction of hypokalemia and increased production of *somatostatin*, may impair insulin secretion and cause diabetes. The hyperglycemia in these cases resolves after successful removal of the responsible tumor.

The mechanism of *drug- or chemical-induced diabetes* depends on the offending agent: β -cell destruction (by the rodenticide Vacor, intravenous pentamidine, or α -interferon with autoantibodies), impaired insulin action (nicotinic acid and glucocorticoids), or peripheral insulin resistance and impaired conversion of proinsulin to insulin (protease inhibitors). In some forms of immune-mediated diabetes, anti-insulin receptor antibodies may cause insulin resistance.

METABOLIC SYNDROME

Also known as the *insulin resistance syndrome*, *Reaven syndrome*, *dysmetabolic syndrome*, and *syndrome X*, the metabolic syndrome is not a subclass of diabetes mellitus,

Table 69-4 Etiologic Classification of Diabetes Mellitus

Type 1 Diabetes Mellitus

Immune mediated
Idiopathic
LADA

Type 2 Diabetes Mellitus

Other specific types
Genetic defects of β -cell function
Genetic defects in insulin action
Diseases of the exocrine pancreas
Endocrinopathies
Drug or chemical induced
Infections
Uncommon forms of immune-mediated diabetes
Other genetic syndromes sometimes associated with diabetes
Gestational diabetes mellitus

LADA, latent autoimmune diabetes of adults.

Table 69-5 General Comparison of the Two Most Common Types of Diabetes Mellitus

	Type 1	Type 2
Previous terminology	Insulin-dependent diabetes mellitus, type I, juvenile-onset diabetes	Non-insulin-dependent diabetes mellitus, type II, adult-onset diabetes
Age of onset	Usually <30 yr, particularly childhood and adolescence, but any age	Usually >40 yr, but increasingly at younger ages
Genetic predisposition	Moderate; environmental factors required for expression; 35%-50% concordance in monozygotic twins; several candidate genes proposed	Strong; 60%-90% concordance in monozygotic twins; many candidate genes proposed; some genes identified in maturity-onset diabetes of the young
Human leukocyte antigen associations	Linkage to DQA and DQB, influenced by DRB3 and DRB4 (DR2 protective)	None known
Other associations	Autoimmune; Graves disease, Hashimoto thyroiditis, vitiligo, Addison disease, pernicious anemia	Heterogeneous group, ongoing subclassification based on identification of specific pathogenic processes and genetic defects
Precipitating and risk factors	Largely unknown; microbial, chemical, dietary, other	Age, obesity (central), sedentary lifestyle, previous gestational diabetes (see Table 69-1)
Findings at diagnosis	85%-90% of patients have one and usually more autoantibodies to ICA512, IA-2, IA-2 β , GAD ₆₅ , IAA	Possibly complications (microvascular and macrovascular) caused by significant hyperglycemia in the preceding asymptomatic period
Endogenous insulin levels	Low or absent	Usually present (relative deficiency), early hyperinsulinemia
Insulin resistance	Only with hyperglycemia	Mostly present
Prolonged fast	Hyperglycemia, ketoacidosis	Euglycemia
Stress, withdrawal of insulin	Ketoacidosis	Nonketotic hyperglycemia, occasionally ketoacidosis

GAD, glutamic acid decarboxylase; IA-2, IA-2 β , insulinoma-associated protein 2 and 2 β (tyrosine phosphatases); IAA, insulin autoantibodies; ICA, islet cell antibody; ICA512, islet cell autoantigen 512 (fragment of IA-2).

although it is extremely common in patients with diabetes and affects at least 50 million people in the United States (one in three to four adults). It consists of a cluster of clinical findings and laboratory abnormalities that include obesity (central, abdominal, or visceral), increased sympathetic nervous system activity, hypertension, glucose intolerance, insulin resistance (the common etiologic factor), hyperinsulinemia (compensatory), T2DM, dyslipidemia (hypertriglyceridemia, increased small dense low-density lipoprotein [LDL₃], and decreased high-density lipoprotein [HDL]), fatty liver, enhanced postprandial lipemia, disordered fibrinolysis (elevated plasminogen activator inhibitor-1 [PAI-1], tissue-type plasminogen activator, clotting factors VII and XII, and fibrinogen, with decreased levels of antithrombotic factors C and S and antithrombin III), hyperuricemia, systemic inflammation (especially vascular), and endothelial dysfunction (**Web Table 69-1**). To date, no national or international agreement exists on the cut-points for these various components, nor a consensus regarding the definition or actual existence of a *syndrome*. Abdominal adiposity, regarded by most authorities as a prerequisite for the diagnosis, is associated with increased lipolysis, increased free fatty acids (FFAs), and tumor necrosis factor- α (TNF- α), with decreased adiponectin. This syndrome is associated with a greatly increased risk for atherosclerotic vascular disease, specifically coronary artery disease, diabetes, and polycystic ovarian syndrome (PCOS).

CARDIOMETABOLIC RISK

Obesity, insulin resistance, metabolic syndrome, T2DM, and cardiovascular disease are all interconnected through the

clusters of cardiometabolic risk factors, which include abdominal obesity, fasting hyperglycemia, hypertension, dyslipidemia (elevated LDL and triglycerides, low HDL), endothelial dysfunction, intravascular inflammation, and thrombotic tendency. Seventy to 80% of these patients will die from cardiovascular disease. To be effective, treatment needs to be initiated as early as possible and target each individual risk factor. Treatment includes lifestyle modifications, such as healthy calorie restricted diet, exercise, and weight reduction and smoking cessation. Achieving a 10% weight loss from baseline leads to improvements in lipids, blood pressure and peripheral insulin sensitivity.

Pathogenesis

TYPE 1 DIABETES

Generally, T1DM is an autoimmune disease in which some environmental insult (microbial, chemical, or dietary) triggers an autoimmune reaction in a genetically susceptible individual. HLA-DR3 or HLA-DR4 is present in 90% to 95% of patients with T1DM compared with 45% to 50% in the general population. Predominantly cell-mediated (mononuclear cells; mainly macrophages and CD8⁺ T lymphocytes) destruction of the β cells of the islets of Langerhans is associated with several autoantibodies to islet cell constituents (see Table 69-5). These antibodies, some of which may occur secondary to release of antigens following β -cell death, serve as markers of the immune destruction. Figure 69-1 illustrates how the autoimmune process may be present for several years, with competing destruction and regeneration of β cells, before the disease becomes clinically apparent. At

Figure 69-1 Natural history of type 1 diabetes mellitus. The *honeymoon* period with temporary improvement in β -cell function occurs with the initiation of insulin therapy at the time of clinical diagnosis. ICA512, islet cell autoantigen 512 (fragment of IA-2); IA-2, IA-2 β , tyrosine phosphatases; GAD, glutamic acid decarboxylase; HLA, human leukocyte antigen; ICA, islet cell antibody; IL-1, interleukin-1; NK, natural killer; Th1, subset of CD4⁺ helper T cells responsible for cell-mediated immunity; Th2, subset of CD4⁺ helper T cells responsible for humoral immunity; TNF- α , tumor necrosis factor- α .

this time, the critical mass of remaining β cells (10% to 20%) is unable to sustain compensatory insulin secretion at a level sufficient to maintain normal blood glucose values. After diagnosis and institution of insulin therapy, patients usually have some degree of recovery of β -cell function to the extent that exogenous insulin requirements drop to extremely low levels (*honeymoon* period). This period usually lasts for a couple of months but may be as long as a year. Patients should continue insulin administration throughout this time, even at these low doses. β -cell insulin secretion eventually fails completely, and, at this point, patients become insulin dependent, with DKA developing in the absence of insulin replacement.

TYPE 2 DIABETES

There is a significant but poorly defined genetic predisposition to the development of T2DM, complicated by the heterogeneous nature of the disease and the influence of acquired factors. Five main elements characterize the pathophysiology: (1) insulin resistance, (2) β -cell dysfunction, (3) dysregulated hepatic glucose production (HGP), (4) abnormal intestinal glucose absorption, and (5) obesity.

Insulin resistance results from defective intracellular signaling following binding of insulin to its receptor. This defect results in decreased intracellular glucose transporter activity. In the preclinical phase, the pancreatic β cells compensate for a genetically predetermined peripheral (skeletal muscle, adipose tissue, and liver) *insulin resistance* by producing more insulin (hyperinsulinemia) to maintain euglycemia. Some patients are identified at this stage while they are clinically asymptomatic.

With time, the β cells gradually fail to compensate for the progressive increase in insulin resistance (stage of IGT or IFG; 40% reduction of β -cell mass), and eventually hyperglycemia becomes clinically manifest as diabetes mellitus (80% to 90% reduction of β -cell mass) (Fig. 69-2). Insulin secretion continues, albeit not in the hyperinsulinemic range, with resultant relative insulin deficiency. Classically, early loss of the first phase of glucose-stimulated insulin secretion occurs (peaking at 10 minutes), with subsequent gradual loss of the second phase (starting 30 minutes after glucose stimulus and peaking at 60 minutes). Other features of *β -cell dysfunction* include dysrhythmic pulsatile insulin secretion, defective glucose potentiation of nonglucose insulin secretagogues (the incretins: glucose-

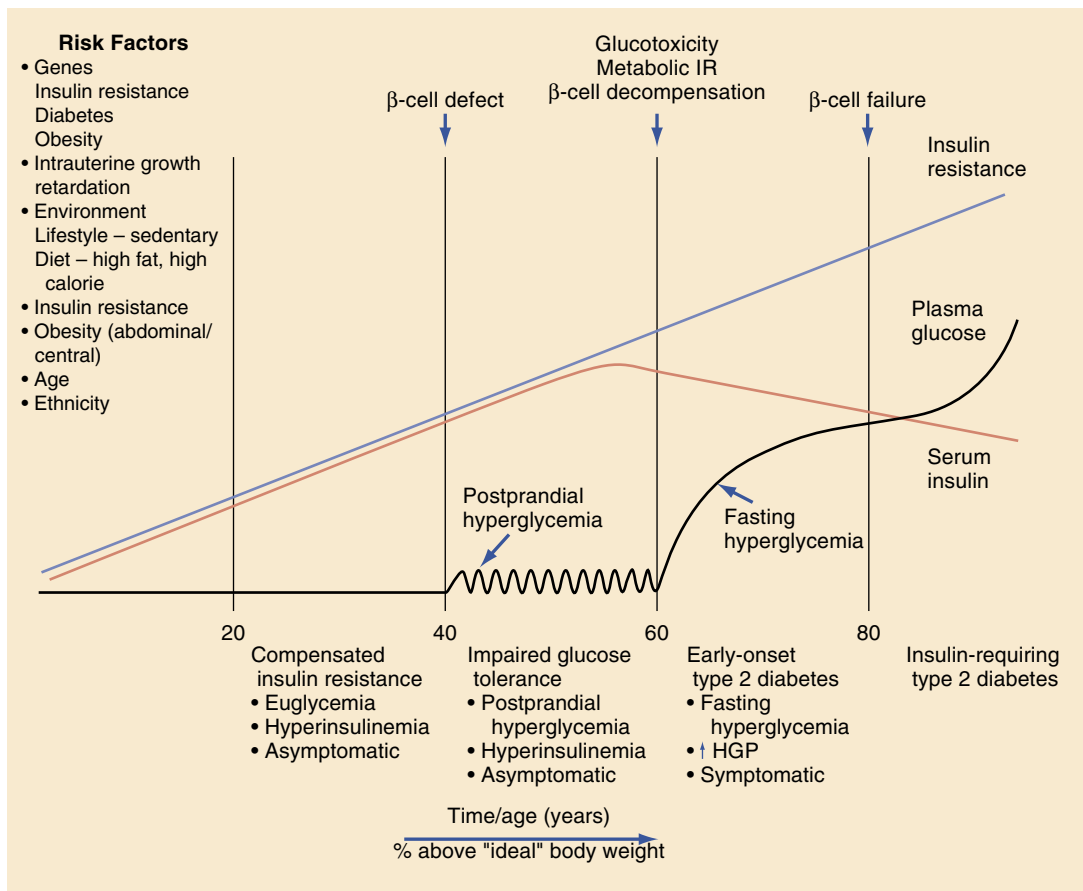

Figure 69-2 Natural history of type 2 diabetes mellitus. The numbers for percentage greater than *ideal* body weight are only approximate. Similarly, the age markers for the different phases of β -cell decompensation toward overt diabetes and an insulin-requiring state are approximate guides. Certain groups are more insulin sensitive and require a greater loss of β -cell function to precipitate diabetes than do obese insulin-resistant people, who develop diabetes after small declines in β -cell function. Use of insulin in patients with type 2 diabetes varies considerably and is not age dependent. Insulin resistance increases proportionately to adiposity, represented here by weight. HGP, hepatic glucose production; IR, insulin resistance.

dependent insulinotropic polypeptide [GIP] and glucagon-like peptide-1 [GLP-1]), increased proinsulin-to-insulin ratio (from defective protease activity), accumulation of islet amyloid polypeptide, increased glucagon secretion from islet α cells, and *glucotoxicity*. Glucotoxicity refers to the effect of chronic hyperglycemia in decreasing insulin secretion (through impaired β -cell sensitivity) and insulin activity (by increasing insulin resistance and insulin receptor tyrosine kinase activity). Glucotoxicity is a function of the duration and magnitude of the hyperglycemia and contributes to the progressive worsening of hyperglycemia. Elevated FFA levels, the result of unrestrained adipose tissue lipolysis in the relative absence of insulin, also have a toxic effect on β cells (*lipotoxicity*) and, together with intracellular protein glycation, contribute further to the failure of these cells. FFAs exacerbate hyperglycemia through increased oxidation in skeletal muscle and liver, where they decrease glucose utilization and increase gluconeogenesis, respectively. In obesity, the increased FFAs released from visceral fat stimulate increased hepatic synthesis of triglycerides and may impair first-pass hepatic metabolism of insulin, contributing to hyperinsulinemia.

Before the appearance of fasting hyperglycemia (elevated FPG), in the latter stages of compensatory hyperinsulinemia, it is possible to demonstrate *abnormal postprandial glucose (PPG) metabolism*, IGT, that is not evident clinically. Therapeutic intervention at this point may prevent or delay the onset of T2DM. The relative contributions of insulin resistance and insulin secretory defect to the pathogenesis in individual patients vary, with insulin resistance playing a dominant role in most patients who are obese (about 80% to 90% of patients in the United States) and failure of insulin secretion being more important in patients of normal weight.

Excessive HGP (25% to 50% higher than normal) results from inadequate suppression of hepatic gluconeogenesis, the result of hepatic insulin resistance, exacerbated by waning insulin secretion from failing β cells. Postprandial HGP is markedly increased, with a variable increase in the basal rate. Within the diabetic liver, decreased glycogen synthesis and increased fat synthesis also occur.

Hyperglycemia, with or without autonomic nerve involvement, may contribute to *gastric dysmotility* (symptomatic or not) and alterations in the rate and timing of glucose absorption (usually increased), with consequent exacerbation of hyperglycemia, resulting in a vicious cycle.

Endothelial dysfunction is the precursor of the extensive vasculopathy seen in patients with diabetes. FFAs that are increased in T2DM acutely impair endothelial function as well as raise blood pressure. Insulin improves endothelium-dependent vasodilation, but with insulin resistance and hyperinsulinemia, impairment of vascular nitric oxide production and insulin-induced vasodilation occur, with proliferation of vascular smooth muscle cells. Several markers of acute *inflammation* (including interleukin-6 [IL-6], C-reactive protein, and TNF- α) have been demonstrated in people with IGT, newly diagnosed diabetes, and atherosclerosis. Low-grade chronic inflammation in this group of patients is associated with insulin resistance through interference with insulin signal transduction.

Other endocrine associations in people with T2DM are subclinical hypercortisolism (7%), mainly adrenal in origin, and lowered levels of testosterone in males.

Management

GOALS

The goals of management can be divided into three stages: (1) short term, involving immediate treatment to relieve symptoms such as polydipsia, polyuria, or acute infections; (2) intermediate term, to return the patient to a physiologic state and social life that are as normal as possible; and (3) long term, to prevent the development, or delay the progression, of the complications of diabetes. People diagnosed with this chronic disease experience a range of emotions, including denial, anger, guilt, and depression, and most require some form of psychological support.

The cornerstones of a comprehensive diabetes management plan include patient education, healthy nutrition, weight control, physical activity, self-monitoring of blood glucose (SMBG), and antihyperglycemic agents when necessary. Patient education aims to *empower patients* by equipping them with the necessary knowledge about diabetes and self-management skills with which to make meaningful decisions about their health on a daily basis. Treatments need to be individualized, addressing medical, psychosocial, and lifestyle issues.

With the rapidly growing therapeutic armamentarium for the management of patients with diabetes, there are innumerable treatment algorithms. It is now possible to prescribe drugs that actually have disease modifying potentials. Certain previously automatically prescribed medications (e.g., sulfonylureas) are now giving way to drugs such as the incretins and amylin mimetics as first-line agents. The early use of insulin in T2DM patients still lags behind the early use of oral agents. Of prime importance is the need to manage each patient individually. It is now possible to fit the diabetes into the patient and not the patient into the diabetes.

BLOOD GLUCOSE MONITORING

Control of blood glucose levels is a crucial component of the diabetes management plan because hypoglycemia and hyperglycemia are major contributors to the complications of diabetes. *SMBG* with blood glucose meters, by all patients, facilitates adjustments in treatment and also acts as an educational tool for the patient. Ideally, SMBG should be performed as frequently as practicable—fasting, preprandial, 2 hours postprandial (especially in GDM; measure at 1 hour postprandial), at bedtime, and occasionally at 2:00 AM to 3:00 AM—and values should be recorded. Continuous glucose monitoring systems (measurement of interstitial fluid, or intravenous, glucose levels at 5-minute intervals for 72 hours) detect trends in glucose levels not possible with regular SMBG. This approach facilitates fine-tuning of diabetes treatments.

The HbA_{1c} value (nonenzymatic irreversible glycosylation of the hemoglobin molecule, HbA_{1c} , depends on ambient plasma glucose levels; the average life span of a red blood cell, and hence its HbA_{1c} , is 120 days), by providing a measure of the average blood glucose level (**Web Table 69-2; Web Fig. 69-1**) over the preceding 2 to 3 months, serves as an indicator of diabetes control (Table 69-6). Testing frequency is 2 or more times per year in patients with T2DM with stable glycemic control and meeting treatment goals, and 4

Table 69-6 Blood Glucose Goals for Glycemic Control in Patients with Diabetes*

Biochemical Index	Normal	Goal	Action Suggested
Preprandial fasting glucose (mg/dL) [†]	60-100 (3.3-5.6)	<100 (6.1)	<80 or >140 (<4.4 or >7.8)
Postprandial glucose (mg/dL) [†]	<140	<140	>180 (10.0)
Bedtime glucose (mg/dL) [†]	<110	100-140	<100 or >160 (<5.6 or >8.9)
HbA _{1c} (%)	<6	<6.5	>8

*These values are generalized to the entire population of nonpregnant adults with diabetes. Glycosylated hemoglobin (HbA_{1c}) is referenced to a nondiabetic range of 4.0% to 6.0% (mean, 5.0%; standard deviation, 0.5%).

[†]Measurement of capillary blood glucose. Postprandial blood glucose refers to the level 2 hours after the beginning of a meal.

Numbers represent venous plasma glucose values in mg/dL. Numbers in parentheses represent venous plasma glucose values in mmol/L.

Data from American Diabetes Association: Clinical Practice Recommendations 2008. *Diabetes Care* 31(Suppl 1): 2008, and American College of Endocrinology consensus statement on guidelines for glycemic control. *Endocr Pract* 8(Suppl 1):5-11, 2002.

or more times per year for patients with T1DM, those with poor glycemic control, or those after therapy change. Caution must be exercised in using HbA_{1c} as the only gauge of diabetes control. Patients with wide fluctuations in blood glucose levels may sometimes have normal, average blood glucose levels and HbA_{1c}. Elevated HbA_{1c} despite normal FPG (*good control*) is frequently the result of elevated PPG (>200 mg/dL in 75% of patients with T2DM with HbA_{1c} values ≥7%; HbA_{1c} = FPG + PPG) (see “Tight Control,” later in this chapter). Records of SMBG are usually more informative and useful for making therapeutic decisions than HbA_{1c}. The HbA_{1c} in measuring the average blood glucose level over the preceding 2 to 3 months may be close to goal while actual daily blood glucose levels fluctuate between hyperglycemia and hypoglycemia. The importance of PPG cannot be overestimated. Elevated PPG, not FPG, is an independent risk factor for cardiovascular disease and all-cause mortality (Web Fig. 69-2). This graph demonstrates the relative contributions of the FPG and PPG to hyperglycemia depending on HbA_{1c} quintiles.

Spuriously low levels of HbA_{1c} may be seen in patients with hemoglobinopathies such as homozygous or heterozygous HbS, C, G, or H. Variable levels of HbA_{1c} may be noted with HbE or persistent HbF. β-thalassemia and sickle cell trait, with increased frequency of hemolysis, result in shortened red blood cell life span, reduced time available for glycosylation of hemoglobin, and thus falsely low HbA_{1c} levels.

Measurement of serum *fructosamine* may be a useful marker for shorter-term assessment of integrated glucose concentrations (2 to 4 weeks), for example, during pregnancy.

STANDARDS OF CARE AND SPECIFIC TREATMENT GOALS

Regular patient assessment includes weight, blood pressure, pulse, SMBG records, foot examination, and discussion

about smoking cessation at every office visit, with quarterly assessment of HbA_{1c} (Web Table 69-3). Determination of microalbuminuria, serum creatinine levels, dilated retinal examination, general physical, neurologic (with autonomic testing), cardiac, nephrology, and dental examinations, with comprehensive foot evaluation, should be performed yearly, provided all are normal. Influenza vaccine should be administered yearly and Pneumovax every 5 years. Following the initial measurement of serum lipids, the frequency of reevaluation is dictated by results and treatment and should be done at least yearly. Web Table 69-3 lists the optimal clinical and biochemical evaluation frequencies in people with diabetes. Regular diabetes education should be an integral part of every patient’s management plan. Patients should be advised to carry some documentation regarding their diabetes status (e.g., Medic Alert bracelet).

Blood glucose goals for glycemic control are listed in Table 69-6.

Aspirin therapy should be considered in every patient with diabetes, provided that no contraindications exist.

Goals for lipid levels are influenced by cardiovascular risk factors (see Chapter 9). Optimal values are LDL cholesterol under 100 mg/dL (2.6 mmol/L) or less than 70 mg/dL in patients with established cardiovascular disease, HDL cholesterol over 45 mg/dL (1.15 mmol/L) for men and over 55 mg/dL (1.4 mmol/L) for women, and triglycerides under 150 mg/dL (1.7 mmol/L). Hydroxymethylglutaryl coenzyme A reductase inhibitors, or *statins*, are highly effective in the management of diabetic dyslipidemia and, together with their anti-inflammatory actions and improvement in endothelial function, may reduce the risk for cardiovascular events by about 30%. Fibrates or niacin (used with caution in patients with T2DM) may be required for lowering triglycerides or elevating HDL, respectively (see Chapter 62). Combined use of several classes of agents may be necessary for lipid control. Combination tablets of ezetimibe and simvastatin, fibrates with statins, and niacin with statins facilitate compliance and efficacy at lower doses than if used separately.

Normal urinary albumin-to-creatinine ratio is less than 30 mcg/mg. Microalbuminuria refers to an albumin-to-creatinine ratio of 30 to 299 mcg/mg and macroalbuminuria greater than 300 mcg/mg.

Blood pressure management is discussed under “Macrovascular Complications.”

The previous paragraphs address the problems of β-cell failure, insulin resistance, and comorbidities. The other major contributors to the modern epidemic of T2DM are excess weight, obesity, and a sedentary lifestyle. These conditions are managed through lifestyle changes including weight loss, healthy nutrition, and exercise (see later discussion).

MEDICAL NUTRITION THERAPY

Medical nutrition therapy should be individualized to the patient’s lifestyle, exercise regimen, eating habits, culture, and financial resources. A prescription for a *diabetic diet* no longer exists, nor is there a need to purchase *diabetic foods*. Be wary of foods that state “no sugar added”; that means that there already is more than enough sugar in that particular food. Patients can now have their cake and eat it. Current medications allow patients that freedom. Moderation is

important, and for most patients there are no absolute inhibited foods, besides possibly juices and sodas (liquid sugar). In treating hypoglycemia when the patient can take orally, a set amount of juice (usually initially 4 ounces) may be drunk, being aware that this is a treatment and not a treat, in having too much. Dietary recommendations are generally in line with those for the general population: increased intake of fruit and vegetables, whole grains and fish, and maintaining moderate calorie restriction. Daily energy requirements include consumption of a balanced, healthy diet composed of 10% to 20% protein (1 g/kg body weight, provided no nephropathy exists), less than 35% total fat (<10% saturated, ≤10% polyunsaturated, 10% to 20% monounsaturated and transunsaturated, and <200 to 300 mg cholesterol), and 45% to 60% carbohydrate (see Chapter 61).

Soluble fiber (>15 g/1000 kcal) in the diet delays carbohydrate absorption (dampening the PPG peak) and improves serum lipid profiles. Insoluble fiber contributes to satiety (especially important if overweight) and *gastrointestinal homeostasis*.

Salt (NaCl) intake should be restricted to less than 6 g per day. Partial substitution of potassium chloride or magnesium chloride may be beneficial.

In addition to dietary counseling, reference to the food pyramid, generated by the U.S. Department of Agriculture (USDA), will provide general guidance for all individuals on daily nutritional requirements and the foods that provide these requirements.

Dietary adjustments are based on nutritional assessment, blood pressure, renal function, and HbA_{1c}, as well as on diabetic treatment goals. The *glycemic index* refers to the increase in blood glucose after ingestion of a particular food, expressed as a percentage of the increase in blood glucose following ingestion of the equivalent amount of glucose. For a given food, the glycemic index will vary according to the method of preparation and the concurrently ingested foods. Current recommendations encourage consumption of foods with a low glycemic index. *Carbohydrate counting* involves using either a simple system of exchanges, or *carbs* (15-g carbohydrate portions), or the more precise carbohydrate gram counting. This method allows for fine-tuning of insulin dosing during mealtimes. Training in nutrition self-management empowers patients to make correct food choices, plan meals, exercise, and calculate bolus doses of insulin.

Alcohol is allowed in moderation (≤2 drinks for men and ≤1 drink for women per day [21 units per week for men, 14 units per week for women]; one alcoholic beverage is equivalent to 12 oz beer, 5 oz wine, or 1.5 oz spirits) and should always be taken with food. Alcohol is not metabolized to glucose, and inhibits gluconeogenesis, an effect that may result in hypoglycemia as late as 8 to 16 hours after consumption. Alcohol should not be substituted for food, but, when alcohol calorie content needs to be calculated as part of a meal plan, it should be counted as fat calories (one alcoholic beverage = two fat exchanges).

WEIGHT-MANAGEMENT THERAPY

Overweight (body mass index [BMI] of 25.0 to 29.9) and obesity (BMI >30) are major risk factors for T2DM and cardiovascular disease. (BMI = weight [kg]/height [m²]). *Healthy, reasonable, achievable, and sustainable* body weights

are more realistic terms than *desirable* or *ideal* body weight. A strong correlation exists between increasing BMI and the risk for T2DM. As little as 5% to 10% weight loss in overweight and obese patients reduces the risk for diabetes and leads to increased insulin sensitivity, with improvement in glycemic control, and the possibility of a reduction or cessation of antihyperglycemic therapy. This degree of weight loss also leads to significant improvements in dyslipidemia and blood pressure, as well as an increase in longevity. Behavioral modification and meal replacements, including low- or very-low-calorie diets, in a structured weight-reduction or maintenance program, are of proven efficacy in patients who are unable to lose weight on their own or with the support of a qualified nutritionist. Portion control and self-monitoring are necessary behavioral adjuncts.

The pharmaceutical agents approved by the U.S. Food and Drug Administration (FDA) for adjuvant use in weight reduction, with close medical supervision, are sibutramine (1 year; longer at physician discretion), orlistat (unrestricted long term), phentermine (limited to 3 months), and diethylpropion, benzphetamine, and phendimetrazine (short term).

BARIATRIC SURGERY

An increasingly recognized therapeutic modality in the diabetes treatment armamentarium is bariatric surgery. These procedures are either *restrictive*, reducing bowel lumen circumference (e.g., lap-band procedure), or *bypass*, usually circumventing stomach and upper small bowel (e.g., Roux-en-Y gastric bypass). This is highly effective in T2DM patients with morbid obesity (BMI > 40 kg/m²) and in obese individuals (BMI > 35 kg/m²), with obesity-associated comorbidities, including hypertension, coronary artery disease, sleep apnea, and visceral obesity. Claims of “cure” of diabetes in T2DM patients who lose between 50% and 75% of their baseline weight are being increasingly recognized. The sooner bariatric surgery is performed following the diagnosis of T2DM, the greater the preservation of β-cell mass and improved resolution of T2DM with recovery of first-phase insulin response.

In addition to weight loss due to the restrictive or malabsorptive nature of the operative procedure, there is a hormonal component that is still being elucidated. Gastric bypass and biliopancreatic diversion-duodenal switch operations specifically stimulate incretin (GLP-1) and postprandial peptide YY (PYY) secretion (both synthesized in the L cells of the terminal ileum) through earlier presentation of food to the ileum, bypassing the foregut. GLP-1 stimulates insulin secretion, inhibits glucagon secretion, and delays gastric emptying. Both these hormones are responsible for early satiety. Diminished ghrelin levels and loss of diurnal variation occur following gastric bypass operations. Gastric bypass patients are in a state of negative energy balance with reduced glucose toxicity and improved β-cell function.

EXERCISE THERAPY

As with nutrition and weight management, physical activity is recognized as a specific therapy for patients with diabetes and is an independent risk factor for death. Benefits, many independent of associated weight loss, include

improvements in the sense of well-being, blood pressure, endothelial function, insulin sensitivity, lipid profile (consistent reduction in very-low-density lipoprotein [VLDL]), cardiorespiratory fitness, and glycemic control, with reduction in HbA_{1c}.

Notably, exercise itself, unless extreme, will not contribute to significant weight loss, but will, however, help in weight maintenance and prevention of weight gain. Ideally, this regimen involves moderate aerobic exercise (e.g., walking) for 60 to 90 minutes per day or vigorous exercise for 35 minutes per day (Specifically, the USDA advocates that everyone should be physically active for at least 30 minutes most days of the week; 60 minutes per day of physical activity to prevent weight gain; 60 to 90 minutes per day of physical activity to sustain weight loss). Resistance exercises do not burn as many calories as an equivalent time of aerobic exercise, and how effective this form of exercise is compared with aerobic exercise is unknown at present. Physical activity can be measured by duration, distance, and intensity. Using a pedometer, recommendations are that 8000 to 10,000 steps per day are necessary for weight maintenance. Medical evaluation is advised to determine the target level of fitness and appropriate exercise based on the presence and degree of microvascular or cardiovascular complications. Blood glucose levels should be measured before any exercise activity is initiated. Exercise should not be undertaken in patients with FPG greater than 250 mg/dL (13.8 mmol/L) with ketones, or greater than 300 mg/dL (16.6 mmol/L) without ketones, because this may paradoxically precipitate DKA. If FPG is less than 100 mg/dL (5.5 mmol/L), exercise may result in hypoglycemia, and carbohydrate should be consumed in advance. With the initiation of an exercise program, SMBG should be performed every 30 minutes during exercise lasting longer than 30 to 45 minutes; glucose or carbohydrate may need to be consumed, depending on glucose levels.

TIGHT CONTROL

With few exceptions, the aim of achieving euglycemia, or *tight control* (see Table 69-6, “Goal” column) in all patients with diabetes is now supported by several large studies. In patients with T1DM, when compared with patients receiving standard care, intensive treatment prevented or slowed the onset or progression of the microvascular complications of diabetes: retinopathy by 76%, neuropathy by 60%, and proteinuria by 54%. The threefold increase in the incidence of significant hypoglycemia should not deter attempts to achieve euglycemia. In patients with T2DM, an overall reduction in microvascular complications of 25% occurs with tight control. Tight glycemic control in several other studies has been associated with statistically significant reductions in macrovascular morbidity and mortality in patients with T2DM.

A continuum of risk for complications and the level of glycemia exists, with no glycemic threshold for complications within or above the normal glucose range. Every percentage point reduction in HbA_{1c} is associated with a 40% reduction in the risk for complications in patients with T1DM and a 35% reduction in patients with T2DM. A target HbA_{1c} value of less than 6.5% is recommended. Pregnant women with diabetes should aim for an HbA_{1c} value of 6%.

Tight control of blood pressure significantly reduces the incidence of stroke, heart failure, microvascular complications, loss of vision, and diabetes-related deaths, supporting the aggressive treatment of even mild to moderate hypertension in patients with diabetes in an attempt to reduce blood pressure to less than 130/80 mm Hg (or 125/75 mm Hg in patients with renal insufficiency and proteinuria >1 g per 24-hour period). The reduction in microvascular complications with improved blood pressure control is independent of glycemic control.

Achieving tight control through intensive therapy of all metabolic derangements and comorbidities, including blood pressure and serum lipids, requires regular, close follow-up with a comprehensive diabetes health care team. In patients with T1DM, the use of multiple daily insulin injections (*basal* [long-acting insulin delivered subcutaneously once or twice daily], *bolus* [regular or rapid-acting insulin administered subcutaneously at mealtimes]), or the use of a programmable insulin infusion pump (continuous subcutaneous insulin infusion [CSII]) is necessary to achieve glycemic control. In patients with T2DM, exercise, medical nutrition therapy, weight reduction, and combination oral antihyperglycemic agents may suffice, although failure to achieve glucose targets necessitates the use of insulin in combination with oral agents or alone (about 58% of patients) (basal-bolus insulin delivery). This regimen should be started sooner rather than later. Seventy-six percent of all patients taking insulin have T2DM. In women with gestational diabetes, when proper diet and exercise fail to achieve acceptable blood glucose control, insulin is required. Until recently, oral antihyperglycemic agents have been contraindicated in pregnancy. New data suggest that use of metformin in women with gestational diabetes is safe and effective. Insulin may be required temporarily in some patients during serious infections or surgery. CSII reduces the frequency and severity of hypoglycemia, especially nocturnal, and allows greater freedom of lifestyle (with exclusion of fixed mealtimes), and its use is equally applicable in patients with T2DM.

Normalization of FPG has been the focus of tight control. Studies now confirm that elevated PPG levels are associated with increased cardiovascular morbidity and mortality, and all-cause mortality in patients with T2DM, and may have greater predictive power than FPG levels. Correction of PPG values may reduce cardiovascular disease and mortality in these patients. Several therapies specifically target PPG and include the rapid-acting insulin analogues (lispro, aspart, glulisine), meglitinides, D-phenylalanine derivatives, α -glucosidase inhibitors, and dietary fiber.

It is now well-established that tight control of blood glucose, by means of intensive insulin therapy (intravenous or subcutaneous [constant or basal-bolus]), in patients with *stress hyperglycemia* undergoing surgery, or in intensive care units, significantly reduces morbidity (e.g., septicemia, acute renal failure requiring dialysis, red blood cell transfusions, critical illness polyneuropathy, wound infections, time on ventilator) and mortality by 30% to 50%, as well as reducing length and cost of hospital stay. This benefit of tight blood glucose control in acute situations is not limited to people with diabetes; it has also been documented in all patients with stress-induced hyperglycemia who do not have diabetes

(and return to euglycemia following hospital discharge), or in people not previously known to have diabetes (newly discovered diabetes).

Tight control may be inappropriate in infants and children younger than 13 years (no long-term studies have been conducted); in patients with a shortened life expectancy, severe cardiovascular disease (in whom hypoglycemia may be deleterious), end-stage microvascular disease, or minimal complications of diabetes after 20 to 25 years; and in those with recurrent hypoglycemia or hypoglycemia, or both, unawareness.

INSULIN DOSING

Standard insulin therapy consists of one to two injections per day using intermediate- or long-acting insulin with or without short- or rapid-acting insulin. This approach provides simplicity, relative safety, and increased compliance. Premixed insulins such as 70/30 (70% neutral protamine Hagedorn [NPH]/30% regular), 75/25 (75% neutral protamine lispro [NPL]/25% lispro or aspart or glulisine), or 50/50 (50% NPH/50% regular), usually administered twice daily, provide ease of use but are less likely to achieve good glycemic control. A split or mixed regimen of NPH/regular or NPL/lispro (or aspart or glulisine) twice daily (two thirds of the calculated total daily dose before breakfast and one third before dinner; at each time two-thirds NPH or NPL and one-third regular or lispro or aspart or glulisine) dictates regular mealtimes and insulin injections.

Intensive insulin therapy refers to multiple (three or more) daily injections (MDIs) or CSII. Multiple-injection regimens include use of regular or rapid-acting insulins 3 times daily (adjusted before meals) in combination with NPH twice daily or at bedtime, or glargine insulin once daily, called *basal-bolus therapy*. By approximating normal physiologic timing of insulin delivery, patients are able to achieve better glycemic control and improve lifestyle flexibility. NPH should be given at least 30 minutes before a meal and can be mixed with regular insulin in the same syringe. Relatively *peakless*, long-acting, once-daily glargine or detemir should be administered at the same time each day and should not be mixed with other insulins. Use of the insulin pump tends to yield significantly better blood glucose values than MDI, using less insulin than nonpump regimens. Use of the pump allows patients more freedom and versatility in their lifestyle with no fixed times for meals or any other activities. CSII compared with MDI is superior in numerous ways, including less severe hypoglycemic events and less DKA. The pump is the next best thing to an artificial pancreas or pancreatic or β -cell transplantation. Insulin absorption is more predictable than with other forms of insulin therapy and allows more flexibility and accuracy with basal rate and bolus dosing calculations.

Calculating insulin doses is still somewhat empirical but may be improved through carbohydrate counting, calculation of insulin-to-carbohydrate ratios, and insulin sensitivity. Starting doses of insulin vary from 0.4 to 1.0 $\mu\text{g}/\text{kg}$ per day (T1DM) and from 0.2 to 1.5 $\mu\text{g}/\text{kg}$ per day (T2DM), depending on patient size, degree of glycemia, and severity of insulin resistance. The calculated total daily insulin requirement is divided according to the administration regimen chosen. In general, 40% to 50% of the total daily

dose provides basal requirements. The other 50% to 60% is divided between meals according to insulin sensitivity at each time of day using the approximate ratios of 0.5 to 1.2 U insulin to 10 g carbohydrate (slightly more at breakfast). This is referred to as *carbohydrate counting*, the approximate insulin requirement to maintain euglycemia following meal-time carbohydrate consumption, for example, before breakfast (rapid or regular insulin), 15% to 25%; before lunch (rapid-acting or regular insulin), 15%; and before dinner (rapid-acting or regular insulin), 15% to 20%. In addition to the insulin dose derived from carbohydrate counting, it is also necessary to add an amount of insulin calculated as the *insulin correction factor*. This is based on insulin sensitivity. Thus, the insulin administered at mealtime is referred to as *prandial* or *nutritional* insulin and consists of the sum of scheduled (above), prandial (I/CHO ratio), and correction dose (amount of insulin calculated to bring blood glucose down to ideal mealtime value of 100 mg/dL (e.g., 1 U for every 50 mg/dL above 100 mg/dL).

Calculating insulin dosing for pump users (**Web Table 69-4**) is done as follows. Starting doses of insulin for total daily dosing (TDD):

- Based on prepump TDD: reduce TDD by 25% to 30% for pump TDD, *or*
- Calculated based on weight: $0.24 \times \text{weight (lb)}$, or $0.53 \times \text{weight (kg)}$

Basal rate is usually 45% to 50% of pump TDD: total basal/24 hours = hourly basal rate. The number of basal rates can be increased with time and data. The initial basal rate may need to be supplemented by other rates to cover different tissue sensitivities at different times of the day. The basal rates stabilize blood glucose levels between meals and during the night (increased hepatic glucose production).

The “other half” of the TDD is used for mealtime bolus dosing. The dose is dependent on (a) premeal blood glucose (correction bolus for high blood glucose values above an ideal of 100 mg/dL), (b) the insulin-to-carbohydrate (I/CHO) ratios; and (c) the level of activity. The following calculations apply:

$$\text{I/CHO ratio} = 2.8 \times \text{weight (lb)}/\text{TDD}$$

500 Rule for estimating the I/CHO ratio: $500/\text{TDD} = x$ g; therefore, the ratio is 1 U to x g (e.g., $500/50 = 10$; 1 U = 10 g)

Correction bolus: Determine how much glucose is lowered by 1 unit of rapid acting insulin; the insulin sensitivity factor (ISF). Use the 1700 rule to estimate ISF. $\text{ISF} = 1700/\text{TDD}$.

Correction bolus calculation: $\text{Current blood glucose (BG)} - \text{ideal BG}/\text{ISF}$.

Bolus insulin may be given as a routine push, as a square wave (extending insulin delivery over a longer period of time than normal), or as a dual wave (also extending insulin delivery over a longer period of time than normal, with a certain percentage being delivered as normal).

Insulin requirements are increased during intercurrent illness, pregnancy, and the adolescent growth spurt. On average, insulin dose adjustments are made every 2 to 3 days,

and increments can be by as much as 10% to 20% of the total daily dose. When blood glucose values rise to greater than 250 mg/dL, patients should check for ketones, which are readily detected in the urine.

ELEVATIONS OF FASTING PLASMA GLUCOSE

The *Somogyi effect* refers to rebound hyperglycemia that follows undetected hypoglycemia, commonly nocturnal, in the early hours of the morning. The elevated FPG in this situation is treated by decreasing the preceding evening dose of insulin or by altering the timing of administration (from predinner to bedtime), or altering the type of insulin used, based on the expected time to maximal effect of the insulin. This approach reduces hypoglycemia and prevents the rebound. In the *dawn phenomenon*, the nocturnal secretion of growth hormone is responsible for a nighttime-to-morning rise in blood glucose. This condition is treated by increasing the evening dose of insulin or by altering the timing of administration or the type of insulin used. In both these situations, meal composition and quantity should also be evaluated. Poor insulin injection technique is an extremely common reason for increasing insulin requirements or unexplained fluctuations in blood glucose values, despite adherence to a strict exercise and nutrition program. Rotating use of different anatomic sites for injection may be responsible for variable and erratic insulin absorption, and repeated injection into a single site leads to local *resistance* through lipohypertrophy and tissue fibrosis. Rotation of injection sites exclusively into the abdominal subcutaneous tissue is optimal.

TYPE 1 DIABETES MELLITUS

Prevention of T1DM, using immune modulation or dietary manipulation, in people at high risk or in newly diagnosed patients is not yet possible.

Patients with T1DM have an absolute requirement of *insulin* for survival. This requirement also applies to patients with diabetes resulting from total or near-total β -cell depletion, as in chronic pancreatitis or pancreatic resection. Most insulin preparations are manufactured enzymatically or by recombinant DNA technology (including insulin analogues), and most are available at a concentration of 100 U/mL (U-100). Based on pharmacodynamic properties, the types of insulins currently available are rapid-acting (ultrashort), regular (short-acting) intermediate-acting, and long-acting preparations (Table 69-7; **Web Fig. 69-3**). Insulin therapy is usually started in the outpatient setting unless DKA with hospital admission is the initial presentation. Multiple different insulin regimens exist.

TYPE 2 DIABETES MELLITUS

Prevention of T2DM has been achieved through *lifestyle changes* (healthy diet, weight reduction, and regular exercise) in people at high risk (e.g., IGT), with the incidence of T2DM reduced by as much as 58%, whereas the use of *metformin* reduced the incidence by only 31%.

The aim of treatment in T2DM is to reverse insulin resistance, control intestinal glucose absorption, normalize HGP, improve β -cell glucose sensing and insulin secretion, and ultimately prevent the occurrence of long-term complications. Provided that pharmacologic therapy is not required immediately (FPG < 250 mg/dL), all newly diagnosed patients should be given at least a 1-month trial of diet, exercise, and weight management. If this regimen does not lead to adequate blood glucose control, the physician will need to prescribe oral or subcutaneous antihyperglycemic agents or insulin, or both. After FPG is controlled, substituting a noninsulin agent in patients who were initiated on insulin may be possible. Maximal-dose sulfonylurea therapy has been used effectively as initial treatment in patients with marked hyperglycemia, with doses decreasing as control improves. The regimen of *bedtime insulin*, NPH, and *daytime sulfonylurea therapy* (BIDS) has been successful in patients with T2DM as regular therapy or as a transition stage from noninsulin antihyperglycemic therapy to total insulin therapy. Metformin could be substituted for the sulfonylurea in BIDS.

The eight classes of *noninsulin antidiabetic agents* currently available are listed in Table 69-8. The insulin secretagogues (sulfonylureas, meglitinides, and D-phenylalanine derivatives) have similar mechanisms of action and may cause hypoglycemia, hence the term *oral hypoglycemic agents*. The other classes of noninsulin agents each target a different pathologic process and are referred to as *antihyperglycemic agents*. T2DM is a progressive disease, and monotherapy is seldom permanently successful.

Combination drug therapy using submaximal doses of two or more agents, including insulin, each targeting a different metabolic abnormality, has synergistic effects that may be far greater than the effects of any agent used alone at maximal dose. The incidence and severity of adverse events are also reduced with combination therapy, and, in addition, improved compliance and, in many instances, a cost savings takes place. Although some physicians still use a stepped-care approach, many now initiate therapy with drugs from more than one class of antihyperglycemic agents, depending on the patient's profile and the predominant pathologic defects (see Table 69-8). Additional agents are added (not substituted) if adequate glycemic control is not achieved at 25% to 75% of the maximal dose. Only one agent from each class should be used in an individual patient at any one time. Regular blood glucose estimations allow timely increases in drug doses and the addition of other agents as necessary. Comprehensive combination therapy requires a multi-pronged approach to the treatment of hyperglycemia, dyslipidemia, obesity, hypertension, and the associated comorbidities, with proactive preventive measures when appropriate.

Sulfonylureas

For many years, the only class of oral hypoglycemic (antihyperglycemic) agents available has as its principal action the stimulation of endogenous insulin secretion from the pancreatic β cells. The drugs in this class also increase β -cell sensitivity to glucose and exert some influence in diminishing insulin resistance. These agents have vasoconstrictive properties, raise blood pressure (chlorpropamide), prevent

Table 69-7 Types of Insulin

Insulin Type	Generic Name	Preprandial Injection Timing* (hr)	Onset* (hr)	Peak* (hr)	Duration* (hr)	Blood Glucose (BG) Nadir* (hr)
Rapid acting	Lispro [†]	0-0.2	0.1-0.5	0.5-2	<5	2-4
	Aspart [‡]	0-0.2	0.1-0.3	0.6-3	3-5	1-3

Insulin Analogue Premixed						
Lispro protamine/lispro	75/25	0.25	0.15-0.25	1	14-24	—
Aspart protamine/aspart	70/30	0.25	0.15-0.3	2-4	24	—

*Time profiles depend on several factors, including dose, anatomic site of injection, method (subcutaneous, intramuscular, or intravenous; above profiles are for subcutaneous injections), duration of diabetes, type of diabetes, degree of insulin resistance, level of physical activity, presence of obesity, and body temperature. Some time ranges are wide to include data from several separate studies. Preprandial injection timing depends on premeal blood glucose (BG) values and insulin type. If BG is low, it may be necessary to inject insulin and eat immediately (carbohydrate portion of meal first). If BG is high, it may be necessary to delay meal after insulin injection and eat carbohydrate portion last.

[†]Insulin analogue with reversal of lysine and proline at positions 28 and 29 on the B chain of the insulin molecule.

[‡]Insulin analogue with substitution of aspartic acid for proline at position 28 on the B chain of the insulin molecule.

[§]Insulin analogue with substitution of glycine for asparagine at position 21 on the A chain and addition of two arginines to the carboxyl terminus of the B chain of the insulin molecule.

[¶]Insulin analogue with substitution of lysine for asparagine at position 3 on the B chain and glutamic acid for lysine at position 29 on the B chain of the insulin molecule.

^{||}Administer at same time each day, unrelated to meals. Morning administration may result in greater glucose lowering and less nocturnal hypoglycemia.

Do not mix glargine, detemir, or Ultralente insulins with other insulins.

70/30, 70% NPH, 30% regular or 70% NPL/30% aspart; 50/50, 50% NPH, 50% regular; 75/25, 75% NPL, 25% lispro; 70/30, 70% NPA, 30% aspart; NPH, neutral protamine Hagedorn; NPL, neutral protamine lispro; NPA, neutral protamine aspart.

ischemic preconditioning in the heart, and increase plasma levels of PAI-1. The drugs differ in potency, time of onset, duration of action, plasma protein binding, absorption characteristics, and route of metabolism and excretion. Some involve novel delivery systems. At maximal dose, these drugs are all equally effective (except tolbutamide) in lowering blood glucose levels. Primary failure to respond to sulfonylureas occurs in 20% to 25% of patients. Secondary failure occurs at the rate of 10% to 15% per year, in part because of progressive β -cell failure and insulin resistance and in part because of poor patient compliance. Replacing one agent with another in this class is unlikely to produce a substantially different effect and is not recommended unless for reasons of patient compliance. The risk for hypoglycemia, the major adverse effect, increases with increasing patient age, use of a preparation with a long half-life (e.g., chlorpropamide), and renal dysfunction. Weight gain is also a recognized side effect. Characteristics of patients best suited for sulfonylurea therapy include diagnosis at greater than 30

years of age, disease presence for less than 5 years, residual β -cell function, relative lack of obesity, and FPG less than 300 mg/dL (see Table 69-8).

Biguanides (Metformin)

The major mechanism of action of this insulin sensitizer is in reducing HGP by inhibiting gluconeogenesis. This drug also increases anaerobic glycolysis with resultant increased lactate production, enhances glucose uptake and utilization by muscle, and decreases intestinal glucose absorption. In addition to its glucose-lowering effect, this drug is associated with weight loss (5 to 10 lb), possibly related to mild nausea and anorexia, a decrease in plasma insulin levels, and significant lipid-lowering effects (decreasing total cholesterol, LDL, and triglyceride by 10% to 20% and increasing HDL). Metformin improves endothelial function, lowers PAI-1 levels, and reduces cardiovascular events. It is well suited for use in obese, hyperlipidemic

patients with T2DM. Metformin's use in patients with IGT and the metabolic syndrome, as prophylaxis against development of diabetes, has proved successful. Primary failure rates are about 12%, and secondary failure rates are between 5% and 10%. Strong evidence-based support can be found for using metformin as initial therapy, especially in overweight or obese individuals, and often in combination with an agent or agents from another class.

Major adverse effects are gastrointestinal and metabolic. Gastrointestinal side effects include metallic taste, anorexia, nausea, abdominal discomfort, and diarrhea; these are usually mild and transient and improve with temporary reduction in dose and administration with meals. The major metabolic side effect is lactic acidosis, which occurs most often in patients with renal disease (creatinine, ≥ 1.5 mg/dL in men and ≥ 1.4 mg/dL in women), low cardiac output, impaired hepatic function, excessive alcohol intake, or concomitant use of radiographic contrast.

α -Glucosidase Inhibitors (Acarbose and Miglitol)

Within the small bowel lumen, α -glucosidase inhibitors competitively inhibit the breakdown of complex carbohydrates by antagonizing pancreatic α -amylase and the microvillar brush border α -glucosidase enzymes, thereby delaying glucose absorption and dampening the PPG (and insulin) peaks, with modest effect on FPG levels. When acarbose is taken with the first bite of a carbohydrate-containing meal, only 1% to 2% of the drug is absorbed. Major common side effects are gastrointestinal, including bloating, abdominal discomfort, diarrhea, and flatulence. These effects occur at the initiation of therapy and with dose increases, but they

commonly disappear with continued use. The side effects can be minimized by starting with a low dose (12.5 to 25 mg once daily) and increasing it gradually over several weeks to a maintenance dose of 50 to 100 mg 3 times daily, depending on the patient's body weight (see Table 69-8). These agents do not cause hypoglycemia when used alone, but hypoglycemia may occur when they are used in combination with insulin, a sulfonylurea, a meglitinide, or a D-phenylalanine derivative. Oral treatment of hypoglycemia during therapy with these agents requires administration of pure glucose, fructose, or lactose (not sucrose, maltose, or starch).

Thiazolidinediones (Rosiglitazone and Pioglitazone)

Thiazolidinediones, which are peroxisome proliferator activated receptor- γ (PPAR- γ) agonists, reduce insulin resistance, improve the peripheral action of insulin (*insulin sensitizers*), and reduce hyperglycemia by increasing glucose uptake and utilization in peripheral tissues and reducing HGP. These agents increase the differentiation of preadipocytes to adipocytes and may cause an increase in total-body fat mass, with remodeling (increased number of small, insulin-sensitive adipocytes) and redistribution (visceral to subcutaneous) of body fat. Improvements in serum lipids (decrease in triglycerides [TGs] and free fatty acids [FFAs], increase in HDL, and increase in large buoyant LDL [LDL₁]) depend on each particular agent and may occur through nuclear PPAR- γ activation. Thiazolidinediones have little effect in the presence of euglycemia and thus tend not to produce hypoglycemia when used as monotherapy. They bind to PPAR- γ to induce transcription of several genes involved in glucose and lipid metabolism. Because of their

DPP-4 Inhibitors	Amylin Mimetics	Incretin Mimetics	Combination Preparations			
25-100 dependent on renal function	Type 1 (15-60 mcg) Type 2 (60-120 mcg)	5-10 mcg (start with 5 mcg; ↑ to 10 mcg after 1 month if necessary)	1.25/250- 20/2000	2.5/250-20/2000	1/500-8/2000	4/1-8/8

mechanism of action on receptors in the cell nucleus, 3 to 4 weeks may be required to produce a clinical effect and 10 to 12 weeks for a full effect. Dosage adjustments should therefore only be made every 3 months.

Activation of PPAR- γ , found predominantly in fat, results in a decrease in FFAs and an increase in insulin sensitivity and glucose uptake, resulting in lowering of plasma glucose levels. Activation of PPAR- α , in liver and muscle, lowers plasma TG levels and raises HDL levels by stimulating fatty acid oxidation and lowering apolipoprotein (apo) CIII and apo AI. In addition to their glucose-lowering properties, their actions include anti-inflammatory effects (especially on the vasculature, with reduction in macrophage migration, macrophage foam cell formation, IL-6, highly sensitive C-reactive protein [hs-CRP], monocyte chemoattractant protein-1, and white blood cell count), mild blood pressure reduction, increased thrombolysis (reduction in PAI-1 activity as well as antigen levels), reduced vascular smooth muscle proliferation (improvement in carotid intima medial wall thickness [IMT], a useful index for monitoring atherosclerosis progress), improved endothelial function and vascular activity, reduced urinary albumin excretion, and preservation of β -cell function (partly through a reduction in the rate of β -cell apoptosis). These agents increase adipose-derived adiponectin levels, thereby enhancing liver and muscle insulin sensitivity and fat oxidation and inhibiting endothelial inflammation. The anti-inflammatory action helps restore insulin sensitivity and reverse the atherosclerotic process. Restoration of endothelial integrity is demonstrated by improvement in endothelium-mediated brachial vasodilation.

Severity of cardiovascular disease is often assessed by determination of IMT, as already mentioned. Some

of the therapies used in the management of diabetes are responsible for a reduction in IMT and may in fact act synergistically, namely exercise, thiazolidinediones, and hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors. They may also improve cardiovascular risk markers.

Pioglitazone, when part of standard therapy, has been shown to reduce the combined risk for heart attacks, strokes, and death by 16% in high-risk patients with T2DM.

Thiazolidinediones (TZD) do not have to be taken with food. Combination with insulin therapy may facilitate a reduction in insulin dose or even its discontinuation. A 25% primary failure rate is probably caused by inappropriate use in patients with minimal endogenous insulin secretion. Rosiglitazone may be given as monotherapy or in combination with metformin or a sulfonylurea. Pioglitazone may be used as monotherapy or with insulin, sulfonylureas, or metformin. Side effects include dilutional anemia, edema, and mild weight gain. These drugs should be used with caution in patients at risk for heart failure. Hypoglycemia is a risk when these drugs are used in combination with oral hypoglycemia agents, amylin, or incretin mimetics. Therapy with this class of drugs should be initiated early while reasonable β -cell function still exists.

Although pioglitazone and rosiglitazone do not appear to cause liver dysfunction, as did their predecessor troglitazone, the FDA recommends that therapy with TZDs should not be initiated if the serum alanine aminotransferase level is greater than 2.5 times the upper limit of normal. Patients should have liver function tests performed every 2 months for the first year and periodically thereafter. No restrictions in renal insufficiency are recommended.

Meglitinides (Repaglinide) and D-Phenylalanine Derivatives (Nateglinide)

The mechanism of action of meglitinides and D-phenylalanine derivatives is similar to that of the sulfonylureas in stimulating insulin secretion from the pancreas. The advantages of these classes over the sulfonylureas are the rapid onset and short duration of action, which suppress postprandial hyperglycemia. They should be taken with meals and omitted in the absence of a meal, a feature that permits flexibility of lifestyle. The stimulation of prandial insulin secretion avoids chronic stimulation of β cells and results in reduced between-meal and nocturnal hyperinsulinemia, a feature of sulfonylurea therapy. The insulin secretagogue action is glucose dependent, sensitizing β cells to secrete more insulin in response to elevated glucose levels. For this reason, hypoglycemia is seen less often than with sulfonylureas. Clinical response to these agents is seen within about 1 week. These drugs may be prescribed in the presence of renal dysfunction. Combination therapy of a sulfonylurea with either of these agents is not FDA approved.

Combination Preparations of Antihyperglycemic Agents

Increasingly, pharmaceutical companies are manufacturing combinations of oral agents (e.g., glyburide and metformin, glipizide and metformin, rosiglitazone and metformin, rosiglitazone and glimepiride, sitagliptin and metformin), which, although in fixed doses, may help improve patient compliance when faced with increasing numbers of drugs to swallow each day (see Table 69-8). Combination therapy, while promoting synergistic effects, also allows for lower doses of each agent with a reduced risk for side effects.

To further enhance patient compliance, certain oral agents are formulated as long-acting, slow, or extended-release preparations (e.g., glipizide XL, metformin XR) and in solution (e.g., metformin) for children.

Currently available antihyperglycemic therapeutic agents, other than insulin, each treat separate metabolic problems in patients with diabetes. Combinations of these drugs target some of the dysfunctions in the spectrum of actions performed by insulin. Research is directed at manipulating endogenous compounds to produce agents able to approximate normal physiologic homeostatic control of hyperglycemia as closely as possible.

Incretin Mimetics

Incretin mimetics constitute a novel class of antidiabetic agents that mimic the actions of naturally occurring incretins (gut hormones) involved in the enteroinsular axis. The importance of this class of hormones with respect to plasma glucose levels following food ingestion is noted in the *incretin effect*: a greater insulin secretory response after similar increases in plasma glucose concentrations following oral, compared with intravenous, routes of glucose administration. **Web Fig. 69-4** demonstrates the incretin effect in normal individuals and its diminution in T2DM. The hormones GLP-1 (accounting for 70% to 80% of the incretin effect), GLP-2, and the gastric inhibitory peptide, GIP, are

secreted from the small intestine (GLP-1 from enteroendocrine L cells of the distal ileum, GIP from enteroendocrine K cells of the proximal jejunum) following nutrient ingestion. Serum GLP-1 levels are generally lower in people with diabetes. GLP-1 regulates blood glucose through several mechanisms: (1) enhancing glucose-dependent pancreatic β -cell insulin secretion with subsequent promotion of insulin-mediated tissue glucose uptake; (2) inhibition of glucagon secretion from pancreatic α cells during hyperglycemia, or the fed state (leading to reduced HGP, insulin requirements, and PPG excursions); (3) restoration of first-phase insulin release (lost early in T2DM); (4) increased second-phase insulin secretion; and (5) insulin-sensitizing effect and delayed gastric emptying (limiting PPG excursions). GLP-1 also protects and preserves β cells from damage by FFAs and cytokines. It does not impair the glucagon response to hypoglycemia. Other effects include depressed appetite and increased satiety, resulting in reduced food intake with subsequent weight loss. Prevention of pancreatic β -cell deterioration (a central feature of T2DM) and increasing β -cell mass involves regeneration through proliferation and differentiation, neogenesis, and antiapoptosis of β cells by GLP-1.

The incretin mimetic available for therapeutic use at present is exenatide (structurally identical to exendin-4, derived from the saliva of the Gila monster lizard), the naturally occurring GLP-1 analogue. This preparation is resistant to inactivation by dipeptidyl peptidase-4 (DPP-4). Used as an adjunct in T2DM when sulfonylureas and metformin do not adequately control blood glucose, exenatide is administered subcutaneously before breakfast and dinner (see Table 69-8). A long-acting GLP-1 analogue, liraglutide, is currently in clinical trials. Compared with a sulfonylurea, this agent, given subcutaneously once daily, produced less hypoglycemia.

Amylin Mimetics

Amylin, a peptide hormone, is synthesized in pancreatic β cells and stored with insulin within secretory granules. It is co-secreted with insulin, in equimolar amounts, in response to nutrient stimuli. Biochemical characteristics are similar to insulin except that it is metabolized and excreted mainly by the kidneys. The main functions of amylin are (1) to control postprandial glucose levels through inhibition of postprandial glucagon secretion, with subsequently decreased HGP; (2) delayed gastric emptying and thus carbohydrate absorption, and (3) reduced food intake through centrally mediated early satiety. Amylin also acts in an autocrine fashion to inhibit pancreatic β -cell insulin secretion.

With β -cell destruction (T1DM), or atrophy and *exhaustion* (T2DM), the secretion of insulin and amylin is absent and reduced, respectively.

Pramlintide, a stable analogue of amylin, is approved for use in both T1DM and T2DM as adjunctive therapy. Concurrent insulin doses should be halved at the initiation of pramlintide therapy. In addition to dampening PPG peaks, pramlintide is also effective in reducing glucose fluctuations throughout the day. It is given subcutaneously and at lower doses in patients with T1DM than those with T2DM (see Table 69-8). Side effects include nausea, vomiting, and transient headaches. Hypoglycemia may result when used in combination with sulfonylureas.

Dipeptidyl Peptidase-4 Inhibitors

DPP-4 inhibitors selectively (no effect on DPP-8 or DPP-9) and reversibly block GLP-1 and other incretin degradation, thereby prolonging the activity of natural incretins. They increase insulin synthesis and release, while suppressing the release of glucagon in a glucose-dependent manner, lowering the potential for hypoglycemia. In patients with T2DM, there is an improvement in β -cell function and insulin sensitivity.

TREATMENT OF THE METABOLIC SYNDROME

Lifestyle modification, including weight reduction and enhanced physical activity, are the most important aspects of treatment in this group of patients. Obviously, each of the dysmetabolic factors present needs to be managed in its own right. All treatments are greatly facilitated by weight reduction, a 10% weight loss being associated with major metabolic improvements. Useful adjunctive pharmacotherapy includes the insulin sensitizers, metformin, and TZDs, with beneficial elevation of adipose tissue-specific adiponectin.

Complications

ACUTE COMPLICATIONS

Hypoglycemia

Hypoglycemia is discussed in Chapter 70.

Lactic Acidosis

A rare event, lactic acidosis is discussed in Chapter 28.

Diabetic Ketoacidosis

Although DKA develops most commonly in patients with T1DM, it can be seen in patients with T2DM, especially during acute illness. DKA is defined as being present in patients with absolute or relative insulin deficiency when the following criteria are met:

1. *Hyperglycemia*: plasma glucose levels greater than 250 mg/dL
2. *Ketosis*: moderate to severe ketonemia (ketone levels positive at a serum dilution of $\geq 1:2$, or serum β -hydroxybutyrate concentration >0.5 mmol/L) and moderate ketonuria (2+ to 3+ by the nitroprusside method). The nitroprusside reagent reacts primarily to acetoacetate and, to a lesser extent, acetone, but does not detect β -hydroxybutyrate. When lactic acidosis coexists with DKA, there is a shift toward more β -hydroxybutyrate production, which decreases the reactivity with the nitroprusside reagent.
3. *Acidosis*: pH less than or equal to 7.3 or bicarbonate less than or equal to 15 mEq/L

Associated metabolic and plasma abnormalities include dehydration, increased osmolality (usually >320 mOsm/kg), increased anion gap (>12 mEq/L), increased serum amylase, elevated white blood cell count, and hypertriglyceridemia.

Precipitating factors for DKA are infection (30%), often minor (respiratory or urinary tract) new-onset diabetes (25%), problems with insulin administration (20%), *stress*, and many less frequent causes. Insulin deficiency and raised insulin counter-regulatory hormones result in increased HGP and decreased peripheral glucose utilization, leading to hyperglycemia and hyperosmolality with consequent osmotic diuresis, electrolyte loss (sodium, potassium, phosphate, magnesium, calcium, and chloride), and dehydration. Activation of insulin-sensitive lipase stimulates release of FFAs from adipose tissues, which are oxidized in the liver to produce ketone bodies. Diminished peripheral utilization of ketones during insulin deficiency results in ketosis and metabolic acidosis.

DKA develops within hours to days. The ill feeling associated with the metabolic acidosis leads patients to seek early medical attention, a feature that accounts for the lower levels of glucose and osmolality compared with those in hyperosmolar nonketotic syndrome (HNKS) (Table 69-9). DKA may not always be obvious at the time of presentation because early signs and symptoms are subtle. Symptoms include nausea, vomiting, thirst, polydipsia, polyuria, abdominal pain, weakness, fatigue, and anorexia. Signs include tachycardia, orthostatic hypotension, poor skin turgor, warm or dry skin and mucous membranes, hyperventilation or Kussmaul respiration,

Table 69-9 Hyperglycemic Crises: A Comparison of Diabetic Ketoacidosis and Hyperosmolar Nonketotic Syndrome

Feature	Diabetic Ketoacidosis	Hyperosmolar Nonketotic Syndrome
Age of patient	Usually <40 yr	Usually >60 yr
Duration of symptoms	Usually <2 days	Usually >5 days
Plasma glucose	Usually <600 mg/dL	Usually >600 mg/dL
Serum sodium	Normal or low (130-140 mEq/L)	Normal or high (145-155 mEq/L)
Serum potassium	Normal or high (5-6 mEq/L)	Normal (4-5 mEq/L)
Serum bicarbonate	<15 mEq/L	>15 mEq/L
Ketone bodies	Positive at $\geq 1:2$ dilution	Negative at 1:2 dilution
pH	<7.35	>7.3
Serum osmolality	Usually <320 mOsm/kg	Usually >320 mOsm/kg
Fluid deficit	$\leq 10\%$ body weight	$\leq 15\%$ body weight
Cerebral edema	Subclinical asymptomatic, rare clinically	Very rare
Prognosis	3%-10% mortality rate (>20% for people >65 yr)	10%-20% mortality rate
Subsequent course	Insulin therapy required in most cases	Insulin therapy not usually required

hypothermia or normothermia, ketones on the breath, weight loss, and altered mental status or coma.

Initial assessment includes mental status, presence of gag or cough reflex, abdominal succussion splash (requiring a nasogastric tube), and urinary output. The search for a precipitating cause (e.g., infection or sepsis, myocardial infarction, pregnancy, cerebrovascular accident, trauma, psychosocial factor) is crucial, both to treating the underlying disorders and to facilitating resolution of the DKA. Baseline investigations should include plasma glucose, plasma acetone, serum electrolytes, serum lipid profile, serum amylase and lipase, full blood count with differential, arterial blood gas determination, blood cultures, culture of abscess or infected site, urine glucose and ketones, urine microscopy and culture, chest radiograph, abdominal radiograph (with abdominal pain), electrocardiogram, cardiac enzymes (if appropriate), CT scan of the brain if appropriate, lumbar puncture (if appropriate), serum osmolality, and anion gap. (Calculation of serum osmolality: $2[\text{Na}^+ (\text{mEq/L})] + 2[\text{K}^+ (\text{mEq/L})] + \text{glucose} [\text{mg/dL}]/18 + \text{BUN} [\text{mg/dL}]/2.8$. Calculation of anion gap: $\text{Na}^+ - [\text{Cl}^- + \text{HCO}_3^-]$).

Most important in the therapy of DKA is the restoration of circulating plasma volume, with maintenance of cardiac output and renal function (**Web Table 69-4**). Intravenous fluid lowers blood glucose through serum dilution and enhanced urinary glucose loss, lowers osmolality and ketones, and improves the peripheral utilization of ketones and glucose. Insulin administration facilitates the peripheral uptake of ketones and glucose, thereby decreasing urinary glucose loss, and, significantly, inhibits hepatic glucose production. Electrolyte imbalances should be corrected concurrently with fluid and insulin replacement and treatment of the precipitating cause. To track the course of treatment, several parameters require regular monitoring:

1. Hourly: Vital signs (temperature, pulse rate, respiratory rate, blood pressure), mental status, fluid intake and output, plasma glucose, insulin infusion rate, arterial blood gases, electrocardiogram (initially, and if in the intensive care unit, preferably continuous monitoring)
2. Every 1 to 2 hours: Serum electrolytes (sodium, potassium, chloride, and bicarbonate), electrocardiogram until stable
3. Every 6 hours: Serum phosphate, magnesium, calcium, blood urea nitrogen, and creatinine

With correction of the metabolic abnormalities, the frequency of their measurements should be reduced appropriately. Weight should be measured initially and then daily. Note that ketones are only measured to help confirm the diagnosis of DKA and subsequently to establish its resolution. With changes in the ratios of the different serum ketones, the routine methods used to measure these may falsely suggest transient elevation in ketones. Tracking the decrease in the anion gap will provide information regarding control of DKA.

Hyperosmolar Nonketotic Syndrome (Hyperglycemic Hyperosmolar State)

HNKS occurs almost exclusively in patients with T2DM, who are usually elderly and physically impaired, with limited access to free water. The pathogenesis of HNKS is similar to

that of DKA but may be distinguished from it by the more marked hyperglycemia, the relative absence of acidosis and ketonemia, and the greater degree of dehydration (see Table 69-9). Low FFA levels result in the absence of ketone bodies, with reduced nausea and vomiting. Increased lactic acid levels result from poor tissue perfusion and are more marked than in DKA. Insulin resistance is usually present, with normal or elevated levels of serum insulin. As many as 30% to 40% of patients over 65 years of age with HNKS may have previously undiagnosed diabetes. HNKS usually develops insidiously over days to weeks. Precipitating and complicating factors may include infection, intestinal obstruction, mesenteric thrombosis, pulmonary embolism, peritoneal dialysis, heat stroke, hypothermia, subdural hematoma, severe burns, and an extensive list of drugs. Some of these conditions may themselves result from the severe dehydration and poor tissue perfusion of HNKS.

Therapy of HNKS follows the same general principles as that of DKA, with particular emphasis on intravenous fluid therapy and potassium replacement. Fluid replacement should follow the same pattern as in DKA, but a greater total volume is usually required. Careful monitoring is necessary because patients often have cardiac and other comorbid conditions. Restoration of the fluid deficit should proceed more slowly than in DKA, ideally over 36 to 72 hours. Insulin therapy should only be started after rehydration is in progress. These patients may be sensitive to insulin and may require reduced doses. In view of the severe dehydration and predisposition to vascular thrombosis, these patients should receive heparin (unfractionated or low molecular weight) prophylaxis (5000 U heparin subcutaneously, usually twice daily).

CHRONIC COMPLICATIONS

Chronic complications include microvascular complications (nephropathy, retinopathy, and neuropathy) and macrovascular or cardiovascular complications (hypertension, coronary artery disease, peripheral vascular disease, and cerebrovascular disease). Several different mechanisms are responsible for the development of chronic complications and include activation of the polyol pathway (with accumulation of sorbitol), formation of glycated proteins and advanced glycation end products (cross-linked glycated proteins), abnormalities in lipid metabolism, increased oxidative damage, hyperinsulinemia, hyperperfusion of certain tissues, hyperviscosity, platelet dysfunction (increased aggregation), endothelial dysfunction, and activation of various growth factors.

MICROVASCULAR COMPLICATIONS

The incidence of microvascular complications is significantly higher in patients with T1DM than in those with T2DM.

Nephropathy

Diabetic nephropathy is the most common cause of ESRD in developed countries (about 30% of cases). About 20% to 30% of people with T1DM and T2DM develop nephropathy, and the incidence increases with duration of diabetes. Fewer people with T2DM than with T1DM progress to ESRD (20%

versus 75%, respectively, after 20 years). Certain ethnic and racial groups have high prevalence rates of severe nephropathy (Native Americans, Mexican Americans, and African Americans).

Initially, increased glomerular filtration rate (GFR) and renal blood flow occur in all patients and are not associated with any histologic changes. This condition progresses to glomerular hypertrophy, renal enlargement, expansion of the mesangial matrix, and thickening of the glomerular basement membrane, resulting in glomerulosclerosis (**Web Figs. 69-5, 69-6, and 69-7**). Subsequently, the GFR returns to normal, with an associated increase in intraglomerular pressure and the appearance of microalbuminuria (20 to 200 mcg per minute, 30 to 300 mg per 24 hours) 10 to 15 years after the diagnosis of diabetes (present in 30% of middle-aged patients with T1DM or T2DM). This *incipient* or *preclinical diabetic nephropathy* is followed by a decline in GFR as the albumin excretion rate increases.

Microalbuminuria is a risk factor for cardiovascular events and is associated with a 10- to 20-fold increased risk for progression to diabetic nephropathy. Rigorous control of blood glucose and blood pressure (using angiotensin II-converting enzyme [ACE] inhibitors or angiotensin II-receptor blockers [ARBs]) or use of ACE inhibitors or ARBs in nonhypertensive patients with microalbuminuria can prevent or even reverse the progression toward renal failure. β -blockers and nondihydropyridine calcium-channel antagonists, effective in reducing cardiovascular events, may also be considered, as may thiazide diuretics.

By about 15 years after the onset of diabetes, macroalbuminuria (>200 mcg per minute, >300 mg per 24 hours; dipstick positive) is generally present. Continued blood pressure control is essential, and some dietary protein restriction (0.6 to 0.8 g/kg per day) is probably helpful, but meticulous blood glucose control is unlikely to prevent the inexorable progression of overt diabetic nephropathy to ESRD. The rate of decline in GFR, however, may be slowed, but not halted, by blood pressure and glucose control with protein restriction. Measurement of serum creatinine is an inaccurate guide to the degree of GFR impairment. Within 5 years of the appearance of macroalbuminuria, GFR will have declined by 50% in about 50% of patients; within a further 3 to 4 years, one half of these patients will have ESRD. Dialysis (hemoperitoneal or peritoneal) or renal transplantation is initiated when the GFR is less than 15 mL per minute (serum creatinine ≥ 10 mg/dL) (see Chapter 28).

Screening for proteinuria should be performed annually in all patients, starting at the time of diagnosis in patients with T2DM and 5 years after the diagnosis in patients with T1DM. The simplest method of screening for microalbuminuria is measurement of the ratio of protein (albumin) to creatinine in a random spot urine specimen. This measurement correlates closely with 24-hour urinary protein estimations.

Retinopathy

The presence and severity of diabetic retinopathy are related to age at diagnosis and the duration of diabetes; 100% of patients with T1DM and 60% to 80% of those with T2DM are affected by 20 years. Retinopathy is the most common cause of blindness in persons between the ages of 20 and 74 years in the developed world. About 25% of patients with

T2DM may already have evidence of retinopathy at the time of diagnosis. The incidence of this complication is increased in Mexican Americans and African Americans.

Diabetic retinopathy is a progressive condition of increasing severity, accelerated by poor glycemic control (**Web Fig. 69-8**). *Background*, or *nonproliferative, retinopathy* consists of increased capillary permeability, dilation of venules, and the presence of microaneurysms (focal, saccular, and fusiform dilations of capillary walls as sequelae of loss of supporting pericytes and ischemic occlusion of retinal capillaries). At this stage, hemorrhages deep in the retina appear as dots, whereas more superficial nerve fiber layer hemorrhages are linear or resemble flames or *blots*. Leakage of plasma through permeable and ischemic capillary walls leads to the formation of hard exudates as the water is reabsorbed, leaving behind deep, intraretinal yellow deposits of proteins and lipids. These deposits may be present at any stage of diabetic retinopathy. Collections of hard exudates in a circular pattern (*circinates*) reflect the presence of retinal edema that pushes these exudates peripherally. When these exudates surround the macula, they highlight macular edema (*maculopathy*), a sight-threatening condition requiring urgent attention.

Retinal venous occlusion results in beading, reduplication, and venous loops. *Intraretinal microvascular abnormalities*, which are abnormal dilated capillaries within the retina, result from widespread capillary occlusion. Superficial retinal microinfarcts result in hypoxic necrosis of retinal nerve fibers and appear as white, *cotton-wool spots* with irregular margins. These changes signify a worsening of the retinopathy into the *preproliferative stage*. The widespread retinal ischemia and hypoxia represented by these changes result in the release of several angiogenic growth factors, which lead to the development of new vessels (*neovascularization*) on the retina, optic disc, or iris (*rubeosis iridis*). Inhibitors of protein kinase C, which block the production of vascular endothelial growth factor, are potentially beneficial. This stage is referred to as *proliferative retinopathy* and is also characterized by scarring. The new vessels are extremely fragile, extending through the internal limiting membrane, where they lie between the retina and vitreous, or attaching to the vitreous and extending into it. Bleeding into the preretinal (subhyaloid) space results in a boat-shaped hemorrhage. Hemorrhage from new vessels in the vitreous may cause sudden loss of vision. Neovascularization and fibrosis at the angle of the anterior chamber prevent normal drainage of aqueous and lead to *neovascular glaucoma* and a blind, painful eye. Shrinkage and retraction of the vitreous from the retina, which occurs with age, may result in hemorrhage from neovascularization, and traction on the retina from associated fibrous tissue. Further proliferation of fibrous tissue may lead to a traction retinal detachment with visual loss, most marked with macular involvement.

Premature development of *senile cataracts* occurs in patients with diabetes. *Snowflake lens opacities* develop in younger patients, particularly during periods of poor glycemic control. Referral to an ophthalmologist for urgent argon laser therapy is mandatory in patients with proliferative retinopathy, diabetic maculopathy, and possibly preproliferative retinopathy. This therapy can be sight-saving. *Vitrectomy* may be performed in patients with extensive, long-standing,

unresolving vitreal hemorrhage or when new traction retinal detachment affects the macula or is associated with a retinal tear.

Annual dilated funduscopy examination by an ophthalmologist should be performed in all patients with diabetes, starting 5 years after diagnosis in patients with T1DM. Improvement of glycemic control may transiently worsen retinopathy, before ultimately improving it over a longer period.

Neuropathy

The likelihood of involvement of the nervous system by diabetes increases with duration of disease and is influenced by the degree of glycemic control (occurring in up to 70% of people with diabetes). Any part of the peripheral or autonomic nervous system may be affected. *Peripheral polyneuropathy* occurs most commonly, which usually presents as a bilaterally symmetrical, distal, primarily sensory (with or without motor) polyneuropathy, with a *glove-and-stocking* distribution. Pain, numbness, hyperesthesias, and paresthesias progress to sensory loss. This condition, together with loss of proprioception, leads to an abnormal gait, with repeated trauma and fractures of the tarsal bones, sometimes resulting in the development of Charcot joints. These changes lead to abnormal pressures in the feet that, together with the soft tissue atrophy related to peripheral arterial insufficiency, result in foot ulcers that may progress to osteomyelitis and gangrene. Detailed, regular neurologic examination of all patients is essential, to elicit the early loss of light touch (using a 5.07/10 g monofilament), reflexes, and vibratory sensation. Painful neuropathies are difficult to treat, and, although they are self-limited, they may persist for years. Improvement in glycemic control should be the primary therapeutic goal. Analgesia should start with aspirin, acetaminophen, and nonsteroidal anti-inflammatory agents before codeine and addictive drugs such as pentazocine or narcotics are prescribed. Anticonvulsants, including phenytoin, carbamazepine, gabapentin, and pregabalin, as well as the antidepressant amitriptyline, may provide moderate relief. Burning pain may respond to the topical application of capsaicin cream. Use of plastic skin (e.g., OpSite film), transcutaneous nerve stimulation, and nerve block are sometimes effective for chronic pain.

Mononeuropathies usually present acutely, may involve any nerve in the body, and are generally self-limiting. The cranial nerves most commonly involved are the third, sixth, and fourth, in that order. *Radiculopathies* are self-limited painful sensory syndromes of one or more spinal nerves, usually of the chest or abdomen. *Diabetic amyotrophy* causing muscle atrophy and weakness commonly involves the anterior thigh muscles and pelvic girdle and may also be self-limited, resolving after several months.

Potential new therapies for diabetic peripheral neuropathy include aldose reductase inhibitors (inhibit excessive activity of the polyol pathway), aminoguanidine (inhibit formation of AGES), γ -linoleic acid (replacement is needed because of impaired production), antioxidants (e.g., α -lipoic acid), vasodilators, and recombinant human nerve growth factor.

Autonomic neuropathy of the sympathetic and/or parasympathetic systems has numerous presentations. Most commonly involved is the gastrointestinal tract, with gastric

dysmotility (30% to 50%), gastroparesis, and small bowel bacterial overgrowth, responsible for delayed gastric emptying, early satiety, postprandial nausea, abdominal fullness, bloating and discomfort, constipation, and diarrhea (usually nocturnal). Gastroparesis is frequently responsible for erratic and unpredictable blood glucose levels, with hyperglycemia itself exacerbating the dysmotility, even in people without diabetes. *Gastroparesis* may respond to treatment with metoclopramide or domperidone (dopamine D2 antagonists), erythromycin (motilin agonist) for bacterial overgrowth, cisapride (cholinergic agonist), or mosapride (selective serotonin 5-HT₄ receptor agonist). *Diarrhea* may respond to loperamide or diphenoxylate and atropine. *Orthostatic hypotension* can be treated by attention to mechanical factors such as elevation of the head of the bed, gradual rising from a lying to standing position, use of support stockings, and sometimes use of fludrocortisone. *Cardiac rhythm disturbances* can result in syncope and cardiorespiratory arrest. *Bladder involvement* may result in urinary retention or incontinence. In men, *erectile dysfunction* is multifactorial and may also be related to vascular insufficiency or venous leaks. Arousal is the main problem in the sexual dysfunction of women with diabetes.

DIABETIC FOOT

Care of the feet of patients with diabetes is extremely important to prevent foot ulcers and amputations. Risk factors include distal symmetrical polyneuropathy, peripheral arterial insufficiency, areas of increased pressure, limited joint mobility and bony deformities, obesity, and chronic hyperglycemia. Patient education about foot care includes advice on daily foot inspection, appropriate footwear, drying and nail cutting, and referral to a podiatrist when necessary. Early detection and treatment of blisters, ulcers, trauma, and cellulitis may prevent progression to osteomyelitis and amputation. Treatment of ulcers may include débridement, antibiotics, growth-stimulating factors, reduction of weight bearing (elevation, casting), and improvement in arterial supply (surgical or medical).

MACROVASCULAR COMPLICATIONS

Cardiovascular and cerebrovascular diseases include hypertension, myocardial ischemia and infarction, transient ischemic attacks and strokes, and peripheral vascular disease. Seventy to 80% of people with diabetes die from a macrovascular event. The risk for such an event (2 to 4 times increased in patients with T2DM or >20% over 7 years) in people with diabetes is equivalent to that of nondiabetic patients with established cardiovascular disease (i.e., those who have already had a macrovascular event, e.g., postmyocardial infarction). Thus, all patients with diabetes and no prior cardiovascular event are considered *coronary heart disease*, or *cardiovascular disease, risk equivalents* (Web Fig. 69-9). Following a first cardiac event in people with diabetes, the chance of a second event increases dramatically to 45%. The pathogenesis of *atherosclerosis* (increasingly recognized as an inflammatory disease) and *vascular thrombosis* in people with diabetes is similar to that in people without diabetes, albeit markedly accelerated in the former. Tight glucose control, including acutely

postmyocardial infarction, results in improvement in cardiovascular disease. Women with diabetes have the same risk profile as men at all ages. *Hypertension* (50% of patients with T2DM), *dyslipidemia* (40% of patients with T2DM at diagnosis), *obesity*, *hyperglycemia*, and *smoking* are major risk factors.

In people with diabetes, the risk for death from hypertension is greater than from hyperglycemia. Aggressive treatment of hypertension, to less than 130/80 mm Hg, reduces both macrovascular and microvascular complications and should preferably start with an ACE inhibitor or ARB, for added renal protection. All other classes of antihypertensive agents may be used, including selective β_1 -blocking drugs, which are also used in the secondary prevention of myocardial infarction. β blockers may increase the severity of hypoglycemia by inhibiting glycogenolysis and gluconeogenesis and may mask the warning symptoms and signs of hypoglycemia by blunting the adrenergic response to hypoglycemia. However, the potential adverse effects of β blockers in patients with diabetes have not been consistently observed in the clinical setting. Most hypertensive patients require combination antihypertensive therapy, using, on average, three different classes of agents, including diuretics. In hypertensive patients with microalbuminuria or macroalbuminuria, nondihydropyridine calcium channel blockers may be added to the list of other drugs.

The procoagulant state of the blood in patients with diabetes is caused by *platelet hypersensitivity* to the aggregating properties of thromboxane (synthesized in excess), as well as disordered fibrinolysis and increased levels of the prothrombotic mediator, PAI-1 (see “Metabolic Syndrome,” earlier in this chapter). Low-dose aspirin (81 to 162 mg per day) is recommended as primary prevention in patients with diabetes who are at high risk for cardiovascular disease, as well as secondary prevention in those with evidence of large vessel disease. Additionally, smoking cessation and management of obesity, dyslipidemia, hypertension, and hyperglycemia, together with initiation of safe exercise, all decrease the risk and severity of macrovascular disease. Lifestyle modification is the single most important therapeutic intervention in addressing insulin resistance, glucose control, and overall cardiovascular risk. Glycemic control is a stronger risk factor for microvascular disease than for macrovascular.

CURE AND PREVENTION OF DIABETES

The concepts of prevention, cure, and treatment of diabetes are all part of a continuum without absolute borders. The influence of any intervention will depend on what point in time action is taken.

Metabolic control of diabetes is possible through replacement of insulin. Insulin replacement may be in the form of exogenous insulin (injections, insulin pump; open or closed loop [artificial pancreas]), endogenous insulin (transplantation of pancreas, islets of Langerhans, or β cells), or insulin gene therapy. Besides the insulin pump and insulin injections, none of these modalities has achieved adequate independence as a viable long term therapy.

Primary prevention of diabetes is the holy grail of diabetes research. Although still limited, the improved ability to predict the development of types 1 and 2 diabetes in certain select high-risk groups has resulted in several separate national and international clinical trials to study whether certain therapies administered to asymptomatic high-risk individuals, or newly diagnosed patients, may prevent the appearance of either type of diabetes. In people at high risk for developing T1DM, preventing or altering the autoimmune process has included avoidance of intact dairy proteins, use of nicotinamide, immune modulators, monoclonal antibody preparations, and administration of intravenous and oral insulins. To date, none of these approaches has proved successful. Several clinical trials are still ongoing. Prevention of T2DM in high-risk individuals (e.g., prediabetes, prior GDM, PCOS [see Table 69-1]) has focused on lifestyle modifications to increase exercise, improve healthy nutrition, and control weight. This approach has proved highly successful in reducing the incidence of T2DM by as much as 58%, compared with a 31% reduction in incidence using pharmacotherapy (specifically metformin). Pharmacotherapy to reduce insulin resistance and improve β -cell function, including use of currently available oral antidiabetic agents, is also being investigated.

Secondary prevention of the development of complications of diabetes and tertiary prevention of progression of established complications to end-stage disease was discussed previously.

Prospectus for the Future

The pathogenesis of diabetes and its complications continue to be elucidated, opening original avenues for targeted therapy. New approaches to controlling and modifying this disease, using endogenous physiologic pathways, include use of amylin and incretin mimetics. The glitazars constitute a group of combination preparations of PPAR agonists: α (target of T2DMs) with γ (target of fibrates), and α with γ and δ . The combination of PPAR- α and γ in a single compound delivers dual management of hyperlipidemia (dose-dependent decrease in TG, increase in HDL, and decrease in apo B) and improved tissue insulin sensitivity, with additional benefits in the metabolic syndrome. They are also responsible for reductions in albumin-to-creatinine ratio, hs-CRP, PAI-1, and fibrinogen. The

improvements in plasma lipid and glucose levels, particularly in the postprandial state, hold promise for cardiovascular risk reduction. The list of additional benefits proposed for these combination agents includes an *antiproliferative* role, angiotensin II antagonism, antioxidant, antihypertensive, correction of endothelial dysfunction, reduction in hypertensive and postmyocardial infarction cardiac fibrosis, reduction in visceral, hepatic, and myocellular adipose accumulation, and upregulation of macrophage lipoprotein lipase. These agents may be responsible for weight gain or dyspnea and should not be used in patients with New York Heart Association (NYHA) class III or IV heart failure or in those already taking TZDs and fibrates. At this time, no member of this class has received FDA approval.

Prospectus for the Future—Cont'd

The endocannabinoid system (ECS) is an endogenous signaling system comprising two types of receptors, CB1 and CB2, and several endogenous ligands, endocannabinoids. This system is tonically overactive in human obesity, leading to weight gain, hepatic lipogenesis, insulin resistance, dyslipidemia, and impaired glucose homeostasis. This system potentially provides novel therapeutic targets to control the host of cardiometabolic risk factors so rife in T2DM.

Ninety percent of the renal filtered glucose is reabsorbed by the low-affinity/high-capacity Na⁺ glucose co-transporter 2 (SGLT-2) and facilitated diffusion glucose transporter 2 (GLUT-2) in the renal proximal tubular cells. Several selective inhibitors of SGLT-2 are being developed. They exhibit glucose-lowering effects independently of insulin secretion and increase urinary glucose excretion by inhibiting renal glucose reabsorption. These drugs may provide a new and unique approach to the treatment of diabetes mellitus.

In the evolving pharmacotherapeutic approaches to treating disease, diabetes, hyperlipidemia, and cardiovascular diseases in particular, the concept of a *polypill* to manage several separate but connected metabolic problems is taking hold (e.g., a combination of antihypertensive, antilipid, antioxidant, antihyperglycemic, antiplatelet, and possibly anti-inflammatory agents).

Adipose cell-derived adiponectin and adipokines will play increasingly important roles in the management of T2DM.

Algorithms that dictate the order of prescribing therapeutic agents for blood glucose control, is changing in the light of new therapies such that drugs responsible for β -cell preservation and regeneration will be advocated as first-line treatments before β -cell secretagogues and the other currently available antihyperglycemic agents.

Evaluation of alternate insulin formulations and analogues, delivery routes, and devices includes oral, buccal, nasal, pulmonary, dermal, rectal, and conjunctival. A long-acting polyethylene glycol (pegylated) inhaled insulin is currently under development. Exubera is the first recombinant human inhaled

insulin powder to be marketed to the public. It is taken before meals and appears to achieve blood glucose levels comparable to levels achieved with injected insulins. This drug has been withdrawn by the manufacturing pharmaceutical company apparently as a result of poor patient and physician acceptance.

Research proceeds on mechanical devices such as an implantable artificial pancreas, continuous glucose monitoring and sensing, and noninvasive glucose sensors.

Inflammatory markers in diabetes are now well established. The role of anti-inflammatory therapy is still a matter for discussion and clinical trial evaluation.

Cure of this multifaceted chronic disease grows closer. Improvements in islet cell transplantation technology and anti-rejection protocols are improving prognosis in these patients. β -cell preservation, regeneration, and proliferation, as well as pancreatic ductal cell differentiation to restore pancreatic β -cell mass with the aid of incretins and islet neogenesis gene-associated protein, are promising lines of investigation. Stem cell and gene therapy, too, hold the potential prospects of cure. Anti-CD3 monoclonal antibody alone and in combination with proinsulin peptide is being tested in human phase III studies in patients with newly diagnosed T1DM. A short course of anti-CD3 in phase II studies of patients with recently diagnosed T1DM has demonstrated preserved β -cell function and reduced insulin need for up to 18 months after treatment. Studies in mice have demonstrated reversal of recent-onset T1DM with no recurrence during their lifetimes.

The status of bariatric surgery in the management algorithm of diabetes is currently under review. Successful, minimally invasive laparoscopic techniques are yielding promising results in morbidly obese individuals.

Prediction and ultimately prevention still depend on elucidation of the exact genetic, constitutional, and environmental factors responsible for the group of diseases called diabetes mellitus.

Hypoglycemia

Philip S. Barnett

Definition

Hypoglycemia is defined as a recorded blood glucose concentration lower than normal. Plasma glucose is maintained on a day-to-day basis within a narrow range of 72 to 144 mg/dL (4 to 8 mmol/L) by several hormonal and neural factors. Failure of any of these glucoregulatory mechanisms may result in hypoglycemia. Clinically significant hypoglycemia is rare and is based on the demonstration of Whipple triad: signs and symptoms of hypoglycemia, in the presence of a low plasma glucose concentration (<45 mg/dL), that are relieved by restoration of plasma glucose to normal concentrations. Low plasma glucose values without signs and symptoms, or vice versa, do not constitute clinical hypoglycemia.

Physiology of Glucose Homeostasis

Normal fasting and preprandial plasma glucose values are less than 110 mg/dL (6.1 mmol/L). Postprandially, increases in blood glucose and insulin concentrations, influenced by meal composition, size, and time of day, peak at 1 hour and return to normal after 3 to 4 hours. Two-hour postprandial glucose values do not exceed 140 mg/dL (7.8 mmol/L). The postprandial state comprises the first 4 to 5 hours after a meal. Insulin is the predominant hormone, suppressing hepatic glucose production, promoting glycogen storage, and stimulating extrahepatic glucose utilization. As plasma glucose levels decline (<80 mg/dL), so does insulin secretion. Peripheral glucose utilization declines, whereas there is an increase in glycogenolysis, gluconeogenesis, lipolysis, and proteolysis, resulting in the synthesis of gluconeogenic precursors: lactate, pyruvate, amino acids, and fatty acids. The postabsorptive state begins 4 to 5 hours after a meal.

The response to low plasma glucose levels, *glucose counter-regulation*, occurs on several levels. Central nervous system detection of low glucose levels stimulates the hypothalamus and pituitary to release growth hormone and adrenocorticotropin. Catecholamines, particularly epinephrine, are

released from the adrenal medulla, and cortisol is released from the adrenal cortex. Insulin secretion is reduced, and glucagon secretion is augmented as a direct effect of low blood glucose concentration on pancreatic islets and in response to central neurogenic stimulation. Of the four counter-regulatory hormones (glucagon, epinephrine, growth hormone, and cortisol), glucagon is the most important in the acute response to hypoglycemia, 65 to 70 mg/dL. It acts rapidly to increase hepatic glucose production through *glycogenolysis*, the major source of fasting glucose, and *gluconeogenesis*, which becomes increasingly important as glycogen stores are depleted. Hepatic glycogen stores are usually sufficient to maintain glucose levels for about 8 hours. In patients with type 1 diabetes mellitus (T1DM) of more than 3 to 5 years' duration, the glucagon response is lost. Epinephrine is also part of the rapid counter-regulatory hormone response to hypoglycemia and plays a major role when it replaces the lost glucagon response in patients with T1DM. Epinephrine is also subsequently lost as a response to hypoglycemia 10 to 15 years after diagnosis in about 25% of patients with diabetes. Epinephrine inhibits insulin secretion and thereby inhibits glucose uptake by muscle. It stimulates glycogenolysis and lipolysis, and the resultant increase in free fatty acids (FFAs) acts as a stimulus for hepatic gluconeogenesis. Growth hormone and cortisol characterize the delayed response to hypoglycemia (2 to 3 hours), enhancing glucagon's effect and antagonizing the action of insulin by accelerating hepatic gluconeogenesis, suppressing muscle glucose utilization, and stimulating lipolysis, ketogenesis, and proteolysis. With prolonged hypoglycemia, the liver responds through autoregulation with an increase in glucose production. For growth hormone, these defense mechanisms start at a blood glucose level of 60 to 65 mg/dL, and less than 60 mg/dL for cortisol.

SIGNS AND SYMPTOMS OF HYPOGLYCEMIA

The various signs and symptoms of hypoglycemia appear at different glycemic thresholds and in response to different

mechanisms. They can be divided into *neurogenic* (increased autonomic nervous system activity) and *neuroglycopenic* (depressed activity of the central nervous system) (Table 70-1). Signs and symptoms may vary among patients but are fairly constant for a given person. Accommodation to hypoglycemia results from a resetting of glycemic thresholds. As many as 25% of patients with diabetes, mainly type 1, may suffer from *hypoglycemic unawareness*, with serious consequences. Loss of warning symptoms and signs results from progressive loss of glucagon and epinephrine responses over time, lowering of the glycemic threshold by intensive therapy or repeated hypoglycemic episodes, and autonomic dysfunction resulting from the diabetic process. The delayed counter-regulatory responses of growth hormone and cortisol are usually too late to prevent neuroglycopenia. A prior episode of hypoglycemia often impairs detection of a subsequent one, especially if it occurs soon after the first. In some patients, hypoglycemia awareness may be restored if hypoglycemia is rigorously prevented.

The definition of a normal blood glucose level depends on the circumstances, the sex of the patient, and the sample tested: arterial, venous, or capillary blood, and whole blood versus plasma or serum. Venous plasma is the usual sample measured, and its glucose concentration is about 15% higher than that of whole blood. Patients with diabetes use capillary whole blood for daily self-monitoring purposes. Some newer glucose-sensing devices sample interstitial fluid. Normal plasma glucose values during a fast are different in men and women; in men, the fasting plasma glucose concentration is 55 mg/dL (3.1 mmol/L) at 24 hours and 50 mg/dL (2.8 mmol/L) at 48 and 72 hours, whereas, in premenopausal women, it may be as low as 35 mg/dL (1.9 mmol/L) at 24 hours without symptoms of hypoglycemia. Exercise in healthy persons generally does not lead to a fall in glucose levels.

Concern about hypoglycemia stems from its possible devastating effects on the brain. The central nervous system cannot synthesize glucose or store enough glycogen for more than a few minutes' glucose supply. The brain cannot use FFAs as an energy source, and ketone bodies, which are generated late, are not useful in acute hypoglycemia. Medium-chain triglycerides appear to protect the brain from injury during acute hypoglycemia. Because glucose is the predominant metabolic fuel for the central nervous system, significant hypoglycemia can cause acute and permanent brain dysfunction, and, if prolonged, it may result in brain death.

Acute hypoglycemia causes cognitive dysfunction, which does not appear to be permanent in most patients with T2DM. Elderly patients do appear, however, to develop a permanent subtle form of cognitive dysfunction. T2DM is associated with an increased risk for dementia. Repeated hypoglycemic episodes appear to modify cognitive responses and reduce hypoglycemic awareness through some form of cerebral adaptation.

GLYCEMIC THRESHOLDS

Despite the ranges of normality discussed previously, the glycemic thresholds discussed in this paragraph apply to the general population. Falling plasma glucose concentrations trigger a set sequence of events. Within the physiologic plasma glucose range, a drop in glucose to less than 80 mg/dL (4.5 to 4.6 mmol/L) results in decreased insulin secretion. At levels slightly lower than the normal range, 70 mg/dL (3.6 to 3.8 mmol/L), secretion of the insulin counter-regulatory hormones occurs: glucagon and epinephrine at 68 mg/dL, growth hormone at 60 mg/dL, and cortisol at 60 mg/dL (3.2 mmol/L). The glycemic threshold for symptoms of hypoglycemia is about 54 mg/dL (3 mmol/L) and, for cognitive dysfunction, about 47 mg/dL (2.6 mmol/L). These glycemic thresholds vary in response to the level of glucose control, particularly in patients with diabetes; poorly controlled diabetes with persistent hyperglycemia results in higher glucose thresholds, whereas lower glucose thresholds are reset after single or repeated hypoglycemic episodes. In some people, major symptoms of central nervous system dysfunction may not occur until the plasma glucose concentration reaches 20 mg/dL because these people have a compensatory increase in cerebral blood flow.

Clinical Classification of Hypoglycemia

Hypoglycemia occurs most commonly as a side effect of the treatment of diabetes mellitus, usually associated with impairment of insulin counter-regulatory responses. Severe hypoglycemia occurs in as many as 25% of patients with diabetes. It is more frequently associated with young patients and older adults, especially if the patient is fasting, has erratic meal times, has alcohol on an empty stomach (decreased endogenous glucose production), has recently engaged in strenuous exercise (up to 12 hours), has renal impairment (reducing insulin excretion), has low glycosylated hemoglobin (HbA_{1c}), has had a short duration of diabetes, or has had

a prior severe hypoglycemic episode, and is more common during sleep. The incidence increases with attempts to achieve euglycemia through tight control of glucose concentrations; 65% of patients with T1DM in the Diabetes Control and Complications Trial and 11% of patients with type 2 diabetes mellitus (T2DM) in the United Kingdom Prospective Diabetes Study had episodes of hypoglycemia that required assistance of a second party to administer therapy with either intramuscular or subcutaneous glucagon or intravenous glucose. Men tend to suffer from hypoglycemia more commonly than women. Patients with T1DM have longer hypoglycemic episodes and greater frequency than patients with T2DM treated with insulin or oral hypoglycemic agents. Two to 4% of T1DM patients will die of a hypoglycemic episode. In patients with T2DM, duration of hypoglycemia is greater at night, especially after midnight, than during the day.

Other causes of hypoglycemia in patients with diabetes include overdose of insulin or oral insulin secretagogues, missed or delayed meals, and uncompensated (without supplemental calories or a decrease in insulin dose) exercise (immediate or delayed, up to 24 hours). Increased insulin sensitivity may also be responsible. *Nocturnal hypoglycemia*, exhibited by night sweats, snoring, vivid dreams, and deep sleep, occurs in as many as 50% of patients receiving insulin. Maximal insulin sensitivity at 2:00 or 3:00 AM may coincide with peak exogenous insulin action. Treatment usually includes changing one or more of the following: timing of intermediate-acting insulin from dinner to bedtime, insulin dose, type of insulin (e.g., glargine), type of insulin delivery (e.g., insulin pump), time of meal, and meal composition. In addition, adding a snack and using uncooked cornstarch can be considered.

The following discussion addresses the separate causes of hypoglycemia listed in Table 70-2.

FASTING (POSTABSORPTIVE) HYPOGLYCEMIA

Fasting (postabsorptive) hypoglycemia results from an imbalance between hepatic glucose production (decreased) and peripheral glucose utilization (increased).

Drugs

Insulin, sulfonylureas, meglitinides, and alcohol are the most common causes of fasting hypoglycemia. Insulin is a well-recognized cause of hypoglycemia in the treatment of diabetes. Elevated serum insulin levels in the absence of elevated C-peptide levels can detect *factitious hypoglycemia* resulting from the covert use of insulin by persons with and without diabetes.

Overdose with sulfonylureas occurs commonly in elderly patients taking long-acting and highly potent agents such as chlorpropamide or glyburide. This overdose is usually inadvertent but occasionally intentional (factitious), and it may be determined by measuring serum or urine sulfonylurea levels. Because of the mechanism of sulfonylurea action (insulin secretagogue), insulin and C-peptide levels are elevated. Patients with sulfonylurea-induced hypoglycemia should not be discharged from the emergency room after

initial normalization of plasma glucose concentrations because hypoglycemia recurs soon afterward as a result of the long half-life of many of these agents, which may be even longer in patients with comorbid conditions such as renal dysfunction. Several days of continuous glucose treatment may be required before the hypoglycemia resolves. Hypoglycemia related to meglitinide, or D-phenylalanine derivative therapy or overdose, would not be expected to be as severe as that caused by sulfonylureas because of its short duration of action.

Excessive alcohol consumption is a common cause of hypoglycemia. In patients with diabetes treated with oral agents or insulin, the combination with alcohol can be dangerous. Hypoglycemia may occur many hours after ingestion of alcohol (*morning after the night before*). Alcohol suppresses hepatic gluconeogenesis, not glycogenolysis, and hypoglycemia occurs in malnourished patients with chronic alcoholism or following a several-day binge of alcohol con-

sumption with minimal food intake (depleted hepatic glycogen reserves).

Nonselective β_2 -adrenergic antagonists may cause hypoglycemia in patients with diabetes (especially type 1) who do not have a normal glucagon counter-regulatory response and depend on the adrenergic response to hypoglycemia. β_2 -Adrenergic antagonists mask the adrenergic symptoms and impair recovery from hypoglycemia. These agents also reduce the glycogenolytic response to epinephrine in muscle. Low doses of β_1 -selective adrenergic antagonists do not produce these effects, although their selectivity is incomplete in high doses.

Pentamidine (particularly parenteral), through β -cell destruction, causes acute insulin release with hypoglycemia. Following this acute phase, the destroyed β cells fail to produce insulin, and hyperglycemia ensues. In children, salicylates may lead to increased insulin secretion through prostaglandin inhibition. Quinine can cause excessive pancreatic insulin release. Sulfonamides may rarely be responsible.

Critical Illness

In hospitalized patients, the most common cause of hypoglycemia is use of drugs, especially insulin. Single- or multiple-organ system failures (particularly hepatic, renal, cardiac, and adrenal), malnutrition, sepsis, and shock are next. The mechanism of hypoglycemia in each setting is multifactorial and not always entirely clear. Disease or failure of one organ system may affect another system, resulting in hypoglycemia, such as that seen in right ventricular cardiac failure causing hepatic congestion. Hepatic failure results in impaired gluconeogenesis as well as an inability to store and release glycogen. Renal failure may lead to prolongation of the half-life of hypoglycemia-inducing agents (sulfonylureas, meglitinides, and insulin). Malnutrition also plays a major role in renal failure as a cause of hypoglycemia. In starvation, there is loss of adipose tissue and gluconeogenic precursors. Insulin antibodies and hypothyroidism may delay insulin clearance and increase the risk for hypoglycemia. In adrenal insufficiency, lack of cortisol, which normally supports gluconeogenesis, may result in hypoglycemia. Sepsis is associated with increased glucose utilization in excess of glucose production. Severe malaria may be associated with hypoglycemia resulting from increased glucose utilization by parasitized red blood cells.

Insulinoma

Insulinoma is a rare pancreatic β -cell tumor that has an incidence of 1 in 250,000 patient-years and is more common in women (60%) than in men. It occurs at all ages; the median age at diagnosis is 50 years in sporadic instances and 23 years in patients with multiple endocrine neoplasia type I syndrome (8% to 10% of patients). Most of these tumors are benign (90% to 95%), solitary (93%), confined to the pancreas (99%), and small (average, 1 to 2 cm). Characteristically, insulinomas remain undiagnosed or misdiagnosed (20%) as psychiatric or neurologic disorders for several years. Long-term excessive insulin secretion, or *hyperinsulinemia*, which is not responsive to falling glucose concentrations in the fasting state, results in persistent hypoglycemia. Patients eat frequently to stave off the hypoglycemia and may gain weight (20%). Adaptation to the hypoglycemia

Table 70-3 Protocol for Performing a 72-Hour Fast

1. Patient admitted to hospital. Stop all nonessential medications. Calorie- and caffeine-free drinks are permitted. Start fast after evening meal at 1800 hr.
2. Blood glucose level monitored by bedside reflectance glucose meter every 4 hr and when symptoms of hypoglycemia develop. The presence of urinary ketones confirms that the patient is fasting.
3. When symptoms of hypoglycemia develop accompanied by a blood glucose level of ≤ 50 mg/dL (plasma glucose of ≤ 45 mg/dL), draw *diagnostic labs*, consisting of a fasting plasma glucose concentration; β -hydroxybutyrate serum insulin, C-peptide, and proinsulin levels; and a serum sample for sulfonylurea agents and insulin-like growth factor I (IGF-I) and IGF-II levels (the latter three to be sent only once per fast). The fast is terminated at this time.
4. In the absence of documented hypoglycemia at the end of 72 hr, the fast is terminated. Vigorous exercise for 2 hr may result in a fall in blood glucose. If the patient is symptomatic, give 1 mg of glucagon, intravenously or intramuscularly.
5. The patient is fed a meal and is discharged from the hospital.
6. If severe, persistent hypoglycemia is documented, the patient may need to be started on medication, such as diazoxide, to prevent further episodes of hypoglycemia while the work-up is proceeding.

over time results in manifestation of neuroglycopenic symptoms far more commonly than neurogenic symptoms. Most patients have fasting hypoglycemia (plasma glucose < 45 mg/dL), demonstrated by a 72-hour fast (Table 70-3), and inappropriately elevated serum insulin, C-peptide, and proinsulin levels ($> 20\%$ of total insulin). Some patients have reactive hypoglycemia as well. A C-peptide suppression test, in which endogenous insulin and C-peptide are normally suppressed during an insulin infusion, is impaired in the presence of an insulinoma. This test is not routinely performed.

After the biochemical diagnosis of an insulinoma, surgical resection by an experienced surgeon is generally recommended, irrespective of negative tumor localization studies. Localization of insulinomas using computed tomography, ultrasound (including endoscopic), magnetic resonance imaging, celiac axis angiography, aortography, or transhepatic portal venous sampling may be unsuccessful because of the generally small size of these tumors. An octreotide scan may prove useful. At operation, tumors are often found by intraoperative ultrasound or palpation of the pancreas. Distal pancreatectomy is sometimes performed if no tumor is found during the surgical procedure.

In patients who are unwilling to undergo surgical treatment, in patients awaiting surgery, or in those in whom surgical treatment has failed, medical therapy using diazoxide, which inhibits insulin secretion, or octreotide is indicated. Continuous subcutaneous infusion of glucagon prevents hypoglycemia. In patients with malignant insulinoma, streptozotocin, with or without doxorubicin or fluorouracil, has been used.

Non- β -Cell Tumors

Fasting hypoglycemia may be caused by a wide variety of rare, non- β -cell tumors. Many (about 50%) are large, slow-growing mesenchymal tumors, which are often malignant. More than one third of these tumors are retroperitoneal, one third intra-abdominal, and the rest intrathoracic. Epithelial tumors include hepatocellular carcinomas (about 25%), adrenocortical carcinomas (5% to 10%), and gastrointestinal (carcinoid) tumors (5% to 10%). Lymphomas account for 5% to 10%. In most patients, overproduction of insulin-like growth factor II (IGF-II) and, more particularly, the incompletely processed form, *big* IGF-II, is responsible for hypoglycemia as a result of their direct insulin-like actions as well as their suppression of glucagon and growth hormone and hence IGF-I levels.

Diagnosis is made based on hypoglycemia in a patient with a known tumor or elevated IGF-II levels. A 72-hour fast reveals hypoglycemia with appropriately suppressed serum insulin, C-peptide, and proinsulin levels. Treatment involves tumor resection. If surgical treatment is not completely successful, glucocorticoids may be beneficial.

Insulin and Insulin Receptor Autoantibodies

Hypoglycemia may result from production of insulin autoantibodies and insulin receptor autoantibodies, which are extremely rare and may be associated with other autoimmune disorders. Antibody binding to insulin may result in hypoglycemia by releasing insulin at an inappropriate time or by preventing its degradation. Insulin receptor antibodies may be *blocking*, causing insulin resistance. Alternatively, antibodies with receptor-agonist activity may produce hypoglycemia with elevated C-peptide levels.

REACTIVE (POSTPRANDIAL) HYPOGLYCEMIA

Reactive (postprandial) hypoglycemia typically occurs within 4 hours of food consumption; glucose levels fall more rapidly than insulin levels. Some people with impaired glucose tolerance initially have a delayed excessive insulin response to a meal that results in reactive hypoglycemia. In all forms of fasting hypoglycemia, patients may also demonstrate reactive hypoglycemia.

Alimentary Hypoglycemia

Alimentary hypoglycemia occurs in people who have undergone gastric surgery (gastrectomy, gastrojejunostomy, pyloroplasty, gastric bypass, or vagotomy) and consists of postprandial vasomotor symptoms: palpitations, tachycardia, lightheadedness, sweating, postural hypotension, and sometimes abdominal discomfort and vomiting. This *early dumping syndrome* occurs within 30 minutes of eating and is caused by rapid emptying of food from the stomach into the duodenum, associated with a large fluid shift into the gut lumen. The *late dumping syndrome* occurs between 90 and 180 minutes after eating, resulting in dizziness, lightheadedness, palpitations, sweating, confusion, and rarely syncope. Rapid emptying into the upper small bowel of a meal rich in simple carbohydrates results in abrupt hyperglycemia, enhanced secretion of insulinotropic incretins,

early marked hyperinsulinemia, and subsequent hypoglycemia. Treatment of both syndromes includes frequent small meals and elimination of simple sugars and liquids at mealtime.

Idiopathic Hypoglycemia

The existence of idiopathic hypoglycemia, an overdiagnosed condition, is still in dispute. In most patients, adrenergic symptoms, which are usually vague, do not occur simultaneously with biochemical hypoglycemia and are not relieved by consuming food. Occasionally, artificial testing situations (5-hour oral glucose tolerance test [OGTT]; 72-hour fast) may suggest the diagnosis, but these findings are not borne out following consumption of a mixed meal.

Diagnostic Work-Up of Hypoglycemia

A thorough history and physical examination are crucial. Hypoglycemia occurs most commonly in patients with drug-treated diabetes mellitus. Confirmation of hypoglycemia is essential before any work-up. Ambulatory patients can be trained in self-monitoring of blood glucose (SMBG), particularly during symptomatic episodes. However, frequent SMBG may miss as many as 50% of hypoglycemic episodes. Use of a continuous glucose monitoring system (CGMS) may be helpful in this setting, with the patient recording symptoms. If blood glucose levels are low (<50 mg/dL) and the symptoms resolve after carbohydrate ingestion, the patient probably has true hypoglycemia. If symptoms are present without documentation of hypoglycemia, an alternate explanation must be sought. If hypoglycemia occurs in the fed state, after excluding a history of gastric surgery, the likely cause is impaired glucose tolerance (confirmed by OGTT) or, in rare cases, idiopathic reactive hypoglycemia (diagnosis by exclusion). If reactive hypoglycemia is diagnosed, the patient should consult a dietitian for a diet plan designed to ameliorate these episodes (e.g., frequent low-carbohydrate meals).

Fasting hypoglycemia is more likely to be caused by an organic medical problem, although some of the underlying disorders (such as insulinoma and adrenal insufficiency) can produce both fasting and reactive hypoglycemia (see Table 70-2). Adrenal insufficiency should be ruled out with a cosyntropin test. When patients are hospitalized and are acutely ill, the distinction between fasting and reactive hypoglycemia is less clear; the work-up is then based on an understanding of the patient's underlying medical problems and therapies and the influence of these factors on blood glucose homeostasis.

The standard evaluation of hypoglycemia attributable to any other underlying cause includes hospital admission for a supervised 72-hour fast (see Table 70-3). During the fast, patients are only allowed noncaloric, noncaffeinated beverages and essential medications. These patients should be active during the day. About 75% of patients with an insulinoma develop symptomatic hypoglycemia within the first 24 hours, 10% in the next 24 hours, and only 5% in the final 24 hours. Difficulties in performing the fast arise when blood glucose levels fall to less than 50 mg/dL and the patient has no symptoms of hypoglycemia or when the patient develops

Table 70-4 Interpretation of Results from a 72-Hour Fast

Condition	Plasma Glucose (mg/dL)	Insulin (mcU/mL)	C-Peptide (nmol/L)	Proinsulin (pmol/L)	Plasma Sulfonylurea Level (nmol/L)	Insulin-like Growth Factor II
Normal*	≥45 in men, >36 in women	<6	<0.2	<5	—	—
Insulinoma	≤45	>6	>0.2	>5	—	—
Exogenous insulin	≤45	≥6 [†]	<0.2	<5	—	—
Sulfonylurea agents	≤45	≥6	≥0.2	≥5	>0.2	—
Tumor secreting	≤45	≤6	<0.2	<5	—	+(↓ IGF-I)

*Normal insulin, C-peptide, and proinsulin levels may be higher if blood glucose levels are not less than 60 mg/dL.

[†]Insulin levels may be very high (100 mcU/mL) in these patients.

IGF, insulin-like growth factor; —, present; + elevated.

symptoms with normal blood glucose levels. In the former situation, continued measuring blood glucose levels should be performed, with the patient under close medical observation, until the concentration falls to less than 50 mg/dL. In the latter instance, the fast can be continued as long as is clinically warranted to convince both patient and physician that the symptoms are not associated with hypoglycemia. Table 70-4 summarizes the expected findings in various conditions at the completion of the fast.

Artificial or pseudo hypoglycemia is a test-tube phenomenon caused by excessive glucose utilization by elevated leukocytes in certain chronic leukemias, hemolytic anemia, and polycythemia. Concern about technical problems with sample collection, storage, and analysis warrants repeat testing.

Factitious fasting hypoglycemia may be seen most commonly in health care workers, patients with diabetes, and their relatives. These patients will have low C-peptide and low proinsulin serum levels.

Treatment

The diagnosis of hypoglycemia should be considered in every unconscious patient. The initial treatment of a confused or comatose patient is to infuse a 50-mL intravenous bolus of 50% glucose, preferably after obtaining a blood sample for laboratory analysis. If hypoglycemia is documented, blood should then be tested for electrolytes, blood urea nitrogen and creatinine, ketones (urine and plasma), insulin (<6 mU/mL), C-peptide, cortisol, drugs, toxins, hypoglycemic agents (e.g., sulfonylurea [<0.2 nmol/L] or meglitinide), and alcohol. A plasma insulin-to-glucose ratio of greater than 0.4 is significant. A portion of the sample should be kept for later analysis of proinsulin, insulin antibodies, and lactate, when necessary.

Intravenous, intramuscular, or subcutaneous glucagon (1 mg) can be used in the absence of an intravenous glucose preparation. The bolus of glucose should be followed by the continuous infusion of 5% to 10% glucose (rarely, 20% to 30%) at a rate sufficient to keep the plasma glucose level greater than 100 mg/dL (starting at 100 mL per hour). The

requirement of 8 to 10 g of glucose per hour to prevent recurrent hypoglycemia suggests diminished glucose production as a cause of the hypoglycemia, with higher requirements reflecting increased peripheral glucose utilization. When the patient is capable of eating, a diet with a minimum of 300 g of carbohydrate per day should be supplied. In many situations, especially after administration of long-acting insulin or oral hypoglycemic agents, hypoglycemia persists for an extended time. Treatment and close observation should continue during this time to prevent a relapse. Mild hypoglycemia can be managed with oral glucose tablets (4 or 5 g), fruit juice, or the equivalent, followed by a snack containing carbohydrate and protein, if the patient has to wait more than 30 minutes for the next meal. Thiamine should be administered when alcohol consumption is suggested.

Long-term therapy depends on the cause of the hypoglycemia. If the hypoglycemia is a secondary process, such as from hepatic or renal failure, or sepsis, treatment of the underlying disorder will resolve the hypoglycemia. If the hypoglycemia results from an insulinoma, surgical removal of the tumor is the treatment of choice.

Recurrent hypoglycemia in patients with diabetes requires a multidisciplinary intervention with attention to detail at every level of management, including education, nutritional advice, frequent glucose monitoring (including CGMS), and physiologic insulin and oral agent therapy (including administration technique).

Dietary therapy is the cornerstone of the management of all types of reactive hypoglycemia. Patients should avoid simple and refined carbohydrates. Some patients also benefit from frequent, small meals or snacks that contain a mixture of carbohydrate, fat, and protein. If a regimen of avoidance of simple carbohydrates and eating more frequently is ineffective, restricting the daily carbohydrate intake to 35% to 40% of total calories and increasing protein intake can be helpful. Drug therapy with propantheline bromide or phenytoin may sometimes be helpful, but it should be reserved for severe cases. If the disorder results from alimentary hypoglycemia, dietary therapy is usually helpful; in refractory instances (rare), surgical treatment to slow gastric transit time may be successful.

Prospectus for the Future

Successful islet transplantation, β -cell regeneration, or implantable artificial pancreas will result in *physiologic* insulin levels and eliminate the curse of hypoglycemia related to mismatches between insulin and serum glucose levels in patients with diabetes mellitus.

New therapeutic approaches in the management of diabetes should reduce the frequency and severity of hypoglycemic epi-

sodes (see Chapter 69), especially as we aim for tight glycemic control.

Heightened awareness of the causes, sequelae, and treatment of hypoglycemia should reduce its frequency and severity.

Women's Health Topics

Deborah Ehrenthal, Patricia Carney, Renee Kottenhahn,
and Pamela Charney

A. Introduction

Over the past few decades, there has been increasing exploration of how a patient's individual characteristics, such as sex and age, affect physiology, health, disease presentation, and management. Science inquiry has gradually expanded to other potential differences such as ethnic and racial background, and the impact of socioeconomic factors and geographic location. At this point, there is adequate information about differences between males and females to alter medical care in many areas. This chapter will review some of the known sex differences, highlighting diseases unique to women and some key areas in which differences between women and men alter health and medical care.

What Is Women's Health?

Women's health is defined currently as a multidisciplinary approach to the health and care of women patients. Specialists in this area come from a wide range of disciplines and often enjoy collaborating. The conceptual growth of women's health beyond gynecologic and obstetrical issues coincided with an increase in the number of women becoming physicians in the United States as well as curiosity among clinicians and researchers in how women and men differ.

Health, both physical and psychological, is affected by biologic, cultural, societal, and economic issues throughout the age spectrum. As the interaction of these factors has been explored, new insights have emerged. For example, tobacco use, as well as the success of smoking cessation, is affected by many factors. Generally, men smoke more than women in America, but there are wide differences between racial-ethnic and educational groups. Among women, Native Americans have the highest tobacco use rates (and represent

the only group in which women smoke at higher rates than men), whereas women self-identified as Asian have the lowest rates of tobacco use. Lower educational level correlates with greater tobacco use, and 1 in 3 high school graduates but only 1 in 10 college graduates smokes. This is one reason why tobacco companies advertise more prominently on billboards in poor neighborhoods. As the price of cigarettes increase, there are lower rates of initiation among teenagers. Similarly, there are important differences in tobacco cessation. Women tend to have more difficulty stopping cigarette consumption both initially and long term than men. Women are more likely to stop smoking in response to social pressure, especially from their children, whereas men are more likely to stop smoking as the result of peer pressure at work. A major barrier to tobacco cessation for women is fear of weight gain. Repeatedly when surveyed, women smokers are not willing to gain *any* weight while stopping tobacco use. However, the average smoker who stops cigarette use gains 10 pounds, and as many as 20% while stopping use gain 20 pounds or more. Black smokers also have more trouble stopping. This difference has been linked to that the finding that black smokers lack an enzyme that breaks down tobacco products and therefore obtain higher levels of nicotine in their bloodstream after smoking than white or Mexican American smokers. This effect is even found after smoking only two cigarettes daily. All smokers, regardless of age or sex, will reap the benefits of smoking cessation, even older smokers and those with tobacco-related diseases. Specific cessation therapies are discussed in Chapter 17.

Women's health focuses on conditions unique in women (pregnancy), conditions that are more common in women (breast cancer, osteoporosis, rape, and hypertension), and conditions that have different presentations, natural history,

risk factors, prevention, or treatments in women and men (heart disease, urinary tract infections, sexually transmitted diseases). As more is known, the specific topic areas included within the field of women’s health has expanded. For example, post-traumatic stress was initially identified among returning war veterans, predominantly male, who had seen extensive combat. Only as successful therapeutic approaches developed was it realized that this syndrome was also present among survivors of non-war-related trauma, especially among many women. In addition, as the number of women in the military has increased and medical care has begun to focus on this group, it has become more common knowledge that women veterans may also experience post-traumatic stress from their experiences in the armed forces. Several women’s health topics are reviewed in detail in other chapters, including osteoporosis, eating disorders, urinary tract infections, and sexually transmitted diseases.

Knowledge expands as critical questions are defined and answered. There have been several important ongoing studies that have dramatically increased knowledge in women’s health. Each study has defined a group of individuals, a cohort, and follows them prospectively over time. As new scientific questions have evolved, it has been possible to use these cohorts to provide preliminary results. One limitation of the earlier studies was the lack of diversity in the participants in the cohort. Results from a more diverse cohort group have broader population implications.

Perhaps the most important cohort studies that have improved our ability to explore sex differences are the Framingham Study, the Nurses Health Study, and the Women’s Health Initiative (WHI). The first was the Framingham Study, a longitudinal prospective cohort of adults living in Framingham, Massachusetts. The initial goal of the study was to identify risk factors for heart disease by following this large and stable cohort of men and women in their 40s. In the initial reports, men with chest pain were more likely to die of heart disease than women who reported chest pain. This supported the perception at the time that heart disease was a disease of men. It wasn’t until women were observed into their 50s that women began developing symptoms and dying of heart disease. When researchers looked back and further defined chest symptoms from the earlier reports, it was found women and men with typical angina symptoms had similar outcomes. However, women were more likely to report any symptoms than men, including some type of chest pain. In fact, angina is the most common presenting symptom of coronary artery disease in women, whereas for men, it is most likely an acute myocardial infarction. The Framingham data set also revealed that silent myocardial infarctions are more common in women than men. The Framingham study is now multigenerational and has been expanded to include the greater diversity of individuals living in Framingham.

The Nurse’s Health Study is a national ongoing survey of a cohort of female nurses that has provided detailed information about risk factors, disease presentation, and outcomes for decades. Participants complete extensive questionnaires regularly and have occasionally provided specimens for analysis. Because it is a prospective cohort group, it has been possible to evaluate many risk factors. Among tobacco smokers, the adverse health effects are dose related, and those smoking one or two cigarettes daily have less

health problems than those smoking a pack of cigarettes daily but more problems than nonsmokers. Higher levels of physical activity have correlated with less weight gain with aging and lower rates of cancer and cardiovascular disease. Detailed dietary information has allowed comparison of fat (olive oil was better than margarine and butter) and other dietary impacts on health outcomes. Limitations of the study include the population and the self-report nature of the data.

Finally, the WHI enrolled women 50 to 79 years of age in three clinical trials and an observational arm. The population of the WHI is the most ethnically and racially diverse of the three studies. The clinical trials were all randomized, double-blinded with placebo control. Two were designed to resolve questions about the impact of estrogens and estrogens plus progesterone on the risk for a variety of important health outcomes for women during the postmenopausal period. These included cardiovascular risk, maintenance of bone density, risk for breast cancer, and development of dementia. Although these pharmaceutical trials have ended, the observational study continues. The WHI clinical trials of hormonal therapy have dramatically changed the therapeutic approach to menopause. Whereas earlier observational studies, including the Nurses Health Study, had suggested that hormonal therapy decreased cardiovascular events after menopause, this careful prospective trial found that there was no substantial cardiovascular benefit with either estrogen alone or estrogen and progesterone. This trial is discussed later in this chapter in more detail.

Biology and Physiology

There are substantial biologic and physiologic differences between males and females. Some differences have been long acknowledged, whereas other areas are just beginning to be explored.

BIOLOGY

Women are generally smaller physically than men—about 5 inches shorter. Renal mass is less, and in the past decade, this has been acknowledged in defining normal renal function. The shorter urethral distance places women at much higher risk for urinary tract infections than men. Physically, an individual’s volume of muscle and fat varies by sex and age. Because of the pelvis requirements needed to allow child-birth, the hip and knee angles from the pelvis are different by sex. This leads to different stresses and lower extremity injuries in women than generally occur in men. Women’s anatomically smaller blood vessels are finally becoming less of a barrier to invasive therapies as smaller catheters have been developed.

Both women and men are most likely to die of cardiovascular disease. Cancer is the second most common cause of death for women and men. However, the most likely new cancer diagnosis and cause of death is breast cancer for women (and prostate cancer for men). The third most common cause of death is stroke. Interestingly for middle-aged women younger than 65 years, white women are most likely to die of chronic obstructive pulmonary disease (of these groups, white women have the highest rate of tobacco use), black women are most likely to suffer a stroke (in a

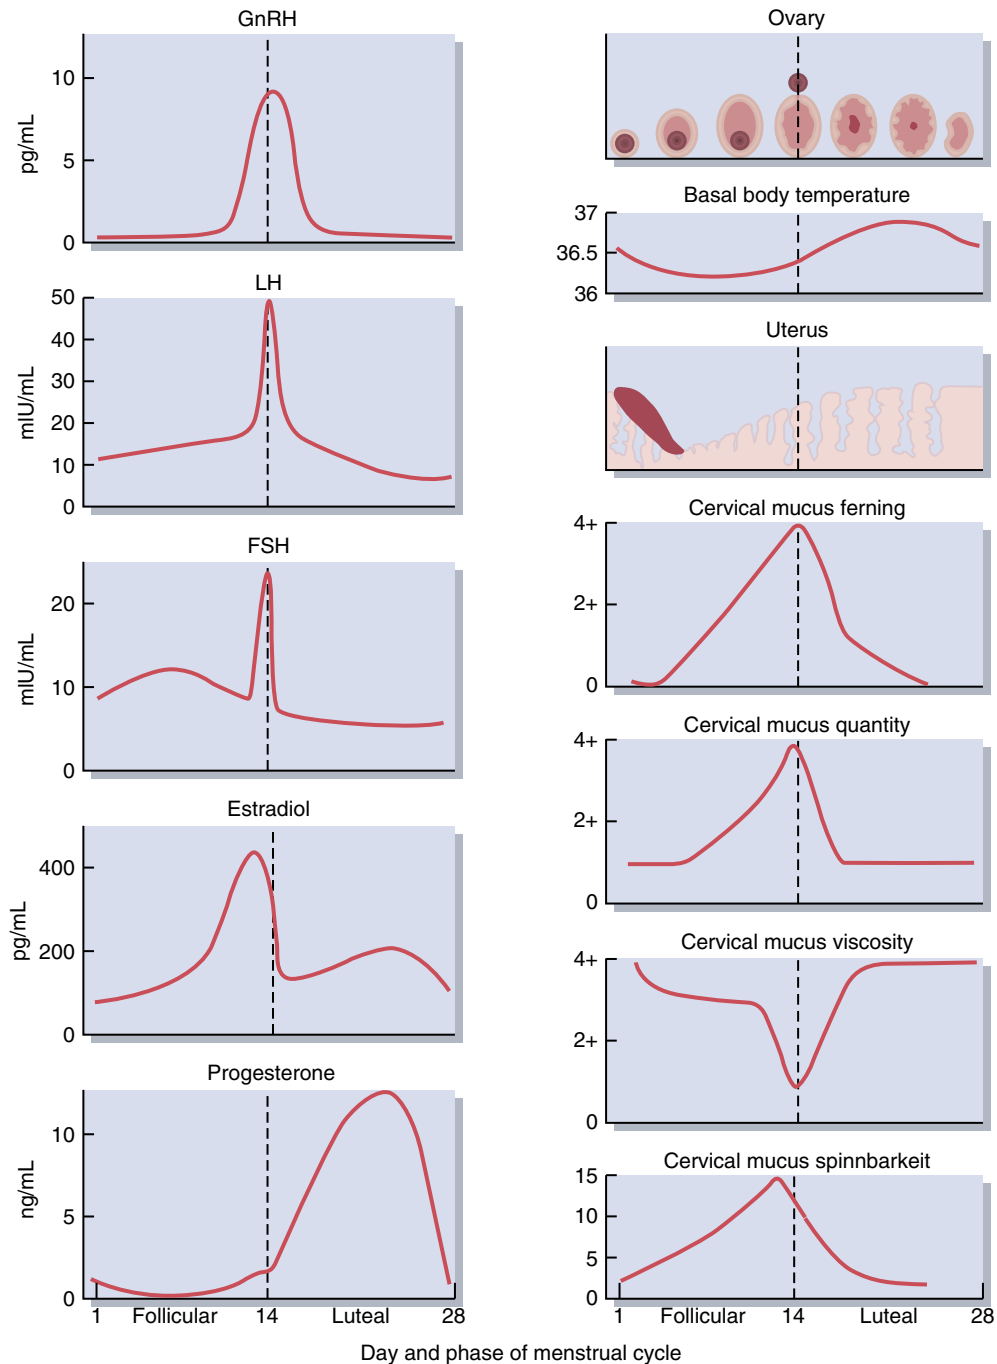

Figure 71-1 Schematic representation of the normal menstrual cycle. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone. (From Braunstein GD: Female reproductive disorders. In Hershman JD [ed]: Endocrine Pathophysiology: A Patient-Oriented Approach. Philadelphia, Lea & Febiger, 1988, p 153.)

population with early onset of hypertension), and Hispanic women are most likely to die of diabetes and its complications (high rates of obesity and diabetes).

PHYSIOLOGY

Comparative Physiology

This section focuses predominantly on reproductive physiology. However, the most interesting and provocative findings have occurred through exploring sex differences in physiology. Substantial cardiovascular physiologic differ-

ences have been documented. For example, in order to increase cardiac output, females increase heart rate, whereas men increase stroke volume. Because increases in stroke volume are limited by the need for relaxation so that the cardiac chambers can refill, there is a greater physiologic cap for increases in cardiac output in women. Sympathetic tone also appears to vary by sex and may be one reason that premenopausal women tend to have lower blood pressure than age-matched men. Gastrointestinal physiologic differences have also been highlighted. Gastric alcohol absorption is faster in women. Hepatic drug clearance varies by sex,

ethnicity, and race, depending on the enzyme studied. Females are more likely to develop gallstones.

Reproductive Physiology

Estrogen levels vary substantially throughout life. Estrogen levels are low in childhood. At the time of puberty, the hypothalamus begins releasing gonadotropin-releasing hormone (GnRH), leading to ovarian stimulation. Eventually, most women develop a regular menstrual cycle with associated periodic increases in estrogen and then progesterone in response to the luteinizing hormone (LH) and follicular-stimulating hormone (FSH) released by the pituitary gland. Increasing numbers of estrogen receptors have been identified in both reproductive and nonreproductive organs, including brain, arterial vessel wall, bone, smooth muscle, and urethra. During pregnancy, hormonal levels further increase. With perimenopause, the time close to the development of menopause, estrogen and progesterone levels become more erratic. These fluctuating levels are often associated with hot flashes, weight gain, and irritability. Finally, with menopause, estrogen levels are generally low. In addition to estrogens, the ovary produces androgens, such as testosterone and androstenedione, which are peripherally converted to estrogen, especially in fat cells. Obese women are exposed to higher circulating estrogen levels after menopause than thinner women.

The *menstrual cycle* consists of three distinct phases: the follicular or proliferative phase; ovulation; and the luteal or secretory phase. The physiologic changes that are a part of the menstrual cycle, including variations in hormones, the uterine lining, cervical mucus, and changes in basal body temperature (when taken upon first awakening), are graphically represented in Figure 71-1. The menstrual cycle duration tends to become consistent for most young women, lasting between 21 and 35 days. Often in perimenopause, the duration will decrease.

During the *follicular phase*, the hypothalamus secretes GnRH, which stimulates the pituitary to release FSH and LH. These hormones in turn stimulate estrogen secretion by a cohort of ovarian follicles. The estrogen secretion simultaneously facilitates proliferation of the endometrium. Eventually, one follicle becomes dominant and is destined for ovulation. *Ovulation* occurs soon after the LH surge.

With ovulation, the oocyte leaves the dominant follicle and migrates toward the fallopian tubes. At this time, the cervical mucus covering the cervical os become less viscous, thus facilitating passage of sperm at the uterine entrance.

The remaining cells in the follicle become the *corpus luteum*, which produces progesterone during this *luteal phase*. If fertilization does not occur, progesterone is secreted for about 14 days, and then the follicle involutes. This is associated with decreasing levels of estrogen and progesterone. The endometrium sheds in response to the falling estrogen and progesterone levels and results in menstruation. If fertilization occurs, progesterone continues to be secreted to support early pregnancy.

Menstrual bleeding is variable, but usually lasts less than 7 days. Bleeding disorders may be associated with heavier menstrual bleeding. Menstrual bleeding may be associated with cramping that is often better relieved with nonsteroidal anti-inflammatory drugs (NSAIDs) than acetaminophen. A menstrual cycle will be *anovulatory* if an oocyte is not released and thus does not create a luteal phase. This may result in a missed period. Women with chronic anovulation will experience irregular bleeding due to an unstable endometrium resulting from unopposed estrogen. Hormonal contraception use tends to produce lighter menstrual bleeding over time owing to the progesterone dominance of the preparation.

Sex Differences in Socialization and Economics

As children grow up, their self-esteem, behaviors, and self-expectations are shaped by those around them—both immediate family and community. Often, expectations vary by sex. Throughout much of the world, girls and women have lower rates of literacy than boys and men. Age of first pregnancy is later in those who have more years of education. Income is generally higher for men than women in both the industrialized and agricultural world. Similarly, poverty rates are higher for women throughout the world.

B. Preventive Health Recommendations for Women

Many organizations put forth recommendations and guidelines for preventive care for women, including specialty organizations such as the American College of Obstetrics and Gynecology, the American Cancer Society, the American Diabetes Association, and the U.S. Preventive Services Task Force. Table 71-1 highlights evidence-based

recommendations for preventive care for women at average risk, including screening recommendations during pregnancy. Additional screening is often recommended for women with specific risk factors, and this list represents the interventions with the best evidence for impact on health outcomes.

Table 71-1 Preventive Health Recommendations for Women

	Recommendation	Age and Interval
Screening		
Obesity	Blood pressure, height and weight, body mass index	Every 1-2 yr
Hyperlipidemia	Lipid panel	Start age 45 yr
Cancer	Mammogram Papanicolaou test Fecal occult blood testing, sigmoidoscopy, or colonoscopy	Start age 40 yr, then annually Every 1-3 yr for women with a cervix Start at age 50 yr
Infectious diseases	Chlamydia	Annual to age 25 yr, then if patient remains high risk
Osteoporosis	Bone densitometry	Begin by age 65 yr
Mental health	Depression	All adults
Other		
Immunizations		
	Influenza Rubella Tetanus-diphtheria—(pertussis)	Yearly Check titer or vaccinate dT every 10 yr (TdAP booster at least once after age 11 yr)
	Human papillomavirus Varicella	To age 26 yr Susceptible women
Chemoprophylaxis		
	Folic acid supplement Calcium intake/supplement	400 mcg daily Periodically
Counseling		
	Tobacco and alcohol misuse Promote healthy diet; promote breastfeeding; counsel regarding sexually transmitted infections, avoiding unintentional injuries, seat belt use	Periodically Periodically
<i>Additional screening and counseling during pregnancy</i>	Rh(D) incompatibility screening, iron deficiency anemia, asymptomatic bacteriuria Rubella Hepatitis B HIV, syphilis, gonorrhea Gestational hypertensive disorders Depression	Testing in the first trimester Check titer, vaccinate postpartum if negative HBsAg Testing in the first trimester Ongoing Postpartum

C. Health Issues Across the Life Course

Adolescence

APPROACH TO THE ADOLESCENT

Providing health care to adolescents requires specific skills of the medical provider. Adolescent patients are naïve health consumers and often do not express their needs clearly because they have yet to develop sophisticated communication skills and often have a very limited knowledge of their own physiology, including what is “normal” and what is not. Many young women are reluctant to engage in the medical encounter because of embarrassment or fear. It is incumbent on the medical provider to acknowledge these issues and

engage the adolescent using developmentally appropriate language and a compassionate manner.

CONFIDENTIALITY

Most adolescents come to office appointments accompanied by an adult. Although parental involvement in minors' health care decisions is desirable, many adolescents will not disclose their social or health history unless they are interviewed alone and with the assurance of confidentiality. Time spent alone with the patient is critical to discovering hidden agendas. Because statutes for the care of minors vary

from state to state, the medical provider must be familiar with what legal rights young patients have to accessing reproductive health services without the involvement of a parent. Online resources from the Alan Guttmacher Institute (<http://www.guttmacher.org>) can provide state-specific policies regarding a minor’s rights to accessing contraception, sexually transmitted infection (STI) services, prenatal care, and abortions, and what rights minors have as parents.

Proactive discussion with patient and parent together detailing office confidentiality policies, including how privacy is maintained and when it must be broken (e.g., abuse and suicidality, STI reporting to health departments), is critical to facilitating effective health care encounters. It is not uncommon, however, for adolescents to underestimate their parent’s understanding of their circumstance. Many dyads share the same but unvoiced concerns (e.g., the need for contraception), in which case the clinician can help facilitate disclosure and open discussions of health care delivery.

SEXUAL HISTORY

Gender and number of past and present partners should be tactfully elicited as part of the sexual history along with history of sexual abuse, assault, date rape, or physically abusive partner. It is also important to know whether the patient is intoxicated during sex because intercourse may not be voluntary or protected. Young women need to be encouraged to be safe and selective in their relationships and encouraged either to abstain from sex (i.e., oral, vaginal, or anal sex) or to be in a long-term, mutually monogamous relationship with an uninfected partner. Health providers may need to teach young patients strategies in self-advocacy and “how not to have sex,” as well as helping young women understand what constitutes a “healthy” relationship. Risk for pregnancy and contraceptive options are also important topics for discussion (see below).

SEXUALLY TRANSMITTED INFECTIONS AND HUMAN PAPILLOMAVIRUS

Adolescents who are sexually active are at particular risk for sexually transmitted diseases. Younger women have relative biologic susceptibility to some diseases, such as chlamydia, because of cervical ectopy. Adolescents frequently have unprotected intercourse because they cannot access, do not like, or cannot negotiate appropriate use of condoms. Many teenagers have sexual partnerships of short duration (serial monogamy) or “primary” and “secondary” (concurrent) sexual relationships further compounding their risk for acquiring disease. Some adolescents have partners of either sex regardless of whether they define themselves as “hetero” or “homo” sexual. Some adolescents, aware of potential infection, cannot access testing because of transportation, lack of insurance, or confidentiality concerns and thus continue to put themselves and others at risk.

Among females, the highest rates of reported chlamydia infection in 2006 occurred among adolescent and young women (2863 cases and 2797 cases per 100,000 females for those aged 15 to 19 and 20 to 24 years, respectively) Because many adolescents with sexually transmitted infections are asymptomatic, young patients will not appreciate their risk

for acquiring, transmitting, or needing treatment for disease. For this reason, it is recommended that any adolescent who has engaged in sexual intimacy be screened for gonorrhea and chlamydia. Patients with confirmed disease should complete therapy, notify their partners to be treated, and abstain from sex until all partners are tested and complete treatment. Because of the risk for reinfection subsequent to treatment, patients with confirmed disease should be rescreened in 3 months.

Many girls acquire human papillomavirus (HPV) infection during their adolescent years. The availability of a quadrivalent HPV vaccine offers an opportunity to decrease the burden of vaccine HPV-type–related cervical cancer, cervical cancer precursors, vaginal and vulvar cancer precursors, and anogenital warts. In 2006, the U.S. Food and Drug Administration (FDA) approved an HPV vaccine, Gardasil, and the Advisory Committee on Immunization Practices (ACIP) has recommended routine vaccination of females aged 11 to 12 years with three doses of the quadrivalent HPV vaccine. Catch-up vaccination is recommended for females aged 13 to 26 years. Papanicolaou (Pap) smear screening is recommended in sexually active adolescents about 3 years after initiation of sexual intercourse regardless of HPV vaccination status.

In addition to appreciating the importance of HPV vaccination, medical providers undertaking women’s health issues are also afforded the opportunity to counsel or provide other vaccinations scheduled during the adolescent years, including the meningococcal vaccination and Tdap (confering added protection against pertussis), and to confirm that childhood vaccinations for hepatitis A and B and varicella have been completed.

PRIMARY AMENORRHEA

By age 14 years, more than 95% of girls have reached menarche. Some girls will quickly establish a regular menstrual cycle; however, early cycles tend to be irregular, and more than half of the cycles are anovulatory owing to an immature hypothalamic-pituitary axis. In general, as the adolescent matures, there is a progression to more regular cycles, but up to one third will still have anovulatory cycles after 5 years. *Primary amenorrhea* is defined as the absence of a first menses by age 16 years. However, when evaluating an adolescent for amenorrhea, it is important to consider other developmental milestones. Figure 71-2 illustrates Tanner staging of breast maturation for girls and adolescents. Menarche is usually seen 2 years after the start of breast development and by the time Tanner stage 4 is reached. Therefore, a girl who has not begun menses by age 14 years or within 2 years of obtaining Tanner stage 4 breast development should be further evaluated.

There is a broad differential diagnosis that must be considered, and pregnancy must always be excluded. The most common cause of primary amenorrhea is ovarian failure, hypergonadotropic hypogonadism. This occurs when there is a failure of the ovary to respond to the signals from the pituitary gland and can be caused by Turner syndrome or other genetic abnormalities, or be a sequelae of chemotherapy or radiation therapy received in the past. The next most common cause of primary amenorrhea is müllerian agenesis, or congenital absence of the female genital tract.

Figure 71-2 Sex maturity ratings of breast changes in adolescent. (From Kliegman, Robert M. et al. *Nelson Textbook of Pediatrics*, 18th ed. Philadelphia, WB Saunders, 2007. Courtesy of JM Tanner, MD, Institute of Child Health, Department of Growth and Development, University of London, London, England.)

In addition, other outflow tract abnormalities, including imperforate hymen, transverse vaginal septum, and androgen insensitivity, may all present in the adolescent girl who has failed to menstruate. Finally, chronic anovulation may be the underlying abnormality.

A detailed history and physical examination will suggest the cause of amenorrhea. As above, developmental milestones should be obtained. Girls with outflow tract obstruction, such as an imperforate hymen, may present with cyclic pelvic pain. A thorough history may uncover evidence of excessive exercise or an eating disorder, often referred to as the *female athlete triad* (amenorrhea, osteopenia, eating disorder). Alternatively, there may be signs and symptoms of androgen excess, such as acne, hirsutism, or obesity, to suggest polycystic ovary syndrome (PCOS) as a cause of chronic anovulation. The physical examination should include inspection of the external genitalia as well as imaging with pelvic ultrasound to further define anatomy. Pregnancy should always be excluded with a sensitive urine human chorionic gonadotropin (hCG) level tested in the office. Further laboratory testing should include FSH, LH, prolactin, and thyroid-stimulating hormone (TSH) to evaluate pituitary and thyroid function. If there are signs of androgen excess, a free and total testosterone level should be measured; if there is a suggestion of hypothalamic hypogo-

nadism, an estradiol level can be helpful to identify hypogonadism. If the FSH and LH are elevated, premature ovarian failure is present, and a karyotype should be obtained to identify androgen insensitivity and other chromosomal abnormalities such as Turner syndrome.

Reproductive Age

Women during their childbearing years are generally free from chronic health problems and often receive their health care episodically from a gynecologist, a primary care physician, or both. They commonly defer their own health care needs while caring for their family. Most women do present nearly annually for cervical cancer screening or for prenatal care. Although women seek care for primarily reproductive needs, perhaps the most important role for the health care provider is to work with women to identify their short- and long-term health risks and support their effort to change behaviors that could affect current reproductive health, as well as future risk for cardiovascular disease and cancer.

Establishment of healthy lifestyles and avoidance of unhealthy behaviors is an important focus for this age group and can have long-term effects. Women should be counseled to continue or begin regular physical activity, increase dietary intake of fruits and vegetables, maintain adequate intake of calcium, and avoid unhealthy behaviors, including tobacco use. Although the health care provider can be key in identifying risk factors and initiating the process of addressing these risks, behavior change is difficult and often requires the ongoing support of the provider as well as a partnership with resources that may be available in the community. This may include referral to smoking cessation programs, weight loss and exercise programs, and programs targeting other risk factors such as substance abuse and mental health.

This section discusses several important health issues that are unique to women in this age group and that reflect areas in which health care for women must be tailored to address important needs. These include pregnancy planning and preconception health, including contraception; the use of medications for women who are pregnant, breastfeeding, or have childbearing potential; the postpartum follow-up of pregnancy complications; and assessment of infertility. In addition, menstrual disorders, often the presenting symptom for important underlying medical problems, are reviewed. Finally, screening for cervical cancer and the management recommendations for the abnormal Pap smear are described.

PRECONCEPTION, PREGNANCY PLANNING, AND POSTPARTUM CONSIDERATIONS

Preconception Health Care and Pregnancy Planning as a Part of Routine Care for Women

The health of a woman at the time of conception can have a major impact on the course of her pregnancy and the health of her child. Because nearly half of all pregnancies in the United States are unplanned, preconception health care must be provided on an ongoing basis for all women regardless of whether they are actively planning to conceive.

As discussed below, pharmaceutical use must be carefully reviewed because there are commonly used medications that are known teratogens that should not be used by women with pregnancy potential. In addition, many common health risks and behaviors are known to increase the risk for fetal anomalies, premature birth, and other adverse pregnancy outcomes. Before pregnancy, the preconception period, is the best time to address these and other risk factors to improve outcomes. Care management before conception and during the prenatal period improves outcomes for women with many common health risks, including obesity, tobacco use, diabetes, seizure disorders, and HIV infection.

Preconception care must be incorporated into routine preventive health care for women of childbearing age by all providers. This includes working with women to develop a reproductive plan, to support their efforts to implement that plan, and to identify important health risks and recommendations to improve their health and therefore improve the odds for a healthy pregnancy if and when they choose to conceive. All women should be advised to take daily supplemental folic acid, in the form of a multivitamin containing at least 400 µg of folic acid, in order to prevent neural tube defects should they conceive. Adequate folic acid levels are critical very early in embryogenesis, and supplementation must begin during the months before conception. This is one of the few public health measures proved to have a meaningful impact on outcomes, but studies show only 30% of women in the United States follow this recommendation. It is also important to verify immunity to rubella, hepatitis B, and varicella before pregnancy and to vaccinate as needed, remembering that women should avoid conception within 1 month of receiving an MMR or varicella vaccine. In addition, screening for risks such as HIV and other STIs should be considered, and women should be advised about the potential risks associated with herbs, over-the-counter medications, and some prescription medications. Finally, as discussed later, contraceptive options should be presented and discussed.

Taking a Sexual History

When obtaining a sexual history, it is important to use concrete and nonjudgmental language that will be familiar to the patient and provide the information needed in making decisions about risk for conception, STIs, and need for contraception. Confidentiality must be assured. If asked “are you sexually active?” an answer “no” does not assure a period of abstinence. The history should include questions about sexual practices, including number of partners, gender of partners, and steps taken to protect against transmission of infections as well as pregnancy prevention. Prior history of STIs, as well as specific risks for HIV and hepatitis, should be elicited. Exploration about safety, especially in relation to sexual activity, should be pursued. Finally, condom use and risk reduction strategies should be discussed.

Contraception

There are currently a variety of contraceptive options available to women with varying levels of effectiveness, as described in Table 71-2. The most common method used by women in the United States is the oral contraceptive pill (31%), followed by tubal sterilization (27%), the male condom (18%), and vasectomy (9%). Younger women rely

Table 71-2 Contraceptive Effectiveness

	Method
Always very effective (0%-1% failure)	Vasectomy, female sterilization, etonogestrel subdermal implant 68 mg, copper-bearing intrauterine device, levonorgestrel intrauterine device
Very effective when used correctly and consistently Effective as commonly used (2%-12% failure)	Combined oral contraceptive pills, patches, vaginal rings, depot medroxyprogesterone acetate injection, progesterone-only pills while breastfeeding
Effective when used correctly and consistently Only somewhat effective as commonly used (15%-30% failure)	Condom, diaphragm, coitus interruptus, spermicide, cervical cap

more often on the oral contraceptive pill, older women on sterilization. The choice of a contraceptive method must be individualized and include careful consideration of the risks and benefits of the method as well as the acceptability of the method and the risks associated with an unplanned pregnancy. In general, most methods are very safe for use by most women; however, the use of hormonal contraception can carry unacceptable risks for women with medical problems, and the decision about optimal contraceptive choice can be complex. The World Health Organization’s *Medical Eligibility Criteria for Contraceptive Use* is an excellent resource, is frequently updated, is available online, and can help the provider balance the risks and the benefits.

Combined Hormonal Contraceptives

These contraceptives contain both estrogen and a progestin and are available in multiple delivery systems in addition to the traditional oral contraceptive pill (OCP). They act to prevent pregnancy through multiple mechanisms, including suppression of ovulation, as well as effects on the uterine lining, tubal function, and cervical mucus. Oral formulations contain estradiol in doses of 20 to 50 µg and various progestins with varying levels of androgen activity. The OCP may be monophasic or triphasic, although triphasic OCPs may be associated with higher rates of breakthrough bleeding. There are two new methods for delivery of combination hormonal contraceptives that do not require daily dosing and therefore are preferred by some women. The Nuvaring is a small plastic ring that is placed in the vaginal vault for continuous absorption of hormones for 3 weeks and then removed for a week, inducing a withdrawal bleed. The estrogen patch is placed on the skin weekly for 3 weeks, followed by a patch-free week, and provides cutaneous absorption of combined estrogen and progestin.

Combined hormonal contraceptives are effective as commonly used and are safe for use by most women and carry noncontraceptive benefits, including a reduced risk for anemia, ovarian cancer, functional ovarian cysts, endometrial cancer, and dysmenorrhea. Use of all combination hormonal contraceptives is *contraindicated* for women older than 35 years who smoke; women with a history of heart

disease or cerebrovascular disease; women with significantly impaired liver function; women with a history of thromboembolic disorders; and those with known or suspected breast or endometrial cancer, severe hyperlipidemia, migraine with aura, uncontrolled hypertension, symptomatic gallbladder disease, undiagnosed vaginal bleeding, or known or suspected pregnancy. The contraceptive patch is approved for use in women weighing up to 199 lbs owing to diminished efficacy for women with higher weight. There is some evidence that women who use the patch may have an increase risk for thromboembolic complications.

Progestin-Only Methods

These methods include the medroxyprogesterone acetate depot injection Depot-Provera and the progestin-only pill and work by inhibiting ovulation as well as impairing transport of sperm and implantation. Both methods can be used by most women with contraindications to estrogens. The long-acting Depo-Provera is administered by an intramuscular injection every 12 weeks and is a highly effective method of contraception. The major side effects and risks associated with its use are breakthrough bleeding, weight gain, and loss of bone density. Loss of bone density appears to be reversible, but consideration should be given to long-term use by women with other risk factors for osteoporosis. Depo-Provera is an excellent choice for women who have contraindications to estrogens. The progestin-only “mini” pill has a lesser degree of effectiveness. This method is less popular and tends to be used in settings in which there is a lower fecundity, such as women in their 40s and women during the postpartum period.

Intrauterine Methods

The intrauterine devices (IUDs) have become popular methods of contraception owing to their high level of reliability, longevity, and favorable side-effect profile. They work by preventing fertilization and implantation, and their effects are rapidly reversible upon withdrawal of the device. The copper IUD is highly effective and can be left in place for up to 10 years. It can be associated with increased menstrual cramping and heavier menstrual flow. The Mirena IUS is a levonorgestrel-releasing intrauterine system that works to prevent pregnancy through multiple pathways. Mirena generally creates a thinner endometrial lining and is better tolerated by some women. The IUD and IUS are typically used by parous women who are in a mutually monogamous relationship. They are contraindicated for use by women with an active cervical infection or with a history of pelvic inflammatory disease (PID). This method can be an excellent choice for women with contraindications to hormonal methods who require highly reliable contraception. One barrier to use of this method is a high cost up front; however, the cost over the lifetime of the device is less than the cost of hormonal methods.

Emergency Contraception

Plan B is an oral progestin-only preparation approved by the FDA to prevent pregnancy after unprotected sexual intercourse or a contraceptive failure. The method does nothing to interfere with an already established pregnancy. The over-the-counter method is most effective if begun within 24 hours, but effectiveness with use within 72 hours is up

to 89%. Counseling before use is undertaken to ensure that the patient understands that this method is not appropriate for use as an ongoing contraceptive, but should be used in the case of emergency or failure of another method of contraception.

PRESCRIBING MEDICATION DURING THE REPRODUCTIVE YEARS

Childbearing potential must be considered when prescribing medications for prevention or to treat chronic and acute conditions. The provider must be aware of a woman’s sexual history, her current and future plans for reproduction, and the reliability of her current contraceptive method before choosing to recommend a medication or an immunization, or give advice about the use of herbs or other complementary strategies. It is important to remember that benefits may outweigh the risks associated with the use of some medications needed to manage serious health risks during pregnancy. There are therefore few medications whose use is absolutely contraindicated in this setting. The concern over the potential adverse effects of medications on a growing fetus has often led providers to underutilize or underdose medications in women because of a current pregnancy or lactation. However, decisions about medication use during pregnancy and lactation are complex and often involve striking a balance between benefit and risk.

The FDA requires that drug labeling include information about drug use during pregnancy and lactation, and the FDA pregnancy categories shown in Table 71-3 were designed

Table 71-3 Food and Drug Administration Categories of Drug Safety During Pregnancy

Category	Interpretation
A	Adequate, well-controlled studies in pregnant women have not shown an increased risk to the fetus in any trimester of pregnancy.
B	Animal studies have revealed no evidence of harm to the fetus; however, there are no adequate and well-controlled studies in pregnant women. Or: Animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester.
C	Animal studies have shown an adverse effect, and there are no adequate and well-controlled studies in pregnant women. Or: No animal studies have been conducted, and there are no adequate and well-controlled studies in pregnant women.
D	Adequate, well-controlled or observational studies in pregnant women have demonstrated a risk to the fetus. However, the benefits of therapy may outweigh the potential risk.
X	Adequate, well-controlled or observational studies in animals or pregnant women have demonstrated positive evidence of fetal abnormalities or risks, and the use of the product is contraindicated in women who are or may become pregnant.

to convey the fetal risks based on animal or human data, or both. However, these categories can be misleading and are often misused by health care practitioners. The FDA is currently revising the required content and format for pregnancy and lactation labeling to enable providers to make more informed decisions with their patients.

The shortcoming of the current FDA labeling system has led some experts to develop other categorization systems. One useful system categorizes medications as generally justifiable, justifiable under certain circumstances, and almost never justifiable. For a more detailed discussion, the reader is referred to *Medical Care of the Pregnant Patient*. A good example of a medication that should never be used when there is a possibility of pregnancy is radioactive iodine, whose use will lead to destruction of the fetal thyroid. On the other hand, decision making about the use of other medications can be more complex (Table 71-4).

Pregnancy potential is also important to consider, especially for medications whose adverse effects are known to occur in the first trimester when pregnancy is often not yet recognized. An interesting dilemma is the use of angiotensin-converting enzyme inhibitors by women in this age group. Their use should be avoided by women with pregnancy potential because of their effects on the fetal renal system throughout pregnancy. On the other hand, they play an important role in the prevention of diabetic nephropathy. Preconception care of diabetic women should weigh the risk against the benefits in diabetic women and develop an individualized approach. This may include discontinuation of the medication or, alternatively, continuation with a vigilant plan to identify pregnancy and discontinue the medication immediately after conception. Antiepileptic medications are another example of medications whose use must be considered carefully during the preconception period. Although these are known teratogens, a woman may require them to control a seizure disorder. Tailoring of these medications in anticipation of pregnancy to as few as possible has been shown to diminish the risk for fetal anomalies.

PREGNANCY COMPLICATIONS AND POSTPARTUM CARE

Women with prior problem pregnancies should receive postpartum care and pregnancy planning advice based on their obstetrical history. Women with a history of *gestational diabetes* are at increased risk for developing adult-onset diabetes later in life. It is recommended that these women have an oral glucose tolerance or fasting plasma glucose testing at the 6-week postpartum visit and then be followed with periodic testing if this test is normal. Because gestational diabetes identifies women who are at high risk for later diabetes, advice should focus on lifestyle changes, including exercise and weight loss. Women whose pregnancies were complicated by a *gestational hypertensive disorder*, such as preeclampsia or gestational hypertension, are at increased risk for hypertension later in life and should have their cardiovascular risk evaluated, lifestyle modification recommended, and blood pressure followed. It is recommended that women with a history of a prior *neural tube defect* take 4 g of folic acid daily, women with a personal or family history of genetic disorders may benefit from genetic counseling before conception. Women with a history of *preterm labor* should

Table 71-4 Medications that Require Consideration of Risks and Benefits

Medication	Associated Risk
Angiotensin-converting enzyme inhibitors/angiotensin receptor blockers	Renal failures, renal tubular dysgenesis, decreased skull ossification
Antiepileptic drugs (e.g., phenytoin, carbamazepine, phenobarbital, valproic acid)	Neural tube defects, congenital heart disease, facial changes, developmental delay
Coumadin	Skeletal and central nervous system defects, Dandy Walker syndrome
Methimazole	Various congenital anomalies
Cytotoxic chemotherapeutic agents (e.g., cyclophosphamide)	Central nervous system malformations
Penicillamine	
Diethylstilbestrol (DES)	Female: genital tract abnormalities, adenosis, increased risk for clear cell cancer and breast cancer Male: anatomic abnormalities, infertility, increased risk for testicular cancer
Isotretinoin	Severe congenital malformations
Methotrexate	Fetal anomalies
Others: tetracyclines, statins, androgens, live-attenuated vaccines, lithium, herbs	Various

plan to see an obstetrical provider who takes advantage of state-of-the-art methods to affect recurrence.

Two important conditions to recognize during the postpartum period are *postpartum depression* and *postpartum thyroiditis*. Although most mothers experience mood fluctuations after delivery, these symptoms do not interfere with their ability to care for themselves or their infants. Women whose symptoms persist for 2 weeks or more should be screened for postpartum depression. Postpartum depression is experienced by 10% to 15% of women, and the symptoms are those of a clinical depression. The two greatest risk factors for postpartum depression are a history of depression before pregnancy and depression during the current pregnancy. Dual diagnoses are found to be common in many high-risk populations, and tobacco use, binge drinking, and adolescent age are associated risk factors. There are several tools that can be used to screen for depression, including the CES-D and PHQ-9. Postpartum psychosis is rare, seen in 1 or 2 per 1000 mothers, can present 2 to 3 days after delivery, and is associated with a high risk for suicide or infanticide if not treated.

Postpartum thyroiditis is an autoimmune thyroiditis that can be seen in 5% to 10% of women during the first postpartum year. The syndrome presents most often 6 months postpartum and is characterized by transient, often unrecognized, thyroiditis followed by hypothyroidism, and

ending with resolution. About 20% to 30% of women will remain hypothyroid. Management focuses on management of symptoms during the hyperthyroid stage, often with β blockers, as well as support with thyroid replacement hormone during the hypothyroid phase. Those women who do return to a euthyroid state are at increased risk for postpartum hypothyroidism during a subsequent pregnancy and at increased risk for hypothyroidism over time. All women will require long-term follow-up with annual thyroid testing.

GYNECOLOGIC COMPLAINTS

Abnormal Menses

For women of reproductive age, a normal menstrual cycle is a marker of general good health. Menstrual disorders are common and generally fall into two main categories: *amenorrhea* and *abnormal uterine bleeding*. When the menstrual cycle is found to be abnormal, the underlying cause must be sought. Abnormalities may indicate problems related to the reproductive system, such as premature ovarian failure, or may be an early sign of an important underlying systemic illness. Management of menstrual cycle abnormalities focuses on addressing the underlying pathology, supporting the consequential anemia, protecting the uterus from endometrial hyperplasia due to unopposed estrogen, and minimizing osteoporosis risk for women with a hypothalamic etiology. Details are discussed below.

Amenorrhea

Amenorrhea occurs in 5% of women each year and is defined as the absence of menses for at least 3 to 6 months outside of the setting of pregnancy or lactation. Primary amenorrhea is generally recognized during the teenage years when menses fail to begin by age 16 years and was discussed earlier. Women who have had a previously established menstrual pattern are considered to have *secondary amenorrhea*. *Oligomenorrhea* occurs when menses are irregular or infrequent, with cycle length usually greater than 35 to 40 days, and is often associated with *chronic anovulation* or oligo-ovulation.

As shown in Table 71-5, pathologic causes of amenorrhea and oligomenorrhea may occur at any point in the endometrial-ovarian-pituitary-hypothalamic axis. The differential diagnosis is broad and can be organized into five main categories: (1) ovarian failure, (2) anovulation, (3) medication induced, (4) uterine outflow tract abnormalities, and (5) physiologic. The most common cause of secondary amenorrhea is pregnancy, which is easily identified by a sensitive urine pregnancy test in the office. Lactation causes amenorrhea as well and may be expected for up to 6 months in a woman who is exclusively breastfeeding her infant. Prolonged amenorrhea can follow cessation of some hormonal contraceptives, especially depot medroxyprogesterone acetate, as well as other medications. Finally, menopause should be suspected in the woman older than 45 years, and this explanation should be considered before an extensive evaluation of amenorrhea is undertaken.

Evaluation should begin with history, physical examination to assess comorbidities and anatomy, and an office test of urine hCG. Further evaluation should include testing of serum TSH, prolactin, and FSH. These tests will identify

Table 71-5 Abnormal Menstrual Cycle

Secondary Amenorrhea	Causes
Physiologic	Pregnancy, lactation, menopause
Ovarian	Radiation- or chemotherapy-induced ovarian failure, chromosomal abnormalities, autoimmune or idiopathic premature ovarian failure
Anovulation	Hyperandrogenism (polycystic ovary syndrome, congenital adrenal hyperplasia), hyperprolactinemia (prolactinoma, phenothiazines, narcotics, and other medications), hyperthyroidism, hypothyroidism, hypopituitarism, pituitary adenoma, Cushing syndrome, hypothalamic hypogonadism (eating disorder, athletic triad, stress)
Medications	Hormonal, cytotoxic, others
Uterine outflow tract abnormalities	Surgery
Abnormal Bleeding	
Structural	Uterine fibroids, endometrial or endocervical polyp, cervical cancer, endometrial hyperplasia, endometrial cancer
Hormonal	Chronic anovulation, hypothyroidism, waning ovarian function, estrogen secreting tumors
Coagulopathies	Thrombocytopenia, platelet dysfunction

women with hypothyroidism, prolactinoma, and ovarian failure. Women who show signs of androgen excess or a history consistent with PCOS should have total or free testosterone and 17- α -hydroxyprogesterone measured at 8:00 AM to rule out testosterone-secreting tumors and congenital adrenal hyperplasia.

Assessment of adequate estrogen can be done by measuring a serum estradiol level or with a progesterone challenge. The progesterone challenge involves administration of oral medroxyprogesterone for 10 days and watching for the expected “withdrawal bleed” after completion. Women who bleed have normal estrogen levels and are likely to have chronic anovulation, most often due to PCOS. Women who fail to have a withdrawal bleed are suspected to have low levels of estrogen, and amenorrhea may be due to anovulation and failure of the hypothalamic-pituitary axis. However, women with a history of uterine instrumentation or other gynecologic surgery may have an outflow tract abnormality and therefore fail to show a withdrawal bleed. This can be identified by creating an artificial cycle with combined estrogen and progestin administration and looking for a bleed after a few months when the uterine lining has had the opportunity to develop. Failure to bleed to combined hormonal cycling suggests a uterine or outflow tract abnormality.

Management of amenorrhea will depend on the underlying abnormality identified. Women with chronic anovulation are at risk for endometrial hyperplasia because of the

unopposed estrogens and should be cycled using oral progesterone to induce a monthly withdrawal bleed. Those with hypogestrogenic states should be evaluated for potential estrogen replacement; women with an endometrial abnormality should be referred to a gynecologist.

Abnormal Bleeding

Abnormal bleeding can be the presenting symptom of a wide variety of abnormalities, including anovulation, endometrial pathology, or a coagulopathy. Evaluation begins with assessment of the pattern of bleeding through a detailed menstrual history. This should include information about the onset, duration, pattern, and quantity of bleeding. Women with *polymenorrhea* have a cycle less than 21 days in length; women with *oligomenorrhea* have an interval greater than 40 days. Women with excessive bleeding in duration or quantity have *menorrhagia*. Women with bleeding between menses are said to have *menometrorrhagia*. Prior menstrual history should be assessed to determine whether the patient has ever established a normal ovulatory cycle.

Key in the evaluation is to elicit evidence of ovulatory cycles by inquiring about *moliminal* symptoms, such as breast tenderness, cramping, or fluid retention, before the onset of bleeding. Identification of anovulatory bleeding focuses the differential diagnosis quickly to hormonal causes. Anovulatory bleeding is the result of failed ovulation and the absence of a luteal phase. The ovary secretes estrogen unopposed by progesterone and leads to a continued proliferation of the endometrium. This endometrium is unstable, which results in periodic, irregular, and often heavy bleeding. Bleeding due to coagulopathy will follow a typically ovulatory pattern and is experienced as heavy regular bleeding. A personal or family history of bleeding disorders should be sought because even in this age group, a large fraction of women with coagulopathies, such as von Willebrand disease, have not yet been diagnosed.

Physical examination will identify evidence of chronic or acute blood loss, verify the source of bleeding, and suggest a systemic etiology such as thyroid disease or PCOS. Genitourinary examination may identify a cervical polyp, typically associated with postcoital bleeding, or an enlarged uterus suggesting uterine fibroids. Pregnancy must always be excluded with a sensitive office urine pregnancy test; a Pap smear and cervical cultures should be obtained to assess for cervical disease or infection as the cause of abnormal bleeding. Laboratory testing should include a complete blood count and thyroid studies; testing for von Willebrand disease should be considered. In women at risk for endometrial hyperplasia or endometrial cancer, including women older than 35 years, and women with obesity or a history of chronic anovulation, evaluation of the endometrium should be pursued. The office endometrial biopsy using a piston-suction device, an ultrasound evaluating endometrial stripe, or a sonohysterogram should be considered to identify women with hyperplasia.

If the evaluation fails to identify an underlying abnormality, a woman is considered to have *dysfunctional uterine bleeding*. Management of abnormal bleeding will depend on the underlying pathology identified and the degree of anemia caused by the bleeding. Control of bleeding is generally achieved through the use of combination of estrogen and progestin preparations such as OCPs.

INFERTILITY

According to the Centers for Disease Control and Prevention, 12% of U.S. women have trouble conceiving or carrying a pregnancy to term. Infertility is generally considered when a couple fails to conceive after 1 year of intercourse without contraception. Infertility is more common with increasing age and is becoming a more frequent cause of infertility as women are deferring pregnancy and attempting to conceive at older ages. Infertility may be due to either female factors or male factors. The most common female factor is anovulation, which is often related to metabolic abnormalities as discussed in the sections above. Other factors are pelvic factors, such as adhesions due to a prior infection, surgery, or endometriosis, and cervical and uterine factors. Male factors include abnormal sperm number, motility, or morphology as well as erectile or ejaculatory dysfunction.

Evaluation should include a complete reproductive, medical, and gynecologic history and a physical examination to help identify any metabolic or structural gynecologic abnormalities. Testing will follow and includes basal body temperature charting for a month to confirm ovulation, an FSH on cycle day 3 to measure ovarian reserve, and prolactin and TSH levels to identify hormonal abnormalities in women with menstrual disorders. Male evaluation begins with a semen analysis. Finally, a hysterosalpingogram will establish patency of the fallopian tubes if the semen analysis is normal. Once this evaluation is complete, the underlying abnormality should be treated. Referral to infertility specialists or urologists is warranted based on findings.

CERVICAL CANCER SCREENING AND THE ABNORMAL PAPANICOLAOU TEST

HPV is highly prevalent in the United States, and it is estimated that 50% of sexually active men and women acquire HPV at some point during their life. Low-risk strains of HPV are associated with genital warts; high-risk strains are associated with cervical cancer. HPV infection can clear spontaneously, but in about 10% of women, the infection remains, putting the host at an increased risk for cervical cancer. The slow and predictable progression from cervical dysplasia to carcinoma has allowed routine cervical cancer screening to successfully reduce the incidence of cervical cancer in the United States. Recommendations on the frequency of testing as well as the management of the abnormal Pap smear have evolved with the utilization of HPV testing to triage Pap tests as well as an improved understanding of the progression and regression of abnormalities.

Screening for cervical cancer screening is strongly recommended for all women in this age group who have been sexually active and who have a cervix. Screening should start within 3 years of a sexual debut and continue annually. Women who are considered to be at low risk for cervical cancer and have had three consecutive normal findings can be screened every 2 to 3 years. Women who have had a hysterectomy with removal of the cervix for benign disease do not require screening for cervical cancer.

A Pap smear is collected by scraping the endocervical canal and is considered *adequate for evaluation* if there are endocervical cells present. Current recommendations for

the management of the abnormal test are age specific. For women in this age group, a Pap reading of atypical squamous cells of uncertain significance (ASC-US) requires follow-up: if the cytologist cannot rule out a high-grade squamous intraepithelial lesion (ASC-H), if testing is positive for high-risk HPV strains, or if repeat testing done at 6 months is abnormal, colposcopy should be recommended. All women with a Pap test showing low-grade squamous intraepithelial lesion (LGSIL) or high-grade squamous intraepithelial lesion (HGSIL) should undergo colposcopy. Pap tests that show atypical glandular cells (AGCs) or endometrial cells should undergo colposcopy or endometrial biopsy, or both.

Women with HIV infection represent a special case because of the increased prevalence of squamous intraepithelial lesions and the more aggressive course of cervical changes. Pap testing twice in the first year is recommended, followed by annual testing if these tests are normal. Women with any testing that shows ASC-US should proceed directly to colposcopy rather than waiting for HPV typing or repeat testing.

Perimenopause and Menopause

Although *menopause* can be explicitly defined (when a woman has not had a menstrual cycle for 12 consecutive months or when her ovaries have been removed), the transition toward menopause can be erratic and prolonged over a 5- to 10-year period. It is characterized by ovarian and endocrine changes that ultimately result in the depletion of primordial oocyte stores and the cessation of ovarian estrogen production. It is a common time for women to present to their physicians with a number of specific complaints and offers an excellent opportunity not only for education but also for counseling on a number of important lifestyle issues.

Even before birth, follicular atresia results in a linear decline in the number of ovarian follicles available for ovulation. At birth, 1 to 2 million follicles remain; by puberty, this number decreases to 300,000 to 500,000. A more accelerated loss of follicles begins at about 37 years of age and is correlated with a small increase in FSH and decrease in inhibin. As FSH increases, the follicular phase of the cycle decreases, and one of the earliest clinical signs of the menopausal transition is the shortening of the menstrual cycle from a mean length of 30 days in the early reproductive years to 25 days in the early menopause transition. Increased levels of FSH may also promote an increase in the number of follicles recruited per cycle, resulting in increased, not decreased, levels of estrogen. This would explain some of the common complaints of perimenopausal women of breast pain, bloating, and heavy menses.

Later in the menopausal transition, the few remaining follicles respond poorly to FSH, and anovulation may occur. Menstrual cycles may become erratic with prolonged periods of oligomenorrhea. Ovulation may still occur, and women in this time period are advised to continue effective contraception until 12 months of amenorrhea have occurred.

Table 71-6 Abnormal Uterine Bleeding Patterns in Perimenopausal Women

Heavy menstrual bleeding (>80 mL), especially with clots
Menstrual bleeding lasting >7 days or ≥ 2 days longer than usual
Intervals of <21 days from the onset of one menstrual period to the onset of the next period
Any spotting or bleeding between periods
Uterine bleeding after sexual intercourse

Data from North American Menopause Society (NAMS). Menopause Practice: A Clinician's Guide, 3rd ed. Cleveland, OH, 2007.

SYMPTOMS IN THE PERIMENOPAUSE

Fluctuations in ovarian hormones can result in a number of symptoms. Changes to the menstrual flow are to be expected. The clinician needs to be aware, however, of bleeding patterns that may represent underlying pathology and not normal, perimenopausal changes. These patterns are summarized in Table 71-6.

The link to hormonal fluctuations for other symptoms is less clear. These include insomnia, mood disturbances, and cognitive changes. Sleep disturbances in perimenopausal women compared with premenopausal women are a well-documented phenomenon. Women experiencing nighttime hot flashes or sweats can have significantly disturbed sleep patterns resulting in a number of daytime complaints, including fatigue, irritability, and difficulty concentrating. Not all women reporting insomnia, however, report vasomotor symptoms. Potentially, hot flashes may not wake a woman from sleep but may interfere with the quality of her sleep. It is also important to investigate other factors in these women, including significant life stresses. Sleep apnea and use of medications that disturb the normal sleep cycle (including alcohol) should also be investigated.

Women experience higher rates of depression than men. The peak incidence for depression for women is in their 30s; most epidemiologic studies do not demonstrate an increased risk for depression during the menopausal transition. Women who do experience significant depression at this time are more likely to have experienced depression earlier in their lives, particularly at times of hormonal change (e.g., postpartum depression, premenstrual dysphoric disorder (PMDD)). Nevertheless, many women during the menopausal transition report symptoms of irritability, fatigue, and general moodiness. Sleep deprivation due to vasomotor symptoms may be one cause. A clear link to hormone levels has not been established; some women may be more sensitive to the changes in their previous cycles. Women in midlife may also experience stressors related to changing relationships with children, parents, and spouses. Issues related to self-concept and body image may emerge or be exacerbated. Mood issues during the perimenopausal transition should be approached in the same multifactorial way as at other ages.

Many women in the perimenopause complain of difficulties with concentration and memory. Sleep deprivation or ongoing stressors and distractions may be contributing factors. Evidence is lacking for a link between hormone levels and a decline in cognitive skills.

MENOPAUSE

The average age for menopause in the Western world is 51.4 years, with a range of 40 to 58 years. Women who smoke experience an earlier menopause in a dose-dependent fashion, an average of 1.5 years sooner. Evidence suggests that the age of menopause has remained unchanged over the past few centuries. What has changed, however, is the number of women who survive into the menopausal years. In the United States, the average life expectancy for a woman is almost 80 years. This means that many women will spend at least one third of their lifetime in the postmenopausal years.

In the 1960s, menopause was considered an estrogen deficiency “disease” in need of treatment. Although symptoms such as hot flashes and vaginal dryness may develop during menopause, the process itself is a normal part of the life cycle. In addition to the physical changes experienced by women, many consider the menopause transition to also be an important psychosocial passage. This transition offers clinicians the opportunity to help women focus on important preventive health measures and detect major chronic diseases as early as possible. Although menopause itself is not a disease, the postmenopausal years are associated with an increased risk for certain disease processes, most notably cardiovascular disease and osteoporosis.

Vasomotor Symptoms and the Use of Estrogen

The “hot flash” is the hallmark symptom of menopause. In the United States, up to 75% of women who experience a natural menopause and 90% of women who experience a surgical menopause will experience hot flashes. About 10% to 15% of women will experience hot flashes that are very frequent or severe. For most women, vasomotor symptoms are self-limited, lasting an average of 1 to 2 years; a significant minority of women, however (up to 25%), may experience symptoms for greater than 5 years.

The exact etiology of a hot flash is not understood, although we do know it is related to a disturbance of hypothalamic thermoregulation and that hot flashes are essentially a vascular phenomenon. During the period of time immediately before the onset of a hot flash, there is an increase in heart rate and cutaneous blood flow. A measurable rise in skin temperature occurs owing to increased vasodilation with a concomitant decrease in core body temperature. The woman experiences the sudden onset of warmth, ranging from noticeable to markedly uncomfortable, especially over the face and upper body. This may be accompanied by significant perspiration. Hot flashes may occur a few times a year or several times a day.

In the 1950s, it was discovered that estrogen could relieve hot flashes. In the 1960s, estrogen use increased not only for the relief of vasomotor symptoms, but as a way of treating “estrogen deficiency.” In 1975, a study published in the *New England Journal of Medicine* showed that women who used estrogen for more than seven years had a 14-fold increase in uterine cancer. In the 1980s, it was discovered that the addition of a progestin significantly decreased this risk. Endometrial hyperplasia is reduced to essentially zero when low-dose progestin is continued for 12 to 13 days per month. Women with an intact uterus must use combination

estrogen-progestin therapy to prevent endometrial hyperplasia and cancer.

Estrogen remains the only FDA-approved medication for the treatment of menopausal vasomotor symptoms as well as the most effective. It is also FDA approved for the treatment of urogenital atrophy and the prevention of osteoporosis. In the 1980s and 1990s, several large observational studies found that estrogen therapy was associated with a 50% decrease in cardiovascular disease among postmenopausal women. The potential benefit of such a decrease was so significant that many clinicians began prescribing estrogen for the sole purpose of cardiovascular protection. This assumption was not subjected to rigorous scientific study until the 1990s, when the results of the HERS trial (Heart and Estrogen/Progestin Replacement Study) found that women with preexisting heart disease developed increased cardiac events when placed on estrogen, not decreased.

The WHI was designed to look at various hormone regimens and their effects on disease prevention in postmenopausal women, particularly cardiovascular disease. More than 16,000 women participated in the trials, which ran for 5.6 years in the combined estrogen-progestin arm and 6.8 years in the estrogen-only arm. In the combined-therapy group, there was an absolute excess risk for events in the global index of 19 per 10,000 person years. Most importantly, the investigators saw an increased risk for *coronary heart disease* (CHD) (heart rate [HR] 1.29, 95% confidence interval [CI] 1.02 to 1.63), an increased risk for stroke (HR 1.41, 95% CI 1.07 to 1.85), an increased risk for pulmonary embolism (HR 2.13, 95% CI 1.39 to 3.25), and a trend toward increased risk for breast cancer (HR 1.26, 95% CI 1.0 to 1.59). The combined trial was discontinued because of this excess risk. The conclusion from the combined-therapy trial was that combination estrogen-progestin therapy should not be initiated or continued for the prevention of CHD.

The estrogen-only trial did not find a significant difference in CHD (HR .91, CI 95% 0.75 to 1.12) or for breast cancer (HR 0.77, 95% CI 0.59 to 1.01). They did, however, see the same increased risk for stroke (HR 1.39, 95% CI 1.10 to 1.77), and this trial was also discontinued early. Overall, the estimated excess risk in the global index was two events per 10,000 person-years (nonsignificant), and the conclusion was that estrogen alone should not be recommended for the prevention of chronic disease in postmenopausal women.

Although much has been written on the findings of the WHI and whether or not it was truly a trial of primary prevention (average age of subjects was 63.2 years), the results did not support the idea that estrogen therapy prevents cardiovascular disease. Additional trials are underway to address this issue in younger postmenopausal women, but until their completion, hormone therapy should not be used in this way.

Current Recommendations for Estrogen

After the WHI, several large societies put together guidelines for the use of postmenopausal hormone therapy, including the American College of Obstetricians and Gynecologists (ACOG) and the North American Menopause Society (NAMS). The general tenor of the guidelines is that estrogen and estrogen-progestin therapy are appropriate for the

treatment of vasomotor symptoms and for urogenital atrophy in women who have been appropriately counseled. Hormone therapy should not be used for the prevention of cardiovascular disease. Estrogen therapy and estrogen-progestin therapy may increase the risk for stroke in postmenopausal women. It is also likely estrogen-progestin therapy increases the risk for breast cancer with use beyond 5 years; the effect with estrogen therapy is less clear. Estrogen therapy and estrogen-progestin therapy significantly reduce the risk for osteoporotic fractures in postmenopausal women; however, other medications are also effective in this regard. Finally, the concepts of “lowest dose” and “shortest period of time” have been incorporated into most guidelines.

Additional research with regard to ultralow doses, route of use (transdermal versus oral), and use in younger postmenopausal women are underway. Until that time, thorough discussion with patients on the benefits and potential risks of therapy is important.

Alternative Therapies

Interest in nonhormonal and “natural” alternatives in the treatment of menopausal symptoms is extremely high. It is estimated that as many as 75% of menopausal women have used some form of alternative or complementary treatment to relieve menopausal symptoms. Many women do not inform their physicians which products they are using, thus creating the risk for serious interactions with prescribed medications or ongoing medical conditions.

Behavioral options such as dressing in layers, regular exercise, stress reduction techniques, and avoidance of known triggers are safe and helpful for a number of women. Some of the more common herbal remedies include isoflavones (soy, red clover), black cohosh, dong quai, ginkgo, ginseng, kava, Vitex, and valerian. Many of these alternatives appear to be effective in the short term, possibly owing to the high placebo effect known to exist in studies of vasomotor symptoms. Others may legitimately improve menopause-related symptoms. A few of the products can result in significant harm (e.g., use of Kava and liver damage). Even if the clinician does not actively promote the use of alternative therapies, it is imperative to be aware of use by patients and to know which products can cause serious side effects.

SEXUALITY

Sexual concerns are often an issue for women at menopause, although a woman may be hesitant to share these concerns with her health care provider. As estrogen levels decline, there is thinning of the vaginal epithelium, which results in decreased vaginal elasticity. Decreased vaginal blood flow results in decreased vaginal secretions and decreased lubrication during sexual activity. Intercourse may become painful. Symptomatic vaginal atrophy can occur in up to 40% of postmenopausal women, but only about 25% will seek treatment for their symptoms. Other causes of vaginal pain, such as infection, should be ruled out.

For some women, vaginal lubricants (used at the time of intercourse) may be sufficient. Vaginal moisturizers (used on a regular basis to retain vaginal moisture) are also available. Topical vaginal estrogen is very effective in relieving the symptoms of vaginal atrophy with very little systemic

Table 71-7 Factors that May Influence Sexual Functioning in Women

Biological	Medications (e.g., antidepressants, antihypertensives) Vaginal atrophy, pain with intercourse Low testosterone levels (e.g., bilateral oophorectomy) Illness (e.g., diabetes, hypothyroidism, cerebrovascular accident) Sleep disturbances, fatigue Disability or pain from illness (e.g., arthritis) Incontinence
Psychological	Depression Body image
Interpersonal	Marital Issues Poor communication Partner’s sexual problems (e.g., erectile dysfunction) Partner’s health problems (e.g., myocardial infarction)
Sociocultural	Ageism (“too old” to want sex) Multiple other obligations and commitments Lack of partner

absorption and should be considered in women who do not obtain relief from over-the-counter measures and have no other contraindications.

Decreased interest in sex is one of the most common sexual complaints of women in midlife (up to 40% in one survey). A large, population-based trial, however, showed that menopausal status had a smaller impact on sexual desire than other factors, such as overall health, partner’s health, and other lifestyle issues. Biologic, psychological, interpersonal, and sociocultural factors all affect sexual functioning in women (Table 71-7). It is important for the clinician to be aware of the high prevalence of sexual issues in this population and to inquire about any sexual concerns. Having appropriate referral resources and patient literature available is helpful.

CARDIOVASCULAR DISEASE

The risk for cardiovascular disease increases for women at the time of menopause. It is estimated that one in eight women aged 45 to 65 years has some form of heart disease. This increases to one in three above the age of 65 years. A woman who has gone through menopause is twice as likely to develop heart disease as a woman of the same age who has not gone through menopause. An early, surgical menopause carries the most risk.

During the premenopausal years, it is thought that estrogen increases levels of high-density lipoprotein (HDL), which promotes the removal of cholesterol from the arteries. Estrogen also appears to exert a vasodilatory effect on blood vessels. Although women enjoy a protection against cardiovascular disease compared with men during their premenopausal years, with diabetes or increasing age, this protection disappears. Counseling women in the early postmenopausal years on the common high risk factors associated with heart disease (such as smoking, obesity, and elevated blood sugar) may help to ameliorate some of the negative effects that occur with decreasing estrogen levels.

OSTEOPOROSIS

A clear link exists between the loss of estrogen production at the time of menopause and the development of osteoporosis. With the onset of menopause, bone loss temporarily accelerates, and women may lose up to 5% of their bone mass per year over the next 5 years. About 20% of white women aged 50 years or older have osteoporosis; this number increases to 52% over the age of 80 years. Up to 90% of all hip and spine fractures in white women aged 65 to 84 years can be attributed to osteoporosis. Women who experience an early menopause are at greater risk. Screening for osteoporosis, education, counseling, and treatment are important aspects in the care of postmenopausal women.

Estrogen therapy is FDA approved for the prevention but not the treatment of osteoporosis. Alternate therapies have become more popular since the results of the WHI. These include bisphosphonates, calcium, and vitamin D. The pathophysiology as well as diagnosis and treatment of osteoporosis are covered elsewhere in this book. Estrogen therapy and estrogen-progestin therapy work best if started within 5 to 10 years of menopause. Estrogen use produces substantial

gains in bone mass with reduction in both vertebral and hip fractures. When the medication is discontinued, bone loss once again accelerates. Effects are also diminished in women older than 75 years.

GENITOURINARY SYMPTOMS

Urinary incontinence rates increase with aging. Urinary incontinence is common after menopause, with about 25% of women affected. Urinary incontinence is often multifactorial. The endothelium of the urethra and bladder becomes more fragile and less elastic with menopause. The tone that maintains the urethra also decreases with aging. Uterine prolapse and the development of a cystocele and rectocele also increase the risk for incontinence. The risk for urinary incontinence is greater as body weight increases and abdominal weight places additional pressure on the urinary bladder. Uterine prolapse, if it occurs, also increases pressure on the bladder. Urinary incontinence and its treatment are discussed in detail in Chapter 133. The number of behavioral and pharmacologic treatment options has dramatically increased.

D. Special Topics

Cardiovascular Disease

Cardiovascular disease includes hypertension, coronary artery disease (CAD), cardiomyopathy, stroke, and sudden death. For all women and men, increasing age is the greatest risk factor for cardiovascular disease. It is estimated that one in eight women aged 45 to 65 years has some form of heart disease. This increases to one in three above the age of 65 years. Black women are at greater risk for death from CAD and stroke than white women. Over the past few decades, CAD mortality has been decreasing among American women less than men. Many experts believe this is probably related to less attention to cardiac risk reduction in women. In a recent telephone survey, the most frequent reason women had not discussed heart health with their physician was that their provider did not bring up this issue.

During adolescence and young adult years, the avoidance of tobacco exposure is key. Individuals should be encouraged to avoid weight gain and to be physically active. Special preventive efforts and screening should occur with families with early-onset hypertension, diabetes, or heart disease. In cohort studies, even adolescent black women have higher blood pressure, weight, and insulin resistance than adolescent white women from the same area.

It is not clear why angina is most often the first symptom of coronary disease in women, whereas myocardial infarction is the most common first symptom in men, or why the onset of clinical heart disease is about 10 years later in

women than men. There is controversy about the reasons for this long-observed difference in age of onset. Some observational data suggest that a woman who has gone through menopause is twice as likely to develop heart disease as a woman of the same age who has not gone through menopause. An early, surgical menopause carries the most risk. However, the early observational studies of women with surgical menopause often did not analyze for tobacco use, and the role of hormonal therapy for these women after early menopause is not clear. Tobacco consumption lowers the age of natural menopause in a dose-related fashion—heavier exposure to tobacco more substantially leads to earlier onset of menopause.

Once diagnosed with CAD, specific medications and treatments improve outcomes for both women and men. At least among women after myocardial infarction, there has been limited improvement in assuring that women also receive best therapy (aspirin, β blockers, angiotensin-converting enzyme inhibitor, and lipid treatment) to reach goal levels. Cardiac rehabilitation improves outcomes after myocardial infarction, but women are less likely to attend. It is not clear whether this is an issue of referral or patient preference.

Sex differences in congestive heart failure have received increased attention. Both with an acute myocardial infarction and afterward women are more likely to experience congestive heart failure symptoms than men. Women are at higher risk for diastolic dysfunction, and its natural history

is still being defined. Systolic dysfunction may occur after ischemia, viral illness, or alcoholism. Regardless of etiology, patients with a low ejection fraction are at risk for fatal arrhythmia. Because implantable cardioverter-defibrillators (ICDs) decrease this risk, they are recommended. Unfortunately, less devices are currently implanted in women than men meeting ICD criteria.

Stroke is the third most common cause of death in the United States (after heart disease and cancer). Stroke rates vary by sex, age, race-ethnicity, educational level, and geographic location. At younger ages, stroke is more common in men, but more older women die from stroke. Increasing age correlates with higher risk for stroke. Native and black Americans have higher rates of stroke than whites and Asian Americans; this may be related to higher rates of hypertension, diabetes, and hyperlipidemia. The risk for stroke is greatest in the Southeast.

Hypertension is perhaps the most common cardiovascular disease. The prevalence increases with age and is most common in black women. Framingham data revealed that with a systolic blood pressure higher than 180 mmHg, the annual incidence of CHD (angina, coronary insufficiency, myocardial infarction, or death from these diagnoses) in women older than 65 years is more than 30%, whereas for men older than age 65 years, it is about 50%. If medication is required, drug side effects aid the choice of medication.

Obesity, Metabolic Syndrome, Polycystic Ovary Syndrome, and Diabetes

The prevalence of obesity has been steadily increasing, with a doubling among Americans older than 20 years from 1980 to 2002. Similarly, the prevalence of diabetes has increased dramatically, and these trends are expected to continue in adults because the metabolic syndrome is becoming more prevalent among children.

Obesity is not only linked to multiple cardiac risk factors but also independently associated with coronary artery event rates. The pattern of weight distribution is also predictive of coronary events, with more events among women with the apple shape, with a greater central or abdominal girth, than among those with the pear shape, with more weight on the hips and buttocks. A greater waist circumference increases health risk regardless of body mass index (BMI). In obesity, loss of even 10% of body weight has very positive metabolic effects.

During the past several years, the metabolic effects associated with obesity have been viewed as a spectrum disorder. Greater weight increases insulin resistance and the incidence of diabetes and hypertension. With more lipid screening, the relationship of obesity and diabetes to lipid levels has been elucidated. A subset of obese individuals have the *metabolic syndrome*, defined in the Third Report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol to include obesity, glucose intolerance, hypertension, and lipid abnormalities.

PCOS is a common metabolic disorder unique to women. Seen in a least 5% to 10% of women, it is characterized by oligo-ovulation or anovulation, evidence of androgen excess, and polycystic ovaries on ultrasound. Reproductive symptoms include irregular menses, acne, hirsutism, infertility, and increased risk for uterine cancer. Metabolic complications are associated with PCOS, including insulin resistance, diabetes, hypertension, and hyperlipidemia, as are higher rates of CAD. Pharmacologic and lifestyle interventions may improve prognosis, including aggressive management of tobacco use, lipoprotein abnormalities, and hypertension. Regular exercise can also improve glucose and blood pressure control as well as insulin resistance.

Diabetes is a growing health epidemic. In the past decade, cardiac mortality rates have increased by 23% for diabetic women yet decreased by 27% for nondiabetic women. In comparison, CAD mortality rates have declined for diabetic (13%) and nondiabetic (36%) men. Black and Hispanic women have especially high prevalence rates of diabetes.

Once a woman is diagnosed with diabetes, her “female advantage” in relation to CAD risk is lost. There is a higher risk for first myocardial infarction as well as more congestive heart failure complications and hospital mortality. It may be that less frequent identification and treatment of cardiovascular risks may be responsible for the differences in outcomes trends for women compared with men. For diabetic women, the dose-response hazards of tobacco use have been documented in the Nurses Health Study with 20 years of follow-up. The relative risk for a CAD event was 2.68 for current diabetic smokers of more than 15 cigarettes daily, 1.66 for current diabetic smokers of less than 15 cigarettes daily, and 1.21 for past diabetic smokers. Diabetic women who had not smoked for 10 years had a cardiovascular risk similar to that of nonsmoking diabetic women. Lipid abnormalities commonly occur in diabetic patients. At the time of diagnosis of type II diabetes, women have substantially lower HDL cholesterol than age-matched nondiabetic women, as well as higher low-density lipoprotein (LDL) and triglyceride levels.

Breast Complaints

Breast complaints can include a variety of symptoms, including pain, nipple discharge, and palpable mass. The risk for breast cancer increases with age, and women in younger age groups are more likely to experience symptoms related to benign breast disease. Regardless of age, women with breast complaints are generally most concerned about the possibility of breast cancer. A sensitive discussion should take place about the difference between benign and malignant disease and the difficulty in differentiating some symptoms based simply on physical examination. Women should be assured that most breast masses are benign. Prompt evaluation and a discussion about the importance of a careful follow-up are essential.

A *palpable mass* may be a cystic or a solid lesion, and these cannot be distinguished accurately by physical examination. A solid lesion may be a benign fibroadenoma or a malignant lesion, but again the characteristics of the physical examination cannot reliably distinguish the two. Some providers will perform a fine-needle aspirate in the office and, if the mass

disappears completely and the fluid is not bloody, will follow-up to ensure resolution before completing a mammograph or ultrasound. Alternatively, a mammograph and targeted ultrasound will provide a more definitive evaluation. All palpable lesions that cannot be identified by breast ultrasound as a simple cyst or other benign lesion will require biopsy for tissue diagnosis. This is true for lesions that cannot be visualized by mammography or ultrasound. The role of mammography in this setting is to look for other coincident lesions, not to establish a diagnosis.

Breast pain, *mastalgia*, is a common complaint but often leads to concern and anxiety about an underlying malignancy. Although it rarely results from cancer, this must be carefully ruled out by physical examination and mammography as well as a careful follow-up after one or two menstrual cycles to ensure a stable examination. Breast pain is usually cyclic in nature and is thought to be associated with hormonal changes. It may be triggered by the use of combined hormonal contraceptives or the initiation of estrogen replacement therapy for the treatment of menopausal symptoms. There is some evidence that reducing intake of caffeine can improve symptoms.

Nipple discharge may be expressed from most women, but *spontaneous* nipple discharge always requires a further evaluation. Bilateral, guaiac-negative, milky discharge, or *galactorrhea*, is typically the result of a hormonal abnormality, most often a prolactinoma. Women with a prolactinoma will typically present with amenorrhea. Galactorrhea can also be seen with other pituitary tumors, caused by a hypothalamic or pituitary stalk lesion, chest wall trauma, hypothyroidism, and host of medications. Evaluation should include serum TSH and prolactin levels followed by magnetic resonance imaging of the head if the prolactin level is elevated. Unilateral bloody discharge is suggestive of a papilloma or other benign lesion; malignancy must always be carefully excluded.

Mastitis is a breast infection that can occur in the postpartum setting as the result of bacterial infection. It will present as the acute onset of a localized pain and erythema and is associated with fever and influenza-like symptoms. Mastitis is most often unilateral and is generally caused by *Staphylococcus* species or *Escherichia coli* and is treated with oral antibiotics and continued breastfeeding to empty the involved breast. It may be complicated by recurrent mastitis or formation of a breast abscess. Nonlactational infection may also occur as a chronic subareolar infection known as *periductal mastitis*. This is treated with oral antibiotics and warm soaks. These may also be complicated by abscess formation or require surgical excision to treat recurrent infection.

Pelvic Pain

Pelvic pain may be acute or chronic and is a common and challenging problem for both the clinician and the patient. Acute pelvic pain can present over hours or days and may be the result of gynecologic, gastrointestinal, or urinary pathology. Gynecologic causes will include complications of pregnancy, acute pelvic infection, or pain related to ovarian processes, including cyst and torsion. The possibility of a ruptured ectopic pregnancy must be quickly assessed by history and pregnancy testing because of its potentially life-

threatening course. Ectopic pregnancy can be excluded by the presence of an intrauterine pregnancy on vaginal ultrasound examination. Other causes of acute pelvic pain include urinary tract infection and acute appendicitis. The evaluation of acute pelvic pain includes a thorough general and reproductive history and a physical examination, including a pelvic examination. Diagnostic testing should include basic laboratory tests, including a complete blood count, a pregnancy test, cervical cultures for chlamydia and gonorrhea, a urinalysis, and a pelvic ultrasound.

Chronic pelvic pain is considered when a woman has noncyclic pelvic pain for at least 6 months. It is highly prevalent, affecting one in seven women in the United States, and is most common among women of reproductive age. The causes of chronic pelvic pain include gynecologic, urologic, gastrointestinal, musculoskeletal, and psychological. The four most commonly diagnosed etiologies are endometriosis, adhesions, irritable bowel syndrome, and interstitial cystitis. It is common for more than one cause to be identified. Important gynecologic causes of chronic pain include endometriosis, adenomyosis, adhesions, and uterine fibroids. A history of physical or sexual abuse is associated with chronic pain and should be investigated sensitively, and safety should be established. In addition to a complete history and physical examination, including a pelvic examination, evaluation of chronic pelvic pain includes basic laboratory tests, including complete blood count, an erythrocyte sedimentation rate, a pregnancy test, cervical cultures for chlamydia and gonorrhea, a urinalysis, and a pelvic ultrasound.

A gastrointestinal evaluation should be considered for women with symptoms suggestive of irritable bowel syndrome. If initial evaluation has failed to lead to a diagnosis, laparoscopy will identify a pelvic abnormality in most cases. Interstitial cystitis should be considered for women with chronic urgency, frequency, nocturia or dysuria, and negative urine cultures. Evaluation must exclude other forms of infectious cystitis, neoplasm, and stones. Urodynamic testing and cystoscopy are often recommended.

Management of chronic pelvic pain will be determined by the underlying etiology identified and will often involve input from subspecialists. For those women who have not had a specific diagnosis, medical therapy includes the use of hormones and NSAIDs. A multidisciplinary approach, which includes medications and addresses dietary and psychosocial factors, has been shown to be superior to medical treatment alone.

Intimate or Domestic Violence

Violence and its impact frequently affect the health of patients and their providers. Interpersonal violence occurs more often between individuals who know each other, rather than among strangers. Intimate partner violence is described by the American Medical Association as “characterized as a pattern of coercive behaviors that may include repeated battering and injury, psychological/emotional abuse, sexual assault, progressive social isolation, deprivation, and intimidation. These behaviors are perpetrated by someone who is or was involved in an intimate relationship with the victim.” Women are more often in the role of being battered than

initiating violence. Surveys of health professionals reveal a higher prevalence of a past history of intimate partner violence than in the general public.

Interpersonal violence occurs at all ages, among all racial and ethnic groups, and regardless of educational or socioeconomic level. Intimate partner violence occurs throughout the world, including within one in four American families. About 25% of American women experience intimate violence sometime during their life. When violence occurs between adults, often the children in these homes also personally experience violence. Although in most states it is not required to report violence between adults, it is always required to report to the appropriate protective services agency if there is a concern that violence is affecting children, disabled individuals, or elderly people.

Sexual assault or being forced to engage in sexual activity can occur as part of intimate partner violence, but also occurs among individuals who are less intimate. Rape implies forced entry with oral, vaginal, or rectal penetration. Multiple surveys have found that the risk for rape is greatest among teenagers and young women. About 20% of American high school women report rape, with 10% reporting that the attack was by an intimate partner.

Women who are battered are at the greatest risk for death at the time they leave their abusive partner. Therefore, it is essential that the woman herself determine the timing of this step to maximize safety. Providers play an essential role by being a witness, treating the woman with respect as the adult she is, and documenting evidence of trauma to be available in the future.

There are several important long-term medical sequelae of interpersonal violence. Victims tend to use more ambulatory and inpatient care. Homicide by an intimate partner was reported as the cause of death in 33% of women killed compared with 4% of men. Psychological complications include post-traumatic stress disorder, depression, substance abuse, and sexual dysfunction. Acute problems include rape, leading to 5% of pregnancies annually, STIs, and other trauma complications. Chronic health problems can include headaches, irritable bowel syndrome, and pelvic pain.

Screening for interpersonal violence is essential. In contrast, many specialists suggest all patients be screened, whereas others suggest screening when certain diagnoses are being considered. Women who have been battered report that nonjudgmental inquiry made by a provider has opened the door for consideration of options besides accepting continued abuse. It is essential that screening for interpersonal violence be completed when the patient has privacy and is separate from friends and family. It is especially important to separate patients from overbearing partners before asking these types of questions. Examples of appropriate screening questions are listed in Table 71-8.

Table 71-8 Potential Screening Questions for Interpersonal Violence: SAFE Questions

Introduce the question:

"I ask all my patients about their experiences with violence."

"Because violence is so common, I ask my patients if they have been hurt by someone close to them."

S—Stress/Safety: "Do you feel safe in your relationship?"

A—Afraid/Abused: "Have you ever been in a relationship in which you were threatened, hurt, or afraid?"

F—Friends/Family—"Are your friends or family aware that you have been hurt? Could you tell them, and would they be able to give you support?"

E—Emergency Plan—"Do you have a safe place to go and the resources you need in an emergency?"

Patients who present with trauma should always be screened directly as well as acquiring details of how the specific injury occurred and when the decision to obtain medical care was made. Women are at higher risk if there are multiple injuries, especially at different stages of healing, or injuries that occur more often with intimate trauma, such as a perforated tympanic membrane, facial fractures, and vulvar or rectal abrasions or wounds. Pregnancy and the postpartum period is a high-risk time for abuse. Women who are abused may have a delay in seeking medical care because they often need to seek permission before presenting for medical care. Women with multiple somatic complaints, especially when many are nonanatomic, should be screened, as well as women with depression, anxiety, chronic sleep disorders, or pelvic pain.

The physician's response to the disclosure of intimate partner violence can have an immediate positive therapeutic impact. It is key to acknowledge that it took courage to share this information and that no one deserves to be treated as described. By treating the victim respectfully as a competent adult, the physician can create an environment that facilitates problem exploration. The first immediate concern is whether the victim and children, if present, will be safe leaving the office. If not, there is a national network of safe houses, and emergency departments often can provide information. The second task is to set up regular follow-up with the option for the patient to receive psychological counseling. Often, coming to a doctor is one of the few places a victim may safely go. There are multiple national as well as local resources available. National hotlines with toll-free numbers listed in phone directories provide access to support as well as information about local resources. In addition, most emergency departments have specially trained staffs that are aware of local resources. Most victims need time and emotional healing to determine a long-term safe plan.

Prospectus for the Future

Current research focusing on the actions of sex hormones throughout the body and in different parts of the life cycle will affect our understanding of physiology and biology. Exploration of cultural factors has the potential to improve communication between providers and patients and improve the

effectiveness of health interventions. Over the next decade, it is expected that clinically important sex differences will be elucidated that will change our approach to the care of individual patients in both health and disease.

Men's Health Topics

Jonathan S. Starkman, Douglas F. Milam, and Joseph A. Smith, Jr.

This chapter addresses disorders unique to men because of involvement of the male genitalia and reproductive

system. It incorporates aspects of voiding, oncology, reproductive function, and infection.

A. Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH), a nonmalignant enlargement of the prostate gland, is a common condition in the aging male patient. It is estimated that more than 90% of all men will develop histologic evidence of BPH during the course of their lifetime; of those, greater than or equal to 50% will develop lower urinary tract symptoms (LUTS) that prompt them to seek medical care. Broadly speaking, LUTS can be divided into two groups: obstructive voiding symptoms and irritative voiding symptoms (Table 72-1).

Although most patients who seek medical care for BPH do so because of the associated LUTS, it is important to realize that these same symptoms can be the result of several different factors, including systemic illnesses such as diabetes mellitus, as well as neurologic conditions including spine disease, parkinsonism, multiple sclerosis, and cerebrovascular disease (Fig. 72-1). It is important to evaluate the patient for these non-BPH-related conditions to ensure optimal management. It is also important to pay close attention to medication use because a number of medications used in the elderly population can result in various urologic symptoms, including both obstructive and irritative voiding symptoms.

Pathophysiology

Prostate growth and the subsequent development of BPH occur under the influence of testosterone and the more

metabolically active dihydrotestosterone. Testosterone, which is produced by the testes and controlled through the hypothalamic-pituitary gonadal axis, is converted to dihydrotestosterone by the action of the enzyme 5 α -reductase. Dihydrotestosterone is the major intracellular androgen and is believed to be responsible for the development and maintenance of the hyperplastic cell growth characteristic of BPH.

The development of BPH occurs predominantly in the periurethral prostatic tissue referred to as the *transition zone* (Fig. 72-2). Tissue growth in this area leads to the phenomenon of bladder outlet obstruction (BOO), which leads to LUTS. BOO occurs as a result of two mechanisms: (1) mechanical obstruction, resulting from an increased tissue volume in the periurethral zone of the prostate; and (2) dynamic obstruction, which is the result of decreased bladder neck relaxation during voiding and increased smooth muscle tone in the bladder neck and prostate gland. Also important, but less well characterized, is the response of the bladder muscle to the increase in outlet resistance provided by the combination of mechanical obstruction and increased prostatic and bladder neck smooth muscle tone. As bladder outlet resistance increases, the bladder responds by increasing the force of contraction. This added work results in physical and mechanical changes in bladder function.

Early in the course of the development of BOO, the bladder is able to compensate; however, with persistent obstruction, the patient will typically develop LUTS, particularly irritative voiding symptoms such as nocturia, frequency,

and urgency. These symptoms frequently drive patients to seek medical care. Later during the course of the obstructive process, the bladder wall becomes thickened and loses compliance. The subsequent loss of compliance results in a decrease in the functional capacity of the bladder, which exacerbates the patient's irritative voiding symptoms.

Diagnosis

The initial evaluation of a patient presenting with LUTS suggestive of BPH should include a detailed medical history,

Table 72-1 Lower Urinary Tract Symptoms

Irritative	Obstructive
Frequency	Hesitancy
Nocturia	Slow stream
Urgency	Stop-and-start voiding
Urge incontinence	Sensation of incomplete emptying

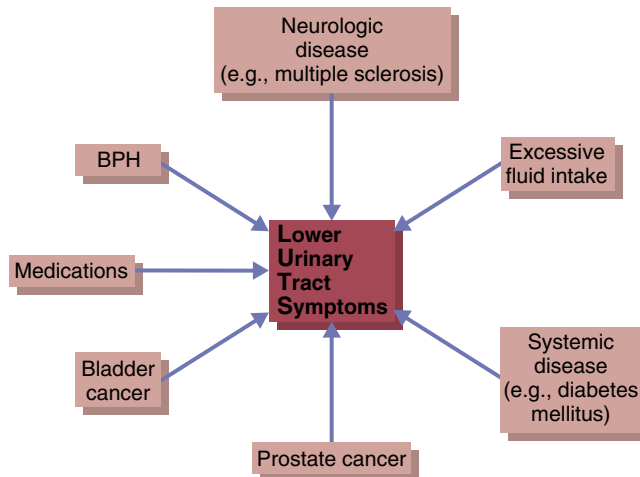

Figure 72-1 Causes of lower urinary tract symptoms. BPH, benign prostatic hyperplasia.

focusing on the patient's urinary symptoms, as well as the patient's past medical history, including comorbid conditions and any previous surgical procedures, general health conditions, and history of alcohol and tobacco use. The assessment of a patient's symptoms can be facilitated with the use of the American Urological Association (AUA) symptom index (also known as the *international prostate symptom score*, IPSS). This is a self-administered validated questionnaire consisting of seven questions related to the symptoms of BPH and BOO. Using the AUA symptom index, symptoms can be classified as mild (0 to 7), moderate (8 to 19), or severe (20 to 35). Validated instruments such as the AUA symptom index are useful during the initial evaluation as an overall assessment of symptom severity and during follow-up visits to assess the effectiveness of any interventions, medical or surgical.

A general physical examination should also be performed that includes a digital rectal examination (DRE) and a focused neurologic examination. Urinalysis, either by dipstick or microscopic examination of urine sediment, is also mandatory to rule out hematuria or evidence of urinary tract infection. Glycosuria can also be a significant finding, particularly if not previously identified. The initial clinical practice guidelines for the diagnosis of BPH recommended a serum creatinine to assess renal function in all patients presenting with signs or symptoms suggestive of BPH. However, this recommendation has come under some scrutiny as a result of its low yield for the detection of renal insufficiency secondary to obstructive uropathy. Serum creatinine is no longer a routine part of the BPH work-up. According to the same clinical practice guidelines, measurement of prostate-specific antigen (PSA) is optional during the initial evaluation. PSA can function as a surrogate for prostate volume measurement in addition to being a screening test for prostate cancer. The National Institutes of Health (NIH)-sponsored study, MTOPI, demonstrated that PSA increases linearly with prostate volume and that PSA greater than 4 ng/mL conveys a 9% risk for requiring surgical therapy for benign disease over a 4.5-year period.

The following additional diagnostic tests are also considered optional; however, they may be useful, particularly in

Figure 72-2 Zonal anatomy of the prostate gland.

patients with moderate to severe AUA symptom scores, in determining whether the patient's symptoms are compatible with obstruction from BPH. Uroflowmetry is a noninvasive method of measuring urinary flow rate. The maximal urinary flow rate, Q_m , is generally considered the most useful method for identifying patients with BOO. However, patients with diminished flow rates may also have impaired bladder contraction. Typical values range from 25 mL per second in a young man without BOO to 10 mL per second or lower in a man with significant BOO. Measurement of postvoid residual (PVR) urine may be accomplished by urethral catheterization or, preferably, ultrasonography. Elevated PVR volumes indicate an increased risk for acute urinary retention and eventual need for surgical intervention. The NIH-sponsored MTOPS study demonstrated that 7% of men with PVR greater than 39 mL required surgical intervention over a 4.5-year period. Elevation of PVR greater than 200 mL raises the question of functional impairment of the bladder and warrants further evaluation with urodynamic testing.

Urodynamic evaluation involves the introduction of pressure monitoring transducers into the bladder and rectum and subsequent measurement of intravesical and intra-abdominal pressures. These relationships, particularly those relating intravesical pressure and flow rate while voiding (pressure-flow studies), can provide significant information about the nature of the patient's symptoms and the presence or absence of BOO. Pressure-flow studies are most useful in distinguishing BOO caused by BPH from impaired bladder contraction (hyper or hypo). However, this is an invasive modality that requires specific urologic expertise for its optimal use. Routine cystoscopic examination is optional in the evaluation of the patient with BPH. It is most frequently performed either in the course of evaluating the patient for a potentially invasive therapy, such as surgical resection, or for the evaluation of a coexisting condition, such as hematuria.

Routine evaluation of the upper tracts (kidneys and ureters) with excretory urography or ultrasonography is not recommended for the average BPH patient unless there is concomitant urinary pathology (i.e., hematuria, urinary tract infection, renal insufficiency, a history of prior urologic surgery, or a history of nephrolithiasis). Likewise, transrectal ultrasonography (TRUS) is not routinely recommended unless it is used for preoperative assessment of prostate gland size while planning surgical intervention.

Differential Diagnosis

Many conditions can cause LUTS in the aging male. DRE and PSA testing are helpful in distinguishing between BPH and prostate cancer. Typically, early-stage prostate cancer is asymptomatic. Therefore, patients may have both conditions concurrently. Although PSA testing is not sufficiently sensitive or specific to reliably differentiate BPH from prostate cancer, it is a useful tool to stratify a patient's risk for the presence of prostate cancer. Prostatitis is another condition that can cause LUTS. It may result from bacterial infection or from a nonbacterial inflammatory process, and the symptoms may substantially overlap those of BPH, particularly in the older male. Diabetes mellitus, neurologic diseases such as Parkinson disease or cerebrovascular disease, or

other conditions of the urinary tract, such as urethral strictures, may result in LUTS seen in patients with BPH. Finally, many medications, particularly those with significant anticholinergic side effects, may mimic the symptoms associated with BPH.

Management

MEDICAL THERAPY

Medical management is the preferred first-line treatment option for patients diagnosed with LUTS from BPH. Most patients can be managed effectively with a minimum of side effects using the medications discussed below. The NIH MTOPS study conclusively demonstrated that combination therapy with both a long-acting α blocker and a 5 α -reductase inhibitor was more effective than single-agent therapy alone. In general, medical management is initiated for patients with moderate to severe AUA symptom scores. However, it is important to note that, in the absence of indications for surgery (refractory urinary retention, hydronephrosis with or without renal impairment, recurrent urinary tract infections, recurrent gross hematuria, or bladder calculi), the decision to embark on any course of therapy, medical or otherwise, is principally driven by the degree of bother caused by the patient's symptoms. Every patient has a different perception of his symptoms; therefore, nocturia twice nightly, while a minor nuisance to some, may represent a significant problem for others. There is no absolute AUA symptom score or other objective measure that dictates the need for initiation of therapy for symptomatic BPH. Each patient must be evaluated individually and his treatment course tailored to his individual situation.

α -adrenergic Antagonists

α -adrenergic antagonists, or α blockers, are the most commonly prescribed medications for the treatment of LUTS associated with BPH. The bladder neck and prostate are richly innervated with α -adrenergic receptors, specifically α_{1a} receptors, which constitute about 70% to 80% of the total number of α receptors in these areas. α_{1b} receptors modulate vascular smooth muscle contraction and are located in the bladder neck and prostate to a lesser degree.

Doxazosin, terazosin, tamsulosin, and extended-release alfuzosin are long acting α -receptor antagonists. They are generally administered once daily, usually at bedtime to minimize the potential for orthostatic hypotension. These medications act through α_1 receptors and can cause vasodilation resulting in transient hypotension and lightheadedness. Blood pressure reduction is greater in patients with hypertension (average reduction of 10 to 15 mmHg) relative to normotensive patients (average reduction 1 to 4 mmHg). Overall, 10% to 20% of patients experience some often transient side effects from these medications, including dizziness, asthenia, headaches, peripheral edema, and nasal congestion. Dose titration is recommended for doxazosin and terazosin to minimize occurrence of these adverse effects and optimize therapeutic response. Doxazosin and terazosin require at least 4 or 5 mg, respectively, to achieve a therapeutic effect. Maximal response is usually seen within 1 to 2 weeks with doxazosin and 3 to 6 weeks with terazosin.

Overall, these drugs reduce symptom scores by 40% to 50% and improve urinary flow rates by 40% to 50% in about 60% to 65% of patients treated.

Tamsulosin is a selective α_{1a} receptor antagonist with a long half-life. It has a significantly lower degree of nonspecific α -receptor binding compared with other α -receptor antagonists. Therefore, side effects such as postural hypotension and dizziness are less common. This drug does not appreciably affect blood pressure in hypertensive or normotensive patients. Maximal response is usually seen within 1 to 2 weeks of the initiation of therapy.

5 α -reductase Inhibition (Finasteride and Dutasteride)

Finasteride and dutasteride block the intracellular conversion of testosterone to 5-dihydrotestosterone by inhibiting the action of the enzyme 5 α -reductase. This results in an approximate 18% to 25% reduction in prostate gland size over 6 to 12 months. It is most effective in reducing symptoms and preventing disease progression in patients with large prostate glands (>40 mL), although recent evidence suggests that symptomatic improvement and stabilization of disease progression may occur in treated men with prostatic size down to 30 mL. 5 α -reductase inhibition has also been shown to decrease the risk for urinary retention and the risk for subsequent surgical intervention, again, predominantly in those patients with larger glands. Initial response is seen within 6 months, and maximal effect occurs 12 to 18 months after the initiation of therapy.

Finasteride and dutasteride reduce serum PSA by about 50%. This must be taken into consideration when interpreting PSA values in men taking these agents. After 6 months of therapy, the effective PSA level in a patient taking finasteride or dutasteride may be calculated by multiplying the measured PSA by 2. Free PSA (the percentage of non-protein-bound PSA) is also reduced by about 50%. Use of finasteride or dutasteride may result in sexual dysfunction, including decreased erectile rigidity, decreased libido, and decreased ejaculate volume. Erectile dysfunction (ED) caused by 5 α -reductase inhibitor therapy is reversible and returns to baseline within 2 to 6 months after discontinuation of therapy.

Phytotherapy

There is a growing body of evidence to suggest that various plant extracts may have a therapeutic effect in the treatment of LUTS associated with BPH. Saw palmetto berry (*Serenoa repens*) extracts are the most widely used and studied. Use of saw palmetto has been shown to improve symptom scores in randomized trials in Europe. The extent of therapeutic improvement is at this point unclear but appears to be substantially less than the U.S. Food and Drug Administration (FDA)-approved medications described previously. *Africanum* (African plum) extract has also been used to treat symptoms associated with BPH. However, less is known about its overall efficacy and mechanism of action.

Use of herbal or plant extracts for the therapeutic management of symptomatic BPH remains somewhat controversial in the United States, despite their widespread use in Europe, particularly Germany. There is, however, growing interest in the evaluation of these compounds in the United

States. Clinical trials are currently ongoing; however, results will not be available for several years.

SURGICAL MANAGEMENT

Minimally Invasive Therapy

Although transurethral resection of the prostate (TURP) remains the gold standard for the surgical treatment of BPH, substantial effort has been devoted to the development of less invasive and less morbid methods of treating patients with symptomatic BPH. This has led to a proliferation of minimally invasive therapies, primarily using different methods of generating heat within the prostate gland, resulting in tissue destruction. The office-based heat techniques described below transiently increase bladder outlet obstruction for 1 to 2 weeks because of postprocedure swelling. Maximal tissue reduction and treatment effect occur within 12 weeks.

Transurethral microwave thermotherapy (TUMT) is one of the most widely studied minimally invasive methods of treating patients with symptomatic BPH. Catheter-mounted transducers use microwave energy (30 to 300 Hz) to heat prostatic tissue, resulting in coagulative necrosis and shrinkage of the prostate gland. The subsequent reduction in prostate transition zone volume results in an improvement in flow rates and symptom scores. Transurethral needle ablation (TUNA) uses low-level radio frequency energy to effect similar changes within the prostate gland. Other therapies currently available or in development include interstitial lasers and high-intensity focused ultrasound. All these therapies are designed to deliver sufficient energy to the prostate to cause tissue destruction, resulting in smaller prostate glands and an attendant improvement in patient symptoms.

The most common side effects of these treatments are temporary increases in irritative voiding symptoms, transient urinary retention (TUR), hematuria, and ejaculatory dysfunction (primarily retrograde ejaculation). Late complications, such as urethral strictures and ED, have been reported but are significantly less common than with traditional surgical approaches. The major benefits of these less invasive therapies are the reduction in traditional surgical morbidities such as bleeding, fluid absorption (TUR syndrome), and the risks associated with general or spinal anesthesia, as well as decreased rates of long-term complications such as incontinence, ED, bladder neck contractures, and urethral strictures. Additional important advantages include decreased anesthetic requirements and potential elimination of hospitalization resulting from the fact that most of these procedures can be accomplished safely on an outpatient basis, either in the office or in an ambulatory surgical setting.

Success rates for the heat-based minimally invasive therapies are intermediate between those achieved with medical management and with traditional surgical therapy, with 65% to 75% of patients experiencing symptomatic improvement and improved flow rates. The long-term durability of these therapies appears good but is presently being evaluated.

Traditional Surgical Management

TURP remains the gold standard for the surgical management of symptomatic BPH. This procedure involves endoscopic removal of periurethral prostate tissue. Improvements

Table 72-2 Success in Medical versus Surgical Management of Benign Prostatic Hyperplasia

	α_1 Blockers	Finasteride	TURP	TUIP	Open Surgery
Percentage of symptom improvement	48	31	82	73	79
Percentage of flow rate improvement	40-50	17	120	100	185
Mean probability of achieving the above improvement (%)	74	67	88	80	98

TUIP, transurethral incision of the prostate; TURP, transurethral resection of the prostate.

in the conventional technique have included using bipolar electro-surgical cutting, which allows saline irrigant and eliminates the chance of TUR syndrome. Newer competitive operating room-based therapies have evolved that produce a similar end result as TURP. These include holmium laser enucleation (HOLEP) and potassium titanyl phosphate (KTP) laser treatment, which use high-energy laser light to remove transition zone tissue. These operating room procedures, all of which produce similar results, produce the greatest improvement in both urinary flow rate, bladder emptying, and symptom score. TURP, HOLEP, and KTP are useful for all but the largest prostate glands (>100 g), which are best managed with open surgical enucleation. Although they are most effective, complications following the operating room-based therapies are higher than those caused by minimally invasive office-based approaches. Urinary incontinence, retrograde ejaculation, and urethral stricture rates are all higher after operating room procedures than office-based therapies. Perioperative morbidity, including the need for blood transfusion, although substantially decreased by technical improvements, is likewise higher after TURP and similar procedures. However, standard electro-surgical resection of the prostate, TURP, is the most effective surgical treatment for symptomatic BPH, short of open surgical enucleation. Success rates, as measured by improvements in symptom score and increases in urinary flow rates, are 80% to 90% following TURP.

Transurethral incision of the prostate (TUIP) is another more limited surgical procedure consisting of incision of the bladder neck and proximal prostatic urethra. Although more invasive than the heat-based therapies, in properly selected patients (i.e., those with prostate glands less than 30 g in size), success rates approach those seen following TURP. Morbidity following TUIP is significantly less than that following TURP, but long-term durability of symptom relief is less than that seen with TURP.

Open surgical enucleation, or simple prostatectomy, is reserved for patients with very large glands. Success rates are high following this approach; however, the rate of complica-

tions following open surgical resection is highest of all the traditional surgical approaches (Table 72-2).

The management of LUTS resulting from BPH has undergone a dramatic shift from principally a surgical approach to a medical approach. Most patients presenting with LUTS believed to be secondary to BPH are initially managed medically as discussed above. This, coupled with the aging of the U.S. population, has resulted in a shift of the care of these patients from the urologist to the primary care physician. In the absence of severe LUTS or indications for early surgical intervention, the primary care physician can now successfully manage most patients with mild to moderate BPH. Patients not responding to medical therapy are often offered office-based minimally invasive surgical therapy.

B. Prostatitis

Prostatitis is an extremely common clinical condition, estimated to account for one in four office visits to urologists. It is the most common urologic diagnosis in men less than 50 years old and is the third most common diagnosis in men older than 50 years. It is associated with a multitude of symptoms ranging from pelvic pain to voiding dysfunction. Until recently, the diagnosis of prostatitis was poorly defined and based primarily on clinical history. Treatment of the prostatitis syndromes remains equally problematic, with the efficacy of the most common therapies lacking evidence-based guidelines. Recently, the NIH developed a standardized classification of prostatitis syndromes:

- NIH category I: acute bacterial prostatitis (ABP)
- NIH category II: chronic bacterial prostatitis (CBP)
- NIH category III: chronic pelvic pain syndrome (CPPS)
- NIH category IIIa: inflammatory CPPS
- NIH category IIIb: noninflammatory CPPS
- NIH category IV: asymptomatic prostatitis

Chronic nonbacterial prostatitis or CPPS (categories IIIa and IIIb) is the most common symptomatic type of prostatitis and may be the most prevalent of all prostate disorders, including BPH. Despite this, chronic nonbacterial prostatitis or CPPS remains enigmatic and has not been conclusively demonstrated to be primarily a disease of the prostate or the result of a defined inflammatory process.

Acute Bacterial Prostatitis

Acute bacterial prostatitis is a relatively uncommon serious systemic illness requiring aggressive treatment with intravenous antibiotics. Patients typically present with fevers, chills, dysuria, and perineal and low back pain. Advanced cases may present with signs of sepsis. Physical examination may reveal a distended bladder, and DRE usually reveals a warm, boggy, and tender prostate. Rectal examination should be performed with caution to minimize the risk for inducing bacteremia as a result of overaggressive manipulation of the gland. Some urologists recommend deferring a rectal examination if the clinical presentation is highly suggestive of acute prostatitis.

Laboratory analysis typically reveals an elevated white blood cell count and a positive urine culture. Localization examination is contraindicated because the pathogen is identified in the midstream urine. If the patient has evidence of urinary retention, a suprapubic cystostomy tube should be considered for bladder drainage to minimize transurethral instrumentation. Those not acutely septic can be managed with an indwelling urethral catheter. Acutely ill patients are typically hospitalized for parenteral antibiotics

and supportive care. Patients should be treated for a total of 30 days with combined parenteral and oral antibiotics to reduce the risk for development of chronic prostatitis. Fluoroquinolones are recommended because they achieve excellent tissue levels within prostate tissue. Although bacterial persistence or conversion to chronic bacterial prostatitis is low, follow-up urine cultures should be obtained to document clearance of the infection. In rare cases, a prostatic abscess may form, especially in immunocompromised patients (i.e., those with diabetes or HIV). This can be evaluated with TRUS or contrast-enhanced pelvic computed tomography (CT) and is treated with surgical transurethral unroofing of the abscess cavity and supplementary antibiotics.

Chronic Bacterial Prostatitis

Chronic bacterial prostatitis is associated with inflammation of the prostate gland and recurrent urinary tract infections with bacteria localized to the prostate through standardized localization testing. Etiologic agents range from common uropathogens to cryptic organisms difficult to culture. The differential diagnosis includes cystitis, urethritis, and CPPS (categories IIIa and IIIb). Symptoms are nonspecific and include LUTS, pelvic pain, and sexual dysfunction, either alone or in combination. Physical examination may reveal abdominal tenderness, testicular or epididymal tenderness, prostate tenderness, or tenderness associated with DRE. The prostate is often normal to palpation, although it may be enlarged secondary to concomitant BPH.

Traditional testing of the urine in this patient population is accomplished by evaluation of urine in the following manner. The first voided urine (VB-1) is collected, followed by collection of midstream urine (VB-2). Following this, a DRE is performed, and the prostate is massaged. Expressed prostatic secretions (EPS) are then collected. The patient is then asked to void again, and the post-prostatic massage urine (VB-3) is collected. Evaluation of each of these fractions can provide evidence of the source of any infection. Chronic bacterial prostatitis is diagnosed when there are 10 times the number of white blood cells in the EPS or VB-3 relative to the VB-1 or VB-2. Alternatively, culture of the EPS or VB-3 must grow 10-fold more organisms than the VB-1 or VB-2. One may also compare preprostatic and post-prostatic massage urine for the presence of white blood cells and uropathogenic organisms. Although these measures are commonly described for the accurate diagnosis of prostatitis, a presumptive diagnosis is often made based on clinical symptoms, EPS, and urinalysis findings.

Treatment involves a 4- to 8-week course of antimicrobial therapy. This can be extended to 12 weeks in those who

respond initially but fail to eradicate the organism from the genitourinary tract. Broad-spectrum antibiotics such as trimethoprim-sulfamethoxazole (TMP-SMX) or a fluoroquinolone are indicated for the treatment of chronic bacterial prostatitis and must be tailored to the suspected pathogen. Studies have shown excellent tissue levels of these drugs within the prostate. Typically, between 60% and 80% of patients are cured with 1- to 3-month treatment courses. One third of patients will relapse with recurrent symptoms and bacteriuria. For patients who have relapsing infections, long-term suppressive therapy may be indicated, whereas patients who have recurrent infections with different organisms are best treated with low-dose prophylactic antibiotics. Surgery is rarely indicated in patients with chronic bacterial prostatitis because cure rates of only 33% are achieved with aggressive TURP, probably because most of the infected tissue lies in the peripheral zone of the prostate, as opposed to the transition zone. Treatment endpoints are the clearance of appropriate cultures and the resolution of the patient's symptoms.

Chronic Nonbacterial Prostatitis or Chronic Pelvic Pain Syndrome

The NIH category III CPPS makes up the largest percentage of patients with clinical prostatitis. These syndromes are the most difficult to diagnose and treat and are the most poorly understood pathophysiologically. In addition, there is a substantial economic impact associated with CPPS, which warrants further research to determine more effective treatment strategies. Patients with CPPS typically present with a combination of pain (perineal, low back, suprapubic, groin, or scrotal), voiding dysfunction (dysuria, weak stream, frequency, urgency, or nocturia), and sexual dysfunction (painful ejaculation or low libido). The presence of pelvic pain, regardless of the degree of associated symptoms, is mandatory for the diagnosis of category III prostatitis. Because of the varied symptoms among patients, the NIH created a validated symptom index that is now available for the initial assessment and subsequent follow-up of patients with chronic prostatitis (NIH-CPSI). It is a 13-item questionnaire with three domain scores: (1) pain, (2) urinary symptoms, and (3) quality of life. The clinical evaluation of patients with CPPS often includes clinical history and examination, administration of the NIH-CPSI, urinary tract localization studies, and urinary flow rate with PVR.

Inflammatory CPPS (NIH category IIIa) is associated with the same symptoms seen in CBP; however, no causative organism is typically identified. Pelvic pain is a frequent symptom that may be exacerbated by stress, certain dietary factors, or vigorous physical exercise. The etiology of the symptoms is unclear, but patients' quality of life is significantly affected by the presence of this disorder. Rectal examination typically reveals nonspecific findings, and the prostate may be tender or indurated, although, more frequently, the examination results are within normal limits. Urinalysis should be normal, and urine cultures should be sterile. The EPS often reveal significant numbers of white blood cells but, again, should be sterile. Treatment can be frustrating

for both patients and providers and includes measures such as warm baths and nonsteroidal anti-inflammatory drugs (NSAIDs), with some urologists recommending prostatic massage for patients who ejaculate infrequently. The routine use of antibiotics is common, but controversial. Generally, antibiotic therapy should be limited to an empirical 2-week course of an appropriate antibiotic and terminated if there is no clinical response to treatment. If the patient responds, extension to a full 6-week course may be indicated.

Noninflammatory Chronic Pelvic Pain Syndrome

Noninflammatory CPPS, also known as *prostatodynia*, is typically seen in younger male patients (20 to 50 years). They typically present with symptoms suggestive of prostatitis, including pelvic pain and voiding symptoms, but have negative urine cultures, normal EPS, and a normal prostate on DRE. Stress is a frequent component of the symptom complex.

Treatment in this population again includes the same supportive measures mentioned previously. α -adrenergic antagonists are the primary pharmacologic agent used to treat this condition, although efficacy data are scant. NSAIDs are also useful and may be used in conjunction with tricyclic antidepressants for the management of chronic pain. The anticholinergic side effects of the tricyclics can also help with the associated frequency and urgency often experienced by these patients. Biofeedback and other stress management techniques have been used with limited success.

Recently, small studies have suggested that the heat-based minimally invasive methods used to treat BPH may have some role in the treatment of noninflammatory CPPS. TUMT has been shown to decrease pain and voiding symptoms in small series of patients. Larger studies are needed to confirm the utility and safety of this approach.

This is a difficult and demanding problem for both patients and physicians. Patients have frequently seen multiple physicians, and some have chronic pain and other psychiatric problems, such as depression or anxiety disorders. It is important to remember that, despite our poor understanding of the pathophysiology of this condition, it is common and has a major impact on quality of life. Appropriate clinical concern, coupled with good patient communication and rational treatment strategies, is the foundation for the successful management of this challenging group of patients.

C. Erectile Dysfunction

Impotence is a condition defined by inability to attain or maintain adequate penile rigidity sufficient for intercourse. Impotence is the most common cause of ED in the United States. Other important, although less common, causes of ED include Peyronie disease, trauma, and rapid ejaculation. About 10 million Americans are affected by ED. Table 72-3 illustrates the prevalence of ED measured in the Massachusetts Male Aging Study. As one can see, at age 40 years, about 5% of men never have penile rigidity sufficient for vaginal penetration. By age 70 years, at least 15% of men experience complete ED, whereas about 50% have varying degrees of ED. Age and physical health are the most important predictors of the onset of ED. Smoking was the most important lifestyle variable, and ED did not correlate with male hormone levels.

Mechanism of Erection

Psychogenic or tactile sexual stimulation, or both, is the initial point in the pathway leading to penile erection. Nerve signals are carried through the pelvic plexus, a portion of which condenses into the cavernous nerves of the penile corpora cavernosa. The pelvic plexus receives input from

both the sympathetic and parasympathetic nervous system. Sympathetic fibers originate in the thoracolumbar spinal cord, condense into the hypogastric plexus located immediately below the aortic bifurcation, and course into the pelvic plexus. Parasympathetic fibers originate in sacral spinal cord segments 2 through 4 and join the pelvic plexus. Discrete nerves carrying both sympathetic and parasympathetic fibers innervate the organs of the pelvis. In 1982, Walsh and Donker demonstrated that nerves coursing immediately lateral to the urethra continue on to innervate the corpora cavernosa. It is now known that branches of those nerves are the principle innervation of the neuromuscular junction, where arterial smooth muscle controls penile blood flow.

Sexual stimulation causes the release of nitric oxide (NO) by the cavernous nerves into the neuromuscular junction (Fig. 72-3). NO activates guanylyl cyclase, which converts guanosine triphosphate (GTP) into cyclic guanosine monophosphate (cGMP). Protein kinase G is activated by cGMP and in turn activates several proteins that decrease intracellular calcium (Ca^{2+}) concentration. Decreased smooth muscle Ca^{2+} concentration causes muscular relaxation, cavernosal artery dilation, increased blood flow, and subsequent penile erection. The control of blood flow on the venous outflow side is less well understood.

Table 72-3 Relationship of Risk Factors to Erectile Dysfunction: Prevalence (%) of Complete Erectile Dysfunction

Risk Factor	Prevalence	Risk Factor Plus Smoking Status		
		Smoker	Former Smoker	Nonsmoker
Age 40 yr	5.1			
Age 70 yr	15			
Diabetes*	28			
Heart disease*	39	56	21	8.5

Figure 72-3 Sexual stimulation causes the release of nitric oxide (NO) by the cavernous nerve into the neuromuscular junction. ATP, adenosine triphosphate; cGMP, cyclic guanosine monophosphate; GMP, guanosine monophosphate; GTP, guanosine triphosphate; PDE-5, phosphodiesterase type 5.

Causes of Erectile Dysfunction

Psychogenic ED was formerly thought to be the most common etiology of ED. Progressive advances in understanding of the mechanics and neurophysiology of erectile function have identified other more common causes of ED. Psychogenic ED is now thought to represent less than 15% of patients seen by ED specialists. The anatomic site now believed to be the most common cause of ED is the neuromuscular junction, where the cavernosal nerves meet the smooth muscle and endothelium of the deep cavernous penile arteries. This is where NO and cGMP play a critical role in regulating penile blood flow. This so-called endothelial dysfunction may be an early tipoff of evolving systemic arterial disease. Other less common causes of decreased erectile rigidity include endocrine disorders, vascular disease, central and peripheral nerve disorders, drug-induced ED, and venogenic ED.

NEUROMUSCULAR JUNCTION DISORDERS

NO is released from cavernosal nerves, causing activation of guanylyl cyclase within the corpus cavernosum. Figure 72-3 illustrates that there are several steps that, if not functioning properly, could impede erectile function. Most research at this time is focused on generation of NO by the cavernous nerves. Further understanding of all the steps in the erectile pathway will likely implicate other biochemical reactions as causing ED. The fact that at least 60% of patients with ED from all causes other than trauma or medical treatment respond to phosphodiesterase type 5 (PDE-5) inhibition is strong evidence supporting the inference that biochemical

dysfunction at the neuromuscular junction is by far the most common cause of ED.

ENDOCRINE DISORDERS

Testosterone plays a permissive role in erectile function. Endocrine disorders may directly or indirectly decrease plasma free or bound testosterone. The most obvious, but one of the least prevalent, causes of ED is hypogonadism. Erectile ability is partially androgen dependent. These patients present with decreased or absent libido in addition to loss of erectile rigidity. Physical examination of the testes in patients afflicted with primary or secondary hypogonadism often demonstrates soft, atrophic gonads. Androgen replacement (testosterone cypionate, 200 mg every 2 to 3 weeks, or daily topical testosterone gel or patch preparations) is expected to induce return of erectile function in patients with very low or undetectable serum testosterone concentrations resulting from hypogonadism. These patients are relatively uncommon, however. More commonly, the impotent patient will have normal or mildly decreased levels of circulating androgens. Testosterone replacement rarely restores erectile function in those with mildly decreased serum testosterone levels and should not be routinely given for that indication. Testosterone supplementation is never indicated for patients with normal circulating androgen levels.

The most common endocrine disorder affecting erectile ability is diabetes mellitus. Diabetes affects both the autonomic and somatic nervous system in addition to causing atherosclerotic vascular disease. The most important effect diabetes has on erectile ability appears to relate to loss of function of long autonomic nerves. Erection is partially mediated by efferent parasympathetic cholinergic neural stimuli. Loss of long cholinergic neurons results in interruption of the efferent side of the erectile reflex arc. Diabetes also appears to produce dysfunction of the neuromuscular junction at the level of arterial smooth muscle in the penile corpora cavernosa. Studies have indicated markedly decreased acetylcholine and NO concentrations in the trabeculae of the corpora cavernosa in diabetic patients. These findings probably represent a combination of neural loss and neuromuscular junction dysfunction.

Other endocrine disorders, including hypothyroidism, hyperthyroidism, and adrenal dysfunction, may uncommonly cause ED. Because of the uncommon occurrence of thyroid and adrenal conditions in those presenting for treatment of ED, testing of those axes is not a part of the routine work-up of ED.

VASCULAR DISEASE

Vascular disease is a frequent cause of ED in the United States. This is primarily due to the high prevalence and often severe nature of peripheral vascular disease. Penile erection is obtained by a combination of relaxation of arteriolar smooth muscle and increasing venous resistance of channels penetrating the wall of the corpora cavernosa. Arterial disease may decrease erectile ability either by mechanical obstruction of the vascular lumen or more commonly by endothelial dysfunction, which as discussed previously interrupts to neural control mechanism of vascular smooth

muscle function. This process leads to complete filling of the corpora cavernosa with blood at systemic blood pressure. The principle blood vessels supplying the corpora cavernosa are the cavernosal arteries. These vessels are terminal branches of the pudendal artery, which is the terminal branch of the internal iliac artery. Either large or small vessel arterial disease may decrease corporal blood pressure, leading to failure to achieve penile lengthening and rigidity.

Normal penile erection requires a functioning vascular tree upstream from the cavernosal arteries. Many cases of ED were formerly attributed to anatomic vascular disease when the problem actually was with control of cavernosal artery smooth muscle. Pharmacologic injection therapy involves injecting vasodilator agents (prostaglandin E₁ [PGE₁], papaverine, phentolamine, or combinations of those) into the corpora cavernosa to produce erection by dilating the corporal artery smooth muscle. More than 90% of patients with ED respond to this type of therapy, indicating that atherosclerotic arterial narrowing is not the etiology of most cases of ED.

Veno-occlusive disease in the penis is also a significant cause of ED. These patients often experience normal initial rigidity, but quickly, and before ejaculation, lose their erection.

NEUROGENIC ERECTILE DYSFUNCTION

Pure neurogenic ED is a frequent cause of erectile failure. Interruption of either somatic or autonomic nerves or their end units may cause ED. These nerves control the flow of blood into and likely out of the corpora cavernosa. Afferent somatic sensory signals are carried from the penis through the pudendal nerve to S2 through S4. This information is routed both to the brain and to spinal cord autonomic centers. Parasympathetic autonomic nerves originate in the intermediolateral gray matter of S2 through S4. These preganglionic fibers exit the anterior nerve roots to join with the sympathetic fibers of the hypogastric nerve to form the pelvic plexus and cavernosal nerves. The paired cavernosal nerves penetrate the corpora cavernosa and innervate the cavernous artery and veins. Parasympathetic ganglia are located distally near the end organ.

Sympathetic innervation also originates in the intermediolateral gray matter but at thoracolumbar levels T10 through L2. Sympathetic efferents course through the retroperitoneum and condense into the hypogastric plexus located anterior and slightly caudal to the aortic bifurcation. A concentration of postganglionic sympathetic fibers forms the hypogastric nerve, which is joined by parasympathetic efferents. Adrenergic innervation appears to play a role in the process of detumescence. High concentrations of norepinephrine have been demonstrated in the tissue of the corpora cavernosa and tributary arterioles. Additionally, the α -adrenergic antagonist phentolamine is routinely used for intracorporal injection therapy to produce erection.

Afferent signals capable of initiating erection can either originate within the brain, as is the case with psychogenic erections, or result from tactile stimulation. Patients with spinal cord injury often respond to tactile sensation but usually require medical therapy to maintain the erection

Table 72-4 Frequency of Decreased Erectile Rigidity and Ejaculatory Dysfunction by Medication Class

Medication Class	Decreased Erectile Rigidity	Ejaculatory Dysfunction
β -adrenergic antagonists	Common	Less common
Sympatholytics	Expected	Common
α_1 agonists	Uncommon	Uncommon
α_2 agonists	Common	Less common
α_1 antagonists	Uncommon	Less common*
Angiotensin-converting enzyme inhibitors	Uncommon	Uncommon
Diuretics	Less common	Uncommon
Antidepressants	Common [†]	Uncommon [‡]
Antipsychotics	Common	Common
Anticholinergics	Less common	Uncommon

*Patients able to ejaculate, but retrograde ejaculation is seen in 5% to 30%.
[†]Uncommon with serotonin reuptake inhibitors.
[‡]Delayed or inhibited ejaculation with serotonin reuptake inhibitors.

through intercourse. There is no discreet center for psychogenic erections. The temporal lobe appears to be important; however, other locations such as the gyrus rectus, the cingulate gyrus, the hypothalamus, and the mammillary bodies also appear to be important.

MEDICATION-INDUCED ERECTILE DYSFUNCTION

Commonly prescribed medications often cause or contribute to decreased erectile function. A complete list of these agents and their mechanisms of action is beyond the purview of this text. Table 72-4 lists the major classes of medications implicated in ED and suggests how commonly these medications interfere with erectile function. Often in clinical practice one finds that patients are on specific classes of medications for important reasons. For that reason, substituting a different medication is usually unsuccessful in restoring erectile function in patients who often have several risk factors for ED. Proceeding directly to treatment of ED is usually the preferred option in all but the most straightforward cases.

Medical and Surgical Treatment

Since the introduction of sildenafil in 1998, the Process of Care Model for the Evaluation and Treatment of ED has been adopted and targets the primary care provider as the initial source of care for patients with ED. Currently available therapies for ED include oral PDE-5 inhibitors, intra-urethral alprostadil, intracavernous vasoactive injection therapy, vacuum constriction devices, and penile prosthesis implantation. A stepwise treatment approach is adopted, starting with oral agents and progressing to more invasive therapeutic interventions as indicated (Fig. 72-4). Informed

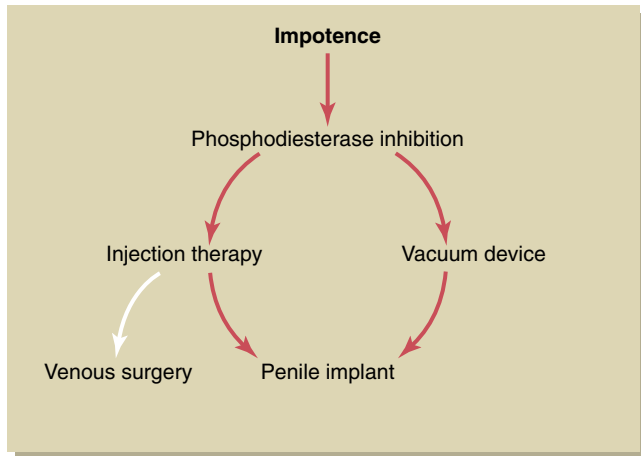

Figure 72-4 A logical treatment algorithm for impotence.

patient decision making is critical toward successful progression through the plan of care pathway. Patient referral is primarily based on failure of specific medical therapy as well as the need or desire for specialized diagnostic testing and management. As a result, most prescriptions for oral PDE-5 inhibitors are written by primary care providers, and specialized diagnostics such as Doppler ultrasound of the penile arteries and nocturnal penile tumescence (NPT) testing are used by urologists to work up select cases.

ORAL PHOSPHODIESTERASE TYPE 5 INHIBITORS

Current medical therapy is based on inhibition of PDE-5. Figure 72-3 illustrates that cGMP is broken down to inactive 5'-GMP by PDE-5. Sildenafil, vardenafil, and tadalafil competitively inhibit PDE-5 breakdown of cGMP by binding to the catalytic domain of PDE-5. Use of a PDE-5 inhibitor results in improved erectile rigidity even in patients with decreased NO or cGMP synthesis. Not all patients respond to PDE-5 inhibition, however. Adequate sexual stimulation and intact neural and vascular pathways are necessary to produce an adequate amount of NO and cGMP to increase deep penile artery blood flow. PDE-5 inhibitors are effective in men with organic, psychogenic, neurogenic, and mixed cases of ED. The overall response rate is 70%, with placebo response rates of 20% to 30%. In terms of disease-specific response to oral agents, improved erections were observed in 70% of hypertensive patients, 80% of spinal cord injury patients, 56% of diabetic patients, and 42% of radical prostatectomy patients.

PDE-5 inhibition should be considered first-line therapy, unless contraindicated. At the present time, there are no evidence-based data or randomized trials supporting superior efficacy of one drug over another. All the agents are hepatically metabolized. Initial concerns about concomitant use of PDE-5 inhibitors and α blockers have been resolved. Phosphodiesterase inhibitors should not be used concurrently with nitrate medications because a large (>25 mm Hg) synergistic drop in blood pressure is observed in many patients. Periodic follow-up is necessary to determine therapeutic efficacy, side effects related to PDE-5 inhibition, and a change in health status, including medications.

PHARMACOLOGIC INJECTION THERAPY

Several vasoactive agents can be safely injected directly into the corpora cavernosa to produce penile erection. Commonly used agents include PGE₁, papaverine, and phentolamine. These agents can be either used alone or in combination. As monotherapy, PGE₁ is most commonly used, and of the three, only PGE₁ has been evaluated in rigorous clinical trials and has specific marketing approval from the FDA for the treatment of ED. PGE₁ and papaverine are often used alone. Phentolamine, in contrast, is used to potentiate the action of papaverine or is used in combination with both PGE₁ and papaverine. These vasoactive drugs are frequently combined (bimix and trimix) to achieve increased efficacy and decreased side effects.

Injection therapy has two principal risks, priapism and corporal scarring causing penile curvature. Priapism has been reported to occur in 1% to 4% of patients. Prolonged erections occur more commonly in patients with neurogenic ED, especially young males with spinal cord injury. Significant acquired penile curvature is seen uncommonly and usually follows several years of injection therapy. Penile curvature appears to be less common with use of PGE₁ than papaverine. The most common problem with pharmacologic injection therapy is not complications from therapy but rather that 50% to 60% of patients stop using the technique by 1 year.

INTRAURETHRAL DRUG THERAPY

PGE₁ can be inserted into the urethra using a pellet applicator. This method of delivery assumes substantial venous communications between the corpus spongiosum surrounding the urethra and the corpus cavernosum. As a consequence, the technique is considerably less effective than intracavernous injection.

VACUUM CONSTRICTION DEVICES

These devices enclose the penis in a plastic tube with an airtight seal at the penile base. Air is pumped out of the cylinder, creating a vacuum. Blood flows into the corporal bodies, leading to penile erection. A constriction band remains on the base of the penis to maintain erection. Simultaneous use of a vacuum device and a phosphodiesterase inhibitor is safe. Many patients couple the two techniques to achieve satisfactory results.

PENILE PROSTHESIS

A penile prosthesis is implanted in the operating room. Two general types of devices can be implanted: semirigid and inflatable. Most patients prefer the inflatable devices because they provide a more natural erection when inflated and a flaccid penis when deflated. Although more invasive than the other techniques, a penile prosthesis is the most effective long-term option for impotence treatment. Ninety percent of patients and partners are satisfied with the result.

FUTURE TREATMENTS

We have just completed a period of rapid expansion in the understanding and treatment of ED. Much of the biochemi-

cal pathway leading to erection has been elucidated, and several effective oral medications have been introduced. Future medical treatments will depend on identification of specific biochemical events in the erection pathway that are unique to penile function. PDE-5 was a good example of this. To this point, other biochemical events such as production of cGMP are ubiquitous in other important systems of the body and do not make good targets for drugs designed to enhance erectile function. We anticipate that other classes of oral medications will have to await further advances in the basic understanding of erectile function.

Important interval improvements have been made in the design of implantable penile prostheses that made the devices more durable and resistant to infection. Improvements in the connection between tubing and corporal cylinders have cut the mechanical failure rate to less than 5% in 5 years. Components also have special coatings that either contain

antibiotics or absorb antibiotics applied topically at the time of implantation. These improvements have cut the rate of postoperative infection in half.

D. Carcinomas of Men

Prostate Cancer

Carcinoma of the prostate is the most common cancer that occurs in men and the second leading cause of cancer death. Prostate cancer incidence increases with advancing age. Clinical diagnosis of prostate cancer is unusual before the latter half of the fifth decade of life but increases progressively thereafter.

Risk factors for prostate cancer are poorly understood (Table 72-5). There is some racial correlation because prostate cancer is more common in African American men than in whites. A high-fat diet has been implicated in some studies. An NIH-sponsored trial evaluating the role of selenium and vitamin E for prostate cancer prevention was terminated early because of apparent lack of effect. There is no demonstrated association between prostate cancer and cigarette smoking, sexual activity, or a prior history of prostatitis or BPH.

There is considerable disparity between the autopsy incidence of prostate cancer and clinical detection of the disease. Pathologic examination of step-sectioned prostate specimens shows histologic evidence of prostate cancer in more than 50% of men older than 60 years. The overwhelming majority of these "autopsy" or "latent" cancers are less than 0.2 mL in volume and of a low pathologic grade. These tumors are distinctly different from their clinically diagnosed counterparts. The reason for this disparity and the factors that may trigger development of clinically aggressive disease are unknown.

DETECTION AND DIAGNOSIS

There is ongoing controversy about the value of prostate cancer screening. Much of this is fueled by the failure to take

into account age and comorbidity. Whereas men with a less than 10-year life expectancy may not benefit from prostate cancer screening, those younger than 70 to 75 years who are otherwise in good health have a substantial risk for morbidity or mortality from untreated prostate cancer. Most experts recommend routine screening in this group.

Both the DRE and serum PSA determination have a role in the early diagnosis of prostate cancer. Prostate cancer typically arises from the peripheral portion of the prostate, which can be palpated on DRE. Induration or nodularity of the prostate on DRE should be considered suspicious for prostate cancer.

PSA is a protein produced by both benign and malignant prostate cells. Serum PSA may be elevated in the face of prostate enlargement, inflammation, or cancer (Table 72-6). Although an elevated PSA is not diagnostic of prostate cancer, it may lead to a prostate biopsy to exclude cancer. Probably because of progressive enlargement in prostate size, serum PSA values increase as men age. The historical view of a value of less than 4 ng/mL as a "normal" PSA has been abandoned with the recognition that PSA represents a continuum of risk with no lower threshold. The comparative rate of change for PSA over time, sometimes termed PSA

Table 72-5 Possible Risk Factors for Prostate Cancer

Age (increasing incidence with advancing age)
Race (highest incidence in African Americans)
Family history
Diet (possible link to high-fat diet)
Genetic (inherited genetic pattern more complex than with some other tumors)

Table 72-6 Causes of Increased Prostate-Specific Antigen

Benign prostatic hyperplasia
Prostatitis
Urinary tract infection
Prostatic trauma (urethral catheterization or prostatic massage)
Carcinoma

velocity, can be informative. In general, a change in PSA of greater than 0.75 ng/mL is considered worrisome and may prompt a prostate biopsy.

Whenever prostate cancer is suspected, either because of an abnormality in DRE or PSA rise, prostate biopsy is performed. TRUS imaging of the prostate is used to guide prostate biopsy. Prostate cancers typically have a hypoechoic appearance. However, TRUS is of limited value for diagnosis and is used primarily to direct biopsies. Transrectal cores of prostate tissue are obtained. This is an office-based procedure, and local infiltration of lidocaine (Xylocaine) around the prostate minimizes discomfort. Usually 12 or more tissue cores are taken systematically from the entire prostate.

Prostate cancer most often is graded according to the Gleason system. This scoring system uses two numbers based on the primary and secondary histologic pattern. Gleason sums of 2, 3, or 4 are uncommon with clinically detected cancers. Gleason 5 or 6 tumors are most common, whereas sums of 8, 9, and 10 imply an aggressive tumor behavior.

DRE is the most useful test for determining local tumor extent. CT scanning is of limited value and usually not indicated clinically for determining either local extent or nodal metastasis. Magnetic resonance imaging (MRI) of the prostate using an endorectal coil is used in some centers, but the ultimate value of the procedure for either detection or staging is uncertain. In patients with high-grade tumors or a substantially elevated PSA, a bone scan is indicated because bone is the most common site of distant spread. Soft tissue metastasis is unusual in the face of a normal bone scan.

TREATMENT OF LOCALIZED DISEASE

There is considerable controversy about the best management approach for clinically localized prostate cancer, and patients should enter in to an informed decision making process (Table 72-7). In men with less than 10-year life expectancy otherwise, active treatment often is unnecessary. The risk for progression and death within 10 years is sufficiently low that observation alone is appropriate. Increasingly, some men with a greater than 10-year life expectancy but a tumor with apparently favorable features pursue a program of active surveillance. In general, active surveillance should be restricted to men with a PSA of less than 10 ng/mL, no palpable prostate nodules, a Gleason sum of 6 or less, and fewer than 2 or 3 positive biopsy cores. Typically, repeat prostate biopsy is recommended every 1 to 3 years in men on active surveillance to ensure that higher-volume or higher-grade tumor is not evident. PSA and DRE are performed every 6 months. The underlying premise of active

Table 72-7 Treatment Options for Localized Prostate Cancer

Radical prostatectomy (robotic or open)
Brachytherapy (iodine-125, etc., seeds)
External-beam irradiation
Cryotherapy
Hormonal therapy
Active surveillance

surveillance (i.e., that treatment can be safely deferred until there is some evidence of disease progression) is unproved, but it is known that many men with favorable features of the primary tumor do not develop progressive disease in their lifetime.

For men with a greater than 10-year life expectancy otherwise, curative therapy usually is indicated. Surgical removal of the prostate (radical prostatectomy) is the treatment with the most proven ability for long-term cure of prostate cancer. Contemporary radical prostatectomy is an operation with limited perioperative morbidity. The greatest drawbacks to the procedure are the risks for long-term consequences. Significant incontinence occurs in only around 2% of men, but up to 10% may have at least some degree of mild stress incontinence. The cavernosal nerves, which are responsible for dilation of the blood vessels that lead to penile tumescence, lie immediately adjacent to the prostate. Dissection of these nerves from the prostate (nerve-sparing radical prostatectomy) is appropriate in patients with tumors localized to the prostate. The success of nerve-sparing prostatectomy is related to patient age and preoperative erectile function. Preservation of potency can be achieved in up to 60% to 80% of patients. Increasingly, robotic-assisted laparoscopic prostatectomy is becoming the preferred surgical approach for radical prostatectomy. The less invasive surgical approach permits quicker patient recovery, less bleeding, and shorter hospital stay compared with open surgery with no distinct differences in continence, potency, or tumor control between the two approaches.

After radical prostatectomy, serum PSA should decline to an undetectable range. No measurable PSA is produced from any source other than prostate cells. Metastatic foci of cancer continue to produce PSA, so an undetectable value is an excellent prognostic sign. Furthermore, an increase in PSA to a detectable range precedes other signs or symptoms of prostate cancer recurrence after radical prostatectomy almost 99% of the time. Thus, PSA is an extremely sensitive and specific marker for following men after radical prostatectomy. PSA values greater than 0.2 ng/mL are considered diagnostic of tumor recurrence after radical prostatectomy.

Radiation therapy is the primary alternative to surgery for localized prostate cancer. Radiation can be administered by external-beam therapy using intensity-modulated radiation treatment (IMRT) or using proton-beam therapy. No significant difference in outcomes has been shown between proton-beam treatment and conventional radiation. Each is delivered over a 7- to 8-week time frame. Brachytherapy is an alternative method of radiation that can be performed with different isotopes, but iodine-125 is used most commonly. Supplementation of brachytherapy with external-beam irradiation is used in some centers.

PSA typically declines after radiation treatment but may not reach nadir levels for 2 years. Determination of treatment failure is more problematic than after surgery. An increase in PSA over nadir levels may prompt a prostate biopsy to rule out residual disease.

Side effects of radiation treatment occur most commonly because of radiation damage to the bladder or rectum. Patients may experience frequency of voiding or bowel movements or blood in the urine or stool. ED appears to occur at about the same frequency as after surgical treatments.

Focal therapy using either freezing of the prostate (cryotherapy) and high-intensity focused ultrasound (HIFU) are being explored. Limitations of this approach include the known multifocal nature of prostate cancer as well as difficulty in adequate imaging of the tumor for localization. Currently, focal therapy is considered highly experimental.

TREATMENT OF ADVANCED DISEASE

Endocrine manipulation remains the primary form of treatment for patients with advanced or metastatic carcinoma of the prostate. The goal of therapy is to deprive the prostate cancer cells of serum androgens. This can be accomplished by either surgical or medical castration. Surgical orchiectomy removes both testes, the source of testosterone production. Luteinizing hormone–releasing hormone (LHRH) analogues are administered by a slow-release depot injection, with formulations lasting from 3 to 12 months. These drugs have the paradoxical effect of decreasing serum luteinizing hormone release from the pituitary gland and, consequently, diminishing testosterone production from the testis. Testosterone declines to castrate values within a few days after surgical orchiectomy and a few weeks after administration of an LHRH analogue.

In response to androgen deprivation, prostate cancer typically undergoes rapid regression. This is manifested by a decrease in prostate size, improvement in any disease symptoms such as bone pain, and a rapid decline in serum PSA. The duration of response varies but is usually on the order of a couple of years for patients who present with metastatic disease. Hormonal therapy generally is well tolerated but frequently causes hot flashes and is associated with some degree of osteoporosis, weight gain, and loss of muscle mass with long-term use (Table 72-8).

Antiandrogens may also be used in hormonal therapy of patients with prostate cancer. These oral medications exert their effect by blocking the metabolism of androgens at the cellular level rather than by decreasing serum values. Antiandrogens may be used in combination with LHRH

Table 72-8 Long-Term Side Effects of Androgen Deprivation Therapy

Hot flashes

Impotence
Osteoporosis
Decreased facial hair
Loss of muscle mass
Weight gain

analogues to block the effect of adrenal androgens in addition to testosterone. Despite multiple randomized studies, the value of combination treatment compared with LHRH analogues alone is still a matter of debate.

Once prostate cancer shows evidence of progression despite hormonal therapy, the prognosis for patients is poor. Bone pain is managed with appropriate analgesics and irradiation. Chemotherapy using docetaxel in combination with steroids has been shown to provide some quality-of-life benefit as well as extend survival but for only a limited period of time.

Penile Carcinoma

Squamous cell carcinoma of the penis is an uncommon tumor in the United States and the rest of the developed world, with a rate of less than 1 case per 100,000 men and an estimated 1470 cases in the United States for 2005. It is diagnosed almost exclusively in uncircumcised men. Neonatal circumcision appears to have a protective effect. Circumcision in adulthood or late childhood does not appear to confer the same level of protection. Chronic irritation and inflammation are key etiologic factors because most men have poor hygiene leading to phimosis of the foreskin. There is further evidence linking the development of penile cancer with some serotypes of the human papillomavirus (HPV types 16 and 18). Smoking and other forms of tobacco use have also been a consistent finding in several epidemiologic studies of penile cancer risk factors.

Squamous cell carcinoma typically presents as a painless, nonindurated, ulcerated mass involving the glans penis and coronal sulcus. Infection of the primary lesion is common and may produce foul-smelling, purulent discharge and reactive inguinal lymphadenopathy. Delay in diagnosis is common because patients often do not seek immediate treatment secondary to fear and embarrassment, whereas prolonged treatment with antibiotics may delay confirmatory biopsy of the lesion.

DIAGNOSIS AND TREATMENT

Evaluation of suspicious lesions begins with clinical assessment of both the tumor and inguinal lymph nodes. Imaging studies are not routinely recommended because physical examination has proved the most accurate predictor of tumor stage. A diagnosis of carcinoma of the penis is confirmed by histologic evaluation of an excisional biopsy. Prognosis is directly correlated with grade of the tumor and extent of invasion. Adverse prognostic factors include high histopathologic grade, vascular invasion, and advanced pathologic stage ($\geq T2$).

The classic operation for squamous cell carcinoma of the penis is partial penectomy with a 2-cm negative margin. If the tumor is confined to the distal penis, a sufficient length of proximal penile shaft can be preserved so that the patient can still void in a standing position.

Larger tumors that invade the more proximal penile shaft require total penectomy. The entire corpora cavernosa are excised back to the ischial tuberosity. A perineal urethrostomy is created that allows voiding in a sitting position.

Contemporary studies are now attempting to stratify patients who would benefit from organ-preserving therapies with improved functional and cosmetic results. These treatment approaches include topical treatments (5-fluorouracil), external-beam radiation therapy, Mohr microdissection, laser ablation (carbon dioxide and Nd:YAG), and complete tumor excision with phallic reconstruction. Patients with Tis, Ta, and T1 (grade 1 and 2) tumors at low risk for metastasis appear to be ideal candidates for this approach. The main drawback is the increased risk for local tumor recurrence.

Inguinal lymph node dissection is indicated in patients with palpable inguinal nodes that persist after antibiotic therapy or in those with nonpalpable nodes with risk factors for regional metastasis (histopathologic grade 3, vascular invasion, and $\geq T2$). Traditionally, there has been significant morbidity associated with inguinal lymph node dissection (lymphedema, skin necrosis, deep vein thrombosis). However, several contemporary studies have shown a decreased incidence and severity of complications. Modified lymphadenectomy and sentinel node biopsy aim to detect occult metastases while minimizing patient morbidity.

The prognosis for patients with distant metastatic disease or nodal metastasis above the inguinal ligament is poor. Squamous cell carcinoma of the penis is moderately chemosensitive, and numerous regimens have been studied, reflecting the lack of superior efficacy of one combination over another. A durable response to chemotherapy is unusual, and further studies with novel agents and multimodal therapy are currently being investigated.

Testis Cancer

The management of patients with testicular carcinoma has become a model for the multidisciplinary approach to solid tumors. As a result of effective surgery, radiation therapy, and combination chemotherapy, survival approaches 99% for low-risk disease and 80% for high-risk disease. Testicular tumors are the most common solid malignancy in men aged 15 to 34 years. The incidence of testis cancer appears to be increasing over the past 25 years.

Cryptorchidism (undescended testicle) is a well-accepted risk factor for subsequent development of carcinoma. Abnormalities in spermatogenesis are well documented (thought to be a primary effect of the tumor), and up to 15% of patients are diagnosed with testicular cancer during a work-up for male factor infertility. Two to 3% of patients present with bilateral tumors, and 5% to 10% of patients develop cancer in the normal contralateral testicle. Despite impairments in spermatogenesis, most men with testicular cancer are capable of fathering children, and a discussion of fertility issues is extremely important, especially in patients who may require adjuvant therapies such as external-beam radiation and systemic chemotherapy.

The most common presenting sign or symptom of testis cancer is a firm, painless mass arising from the testis. Patients may present with an acute scrotum as a result of tumor hemorrhage, and up to 33% of patients are treated for presumed epididymitis. Scrotal ultrasonography is diagnostic because testis cancer is usually distinguishable from benign scrotal disease because of the clear involvement of the

testicular parenchyma rather than the paratesticular tissues. Signs and symptoms of advanced disease include cough, gastrointestinal symptoms (mass), back pain (retroperitoneal metastasis), neurologic symptoms (brain metastasis), lower extremity swelling (iliac or inferior vena cava thrombus), and supraclavicular lymphadenopathy.

DIAGNOSIS AND STAGING

Initial management of the primary tumor is inguinal orchiectomy with high ligation of the spermatic cord. Histopathology distinguishes germ cell tumors (GCTs) from stromal tumors. Seminoma is the most common GCT occurring in pure form. Teratoma, yolk sac tumors, embryonal carcinoma, and choriocarcinoma are classified as nonseminomatous GCT and frequently occur as mixed GCT (more than one histologic pattern within the primary tumor).

Testicular cancer is unique in that serum tumor markers (STMs) play an important role in tumor staging. STMs include β -human chorionic gonadotropin (β -hCG), α -fetoprotein (AFP), and serum lactate dehydrogenase. Elevations of the serum hCG may be seen in choriocarcinoma, embryonal carcinoma, and 15% of seminomas. Elevated AFP can be seen in yolk sac tumors and embryonal carcinoma, and excludes a diagnosis of seminoma. These markers may be secreted either by the primary tumor or by metastatic foci (Table 72-9).

The retroperitoneal lymph nodes are the most common initial site of metastasis. Therefore, staging of the retroperitoneum with an abdominal CT scan is important in evaluating the extent of disease. However, accurate staging of the retroperitoneum remains problematic, with the literature quoting a 20% to 30% false-negative and false-positive rate with CT scanning. Common landing zones for lymph node metastasis include the precaval, inter-aortocaval, and preaortic lymph nodes below the renal hilum and above the aortic bifurcation. Chest x-ray or thoracic CT completes the clinical staging because the lungs and posterior mediastinum are the most common sites of distant metastatic disease.

TREATMENT

Histopathology, pathologic stage, and serum tumor marker status are used to determine subsequent treatment following inguinal orchiectomy. All patients with elevated serum tumor markers after orchiectomy receive cisplatin-based chemotherapy, regardless of histology. Radiation therapy and retroperitoneal lymph node dissection (RPLND) have a

Table 72-9 Testis Cancer Staging Studies

Tumor markers
AFP—elevated only with nonseminomatous tumors
β -hCG—may be increased with either seminoma or nonseminomatous tumor
Abdominal CT scan—retroperitoneal nodes most common site of regional nodal metastasis
Chest radiograph or CT scan—lung is most frequent site of distant metastasis
AFP, α -fetoprotein; β -hCG, β -human chorionic gonadotropin; CT, computed tomography.

high likelihood of failure in the face of elevated serum markers.

Seminoma presents as clinical stage I in 70%, stage II in 20%, and stage III in 10% of cases. Although surveillance and single-agent carboplatin are options in patients with stage I seminoma, most experts recommend radiation therapy to the retroperitoneum in patients with stage I and II disease due to the radiosensitivity of seminomas. Patients with bulky stage II (lymph node >5 cm) and stage III disease receive combination chemotherapy.

Nonseminomatous GCT present more frequently with advanced stage (stage I, 30%; stage II, 40%; and stage III, 30%). RPLND is frequently recommended in patients with clinical stage I or low-volume stage II disease. Reasons for recommending RPLND include accurate pathologic staging of the retroperitoneum, low relapse rate (< 2%) after properly performed RPLND, curative potential in the face of viable GCT, and the potential for retroperitoneal teratoma, which is resistant to chemotherapy. Side effects associated with RPLND include lymphocele, chylous ascites (0.4%), and small bowel obstruction (1% to 2%). Nerve-sparing RPLND is able to preserve antegrade ejaculation in greater than 80% of patients. Primary chemotherapy is sometimes recommended to patients with stage I or II nonseminomatous testis cancers. Also, some men may choose surveillance alone for a stage I tumor, which implies normal serum markers and abdominal CT scan. Up to 25% may be expected to develop recurrence, usually within 2 years, and chemotherapy is used upon evidence of recurrence.

Platinum-based chemotherapy is the standard for patients with advanced disease. Cure rates of 70% to 80% are achieved even in patients who present with relatively bulky metastatic disease. Side effects of chemotherapy include renal dysfunction, neuropathy, Raynaud phenomenon, hematologic toxicity, cardiovascular toxicity, and 0.5% risk for secondary leukemias.

E. Benign Scrotal Diseases

Varicocele

Varicoceles are classically described as abnormal dilation of the veins of the pampiniform plexus. Subclinical varicocele can be present in up to 15% of the male population, whereas the prevalence increases to 30% to 50% of men presenting with primary infertility, and as high as 70% to 80% of patients with secondary infertility. Varicoceles are diagnosed during work-up for male factor infertility, scrotal pain syndromes, and asymptomatic testicular atrophy. Physical examination can reveal the classic “bag of worms”: testicular atrophy and tender scrotal contents. Semen analysis reveals multiple abnormalities reflecting a characteristic “stress pattern,” although this is not pathognomonic. The diagnosis of varicocele remains a clinical one, although scrotal ultrasound with Doppler is helpful in certain situations. The presence of two or three veins with diameter larger than 3 mm and retrograde flow with Valsalva maneuver is consistent with clinical varicocele. Surgical intervention for subclinical varicoceles is not indicated. Pathophysiology of varicocele has historically been poorly understood. Regardless, there is dilation of the internal spermatic vein and transmission of increased hydrostatic pressure across dysfunctional venous valves. Stasis of blood in the venous system disturbs countercurrent heat exchange responsible for maintaining testicular temperature and results in testicular parenchymal damage and impaired spermatogenesis. Because of anatomic considerations, varicoceles are more commonly left sided. However, unilateral varicoceles have a bilateral effect on spermatogenesis and local testicular steroidogenesis. Indications for surgical correction of a clinical varicocele include male factor infertility, testicular atrophy in adolescents with ipsilateral varicocele, and intractable pain attributed to the varicocele. It should be noted that pain is rarely caused by clinical varicoceles, and surgical varicocelectomy often does not produce symptomatic relief for the patient. Common surgical techniques include high retroperitoneal ligation of the internal spermatic vein, microsurgical inguinal and subinguinal varicocelectomy, and laparoscopic varicocelectomy. The inguinal approach using surgical magnification has the highest success and lowest complication and recurrence rates. Semen parameters improve in 60% to 80% of men with pregnancy rates of 20% to 60%. The most common complication is hydrocele formation, whereas a rare complication is inadvertent ligation of the testicular artery resulting in testicular atrophy and loss.

Epididymitis

Acute epididymitis is a clinical syndrome that presents with fever, acute scrotal pain, and swelling as a result of inflammation and infection of the epididymis. Pathophysiologically, epididymitis is caused by retrograde bacterial spread

from the bladder or urethra. In men younger than 35 years of age, the most common causes are organisms associated with urethritis, namely gonococcus and *Chlamydia trachomatis*. In older men, *Escherichia coli* and other coliform bacteria are the causative organisms, usually in association with lower urinary tract infection associated with symptoms of bladder outlet obstruction. Patients with acute epididymitis have significant inflammation, and the causative organism can be determined by Gram stain and culture of a urethral swab or midstream urine specimen. Interestingly, the antiarrhythmic amiodarone is associated with a noninfectious cause of epididymitis secondary to concentration of the drug in the epididymis. The most important consideration in diagnosing acute epididymitis is differentiating this disease from acute testicular torsion. Physical examination can be nonspecific, although focal epididymal swelling and tenderness are suggestive, and the presence of white cells in the urine or urethral swab is indicative of an infectious etiology. Scrotal ultrasound with Doppler flow can be extremely helpful in differentiating acute epididymitis from torsion in difficult cases. Treatment is generally supportive, including narcotic analgesics, NSAIDs, scrotal support with an athletic supporter, cold ice packs, and targeted antimicrobial therapy. In general, patients younger than 35 years should be treated with ceftriaxone (Rocephin) and doxycycline, or a single dose of azithromycin (Zithromax). Older patients are empirically treated with a fluoroquinolone or TMP-SMX for 2 to 4 weeks. Complications associated with acute epididymitis include abscess formation, testicular infarction, infertility, and chronic epididymitis or orchalgia. Surgical intervention is rarely necessary, although in select cases, orchiectomy and epididymectomy can be therapeutic when solid indications are present.

Hydrocele

A hydrocele is a serous fluid collection within the parietal and visceral layers of the tunica vaginalis of the scrotum. Hydroceles may surround the testicle or the testicle and spermatic cord, or communicate with the peritoneal cavity through a patent processus vaginalis. These communicating hydroceles are uncommon in the adult population and are more commonly identified in the pediatric age group in association with an indirect hernia. Patients usually present to the physician with complaints of heaviness in the scrotum, scrotal pain, and an enlarging scrotal mass. Diagnosis is easily made with physical examination and transillumination of the hydrocele. If the testis is not easily palpable in a young patient, ultrasound can rule out an occult testicular tumor with secondary or reactive hydrocele. Hydroceles are caused by increased secretion or decreased reabsorption of serous fluid by the tunica vaginalis. Infection, trauma, neoplastic disease, and lymphatic disease are causative in most

adults, whereas the remainder of cases are idiopathic. Treatment of symptomatic hydroceles is surgical. Although the recurrence rate is significantly higher with aspiration and sclerotherapy, this can be a good option in patients who are considered poor surgical candidates. Hydrocelectomy procedures involve either some form of excision of the redundant tunica vaginalis versus a plication of the sac without excision. Overall complications occur in up to 20% of patients, with hematoma seen in 15%, infection or abscess and hydrocele recurrence in 9%, and chronic pain in 1%.

Testicular Torsion

Testicular torsion is considered a true urologic emergency. The testicular blood supply is through the testicular artery (aorta), the vasal artery (inferior vesicle artery), and the cremasteric artery (inferior epigastric artery). All three vessels are transmitted to the testicle through the spermatic cord. Torsion of the spermatic cord impairs arterial inflow as well as venous outflow producing the characteristic symptoms of acute scrotal pain, swelling, and nausea and vomiting. If detorsion is not performed within 6 to 8 hours, testicular infarction and hemorrhagic necrosis are likely to occur. Typically, patients are younger than 21 years, although

testicular torsion can occur into early adulthood. Symptoms usually include the acute onset of testicular and scrotal pain, scrotal swelling, and nausea and vomiting. Ecchymosis and involvement of the scrotal skin occur in more advanced cases, but the testis has infarcted by that point. Delay in presentation and diagnosis is more common in the adult patient population and is related to patient and physician factors. Often there is an antecedent history of trauma or physical activity. The diagnosis of testicular torsion remains a clinical one, and surgical exploration is undertaken when the index of suspicion is high. Doppler ultrasonography is extremely useful in differentiating testicular torsion from other causes of the acute scrotum, such as acute epididymitis, torsion of the appendix testis, and trauma. Important surgical principles include surgical detorsion and assessment of testicular viability in the operating room. If the testis is determined to be viable, bilateral orchiopexy is performed using the technique of three-point fixation (sutures placed medially, laterally, and inferiorly). Otherwise, in the presence of infarction, orchiectomy is recommended. Orchiopexy of the contralateral testicle is always performed simultaneously. When diagnosis and surgery occur in a timely fashion, testicular salvage rates approach 70%. Delayed surgical therapy, for whatever reason, results in the salvage rate dropping off to 40%.

Prospectus for the Future

- Improved basic science understanding of the molecular biology of benign prostate growth
- Improved understanding of the neurophysiology of detrusor function associated with bladder outlet obstruction
- Refined methods for the minimally invasive management of symptomatic BPH
- Improved outcomes research regarding long-term benefits of less invasive therapy for BPH, both medical and surgical
- Improved understanding of the immunourologic characteristics and mechanisms of the prostate and urethra
- Enhanced understanding of the neuroanatomy and neurophysiology of the prostate and bladder, with an emphasis on pain and sensory mechanisms in the prostate, bladder, and surrounding tissues
- Better standardized protocols for therapeutic intervention trials for the treatment of noninflammatory chronic pelvic pain syndrome
- Novel therapies for noninflammatory chronic pelvic pain syndrome (e.g., thermotherapy, phytotherapy)
- Better markers of tumor aggressiveness for men with localized prostate cancer
- Improved specificity of prostate cancer screening methods
- Understanding of the cause and prevention of testis cancer

Normal Physiology of Bone and Mineral Homeostasis

Andrew F. Stewart

Calcium Homeostasis

The maintenance of normal calcium homeostasis is critical to survival for at least three reasons. First, serum calcium concentrations regulate the degree of membrane excitability in muscle and nervous tissue. Increases in serum calcium lead to refractoriness to stimulation of neurons and muscle cells, which translates clinically into coma and muscular weakness. Conversely, reductions in serum calcium lead to increases in neuromuscular excitability that translate clinically into convulsions and spontaneous muscle cramps and contractions referred to as *carpopedal spasm* or *tetany*. Second, terrestrial life requires the existence of a skeleton, and calcium is the major structural cation in the skeleton. Specifically, the mineral phase of the skeleton is composed of a calcium salt called *hydroxyapatite*, and reductions in bone mineral content lead to spontaneous fractures. Third, intracellular calcium has a major intracellular signaling role, and control of intracellular calcium is essential to the survival of all cells. This mechanism is used to advantage pharmacologically through the widespread clinical use of drugs that regulate intracellular calcium concentrations and calcium-channel activity for the treatment of a wide variety of human diseases. Thus, physicians, regardless of their specialty, will encounter disorders of calcium homeostasis on a regular basis.

The serum total calcium concentration is normally maintained at about 9.5 mg/dL. Of this amount, about 4.5 mg/dL is bound to serum proteins, principally albumin, and about 0.5 mg/dL circulates as insoluble complexes such as calcium sulfate, phosphate, and citrate. The remaining about 4.5 mg/dL circulates as free or unbound or ionized calcium. This free, ionized serum calcium is important clinically and physiologically. This calcium is available (1) to be

filtered at the glomerulus, (2) to interact with cell membranes to regulate their electrical potential or excitability, and (3) to enter and exit the skeletal hydroxyapatite crystal lattice. Thus, it is important to maintain a normal ionized serum calcium, although total serum calcium is customarily measured in most clinical laboratories. From a clinical standpoint, recognizing that, in some instances, total serum calcium can change without a change in the ionized calcium is also important. For example, if a decline in serum albumin occurs as a result of hepatic cirrhosis or the nephrotic syndrome, a corresponding decline in the total serum calcium will ensue, but the ionized serum calcium concentration will remain normal. Thus, at times, measuring the ionized serum calcium directly is important.

Given the central importance of calcium homeostasis to terrestrial life, the fact that a complex group of regulatory processes have evolved to protect the integrity of this system is not surprising. A corollary of this concept is that, when a physician encounters patients in whom hypercalcemia, hypocalcemia, or disorders of skeletal mineralization have occurred, multiple safety control points have been breached. These control points are discussed here.

From a homeostatic control point of view, the calcium ion interfaces with three important compartments, as shown in the calcium *physiologic black box* in Figure 73-1. An important point to recall is that, although intracellular calcium is important in intracellular signaling, it is quantitatively unimportant in overall systemic calcium homeostasis, largely because intracellular calcium concentrations are tiny (nanomolar) compared with extracellular calcium concentrations (millimolar). Thus, the three critical regulatory fluxes that maintain normal serum calcium concentration are with the intestine, the kidney, and the skeleton.

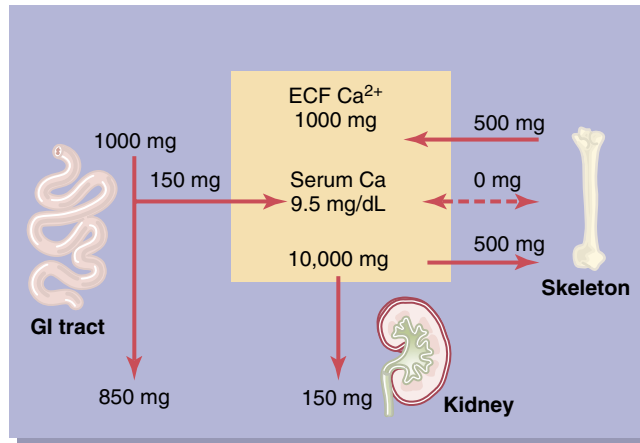

Figure 73-1 The calcium *physiologic black box*. The central box represents extracellular fluid (ECF), which contains a total of about 1000 mg of calcium. This black box has three interfaces with the gastrointestinal (GI) tract, the skeleton, and the kidney, as discussed in detail in the text. The fluxes into and out of the ECF are measured in milligrams per day.

CALCIUM FLUXES INTO AND OUT OF EXTRACELLULAR FLUID

Intestinal Calcium Absorption

The normal dietary calcium intake for an adult human is about 1000 mg per day. Of this amount, about 300 mg is absorbed (i.e., unidirectional absorption is about 30%), and this absorption occurs in the duodenum and proximal jejunum. Interestingly, about 150 mg per day of calcium is secreted by the liver (in bile), the pancreas (in pancreatic secretions), and the intestinal glands such that net absorption (called *fractional absorption*) of calcium is about 15% of intake. The mechanisms that regulate the 150 mg per day of calcium secreted by the gastrointestinal (GI) tract have not been well studied, despite their obvious quantitative importance. The efficiency of calcium absorption is regulated at the level of the small intestinal epithelial cell, the enterocyte, by the active form of vitamin D, 1,25-dihydroxyvitamin D (1,25[OH]₂D, also called *calcitriol*), with increases in 1,25(OH)₂D leading to enhanced calcium absorption and decreases in 1,25(OH)₂D causing reduced absorption of dietary calcium. Thus, dietary calcium absorption can be increased, at least over the short term, by increasing calcium intake, by increasing plasma 1,25(OH)₂D concentrations, or by both measures. Pathologic increases in serum calcium (hypercalcemia) can be caused by increases in circulating 1,25(OH)₂D (as in sarcoidosis) or by excessive calcium intake (the milk-alkali syndrome). Conversely, hypocalcemia can occur as a result of a decline in 1,25(OH)₂D (chronic renal failure and hypoparathyroidism are examples). An overall view of the impact of the GI tract can be summarized as follows: If an individual consumes 1000 mg of calcium per day, and if net absorption is 150 mg per day, then he or she will excrete 850 mg of calcium in feces per day.

Renal Calcium Handling

The normal ionized serum calcium concentration, as noted previously, is about 4.5 mg/dL. The normal glomerular filtration rate is 120 mL per minute. Multiplying these two

numbers produces the filtered load of calcium, which proves to be about 10,000 mg per day. In terms of overall regulation of calcium homeostasis, this number is very large, making the point that the kidney is the most important moment-to-moment regulator of the serum calcium concentration. The amount also emphasizes that disorders of renal calcium handling (e.g., thiazide diuretic use, hypoparathyroidism) can be expected to lead to significant abnormalities in serum calcium homeostasis.

Of the 10,000 mg filtered at the glomerulus each day, about 9000 mg (90%) is reabsorbed *proximally*, meaning in the proximal convoluted tubule, the pars recta, and the thick ascending limb of Henle loop. This 90% is absorbed in conjunction with sodium and chloride reabsorption and is not subject to regulation by parathyroid hormone (PTH). In contrast, the remaining 10%, or 1000 mg, that arrives at the distal tubule on a daily basis is subject to regulation, with PTH stimulating renal calcium reabsorption. This anticalciuric effect of PTH can be extremely efficient, and elevated PTH concentrations can essentially eliminate calcium excretion into the urine. This action is a potent mechanism for retaining calcium under conditions of calcium deprivation (e.g., a low-calcium diet, vitamin D deficiency, intestinal malabsorption) and can contribute to hypercalcemia under pathologic conditions, as in primary hyperparathyroidism.

About 150 mg of calcium is excreted by the kidney in the final urine on a daily basis in a healthy individual. If the kidney filters 10,000 mg of calcium each day, and if 150 mg is excreted in the final urine, 9850 mg is reabsorbed at proximal and distal sites. Thus, 98.5% of filtered calcium is reabsorbed by the nephron. Conversely, the normal *fractional excretion of calcium* is about 1.5%.

Viewed from a whole-organism standpoint, a healthy person is in zero calcium balance with respect to the outside world: intake (1000 mg per day) – output [(850 mg in feces per day) + (150 mg in urine per day)] = 0.

Skeletal Biology and Calcium Homeostasis

The skeletal compartment contains about 1.2 kg of calcium in a male adult and 1.0 kg in a female adult. As noted earlier, most of this calcium is in the crystal hydroxyapatite, a calcium phosphate salt. Although calcium contributes in an important way to the structural integrity of the skeleton, as noted previously, the skeleton also serves as a quantitatively large reservoir, as well as a sink, for adding and removing calcium to and from the extracellular fluid (ECF) compartment at appropriate times.

The adult skeleton is composed of two fundamental types of bone: (1) cortical (or lamellar) bone and (2) trabecular (or cancellous) bone (Fig. 73-2). Cortical bone predominates in the skull and the shafts of long bones, and trabecular bone predominates at other sites, such as the distal radius, the vertebral bodies, and the trochanters of the hip. Bone is not an inert tissue, as might be imagined from visiting the dinosaur room at a natural history museum; instead, bone is a vital tissue that is continually turning over. The adult skeleton is completely remodeled every 3 to 10 years. This remodeling is perhaps best appreciated by recalling that orthopedic surgeons routinely and intentionally set fractures imperfectly, knowing that the normal processes of bone

Figure 73-2 The structure of human bone. This figure depicts a human proximal femur examined using a gross pathologic specimen (*left panel*) and a radiograph of the same section (*right panel*). Note that two different types of bone are represented. One type is called *cortical bone* (also called *lamellar bone*) and the other *cancellous bone* (also called *trabecular bone*). Note that the proportion of trabecular and cortical bone differs by location. For example, the shaft of the femur contains mostly cortical bone, whereas the proximal end of the femoral neck and the greater trochanter contain little cortical bone and almost exclusively trabecular bone. This distinction is important because most osteoporotic fractures occur at sites in which trabecular bone predominates, including the greater trochanter, the femoral neck, the vertebrae, and the distal radius. (Courtesy of Webster S. S. Jee, MD, University of Utah.)

remodeling will lead to restoration of the original shape of a given bone with the passage of time.

The cells that regulate bone turnover can be divided into those that remove old bone, those that provide new bone (Fig. 73-3; see also Chapter 75), and those that regulate these two processes. Cells that remove (or *resorb*) old bone are *osteoclasts*. These cells are large, metabolically active, multinucleated cells derived from the fusion of circulating macrophages. They deposit themselves on the surface of bone and form a *sealing zone* over the bone surface into which they secrete protons (acid), proteases (such as collagenase), and proteoglycan-digesting enzymes (such as hyaluronidase). The acid solubilizes hydroxyapatite crystals, releasing calcium, and the enzymes digest bone proteins and proteoglycans (e.g., collagen, osteocalcin, osteopontin), which constitute the nonmineral or *osteoid* component of bone. Osteoclasts literally move along the surface of trabecular bone plates and drill tunnels in cortical bone, periodically releasing the digested contents within their sealed zones into the bone marrow space and thereby creating resorption lacunae, called *Howship lacunae*, on the trabecular bone surface. The released calcium contributes to the ECF calcium pool, and the released proteolytic products, such as deoxypyridinoline cross-links (collagen fragments and hydroxyproline) can be used clinically as indices of bone resorption.

On the other side of the bone turnover equation is new bone formation. This task is accomplished by *osteoblasts*,

which, in turn, are derived from marrow stromal cells or bone surface lining cells. Osteoblasts synthesize and secrete the components of the nonmineral phase of bone, called *osteoid*. These components are mostly proteins and include collagen, osteopontin, osteonectin, osteocalcin, and a plethora of growth factors, including transforming growth factor- β and insulin-like growth factor I, as well as proteoglycans. This complex serves as the scaffolding into which the mineral crystal hydroxyapatite forms its lattices.

In the past decade, attention has focused on a third, previously underappreciated, bone cell type: the *osteocyte*. These cells are descendants of osteoblasts and are embedded into the mineralized phase of bone. Osteocytes physically connect with one another, as well as cells at the mineral surface, through long dendritic processes. These dendritic processes extensively permeate the mineralized phase of bone through an elaborate canalicular network. Osteocytes serve a critical role in sensing biomechanical strain within bone, and through their cellular extensions to the cell surface, also communicate signals that attract, activate, or repress osteoclasts and osteoblasts. That is, they determine which areas of the skeleton require new bone formation and which need to be targets of osteoclastic bone remodeling.

Through this process of bone turnover, or bone remodeling, osteoclasts continually remove old bone, and osteoblasts continually produce new osteoid that mineralizes, in the end, replacing the old bone removed by osteoclasts with new bone. Teleologically, this process is viewed as serving to

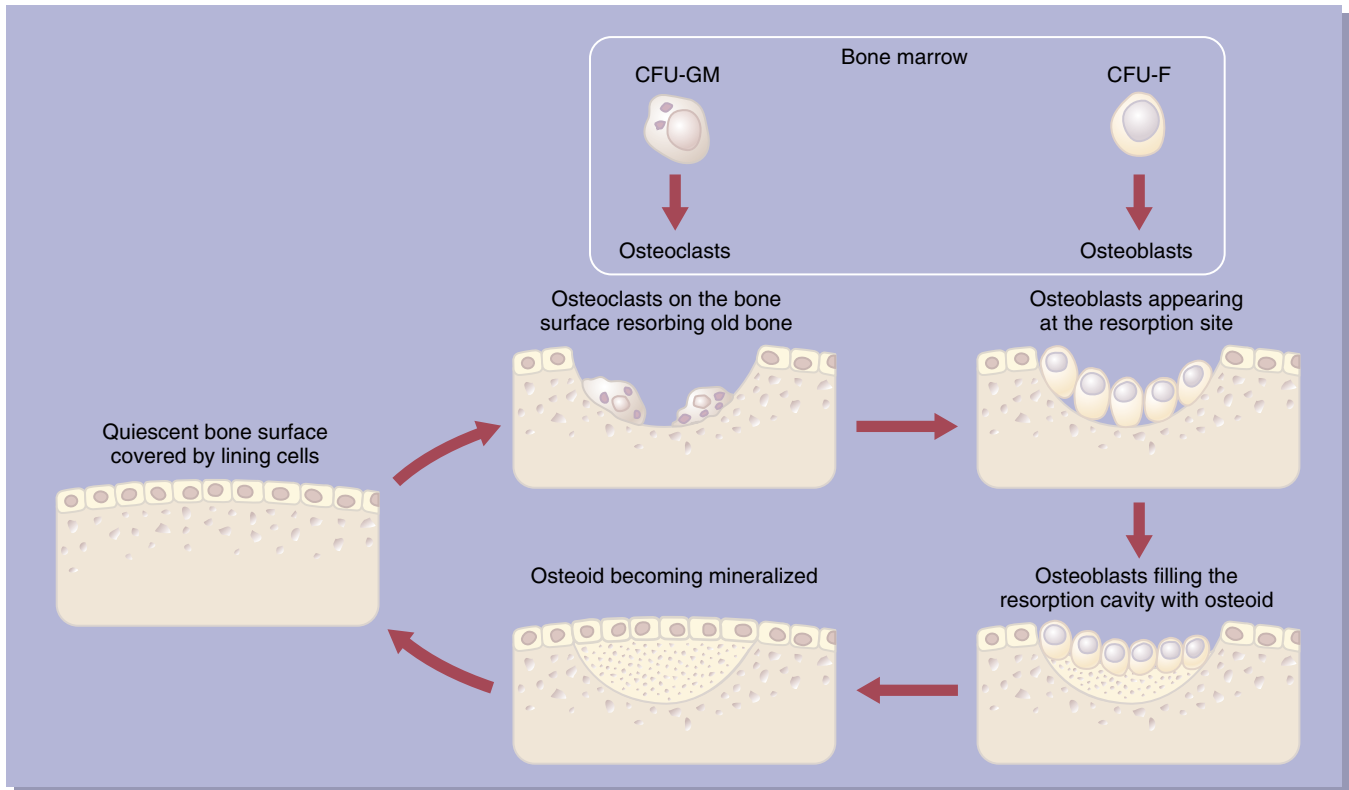

Figure 73-3 The cellular components of bone remodeling. As described in the text in detail, bone remodeling is a continuous process that involves the activation of osteoclast precursors in the macrophage lineage (abbreviated here as CFU-GM) to become actively resorbing osteoclasts, which literally tunnel into the bone surface to dig *resorption lacunae*. Osteoblast precursors in the fibroblast–bone marrow stromal cell lineage (abbreviated here as CFU-F) then appear and become active at the sites of prior resorption, and secrete new osteoid, which later mineralizes to *fill* the lacunae created by osteoclastic bone resorption. (From Manolagas SC, Jilka RL: Bone marrow, cytokines, and bone remodeling: Emerging insights into the pathophysiology of osteoporosis. *N Engl J Med* 332:305-311, 1995.)

replace old bone (and by implication defective or damaged bone with microfractures and reduced mechanical strength) with new, mechanically strong bone, although the evidence for this action is limited. Indeed, the principal therapy for osteoporosis at present is with so-called antiresorptives such as estrogens, estrogen-like drugs, and bisphosphonates, which dramatically reduce bone turnover and yet appear to improve not only bone mass but also bone mechanical properties.

From a systemic calcium homeostatic standpoint, however, this process is important. Osteoclasts can be used to access calcium from the skeleton in times of need to maintain a normal serum calcium concentration. Conversely, unmineralized osteoid produced by osteoblasts can be used at appropriate times as a sink into which excess serum calcium can be deposited. Under normal circumstances, estimates are that osteoclasts resorb bone at a rate such that about 500 mg of calcium is removed per day from the skeleton and delivered into the ECF compartment. At the same time, osteoblasts produce osteoid that mineralizes at a rate such that about 500 mg of calcium leaves the ECF and enters the skeleton at new sites. Seen from the perspective of the *black box* in Figure 73-1, the skeleton is in zero calcium balance with the ECF, and the whole organism is in zero calcium balance with the external world, as described previously.

Considering the complexity of this calcium homeostatic system and the importance of maintaining tight control over

serum calcium, an obvious need exists for systemic regulation and integration of the fluxes across the GI tract, the skeletal compartment, and the kidney. The two key metabolic regulatory hormones that coordinate these activities are PTH and the active form of vitamin D, 1,25(OH)₂D.

REGULATORY HORMONES

Parathyroid Hormone

PTH is a peptide hormone produced by the four parathyroid glands (Fig. 73-4). These glands are located behind the normal thyroid lobes, two on the right, and two on the left. Through the calcium sensor—a G-protein-coupled receptor for calcium that is located on the surface of the parathyroid cell—the serum ionized calcium concentration is continuously monitored. This exquisitely sensitive system functions such that minor (e.g., 0.1 mg/dL) reductions in serum ionized calcium lead to PTH secretion and, similarly, minor increments in serum calcium lead to suppression of PTH secretion.

PTH is secreted as an 84–amino acid peptide hormone and is rapidly (half-life of about 3 to 5 minutes) cleaved by the Kupffer cells in the liver into amino-terminal and carboxy-terminal species. Of these forms, the intact 84–amino acid peptide and the amino-terminal species are biologically active. The amino-terminal form of PTH is also cleared rapidly (half-life of about 5 minutes) in this case in

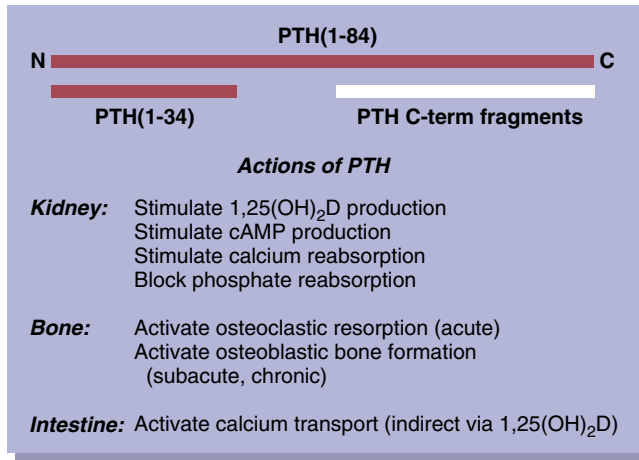

Figure 73-4 The structure and actions of parathyroid hormone (PTH). PTH is secreted as an 84–amino acid protein, which is cleaved in the liver to derivative amino- and carboxy-terminal forms. The actions of the amino-terminally intact forms of PTH are listed here and discussed in detail in the text. cAMP, cyclic adenosine monophosphate.

the kidney through glomerular filtration and proteolytic destruction by apical proteases. The continuous monitoring of the serum calcium concentration by the parathyroid glands, the immediate secretion of PTH in response to hypocalcemia, and the rapid clearance of PTH after secretion allow the parathyroid gland and PTH to act as critical, moment-to-moment regulators of the serum calcium. This tight regulatory control maintains the serum calcium at a normal level with rather remarkable precision.

PTH has three target organs, two direct and one indirect. The first direct target organ is the kidney, where renal calcium excretion is inhibited. Additional renal effects of PTH are to inhibit phosphate and bicarbonate reabsorption, which produce phosphaturia and hypophosphatemia, as well as a proximal renal tubular acidosis, respectively. These renal actions of PTH are essentially immediate. PTH has an additional direct effect on the proximal tubule to stimulate the production of the active form of vitamin D, 1,25(OH)₂D, as described later. The second direct target organ of PTH is the skeleton. Here, PTH has the ability to mobilize calcium immediately from the skeleton through activation of osteoclastic bone resorption. Over the longer term (days to weeks), PTH also stimulates the activity of osteoblasts to produce new bone and thereby removes calcium from the circulation. The skeletal effects of PTH are discussed in more detail later. The ability to stimulate osteoclasts acutely without activating bone formation is important for the rapid delivery of calcium to the ECF. Finally, PTH has the indirect effect of increasing intestinal calcium absorption through its ability to increase renal synthesis of 1,25(OH)₂D. This action, too, is described in more detail in the following section on vitamin D absorption. Seen in concert, PTH is secreted in response to hypocalcemia, and the actions of PTH combine to restore a low serum calcium to normal by preventing renal calcium losses, by adding calcium to the ECF from the skeleton, and by stimulating, indirectly through 1,25(OH)₂D, increases in intestinal calcium absorption.

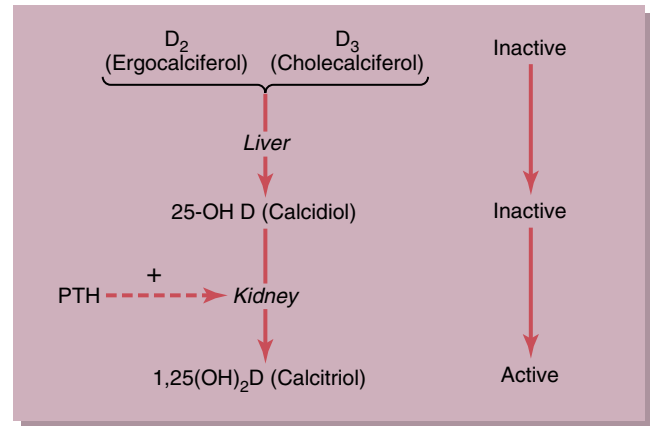

Figure 73-5 The vitamin D metabolic pathway. Vitamin D exists in two forms, D₂ and D₃, that pass through two steps in the liver and kidney to yield the biologically active form of vitamin D, 1,25(OH)₂D. See text for details.

Vitamin D Metabolism

Vitamin D is really two different compounds, ergocalciferol (vitamin D₂) and cholecalciferol (vitamin D₃) (Fig. 73-5). These compounds were identified through their ability to prevent rickets in humans and laboratory animals. In fact, both substances are actually inactive precursors, one (D₃) derived principally from skin exposed to sunlight, and the other (D₂) derived from plant sterols. Both D₂ and D₃ are present in multivitamins and commercial dietary supplements. These two precursors are converted passively by the enzyme vitamin D-25-hydroxylase in the liver to the respective 25-hydroxyvitamin D (25-OH D) derivatives. These derivatives, too, are inactive precursors, but they have clinical significance of two types. First, severe liver disease such as cirrhosis prevents this essential step and leads to vitamin D–deficient syndromes collectively called *hepatic osteodystrophy*. Second, 25-OH D is the standard clinical laboratory measure of the vitamin D status (repletion versus deficiency) in a patient with hypocalcemia, osteomalacia or rickets, osteoporosis or intestinal malabsorption, and other similar conditions.

25-OH D is next converted, or activated, in the renal proximal tubule by the enzyme 25-hydroxyvitamin D 1- α -hydroxylase to the active form of the vitamin, 1,25(OH)₂D. This substance is also called *calcitriol*, in contrast to 25-OH D, which some call *calcidiol*. Because 1,25(OH)₂D is the active form of vitamin D, its production is necessarily regulated, and this is accomplished primarily by PTH, with increases in PTH-stimulating 1,25(OH)₂D production and decreases in PTH-diminishing 1,25(OH)₂D synthesis. As noted previously, the primary action of 1,25(OH)₂D is to regulate intestinal calcium absorption. Thus, PTH, through 1,25(OH)₂D, indirectly regulates calcium absorption from the diet by the intestine. This action has importance clinically because the hypocalcemia of hypoparathyroidism is, in an important way, a result of inadequate intestinal calcium absorption. Conversely, hyperparathyroidism is associated with hypercalciuria and nephrolithiasis, both of which are direct results of increases in circulating 1,25(OH)₂D. Finally, as should be clear from the previous discussion, measurement of 1,25(OH)₂D can be

used as an index of both parathyroid function and intestinal calcium absorption.

Calcitonin

Calcitonin is produced by the parafollicular or C cells of the thyroid gland in response to hypercalcemia. It was once viewed as an essential calcium-regulating hormone. Clearly, pharmacologic doses of calcitonin may reduce the serum calcium, and although everyone agrees that it is secreted in response to hypercalcemia, little evidence exists that calcitonin has homeostatic relevance in humans. Indeed, compelling evidence suggests that calcitonin is unimportant in human physiology. First, malignant tumors of the parafollicular cell (medullary carcinomas of the thyroid) routinely overproduce calcitonin and lead to enormous, long-term (years or decades) elevations in circulating calcitonin concentrations. This has no effect on serum calcium or any apparent skeletal effect. Conversely, thyroidectomy, whether achieved surgically or medically using radioiodine ablation, removes calcitonin, but this, too, has no apparent adverse effect on serum calcium or skeletal homeostasis. Thus, calcitonin is a hormone in search of a function, at least in humans.

INTEGRATION OF CALCIUM HOMEOSTASIS

The foregoing regulatory system would be all that is needed to control calcium homeostasis if humans received continuous GI infusions of calcium. Of course, all normal people experience periods of high calcium intake (e.g., diets including cheese, milk, ice cream, yogurt) as well as periods of low calcium intake (diets without these dairy products). Even on a daily basis, normal people eat at times and fast at other times between meals. Given the importance of maintaining the serum calcium concentration in a very narrow range, all these regulatory processes must be, and are, coordinated during periods of high calcium intake and of low calcium intake.

Ingestion of a greater than normal dietary calcium load (Fig. 73-6A) leads to a mild rise in serum calcium followed

by immediate suppression of PTH. This action leads to an immediate *opening* of the renal distal tubular calcium *flood-gates*. It also leads to an immediate reduction in osteoclastic activity. This latter effect not only prevents continued bone resorption but also allows continuation of calcium entry from ECF to an unmineralized osteoid *sink*. These two effects lead to a rapid and short-term reduction in serum calcium to normal. However, if the high-calcium diet is maintained over the long term, these adaptations are insufficient; continued renal calcium wasting would lead to hypercalciuria (with nephrolithiasis and nephrocalcinosis) and to excessive skeletal mineralization (osteopetrosis). Hence, two additional responses (see Fig. 73-6B) are required to prevent these potential long-term adverse effects of a high-calcium diet. First, subacute or chronic suppression of PTH results in a reduction in circulating 1,25(OH)₂D. This action, in turn, leads to a reduction in the efficiency of calcium absorption from the intestine and a reduction of calcium entry into the ECF and hence a reduction of urinary calcium excretion. Second, a chronic decrement in PTH leads to a chronic decline in osteoblastic activity such that no osteoid is formed, and the ability to deposit calcium into the skeletal sink is lost.

Conversely, during brief periods of dietary calcium deficiency (Fig. 73-7A), as occurs between meals, for example, the serum calcium declines almost imperceptibly, the PTH rises, and this increase immediately prevents renal calcium losses from continuing. At the same time, an acute activation of osteoclasts occurs, and this action delivers calcium into the ECF. Thus, the acute response to low calcium intake is the appropriate elimination of renal calcium losses and the development of a new source of calcium entry into the ECF. Over the longer term, however, this response is inadequate and would lead to skeletal demineralization. Hence, a longer-term solution is required. This adaptation is again twofold (see Fig. 73-7B). First, a chronic low calcium intake, as would occur in a person with lactose intolerance, for example, leads to a chronic elevation in PTH, and this, over a matter of days to weeks, leads to an increase in 1,25(OH)₂D. This increase, in turn, leads to an increase in the efficiency of calcium absorption from the intestine (an increase in the

Figure 73-6 The response to increases in calcium intake. **A**, The acute response. **B**, The chronic response. Details are provided in the text. GI, gastrointestinal; PTH, parathyroid hormone.

fractional absorption of calcium) to compensate for the reduction in dietary intake. Second, a chronic elevation in PTH will lead to an increase in osteoblast activity and osteoid synthesis, with resultant increases in skeletal calcium deposition. In this new steady-state adaptation to a low-calcium diet, PTH will be elevated, and coupled increases in both osteoclastic and osteoblastic activities will take place (i.e., an increase in bone turnover), but net skeletal calcium losses will be negligible or normal.

In summary, from an evolutionary standpoint, as life moved from a calcium-rich marine environment to terrestrial life, in which calcium availability is variable and unpredictable, a complex, but rather beautiful, regulatory mechanism has evolved that permits survival without requiring intentional behavioral adaptations for the vagaries of calcium availability. This evolution was essential in evolutionary terms because calcium is so essential for all aspects of mammalian, indeed all eukaryotic, life. As discussed in Chapter 74, disorders that cause hypercalcemia or hypocalcemia are always caused by abnormalities at the interface of the ECF with the intestine, the kidney, or the skeleton, and in several of these interfaces. Moreover, given the robustness of these homeostatic adaptive processes, disorders that cause hypocalcemia or hypercalcemia are rarely subtle: The physician need only recall these homeostatic premises to dissect the pathophysiologic process with precision and accuracy and treat the underlying disorder effectively.

Phosphate Homeostasis

The terms *phosphorus* and *phosphate* are often used interchangeably. To be parochial, phosphorus is an inorganic element, abbreviated as *P* in physical chemistry literature and as *P_i* in physiologic usage. Of course, the biologically relevant molecule is the negatively charged, trivalent phosphate ion PO_4 . Phosphorus is the form that most clinical laboratories measure rather than the more biologically relevant phosphate ion. To make matters more complex, phosphate is an important physiologic buffer, and, at neutral pH in blood, phosphate is apportioned between HPO_4 (diva-

lent) and H_2PO_4 (monovalent). The practical effect of this dichotomy is that, whereas physicians receive phosphorus measurements in milligram per deciliter (mg/dL) units, pharmaceutical preparations contain phosphorus in millimoles (mmol). Many physicians are unable to convert milligrams to millimoles, and dosing errors are common. An example is the replacement of potassium-using K-Phos, in which relatively standard amounts of potassium ion (e.g., 40 mEq) given intravenously are coupled with potentially life-threatening amounts of phosphate (30 mmol, or 900 mg). A chart converting milligrams to millimoles in common phosphate-containing preparations is provided in Table 73-1.

Phosphate regulates or participates in the regulation of an enormous number of biologic processes. These actions of phosphate are fundamental to life itself and range from (1) being an integral component of the DNA double helix, to (2) shuttling oxygen from hemoglobin to cells and vice versa using 2,3-diphosphoglycerate (2,3-DPG), to (3) intracellular signaling through kinases that attach phosphate groups to other molecules, to (4) facilitating critical intracellular messenger systems such as cyclic monophosphate (cAMP) and inositol phosphates, to (5) maintaining basic intracellular redox status through the nicotinamide adenine dinucleotide phosphate (NADP-NADPH) system, to (6) serving as the gateway to the glucose metabolic pathway through glucose 6-phosphate. These actions are but a handful of examples, and, although they illustrate the central importance of adequate phosphorus supplies for life, they also underscore the point that phosphorus is primarily an intracellular ion. Extracellular concentrations are less important because the ECF functions mainly as a transport conduit through which phosphorus must travel from the skeleton or intestine to reach the cell interior. In addition to these critical intracellular roles, phosphate does have a key extracellular role as well: The anion pairs with calcium in the hydroxyapatite crystal lattice that provides structural integrity to the skeleton (see previous discussion). Thus, as with calcium, phosphate is critical to skeletal strength, and disorders of phosphorus homeostasis, such as hypophosphatemic rickets, lead to pathologic skeletal fractures. Also in parallel

Table 73-1 Examples of Therapeutic Phosphorus Preparations

Preparations	Composition* (per mL)	pH	mOsm/ kg H ₂ O	Phosphate (mmol/mL)	Phosphorus (mg/mL)	Sodium (mEq/mL)	Potassium (mEq/mL)
Oral							
Cow's milk (whole)	—	—	288	0.029	0.9	0.025	0.035
Neutra-Phos [†]	Na ₂ HPO ₄ , NaH ₂ PO ₄ , K ₂ HPO ₄ , KH ₂ PO ₄	7.3	—	0.107	3.33	0.095	0.095
Phospho-Soda [†]	180 mg Na ₂ HPO ₄ • 7H ₂ O + 480 mg NaH ₂ PO ₄ • H ₂ O	4.8	8240	4.150	128.65	4.822	0
Acid sodium phosphate	136 mg Na ₂ HPO ₄ • 7H ₂ O + 58.8 mg H ₃ PO ₄ (NF 85%)	4.9	1740	1.018	35.54	1.015	0
Neutral sodium phosphate	145 mg Na ₂ HPO ₄ • 7H ₂ O + 18.2 mg NaH ₂ PO ₄ • H ₂ O	7.0	1390	0.673	20.86	1.214	0
Parenteral							
Neutral sodium phosphate	10.07 mg Na ₂ HPO ₄ + 2.66 mg NaH ₂ PO ₄ • H ₂ O	7.35	202	0.090	2.80	0.161	0
Neutral sodium, potassium phosphate	11.5 mg Na ₂ HPO ₄ + 2.58 mg KH ₂ PO ₄	7.4	223	0.100	3.10	0.162	0.019
Na Phosphate [†]	142 mg Na ₂ HPO ₄ + 276 mg NaH ₂ PO ₄ • H ₂ O	5.7	5580	3.000	93.00	4.000	0
K Phosphate [†]	236 mg K ₂ HPO ₄ + 224 mg KH ₂ PO ₄	6.6	5840	3.003	93.11	0	4.360

*Hydration states are important. For example, 268 mg Na₂HPO₄ • 7H₂O (molecular weight 268) equals 1.00 mmol, whereas 268 mg Na₂HPO₄ (molecular weight 142) equals 1.89 mmol.

[†]Commercial preparations: Neutra-Phos, Willen Drug Company, Baltimore (Neutra-Phos K has twice as much potassium and no sodium); Phospho-Soda, C. B. Fleet Company, Lynchburg, Virginia (enema is one third the strength of Phospho-Soda and can be used orally); Na Phosphate, Abbott Laboratories, North Chicago, Illinois; K Phosphate, Invenex Pharmaceuticals, Grand Island, New York, or Abbott Laboratories. Because Neutra-Phos was not readily dissolved and its specific composition is unknown, data shown are those provided by the manufacturer.

H₂O, water; K₂HPO₄, dipotassium hydrogen phosphate; KH₂PO₄, potassium dihydrogen phosphate; Na₂HPO₄, disodium hydrogen phosphate; NaH₂PO₄, sodium dihydrogen phosphate.

From Lentz RD, Brown DM, Kjellstrand CM: Treatment of severe hypophosphatemia. *Ann Intern Med* 89:941-944, 1978.

with calcium, the skeleton serves as a major storage site for phosphate that can be, and is, accessed in times of severe phosphate deficiency.

Two corollaries of these broad and critical intracellular roles for phosphate are that: (1) clinically significant intracellular phosphate deficiency may exist without marked hypophosphatemia (ideally, assessing intracellular phosphorus concentrations would be preferred, but this is not clinically possible); and (2) importantly, severe, life-threatening phosphate deficiency is often unrecognized because its manifestations are so completely nonspecific yet common in intensive care unit settings (reduced levels of consciousness, hypotension, respirator dependence, and weakness). Astute clinicians learn to recognize general debility as a potential sign of phosphorus deficiency. Phosphate repletion in this setting may produce dramatic results.

In contrast to the regulation of serum calcium concentration, which is very tight, the regulation of serum phosphate concentrations is relatively lax. The serum phosphorus is maintained in a broad range between about 3.0 and 4.5 mg/dL. At least two reasons for this lax maintenance exist. First, as noted previously, in contrast to extracellular calcium concentrations, the precise maintenance of which are critically important to survival, extracellular phosphate concentrations are not critically important. Thus, room can be found for laxity in the system. Second, because phosphate is so abundant inside plant and animal cells, phosphate is abundant in almost any diet such that evolutionary pressure has not been intense to develop a systemic regulatory mechanism for phosphate.

Figure 73-8 The phosphate *physiologic black box*. See Figure 73-1 for nomenclature and the text for details. GI, gastrointestinal; ICF, intracellular fluid.

As with calcium, a *black box* can be developed for phosphate metabolism as well (Fig. 73-8). This black box represents ECF and, as with calcium, has interfaces with the GI tract, the kidney, and the skeleton. In addition, because most phosphate is contained within cells, the phosphate black box has a quantitatively significant interface with the intracellular compartment.

INTESTINAL PHOSPHATE ABSORPTION

A normal diet contains about 1200 to 1600 mg of phosphorus, and about two thirds of this amount, or 800 to 1200 mg, is absorbed each day. Absorption occurs in the duodenum and jejunum. Although vitamin D compounds can increase the intestinal absorption of phosphorus, this effect is modest, and phosphate absorption in the intestine can be considered as occurring with a fixed fractional absorption of about 67%. In the normal world of phosphate abundance, this amount is more than ample. Conversely, under conditions of dietary phosphorus deficiency, as occurs in chronic alcoholism (alcoholic beverages generally do not contain phosphorus), intensive care units (without adequate oral or parenteral alimentation), intestinal malabsorption, or phosphate-binding antacid use, failure to provide this amount of phosphorus presents a physiologic challenge for which no physiologic remedy exists.

SKELETAL PHOSPHATE FLUXES

As with calcium, osteoclastic bone resorption and osteoblastic new bone formation (see Figs. 73-1 and 73-3) lead to phosphate exit and entry, respectively, from the skeleton. Although the skeleton can thus be used as a source of phosphorus, in general, phosphorus can be viewed as a passive passenger with calcium in the calcium regulatory process described previously in the section on calcium. Again, however, under pathophysiologic conditions, skeletal calcium fluxes may become important. Skeletal destruction in multiple myeloma or severe immobilization syndromes leads not only to hypercalcemia but also to hyperphosphatemia, which, with the concomitant hypercalcemia, leads to nephrocalcinosis and renal failure. Conversely, osteoblastic metastases in prostate cancer and breast cancer and the hungry bone syndrome following parathyroidectomy all lead to clinically significant hypophosphatemia.

INTRACELLULAR-EXTRACELLULAR PHOSPHATE FLUXES

As noted previously, phosphate shuttles from extracellular to intracellular compartments. In general, the control of these fluxes can best be envisioned as being performed at the cellular level by as yet incompletely understood cellular mechanisms. From a clinical standpoint, these issues become important under certain settings. For example, in the setting of metabolic acidosis, phosphate leaves the intracellular compartment and may lead to hyperphosphatemia, whereas, under conditions of alkalosis, serum phosphate concentrations decline, and hypophosphatemia develops as phosphate enters the intracellular compartment. Other clinical situations in which intracellular phosphate has important clinical implications are in the settings of crush injury (rhabdomyolysis) and the tumor lysis syndrome, in both of which large intracellular loads of phosphate are delivered into the ECF and result in hypocalcemia, seizures, nephrocalcinosis, and renal failure. Finally, glucose shifts phosphate into cells as glucose 6-phosphate, and overzealous intravenous or oral caloric restitution in the undernourished patient can result in severe hypophosphatemia and sudden death.

RENAL PHOSPHATE HANDLING

By far the most important mechanism for maintaining a normal serum phosphorus concentration is renal phosphorus handling. As with calcium, phosphate is filtered by the glomerulus. *Tubular reabsorption of filtered phosphate* (TRP) occurs at a rate such that about 90% of phosphate is reabsorbed (i.e., the TRP is normally about 90%), and the remaining 10% is excreted. This 10% represents the *fractional excretion of phosphorus* (Fe_{Pi}). The Fe_{Pi} can be calculated in a spot urine sample as follows:

$$Fe_{Pi} = \left(\frac{\text{urine Pi [in mg/dL]}}{\text{urine creatinine [in mg/dL]}} \right) \times \left(\frac{\text{serum creatinine [in mg/dL]}}{\text{serum phosphorus [in mg/dL]}} \right)$$

The TRP is simple to calculate:

$$TRP = 1 - Fe_{Pi}$$

The renal handling of phosphorus is best considered as a tubular maximum (T_m)-regulated process. For example, a renal T_m for glucose exists and is set at about 180 mg/dL. When the serum glucose rises above 180 mg/dL, glycosuria occurs. Of course, the serum glucose normally does not rise above 180 mg/dL; therefore, glucose does not normally appear in the urine. A similar process occurs with the T_m for phosphorus (T_mP), with one exception. The T_mP is normally identical to a normal serum phosphorus concentration in blood, about 3.3 mg/dL. If the serum phosphate concentration rises above this level, phosphaturia occurs, and the serum phosphorus declines to 3.3 mg/dL. If the serum phosphate concentration declines below 3.3 mg/dL, then filtered phosphate is entirely reabsorbed, and urinary phosphate excretion declines to zero. Thus, the T_mP can be considered as a *dam* in the *phosphate reservoir*, over which excess phosphate *spills*, and whose level controls the *level* or concentration of serum phosphorus.

The one exception to this concept is that, unlike the glucose T_m , which is fixed at 180 mg/dL, the T_mP is not fixed but can be moved upward or downward, depending on metabolic needs and prevailing metabolic conditions, as described in the following section.

The TRP or Fe_{Pi} , as described previously, can be readily calculated, and then the T_mP can be derived from the nomogram of Bijvoet, shown in Figure 73-9. This process proves enormously useful in clinical practice because it is the central starting point for determining whether hypophosphatemia is principally renal or nonrenal in origin.

PARATHYROID HORMONE AND PHOSPHATONINS

PTH has long been appreciated to be phosphaturic, that is, to lower the T_mP or, more accurately, to inhibit proximal renal tubular phosphate reabsorption. Indeed, the initial bioassay for PTH action in humans, the Ellsworth-Howard test, assessed the responsiveness of the TRP to infusion of bovine parathyroid gland extract. This characteristic also explains the hypophosphatemia associated with primary and secondary hyperparathyroidism and, conversely, the hyperphosphatemia associated with hypoparathyroid states. Thus,

Figure 73-9 The tubular maximum for phosphorus-glomerular filtration rate (TmP-GFR) nomogram. This nomogram allows the conversion of the fractional excretion of phosphorus (or its inverse, the tubular reabsorption of filtered phosphate [TRP]) into the TmP-GFR. The TRP is calculated, as described in the text, and a line is drawn extending from the serum phosphorus (*leftmost line*), through the TRP (*middle, diagonal line*), to the left line, which represents the TmP/GFR. TmP values are provided in both millimolar (mmol) and milligram per deciliter (mg/dL) units. TmP values below 1.0 mmol or 2.5 mg/dL are abnormal and indicate phosphaturia. (From Walton RJ, Bijvoet OLM: Nomogram for derivation of renal threshold phosphate concentration. *Lancet* 2:309-310, 1975.)

in TmP terms, excessive PTH lowers the TmP, whereas low PTH values allow the TmP to rise to supranormal levels.

It has been clear for many years, however, that other factors regulate the level of the TmP. For example, experimental dietary phosphorus deprivation in laboratory animals and humans leads to a PTH-independent increase in the TmP, and high-phosphate feeding results in a PTH-independent decline in the TmP. Thus, for decades, investigators in this area have postulated the existence of a phosphaturic hormone that has been called *phosphatonin*. Despite decades of research, phosphatonin has remained elusive. This area has become one of intense focus recently with the discovery of the cause of three disorders. In one of these disorders, X-linked hypophosphatemic rickets, also known as *vitamin D-resistant rickets*, causative inactivating mutations have been identified in the *PHEX* enzyme. Current models suggest that mutant *PHEX* fails to inactivate normal amounts of phosphatonin, and this failure leads to phosphaturia and hypophosphatemia. In two other disorders, autosomal-dominant hypophosphatemic rickets and oncogenic osteomalacia, overproduction of fibroblast growth factor-23 (FGF-23) has been demonstrated, and many clinicians believe that FGF-23 is the long-sought phosphatonin. Other investigators have suggested that matrix extracellular phosphoglycoprotein (*MEPE*) or secreted frizzled-related protein 4 (*sFRP4*) may serve as phosphatonins as well. Much remains to be worked out in this arena, but clearly, a hormonal

system that regulates renal phosphorus handling exists, and the kidney is the prime regulatory organ for phosphate homeostasis.

Regulation of Serum Magnesium

Magnesium is a divalent cation, as is calcium. With this exception, magnesium homeostasis has closer parallels with phosphorus homeostasis. Both magnesium and phosphate are principally intracellular, with concentrations inside the cell that far exceed those outside the cell. Both substances govern key intracellular regulatory processes. In the case of magnesium, these processes include such fundamental events as DNA replication and transcription, translation of RNA, the use of adenosine triphosphate as an energy source, and regulated peptide hormone secretion. Both magnesium and phosphate are abundant in the marine environment and therefore became incorporated into basic life processes early in the evolution of single-celled organisms. Both substances are abundant in terrestrial diets, whether vegetarian or carnivorous, given their abundance inside all kinds of cells. Given this abundance, little evolutionary pressure to develop a complex regulatory network exists. As with phosphate, because the important site of magnesium availability is within the cell, ECF serves only as a conduit for magnesium, and serum magnesium concentrations are not tightly regulated. As with phosphate, because magnesium is principally intracellular, measurement of serum magnesium may provide false estimates of actual total-body and intracellular magnesium status. Finally, as with phosphate, because magnesium is so essential for fundamental processes such as gene transcription and cellular energy use, life-threatening magnesium deficiency is often unrecognized because its symptoms are frustratingly nonspecific: weakness, respirator dependence, diffuse neurologic syndromes including seizures, and cardiovascular collapse.

Magnesium, as noted previously, is a divalent cation. Its molecular weight is 24, which is to say that 1 mole is 24 g, and, because it is divalent, one equivalent is 12 g. These considerations are significant clinically because magnesium measurements in blood are often provided in mg/dL or milliequivalents per liter (mEq/L), oral magnesium supplements in milligrams per tablet or milliequivalents per vial, and urinary magnesium excretion in milliequivalents or milligrams per 24 hours. Quantitative perspective in this clinical world of variable units can easily be lost. Constructing a *black box* for magnesium is helpful, as shown in Figure 73-10, in which magnesium is provided in both milligram and milliequivalent units.

As with phosphorus, magnesium has quantitatively important interfaces with the intestine, the skeleton, intracellular supplies, and the kidney. At the level of the intestine, as noted previously, magnesium is widely available in normal diets, and regulation here is limited: the body absorbs about one third of what is ingested. Under normal circumstances, dietary magnesium is abundant, absorption is ample, and magnesium deficiency does not occur. However, with alcoholism (a pure alcohol diet contains no magnesium), in intensive care unit settings in which adequate nutrition often

Figure 73-10 The magnesium *physiologic black box*. See Figure 73-1 for nomenclature and the text for details. Magnesium values are provided in both milligram (mg) and milliequivalent (mEq) units. GI, gastrointestinal; ICF, intracellular fluid.

is not provided, or with intestinal malabsorption, magnesium deficiency may occur.

At the level of the skeleton, magnesium is incorporated into the hydroxyapatite crystal as mineralization of osteoid occurs, and it is released by osteoclastic bone resorption (see Figs. 73-1 and 73-3). In quantitative terms, these fluxes are small.

Many instances of magnesium deficiency are caused by excessive renal losses. Examples include the magnesuria that accompanies saline infusions, diuretic use, alcohol use, and secondary hyperaldosteronism states such as cirrhosis and ascites. As with calcium and phosphorus, the fractional excretion of magnesium (FeMg) can be calculated, and this should be used as an index as to whether the kidney is appropriately conserving magnesium in states of hypomagnesemia or whether renal magnesium wasting is the cause of the hypomagnesemia. The normal FeMg is 2% to 4%. Hypomagnesemic individuals should display FeMg values below 1% to 2%.

With regard to homeostatic regulation, magnesium homeostasis can best be viewed as a renal T_m -regulated process (see the general principles described previously for the T_mP under “Renal Phosphate Handling”), with the renal T_m for magnesium set at a fixed level of about 2.2 mg/dL. In this scenario, abundant dietary magnesium exists, and excessive magnesium intake is managed by spillage of excess magnesium, over the T_m set at 2.2 mg/dL, into the urine. Conversely, in settings of dietary magnesium deficiency, which equate evolutionarily with caloric deficiency, short-term magnesium deficiency is prevented when serum levels fall below the renal T_m of 2.0 mg/dL, and long-term deficiency is associated with, and becomes of lesser importance than, death by starvation. With regard to hormonal regulation, no known independent regulatory system for magnesium exists.

Prospectus for the Future

Although it may seem from this chapter that calcium, PTH, vitamin D, magnesium and phosphorus homeostasis, and skeletal biology are well understood, it should be clear that many of the details of the physiology as described in this chapter have been elucidated over the past 10 to 15 years, and indeed, new hormones (e.g., FGF-23) and diseases continue to accumulate at a rapid rate. The truth is that this area of research is dynamic, with many central unanswered questions. For example, although we know that the GI tract (pancreas, biliary system, and intestinal glands) secretes calcium and that this action is important quantitatively (150 mg per day), we know nothing about how this process is regulated or whether daily losses can be prevented. Similarly, although we now appreciate that phosphate has direct effects on the parathyroid gland and that these effects may be important in chronic renal failure, we do not know precisely what constitutes the parathyroid phosphorus sensor. Moreover, we know that hypomagnesemia and hypophosphatemia result in substantial intensive care unit morbidity and mortality, yet we remain inadequate at recognizing the nonspecific signs and symptoms of these diseases.

We know that bone density is a critical determinant of osteoporotic fracture, but we also know that *bone mass* accounts for only about 50% of fracture risk, with the other 50% representing issues of *bone quality*. Yet we have little understanding of what, at a molecular or structural level, determines or defines *bone quality*. In osteoporosis, most of the currently available pharmacologic agents inhibit osteoclast activity and are therefore *antiresorptives* or *anticatabolic agents*. What we really need for osteoporosis are agents that can potentially stimulate osteoblasts to synthesize new bone, called *skeletal anabolic agents*. One agent, recombinant PTH, has recently been approved, and others are in the pharmaceutical pipeline. Another example of the limitations of our current understanding is a debate over the pulsatile secretion of PTH. Is the secretion pulsatile, and if so, how frequent are the pulses? Is pulsatile secretion important for PTH physiology as it obviously is for gonadotropin-releasing hormone biology, and is it important in pathophysiology? Whereas to the new initiate in mineral and bone physiology, everything has seemingly been discovered already, this assumption is far from the truth!

Disorders of Serum Minerals

Steven P. Hodak and Andrew F. Stewart

In this chapter, disorders that lead to increases or decreases in the circulating concentrations of calcium, phosphorus, and magnesium are considered. The reader is urged, in considering these disorders, to review the appropriate section in Chapter 73 describing the normal physiology of calcium, phosphorus, and magnesium metabolism. The optimal approach to diagnosing and treating these disorders is to understand their underlying physiology and pathophysiology. Beginning here, coherent diagnostic and successful therapeutic plans can best be developed. Although obvious at one level, years of experience suggests a common and persistent propensity to jump to the common items on the differential diagnosis list without fully considering the other options, and, in so doing, to overlook the correct, and often easily treatable, diagnosis. For example, hypercalcemia in the setting of a pulmonary nodule may indicate the presence of humoral hypercalcemia of malignancy, and many physicians will jump to this diagnosis with its grim prognosis. However, this complex might also represent hypercalcemia in a patient with treatable tuberculosis (TB) or primary hyperparathyroidism (HPT) in a person with a longstanding and inactive pulmonary scar.

Complete differential diagnoses are provided in the tables that follow. My practice is to consider every diagnosis in the appropriate table in every patient with a disorder of mineral metabolism. Hypercalcemia attributed by some physicians to *cancer* has proved in many instances to be due to sarcoid, HPT, hyperthyroidism, milk-alkali syndrome, and a host of other conditions, and hypocalcemia attributed by some physicians to *hypoparathyroidism* has proved to be due to easily treatable causes such as hypomagnesemia resulting from sprue or chemotherapy with cisplatin in some cases and in others to reductions in albumin in patients with the nephrotic syndrome. Each of these examples was incorrectly diagnosed initially but became obvious with appropriate consideration and testing.

Hypercalcemia

SYMPTOMS AND SIGNS

Hypercalcemia causes hyperpolarization of neuromuscular cell membranes and therefore refractoriness to stimulation (see Chapter 73). This condition presents clinically as skeletal muscular weakness, smooth muscle hypoactivity with constipation and ileus, and the full spectrum of mental dysfunction, progressing from lassitude to mild confusion to deep coma. Hypercalcemia also leads to renal failure. It causes a reduction in the glomerular filtration rate (GFR) through afferent arteriolar vasoconstriction and, through activation of the calcium receptor in the distal nephron, causes a form of nephrogenic diabetes insipidus, associated with polydipsia and polyuria. These events lower the extracellular fluid (ECF) volume and lower the GFR as well. Hypercalcemia may lead to interstitial calcium phosphate crystal deposition in the kidney (nephrocalcinosis or interstitial nephritis) and nephrolithiasis with obstructive uropathy. Hypercalcemia may also lead to shortening of the QTc interval on the electrocardiogram. Frequently, however, hypercalcemia is discovered on routine laboratory testing.

Whether a person develops symptoms depends on several factors. One of these factors is the degree of hypercalcemia. People with serum calcium values above 13 mg/dL are generally symptomatic. Also important is the duration of hypercalcemia. A gradual increase in serum calcium, even into the severe 15- to 17-mg/dL range, may cause little in the way of symptoms if it occurs slowly enough. Finally, the overall health, age, and general status of the person in whom hypercalcemia occurs will influence the severity of symptoms. For example, a child with severe immobilization-induced hypercalcemia in the 15-mg/dL range may be completely alert, whereas an elderly person with underlying

Alzheimer disease and narcotic use may become comatose with a serum calcium of 11.5 mg/dL.

PATHOPHYSIOLOGY

The physiologic *black box* described in Chapter 73 can and should be considered when attempting to diagnose or treat hypercalcemia. These disorders can be grouped into factitious disorders (e.g., caused by abnormalities in serum proteins), renal disorders (e.g., thiazide diuretic or lithium use), gastrointestinal disorders (e.g., sarcoid or the milk-alkali syndrome), skeletal disorders (e.g., hypercalcemia of malignancy, immobilization hypercalcemia), and combined disorders (primary HPT is a good example, with important gastrointestinal [GI] and renal components). Considering each diagnosis in Table 74-1 in the context of the mechanism that might be operative in a given patient brings clarity of diagnosis and corresponding appropriateness to therapy.

DIFFERENTIAL DIAGNOSIS

Malignancy-Associated Hypercalcemia

The most common cause of hypercalcemia among hospitalized patients is cancer. Hypercalcemia occurs late in the course of cancer, and rapid progression to more severe hypercalcemia and rapid death is the rule. The 50% survival rate among patients with cancer following the development of hypercalcemia is about 30 days. In general, hypercalcemia is only encountered in patients with large tumor burdens. Conversely, small, occult cancers rarely cause hypercalcemia. The exceptions to this rule are small tumors of the neuroendocrine variety, such as islet cell tumors and bronchial carcinoids. Certain tumors are common causes of hypercalcemia, including breast, renal, squamous, and ovarian carcinomas, as well as multiple myeloma and lymphoma. Conversely, certain other common cancers are not commonly associated with hypercalcemia, exemplified by colon, prostate, and gastric carcinoma. The occurrence of hypercalcemia should always provoke a complete search for the entities described in Table 74-1, particularly in patients with these latter types of cancer, given the likelihood that a vigorous search will reveal a second, more treatable form of hypercalcemia.

Cancer may lead to hypercalcemia through several mechanisms, the most common of which is *humoral hypercalcemia of malignancy* (HHM). HHM accounts for about 80% of patients with malignancy-associated hypercalcemia (MAHC) and is the result of secretion by tumors of parathyroid hormone–related protein (PTHrP). PTHrP mimics the actions of parathyroid hormone (PTH) on the kidney to prevent calcium excretion and on the skeleton to activate osteoclasts and induce bone resorption. PTHrP is the product of many normal cell types and is normally produced at low levels. The cause of the increase in PTHrP synthesis in cancer is most often not known but has been demonstrated to be due to PTHrP gene duplication or transcriptional upregulation of the PTHrP gene in some patients. Tumors classically associated with the HHM mechanism are squamous carcinomas of any site (including larynx, lung, cervix, and esophagus), renal carcinomas, ovarian carcinomas, and lymphomas associated with human T-cell lymphotropic virus type I (HTLV-I). More recently, the fact that

Table 74-1 Disorders Associated with Hypercalcemia

Malignancy-Associated Hypercalcemia

Humoral hypercalcemia of malignancy
Hypercalcemia caused by 1,25(OH)₂D-secreting lymphomas
Hypercalcemia caused by direct skeletal invasion
True ectopic hyperparathyroidism

Primary and Tertiary Hyperparathyroidism

Familial Hypocalciuric Hypercalcemia or Familial Benign Hypercalcemia

Granulomatous Disorders

Sarcoid
Berylliosis
Foreign body
Tuberculosis
Coccidioidomycosis
Blastomycosis
Histoplasmosis
Granulomatous leprosy
Eosinophilic granuloma
Histiocytosis
Inflammatory bowel disease

Endocrine Disorders Other than Hyperparathyroidism

Hyperthyroidism
Pheochromocytoma
Addisonian crisis
VIPoma (WDHA syndrome)

Medications

Thiazides
Aminophylline
Lithium
Estrogen/antiestrogen in breast cancer with bone metastases (*estrogen flare*)
Vitamin D and derivatives (calcitriol, dihydroxycholesterol)
Vitamin A (including retinoic acid derivatives)
Foscarnet

Milk-Alkali Syndrome

Immobilization plus High Bone Turnover

Juvenile skeleton
Paget disease
Myeloma and breast cancer with bone metastases
Prehumoral hypercalcemia of malignancy
Mild primary hyperparathyroidism
Secondary hyperparathyroidism (e.g., from continuous ambulatory peritoneal dialysis)
Chronic and acute renal failure
Recovery phase of rhabdomyolysis-induced acute renal failure
Chronic hemodialysis
Calcitriol
Immobilization
Decreased calcium clearance
Calcium carbonate

Total Parenteral Nutrition (TPN)

Calcium-containing TPN in patients with decreased glomerular filtration rate
Chronic TPN in patients with short bowel syndrome

Hyperproteinemia

Volume contraction with hyperalbuminemia
Myeloma with calcium-binding immunoglobulin

End-Stage Liver Disease

Manganese Intoxication

1,25(OH)₂D, 1,25-dihydroxyvitamin D; VIPoma, vasoactive intestinal peptide–producing tumor; WDHA, watery diarrhea, hypokalemia, and achlorhydria.

breast cancer commonly produces hypercalcemia through this mechanism, as well, has become known. In general, hypercalcemia in HHM occurs in the absence of skeletal metastases or in the presence of a limited number of skeletal metastases, and, if tumor resection or ablation is possible, hypercalcemia reverses. These observations, together with histologic evidence for aggressive bone resorption at sites within the skeleton not involved by tumor, make clear that HHM is indeed the result of a tumor-derived *humor* or hormone. This example is perhaps the only one in which PTHrP acts in an *endocrine* fashion, more typically behaving as a paracrine, autocrine, or intracrine growth and developmental factor. In addition to hypercalcemia, these patients display reductions in PTH, reductions in 1,25-dihydroxyvitamin D ($1,25[\text{OH}]_2\text{D}$), elevations in PTHrP, and reductions in serum phosphorus and the tubular maximum for phosphorus (TmP) (see Chapter 73).

A second form of MAHC is that caused by local tumor invasion of the skeleton, a process referred to as *local osteolytic hypercalcemia* (LOH). LOH accounts for about 20% of patients with MAHC. In these patients, in contrast to those with HHM, the skeletal metastatic or primary tumor burden is large, and the offending tumor is most often a breast cancer or a hematologic neoplasm such as multiple myeloma, leukemia, or lymphoma. The local factors within the skeleton that are secreted by tumors to induce osteoclastic bone resorption include PTHrP, macrophage inflammatory protein-1- α (MIP1 α), receptor-activating nuclear factor kappa B ligand (RANKL), interleukin-6, interleukin-1, and likely others as well. These patients display reductions in both PTH and PTHrP, as well as $1,25(\text{OH})_2\text{D}$, and generally have normal to elevated serum phosphorus values.

A third form of MAHC is due to *secretion of $1,25(\text{OH})_2\text{D}$ by lymphomas and dysgerminomas*. These instances are unusual and are interesting from a mechanistic standpoint. Although direct bone involvement may occur and may contribute to hypercalcemia, the increase in $1,25(\text{OH})_2\text{D}$ leads to intestinal calcium hyperabsorption as well as to systemically driven bone resorption. Thus, this condition is in essence a malignant version of the hypercalcemia that occurs in sarcoidosis (see “Granulomatous Disorders,” later). The fact that macrophages produce $1,25(\text{OH})_2\text{D}$ and that overproduction of $1,25(\text{OH})_2\text{D}$ occurs in some lymphomas is now well documented. Under normal circumstances, $1,25(\text{OH})_2\text{D}$ behaves as an immunomodulatory cytokine, produced locally in small amounts by lymphoreticular cells but not contributing significantly to systemic concentrations of $1,25(\text{OH})_2\text{D}$. However, under certain conditions, large amounts of $1,25(\text{OH})_2\text{D}$ are produced by a given lymphoma, and hypercalcemia ensues. Thus, lymphomas are particularly interesting in that they may cause hypercalcemia through an HHM mechanism with systemic PTHrP secretion through a local skeletal invasion mechanism and through systemic production of $1,25(\text{OH})_2\text{D}$. Recently, the syndrome has been observed in association with ovarian dysgerminomas.

Finally, although most instances of HHM are due to PTHrP, several well-documented case reports of *ectopic secretion of authentic PTH* have come to light. These case reports have included a colon carcinoma, a squamous carcinoma of the lung, a small cell carcinoma of the ovary, and a neuroendocrine tumor.

Primary and Tertiary Hyperparathyroidism

Although MAHC is the most common cause of hypercalcemia among inpatients, primary HPT is by far the most common cause among healthy outpatients. Together, MAHC and HPT account for about 90% of cases of hypercalcemia. Most often, the hypercalcemia is mild, with serum calcium values in the 10.6- to 11.5-mg/dL range. However, HPT can occasionally produce spectacular hypercalcemia in the 20-mg/dL range. About 85% of the time, hypercalcemia results from a single parathyroid adenoma that overproduces PTH, and in about 15% of patients, it is due to multiple-gland hyperplasia. In less than 1% of patients, HPT may result from parathyroid carcinoma. The diagnosis is made by the discovery of an elevated serum PTH in a patient with hypercalcemia. Hypophosphatemia, a reduction in the TmP, increased plasma $1,25(\text{OH})_2\text{D}$, an increase in serum chloride, and a reduction in serum bicarbonate are also typical features.

Most often, primary HPT is asymptomatic. However, some patients develop hypercalciuria and calcium nephrolithiasis, most often as a result of calcium oxalate and, less commonly, calcium phosphate stones. In addition, some patients with HPT, especially those with more severe HPT, experience a reduction in bone mineral density characterized histologically as hyperparathyroid bone disease or *osteitis fibrosa cystica* (see Chapter 75). Other patients may develop mild to severe renal failure as a result of the considerations described under “Symptoms and Signs” of hypercalcemia earlier. Each of the previously mentioned conditions—significant osteopenia, hypercalciuria, kidney stones, reduced renal function, and a serum calcium greater than 1 mg/dL above normal—is considered an indication for parathyroidectomy. Other patients may be monitored conservatively. Some authors believe that cognitive dysfunction, peptic ulcers, and hypertension may result from HPT, but many disagree. Most people would regard these indications as *soft* indications for surgery at best.

The cause of parathyroid adenomas is most often not known, but mutations of the cyclin D1 and parafibromin genes have been described in some patients, and mutations in other genes have been identified in the adenomas of others. Mutations in *pRb*, the retinoblastoma gene, and in the parafibromin gene, have been identified in some parathyroid carcinomas.

HPT can occur as part of one of the multiple endocrine neoplasia (MEN) syndromes, in association with pituitary and islet tumors (MEN-I) or with pheochromocytomas and medullary carcinoma of the thyroid (MEN-II).

Secondary HPT, by definition, is an appropriate increase in circulating PTH associated with eucalcemia or hypocalcemia, occurring in an attempt to correct hypocalcemia resulting for example from vitamin D deficiency or chronic renal failure. *Tertiary* HPT refers to HPT associated with hypercalcemia that appears in the setting of prolonged stimulation of the parathyroid glands, such as chronic renal failure with hypocalcemia or chronic vitamin D deficiency resulting from malabsorption. Chronic parathyroid stimulation leads to parathyroid hyperplasia and at times adenomas, and these may, if they fail to suppress with the development of hypercalcemia, cause hypercalcemia. The classic example is

the development of PTH-dependent hypercalcemia following successful renal transplantation.

Familial Hypocalciuric Hypercalcemia

Familial hypocalciuric hypercalcemia (also known as *familial benign hypercalcemia*) is an autosomal dominant, inherited disorder that is due to heterozygous inactivating mutations in the calcium receptor. Thus, parathyroid glands that bear this receptor on their surface (see Chapter 73) inappropriately perceive circulating calcium concentrations to be low, therefore behaving as though the patient is hypocalcemic, and appropriately secrete additional PTH. This action causes the serum calcium to rise, and, with an elevated calcium, the PTH returns to a high-normal level. The hypercalcemia is usually mild, in the 11- to 12-mg/dL range, but may be higher. Importantly, because the calcium receptor is also expressed in the kidney, the kidney inappropriately conserves calcium, leading to hypocalciuria and contributing to hypercalcemia. Urine calcium excretion is in the 20- to 100-mg per day range. Finally, because the defective calcium receptor is also expressed in the central nervous system (CNS), the hypercalcemia goes unperceived by the CNS, and affected individuals are therefore asymptomatic. Thus, the two names of this syndrome describe it accurately.

With the exception of the hypocalciuria and the autosomal dominant pattern of inheritance, these individuals are similar to patients with primary HPT; they have mildly elevated calcium concentrations in the setting of a high-normal to mildly elevated PTH. Because affected individuals are asymptomatic and do not develop adverse sequelae from the syndrome, its primary importance is that affected individuals be properly identified and protected from unnecessary parathyroidectomy. Partial or subtotal parathyroidectomy has no effect on these individuals, and total parathyroidectomy causes hypoparathyroidism.

In some patients, two defective alleles of the calcium sensor are inherited. These individuals may have complete inability to sense calcium and therefore develop severe and symptomatic hypercalcemia, with serum calcium values in the 15- to 20-mg/dL range. Because of the severity of this disorder, homozygous individuals usually present in infancy with so-called neonatal severe hyperparathyroidism. In contrast to the mild heterozygous condition described previously, homozygous individuals require urgent total parathyroidectomy in infancy.

Granulomatous Disorders

Almost all granulomatous disorders can lead to hypercalcemia, as noted in Table 74-1. The prototypes are sarcoidosis, TB, and the fungal diseases listed. Briefly, as previously described for lymphomas, granulomas, as with the kidney, have the ability to convert inactive 25-hydroxyvitamin D to the active metabolite, 1,25(OH)₂D. Thus, individuals with these disorders, when exposed to sunlight, ultraviolet radiation, or relatively trivial quantities of dietary vitamin D, may develop mild to severe hypercalcemia. Examples include sunlight-induced (i.e., summertime) hypercalcemia in patients with sarcoidosis and hypercalcemic flares in patients with TB given dietary supplements with multivitamins after hospitalization. Hypercalcemia results from components of both intestinal calcium hyperabsorption and 1,25(OH)₂D-

induced bone resorption, with the former being the most important in most cases. Because of the hypercalcemia, PTH is suppressed, and serum phosphorus is elevated. The combination of hypercalcemia and hyperphosphatemia may lead to nephrocalcinosis and renal failure. The treatment is a low dietary calcium intake, a low vitamin D intake, limiting sun exposure, hydration and loop diuretics to accelerate calcium clearance, and, if the hypercalcemia is severe, glucocorticoids. Of course, treatment of the underlying granulomatous disorder is the most effective and prudent long-term therapy.

Endocrine Disorders Other than Hyperparathyroidism

In addition to HPT, four other endocrine disorders have been associated with the development of hypercalcemia. One of these disorders is *hyperthyroidism*. As many as 50% of people with hyperthyroidism have been described as having at least mild hypercalcemia. The hypercalcemia is only rarely greater than 11 mg/dL but may be as high as 13 mg/dL. The mechanism is believed to be an increase in osteoclast activation by thyroid hormone. A second disorder is *pheochromocytoma*. Some of these individuals are hypercalcemic as a result of primary HPT occurring as part of the MEN-II syndrome (discussed previously under “Primary and Tertiary Hyperparathyroidism”), but others have been reported to become hypercalcemic as a result of PTHrP secretion by their pheochromocytoma. Severe *hypoadrenalism* with hypotension, so-called Addisonian crisis, has been reported to lead to hypercalcemia that responds to volume replacement and glucocorticoids. The mechanism is not known. Finally, islet cell tumors that produce vasoactive intestinal polypeptide (VIP), called *VIPomas*, although rare, are regularly associated with hypercalcemia. *VIPomas* lead to the watery diarrhea, hypokalemia, achlorhydria (WDHA) syndrome, also referred to as pancreatic cholera.

Medications

Certain medications may cause hypercalcemia. These drugs include thiazide diuretics and lithium, which appear to increase renal tubular calcium reabsorption, and the phosphodiesterase inhibitors aminophylline and theophylline, for which the hypercalcemic mechanism is unknown. Both vitamins D and A and their more active congeners, such as 1,25(OH)₂D and *cis*-retinoic acid, respectively, may also cause hypercalcemia. Vitamin D causes hypercalcemia primarily by stimulating intestinal calcium absorption but can also stimulate osteoclastic bone resorption. Vitamin A stimulates bone resorption. The antiviral agent, foscarnet, has been reported to cause hypercalcemia by unknown mechanisms. Finally, estrogens and tamoxifen have been described to cause hypercalcemia in the setting of breast cancer with extensive skeletal metastases, the so-called estrogen flare.

Milk-Alkali Syndrome

The normal intake of calcium is in the range of 600 to 1200 mg per day for most people, and, as reviewed in Chapter 73, absorption of calcium from the diet is tightly controlled. However, ingestion of very large quantities of calcium may overwhelm this system and lead to hypercalcemia. This condition was originally described in the 1940s in patients ingesting enormous quantities of milk, cream, and antacids but is still encountered today with some regularity in patients

ingesting large quantities of calcium carbonate or other calcium-containing antacids for peptic disease. In general, for hypercalcemia to occur, calcium intake must exceed 4 g per day and is often in the 10- to 20-g per day range. Severe hypercalcemia is common and may lead to renal failure.

Immobilization

Beginning with the polio epidemic in the 1950s, continuing with space missions in the 1970s, and now most commonly observed in the setting of quadriplegia in young adults or children, immobilization hypercalcemia is common and often severe. Development of the syndrome requires two conditions: essentially *complete immobilization* or weightlessness for a period of at least weeks and occurring on a *background of high bone turnover*, as occurs in young adults or children, mild primary or secondary HPT, Paget disease, and malignant skeletal disease such as breast cancer with bone metastases or multiple myeloma. The basis for the syndrome is that immobilization or weightlessness activates osteoclastic bone resorption and at the same time inhibits osteoblastic activity, producing a severe uncoupling of bone resorption from formation, with rapid and enormous net losses of calcium from the skeleton into the ECF. Left untreated, the condition results in severe demineralization. The syndrome is associated with hypercalciuria as well, and this, together with chronic urinary catheterization, leads to urinary tract infection and severe calcium nephrolithiasis. The most effective treatment for the hypercalcemia is active weight bearing. Hydration and antiresorptive drugs such as the bisphosphonates may be used.

Chronic and Acute Renal Failure

Chronic and acute renal failure has been associated with hypercalcemia. The more common initial abnormality is hypocalcemia induced by a reduction in kidney-derived $1,25(\text{OH})_2\text{D}$ and an increase in serum phosphate as a result of diminished glomerular filtration. However, hypercalcemia may occur in patients with chronic renal failure as a result of calcium antacid use or as a result of $1,25(\text{OH})_2\text{D}$ or paracalcitol treatment to prevent renal osteodystrophy. Moreover, immobilization in the setting of chronic renal failure—for example, for peritonitis in the setting of peritoneal dialysis—may also lead to hypercalcemia. In the setting of acute renal failure resulting from rhabdomyolysis (crush injury), transient rebound hypercalcemia has been described as renal failure resolves and serum phosphate concentrations decline.

Parenteral Nutrition

Enteric and parenteral nutrition have both been associated with hypercalcemia. Large doses of oral calcium provided in hypercaloric enteric feeding regimens, particularly in the setting of reduced renal function, may lead to what is in essence a form of the milk-alkali syndrome. More mysterious is the well-described hypercalcemic syndrome occurring in patients treated with total parenteral nutrition (TPN). These patients typically have short bowel syndrome and are on long-term TPN. In some patients, the hypercalcemia can be traced to large amounts of calcium, vitamin D, or aluminum in the TPN solution. In other patients, however, these factors do not appear to be operative, and the pathophysiologic mechanisms remain unexplained.

Hyperproteinemia

About 50% of circulating calcium is bound to serum albumin and other proteins. Thus, increases in serum proteins will naturally lead to an increase in total, but not ionized, serum calcium concentrations. This increase is commonly observed in settings of volume depletion and dehydration and may account for the hypercalcemia observed in patients with Addisonian crisis described previously under “Hypercalcemia.” A more unusual form of this syndrome occurs in patients with myeloma or Waldenström macroglobulinemia, whose abnormal immunoglobulin specifically binds calcium and leads to an increase in total, but not ionized, serum calcium. This scenario, of course, is not the norm in patients with myeloma and hypercalcemia, who have increases in the ionized component of serum calcium. Patients with this syndrome do not display features typical of authentic hypercalcemia: reduced mental status, prolonged QTc interval on electrocardiogram, and hypercalciuria.

End-Stage Liver Disease

Patients with end-stage liver disease awaiting transplantation have been described as being hypercalcemic. The pathophysiologic mechanism underlying this syndrome is not known.

Manganese Intoxication

Manganese intoxication in individuals who drink water from contaminated wells has been described. Again, the pathophysiologic mechanism is not understood.

TREATMENT OF HYPERCALCEMIA

Therapy for hypercalcemia is optimally directed at reversing the underlying pathophysiologic abnormality. Although this principle may seem obvious, it is often overlooked in practice. Thus, reversal of hypercalcemia associated with cancer is most effectively treated over the long term by antineoplastic therapy; correction of hypercalcemia in sarcoidosis is best treated using effective antisarcoid therapy. Seen from this perspective, all other therapies are temporizing, intended to lower calcium while waiting for a response to more definitive therapy. In general, disorders associated with increased intestinal calcium absorption (e.g., sarcoid, milk-alkali syndrome, $1,25[\text{OH}]_2\text{D}$ -secreting lymphomas) are best treated by consuming a low-calcium diet and avoiding vitamin D. Hypercalcemia in the setting of volume depletion and diminished renal function is best treated by expanding the ECF volume and GFR with saline and encouraging diuresis with loop diuretics. Medication-induced hypercalcemia, such as thiazide-induced hypercalcemia, is best treated by discontinuation of the offending medication. Disorders associated with increased osteoclastic bone resorption, such as MAHC and immobilization hypercalcemia, are best treated using inhibitors of bone resorption such as the bisphosphonates, pamidronate or zoledronate. Disorders with multiple abnormalities will require combinations of these measures. Resection of parathyroid tissue in patients with parathyroid disease is effective. A point worth emphasizing is that not everyone requires treatment for hypercalcemia: Patients with mild HPT with borderline serum

calcium values and without other complications may be observed. Patients with end-stage refractory cancer with severe hypercalcemia may arguably be best served by withholding therapy. Familial hypocalciuric hypercalcemia is best left untreated.

Hypocalcemia

SYMPTOMS AND SIGNS

As described in Chapter 73, hypocalcemia leads to a reduction in the potential difference across cell membranes, which leads to hyperexcitability, particularly of cells of the neuromuscular class. Hence neuromuscular cells spontaneously fire and produce spontaneous seizures, paresthesias, and skeletal muscle contractions (referred to as *carpal spasm*, *pedal spasm*, or *tetany*). Two physical signs are observed on examination: Trousseau sign, which is spontaneous contraction of the forearm muscles in response to application of a blood pressure cuff around the upper arm and inflation to above systolic pressure, and Chvostek sign, which is twitching of the facial muscles with gentle tapping of the facial nerve as it exits the parotid gland. An electrocardiographic sign is a prolonged QTc interval. Rarely, severe hypocalcemia has been reported to cause hypocontractility of the myocardium and congestive heart failure because calcium is required for muscle contraction. Finally, prolonged hypoparathyroidism may be associated with basal ganglia calcification, which is asymptomatic but impressive on computed tomography scans and plain x-ray films of the skull.

PATHOPHYSIOLOGY

Hypocalcemia may result from five general mechanisms: (1) a reduction in serum binding proteins (albumin), (2) an increase in serum phosphate with a resultant increase in the calcium-phosphate solubility product, (3) an increase in renal calcium excretion, (4) a reduction in intestinal calcium absorption, or (5) a loss of calcium from the ECF into the skeleton. The reader is referred to Chapter 73 for more details regarding normal calcium homeostasis. In practice, several of these factors are operative in several disorders. For example, in hypoparathyroidism, a reduction in intestinal calcium absorption combines with an inability to reabsorb calcium from the distal tubule to cause hypocalcemia; or, in breast cancer with extensive osteoblastic metastases, increases in osteoblast activity remove calcium from the ECF, and anorexia leads to a reduction in intestinal calcium intake. From a diagnostic perspective, understanding pathophysiologic mechanisms is important because the clinical setting and routine biochemistry analyses will help include or exclude certain diagnoses. From a therapeutic standpoint, this knowledge is important as well because effective therapy requires that the underlying disorder be appropriately managed. Thus, giving oral vitamin D supplements to a patient with sprue may not be effective unless the underlying malabsorption is treated; parenteral vitamin D may be more effective.

DIFFERENTIAL DIAGNOSIS

The disorders that may lead to hypocalcemia are summarized here and in Table 74-2.

Table 74-2 Differential Diagnosis of Hypocalcemia

Hypoparathyroidism

Surgical
Idiopathic and autoimmune
Infiltrative diseases
Wilson disease (copper)
Hemochromatosis
Sarcoidosis
Metastatic (breast) cancer
Congenital
Isolated, sporadic
DiGeorge syndrome
Infant of mother with hyperparathyroidism
Hereditary
X-linked
Parathyroid gland calcium receptor–activating mutations
PTH signal peptide mutation
GCMB mutation

Pseudohypoparathyroidism

Type Ia—multiple hormone resistance, Albright hereditary osteodystrophy
Type Ib—PTH resistance without other abnormalities
Type Ic—specific PTH resistance, resulting from defect in catalytic subunit of PTH-receptor complex
Type II—specific PTH resistance, postreceptor–adenylyl cyclase defect, undefined

Vitamin D Disorders

Absent ultraviolet exposure
Vitamin D deficiency
Fat malabsorption
Vitamin D–dependent rickets, renal 1- α -hydroxylase deficiency, 1,25-dihydroxyvitamin D–receptor defects
Chronic renal failure
Hepatic failure

Hypoalbuminemia

Sepsis

Hypermagnesemia and Hypomagnesemia

Rapid Bone Formation

Hungry bone syndrome after parathyroidectomy or thyroidectomy
Osteoblastic metastases
Vitamin D therapy of osteomalacia, rickets

Hyperphosphatemia

Crush injury, rhabdomyolysis
Renal failure
Tumor lysis
Excessive PO₄ administration (PO, IV, PR)

Medications

Mithramycin, plicamycin
Bisphosphonates
Calcitonin
Fluoride
EDTA
Citrate
Intravenous contrast
Foscarnet

Pancreatitis

Hypoalbuminemia
Hypomagnesemia
Calcium soap formation

EDTA, ethylenediaminetetraacetic acid; IV, intravenous; PO, by mouth; PO₄, phosphate; PR, per rectum; PTH, parathyroid hormone.

Hypoparathyroidism

Hypoparathyroidism causes hypocalcemia as a result of a decrease in intestinal calcium absorption (a result of low circulating $1,25[\text{OH}]_2\text{D}$ concentrations, which are a result of low circulating PTH), combined with reduced renal calcium reabsorption in the distal tubule (as a result of decreased circulating PTH). Hypoparathyroidism may be idiopathic or autoimmune, occurring either in isolation or as part of the polyglandular failure syndrome in association with Graves hyperthyroidism, Hashimoto thyroiditis, Addison disease, type 1 diabetes, vitiligo, mucocutaneous candidiasis, and other autoimmune disorders. Hypoparathyroidism may also be commonly encountered as surgical hypoparathyroidism in patients who have undergone thyroid, parathyroid, or laryngeal surgery for multinodular goiter or Graves disease, for parathyroid hyperplasia, or for carcinoma of the larynx or esophagus. Surgical and autoimmune hypoparathyroidism together account for most patients with hypoparathyroidism. Less common causes include congenital hypoparathyroidism caused by DiGeorge syndrome, isolated parathyroid failure, or activating mutations in the calcium receptor gene (autosomal dominant hypoparathyroidism), the PTH gene, or the glial cell missing-B (*GCMB*) gene. Finally, rarely, tissue infiltrative diseases such as breast cancer, Wilson disease (copper deposition), hemochromatosis (iron deposition), or sarcoidosis may destroy or replace normal parathyroid tissue.

The diagnosis is made by finding a low serum ionized calcium level in a patient with an inappropriately reduced serum PTH concentration. In general, the phosphorus concentration is high normal or frankly elevated, and plasma $1,25(\text{OH})_2\text{D}$ concentrations are reduced (see Chapter 73 for the underlying physiologic factors).

One potential treatment for hypoparathyroidism is subcutaneous injection of PTH. Although this treatment has been accomplished successfully in clinical trials, PTH is not approved for this indication. Thus, treatment is normally directed at increasing intestinal calcium absorption through the use of large doses of calcium (about 2000 mg per day) and the active form of vitamin D, $1,25(\text{OH})_2\text{D}$, in normal replacement amounts (0.25 to 1.0 μg per day). The goal is to induce sufficient intestinal calcium hyperabsorption to overwhelm the ability of the kidney to excrete it. Although this method is the only tenable therapy, it carries the risk for inducing significant hypercalciuria and therefore nephrocalcinosis and nephrolithiasis. Accordingly, 24-hour urinary calcium must be measured regularly, and hypercalciuria minimized, which generally means maintaining the serum calcium in the low-normal range, about 8.5 to 9.0 mg/dL. In some instances, calcium and vitamin D alone may be ineffective or may induce severe hypercalciuria. In such cases, addition of a thiazide diuretic such as hydrochlorothiazide, which stimulates renal calcium reabsorption, may be effective in preventing hypercalciuria and at the same time raising the serum calcium.

Pseudohypoparathyroidism

Pseudohypoparathyroidism refers to a group of disorders that have in common resistance to the actions of PTH. In most cases, the resistance is due to different types of

inactivating mutations in the signal-transducing protein Gs- α . Patients may be resistant only to PTH, or they may be resistant to multiple peptide hormones, including thyroid-stimulating hormone (with hypothyroidism) and follicle-stimulating hormone and luteinizing hormone (with hypogonadism). The most common form of the syndrome, type Ia, is associated with multiple hormone resistance and a phenotype referred to as *Albright hereditary osteodystrophy*, which includes short stature, shortened fourth and fifth metacarpals and metatarsals, obesity, mental retardation, subcutaneous calcifications, and café-au-lait spots. Because the disorder is hereditary, a clear family history of this phenotype is often present, as well as a family history of hypocalcemia or seizures.

Biochemically, these patients resemble those with hypoparathyroidism; they are hypocalcemic and have hyperphosphatemia. The diagnosis is made by the finding of an elevated circulating PTH in a patient with hypocalcemia and hyperphosphatemia in whom other causes of hypocalcemia and secondary hypoparathyroidism have been excluded. The diagnosis can be confirmed by infusing PTH and failing to observe the normal phosphaturic, cyclic adenosine monophosphate, and calcemic responses.

The treatment is similar to that of hypoparathyroidism.

Vitamin D Disorders

Active vitamin D, $1,25(\text{OH})_2\text{D}$, is required to absorb calcium from the intestine. Activation of vitamin D requires adequate exposure to vitamin D from diet or by sunlight exposure, an intact intestine through which to absorb calcium and vitamin D, an intact liver with which to convert vitamin D to 25-hydroxyvitamin D, and an intact kidney to convert 25-hydroxyvitamin D to $1,25(\text{OH})_2\text{D}$ (see Chapter 73). Therefore, developing hypocalcemia and osteomalacia or rickets (see Chapter 75) in settings in which one or more of these steps is disrupted is common. Specifically, malabsorption syndromes, such as short bowel syndrome and celiac sprue, lead to hypocalcemia as a result of calcium and vitamin D malabsorption. Chronic liver diseases, particularly primary biliary cirrhosis, lead to hypocalcemia and osteomalacia. Chronic renal insufficiency leads to failure to produce $1,25(\text{OH})_2\text{D}$, with reductions in serum calcium and inefficient absorption of intestinal calcium. Normal diets contain little in the way of vitamin D. Although Western diets are supplemented with vitamin D in milk and multivitamins, diets composed of no milk, human milk, or unsupplemented bovine milk are vitamin D deficient. Relatively trivial exposure to sunlight can provide ample vitamin D and replace dietary needs for vitamin D. However, in settings in which both sun exposure and dietary intake of vitamin D are poor (cloudy climates, excessive clothing or body covering, prolonged nursing in infants, and the standard *tea and toast* diet of older adults), vitamin D deficiency is the rule rather than the exception.

Certain genetic syndromes occur in which the enzyme vitamin D 1- α -hydroxylase is mutated (vitamin D-dependent rickets type I) or in which the vitamin D receptor is mutated (vitamin D-dependent rickets type II). Affected individuals have severe hypocalcemia, alopecia, severe rickets, and dental abnormalities, and are easy to recognize and confirm if the diagnosis is considered.

Finally, long-term, high-dose treatment with anticonvulsants such as phenytoin or phenobarbital or their derivatives may lead to hypocalcemia and osteomalacia.

Hypoalbuminemia

Reductions in serum albumin, as occur in burn patients, the nephrotic syndrome, malnutrition, and cirrhosis, lead to reductions in serum total calcium without a reduction in the ionized serum calcium. Of course, these disorders may also be associated with other conditions that lead to bona fide reductions in the ionized serum calcium as well. Several formulas exist for correcting total calcium for albumin, but none is entirely accurate. Therefore, measuring ionized calcium directly is important if the authentic ionized serum calcium concentration level is needed.

Sepsis

Gram-positive and gram-negative sepsis has been associated with hypocalcemia that is generally mild. The mechanisms are poorly understood. Hypocalcemia occurring in the setting of sepsis appears to confer a particularly adverse prognosis.

Hypermagnesemia

Magnesium is a divalent cation, as is calcium, and in very high concentrations may therefore mimic the actions of calcium to suppress PTH and, in so doing, lead to a functional type of hypoparathyroidism and hypocalcemia. In practice, this condition is uncommon and is seen typically in patients with severe hypermagnesemia (serum magnesium concentrations in the 10-mg/dL range) caused by renal failure accompanied by magnesium antacid ingestion or following the treatment of eclampsia with large doses of intravenous magnesium.

Hypomagnesemia

Hypomagnesemia is one of the most common causes of hypocalcemia. It is encountered often in patients with alcoholism, malnutrition, cisplatin therapy for cancer, and intestinal malabsorption syndromes. Hypomagnesemia both inhibits PTH secretion (a magnesium adenosine triphosphatase is required for PTH secretion) and prevents the calcemic actions of PTH on the kidney and skeleton. Thus, magnesium deficiency causes a functional form of hypoparathyroidism as well as resistance to PTH. The treatment is straightforward: magnesium replacement (see “Hypomagnesemia,” later). This treatment corrects the syndrome in minutes to hours. The clinical reality, however, is that this common syndrome is often overlooked and mistreated with intravenous calcium or vitamin D, which are unnecessary and, unless the hypomagnesemia is corrected, ineffective.

Rapid Bone Formation

Increased rates of bone mineralization, out of proportion to the rate of bone resorption, will lead to net calcium entry into the skeleton and, if these rates are large, hypocalcemia. This state occurs in several clinical settings. One condition is the *hungry bone* syndrome that may follow parathyroidectomy. In this syndrome, a patient, usually with severe primary or secondary HPT, undergoes parathyroidectomy. Preoperatively, the rates of bone turnover, both resorption and formation, are very high but are approximately coupled.

Postoperatively, the rate of osteoclastic bone resorption abruptly declines with the decline in PTH, but the elevated rate of mineralization of previously formed osteoid remains the same as it was preoperatively for days to a week or more (see Chapter 73 for mechanisms). Because of this acute postoperative imbalance, the skeleton becomes a *sink* for calcium, and hypocalcemia ensues. Another example of this phenomenon may occur in patients with vitamin D deficiency who have severe osteomalacia or rickets and large amounts of unmineralized osteoid. When these patients are treated with vitamin D, rapid mineralization of unmineralized osteoid occurs, and, again, the skeleton becomes a *sink* for calcium, and hypocalcemia ensues. A final example of rapid bone formation leading to hypocalcemia occurs in the setting of extensive osteoblastic bone metastases, as may occur in prostate cancer or breast cancer and occasionally other types of malignancy.

Hyperphosphatemia

Disorders that lead to hyperphosphatemia (see the later section on “Hyperphosphatemia”) may cause hypocalcemia as a result of exceeding the calcium-phosphate solubility product in serum. Examples of disorders that may cause the kind of severe hyperphosphatemia required include rhabdomyolysis (from crush injuries), renal failure, and the tumor lysis syndrome. Severe hyperphosphatemia may also be seen following the ingestion of large amounts of phosphate-containing purgatives in preparation for colonoscopy, by the inadvertent perforation of the rectum during the administration of phosphate enemas, and with overzealous administration of intravenous phosphate. In all these examples, the onset of hyperphosphatemia is relatively abrupt, and the hypocalcemia is immediate and severe. Commonly, the first sign of this sequence of events is a seizure. The treatment involves reducing the serum phosphorus by whatever means necessary. Giving intravenous calcium should be avoided because it will simply be precipitated into soft tissues.

Medications

Certain medications may cause hypocalcemia, including those used to treat hypercalcemia, such as mithramycin (plicamycin), the bisphosphonates (e.g., pamidronate, zoledronate), and calcitonin. Hypocalcemia induced by these agents is rare but has been reported. Fluoride intoxication from ingestion of sodium fluoride, inhalation of fluoride-containing anesthetic gases, or drinking of fluoride-contaminated water may cause hypocalcemia. Ethylenediaminetetraacetic acid is a calcium chelator that causes hypocalcemia if infused intravenously. Citrate, as is used in citrated blood for transfusion, is also a calcium chelator and may cause hypocalcemia in the setting of large-volume transfusions. Radiographic intravenous contrast agents may also cause hypocalcemia, as may the antiviral drug foscarnet.

Pancreatitis

Pancreatitis commonly causes hypocalcemia. The classic mechanism is the formation of calcium-free fatty acid soaps, according to the following scenario. Pancreatitis occurs and releases lipase into the retroperitoneum and peritoneum, which leads to the autodigestion of retroperitoneal and omental fat. This action releases free fatty acids such as

palmitate, linoleate, and stearate from triglyceride fat stores, and these negatively charged ions tightly bind (chelate) calcium in ECF. This binding leads to the formation of insoluble calcium-free fatty acid salts in the retroperitoneum and rapidly depletes the extracellular calcium, causing hypocalcemia. The hypocalcemia is reversible by calcium infusion and will self-terminate when the pancreatitis improves. Hypocalcemia is a poor prognostic sign among patients with pancreatitis. An important point to remember is that other causes of hypocalcemia occur in patients with pancreatitis, including hypoalbuminemia, hypomagnesemia, and vitamin D deficiency, and these causes should be specifically excluded.

Hyperphosphatemia

SYMPTOMS AND SIGNS

Hyperphosphatemia produces no specific signs per se. It is usually identified incidentally on routine chemical screens or as a result of the induction of hypocalcemia, as described in the preceding section.

PATHOPHYSIOLOGY

Hyperphosphatemia develops as a result of two general mechanisms. One mechanism is a large load of phosphate into the ECF, delivered through the GI tract, intravenous medications, or endogenous sources such as muscle or tumor. The second mechanism is the inability to excrete phosphate, as occurs in renal failure (acute or chronic). As noted in Chapter 73, essentially all natural foods contain phosphate, and therefore almost any diet will contain substantial quantities of phosphate. Normally, this phosphate is easily cleared by the healthy kidney, but this ability is lost as the GFR declines below about 20 to 30 mg/dL.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of hyperphosphatemia is listed here and in Table 74-3.

Table 74-3 Causes of Hyperphosphatemia

Artificial

Hemolysis

Increased Gastrointestinal Intake

Rectal enemas

Oral Phospho-Soda purgatives

Gastrointestinal bleeding

Intravenous Phosphate Loads

K-Phos

Blood transfusions

Endogenous Phosphate Loads

Tumor lysis syndrome

Rhabdomyolysis (crush injury)

Hemolysis

Reduced Renal Clearance

Chronic or acute renal failure

Hypoparathyroidism

Acromegaly

Tumoral calcinosis

Artificial

Hyperphosphatemia may occur artifactually as a result of hemolysis in blood collection tubes. Erythrocytes, as with all cells, are rich in phosphate, and, if they are allowed to remain for prolonged periods at room temperature or if blood is obtained too rapidly or through too narrow a needle, they will lyse and release their contents into serum, which will then be reported as being hyperphosphatemic. One clue is that the same phenomenon occurs with potassium. Thus, the occurrence of unexplained hyperkalemia and hyperphosphatemia should trigger the collection of a fresh sample and immediate repeat determination of serum phosphate.

Increased Gastrointestinal Intake

Hyperphosphatemia may occur in patients receiving large oral phosphate loads. In a recent literature review, most cases of phosphate-induced hypocalcemia were caused by the administration of phosphate-containing purgatives as preparation for colonoscopy. Another underappreciated cause of this phenomenon is the inadvertent perforation of the rectum during the administration of a rectal Phospho-Soda enema, with delivery of large amounts of phosphate directly into the peritoneal cavity, from which it is rapidly absorbed. Finally, upper GI tract bleeding from ulcers of gastritis provides a large GI phosphate load and may be associated with hyperphosphatemia.

Intravenous Phosphate Loads

Large amounts of phosphate may be administered as part of a means to replete potassium using potassium phosphate preparations. What appear to be trivial quantities of potassium preparation (e.g., 20 to 40 mEq of K-Phos) actually contain large amounts of phosphate and may lead to severe hyperphosphatemia and hypocalcemia (see Chapter 73). A second vehicle for delivering phosphate intravenously is transfusions of red blood cells, which ultimately hemolyze and release their copious phosphate stores.

Endogenous Phosphate Loads

Hyperphosphatemia may result from the destruction of large amounts of tissue. This destruction is encountered in three situations. Tumor lysis syndrome is one such situation, typified by a large Burkitt lymphoma responding promptly to chemotherapy with massive cell death. A second phenomenon is acute rhabdomyolysis resulting from a crush injury or drug overdose, which leads to massive release of phosphate from within skeletal muscle cells. A third example is severe hemolysis resulting from autoimmune causes or blood group mismatch. In each of these cases, a large phosphate load is delivered into the ECF, and, in addition, other nephrotoxic molecules such as hemoglobin, myoglobin, and uric acid are released, which reduces the ability of the kidney to clear the large phosphate load. This combination is potentially lethal, resulting in renal failure, severe hypocalcemia, seizures, and sometimes death.

Reduced Renal Clearance

As noted in Chapter 73, renal clearance of phosphate is the main mechanism for maintaining phosphate homeostasis. Thus, the fact that disorders of the kidney lead to hyperphosphatemia is not surprising. These disorders include

both acute and chronic forms of renal failure. In addition, functional renal abnormalities occur that may lead to hyperphosphatemia. First, because PTH prevents phosphate reabsorption in the proximal nephron, hypoparathyroidism is typically associated with high-normal to frankly elevated serum phosphorus values. Second, acromegaly is associated with hyperphosphatemia. The mechanisms for this association are not well understood, but it appears to be renal in origin. A condition called *tumoral calcinosis*, in which the ability of the kidney to clear phosphate is specifically defective, leads to chronic hyperphosphatemia and accumulation of calcium-phosphate salts around large joints of the appendicular skeleton. Recently, this syndrome has been shown to be due to inactivating mutations in the *FGF-23* or *GALNT3* genes. Finally, children, particularly adolescents, have higher serum phosphate concentrations than adults.

Hypophosphatemia

SYMPTOMS AND SIGNS

As noted in Chapter 73, phosphate participates in a vast array of key cellular processes, from DNA synthesis and replication, to energy generation and use, to oxygen uptake and delivery by erythrocytes, to maintaining the redox state of every cell in the body. The signs of phosphate depletion are therefore nonspecific, diffuse, and often life threatening. These signs may include respirator dependence, congestive heart failure, coma, hypotension, and generalized weakness and malaise. Because the signs and symptoms are so nonspecific, they are frequently attributed to other causes and are left untreated. They typically occur in intensive care unit (ICU) settings, in which oral nutrition is nonexistent and intravenous phosphate repletion inadequate and in which diuretics and saline infusion accelerate renal phosphate losses. Appropriate therapy can produce startling results, with patients suddenly returning from being moribund to being ambulatory, extubated, and conversant.

Chronic hypophosphatemia leads to defects in skeletal mineralization, a phenomenon called *rickets* in children or *osteomalacia* in adults. These syndromes produce weakness, bone pain, bowing of the long bones, and fractures or pseudofractures (see Chapter 75).

DIFFERENTIAL DIAGNOSIS

Disorders can be divided into hypophosphatemia resulting from inadequate intake, from excessive renal losses, from excessive skeletal uptake, or from shifts of phosphate from the ECF into cells (Table 74-4). These abnormalities are discussed individually later. From a diagnostic standpoint, measuring the TmP, as described in Chapter 73, is important because it provides rapid determination of which class of hypophosphatemia the patient is confronting.

Inadequate Phosphate Intake

Disorders that involve inadequate phosphate intake are associated with a high TmP. Because essentially all foods are rich in phosphate, becoming phosphate depleted based on inadequate dietary intake is difficult. However, in settings of severe caloric deprivation, inadequacies can occur. Examples include anorexia nervosa, prisoner-of-war camps, prolonged

Table 74-4 Causes of Hypophosphatemia

Inadequate PO₄ Intake

Starvation
Malabsorption
PO₄-binding antacid use
Alcoholism

Renal PO₄ Losses

Primary, secondary, or tertiary hyperparathyroidism
Humoral hypercalcemia of malignancy (parathyroid hormone-related protein)
Diuretics, calcitonin
X-linked hypophosphatemic rickets
Autosomal dominant hypophosphatemic rickets
Oncogenic osteomalacia
Fanconi syndrome
Alcoholism

Excessive Skeletal Mineralization

Hungry bone syndrome after parathyroidectomy
Osteoblastic metastases
Healing osteomalacia, rickets

PO₄ Shifts into Extracellular Fluid

Recovery from metabolic acidosis
Respiratory alkalosis
Starvation refeeding, intravenous glucose

PO₄, phosphate.

ICU care, malabsorption syndromes, and chronic alcoholism. In the first three disorders, caloric intake is scant, and therefore little phosphate is consumed. In alcoholism, caloric intake may be high, but alcohol is devoid of phosphate. Finally, the use of phosphate-binding antacids such as aluminum hydroxide gels may lead to severe phosphate deficiency, hypophosphatemia, and osteomalacia.

Excessive Renal Phosphate Losses

Disorders involving excessive losses are associated with a low TmP. PTH is phosphaturic, and therefore all types of HPT are associated with hypophosphatemia, as long as renal function is normal. This state is widely appreciated for primary HPT but is less well appreciated for secondary HPT, particularly occurring in the setting of vitamin D and calcium malabsorption. Indeed, a low serum phosphate may be the first and only noticeable clue to severe vitamin D deficiency. In my experience, this fact has led to the diagnosis of celiac sprue in unsuspected cases on many occasions.

PTH-related protein (PTHrP, see earlier section on “Malignancy-Associated Hypercalcemia”) is also phosphaturic, as is PTH, and patients with humoral hypercalcemia of malignancy are commonly hypophosphatemic for this reason, as long as their renal function is intact. They frequently become more hypophosphatemic during hospitalization as a result of saline infusion, diuretics, and inadequate oral or intravenous phosphate nutrition.

Medications such as calcitonin, as well as thiazide and loop diuretics, are potent phosphaturic agents, and their use without phosphate replacement therapy will lead to hypophosphatemia. Ethanol is also in this category.

Certain genetic disorders may lead to severe renal phosphate wasting (see Chapter 75). These disorders include X-linked hypophosphatemia (XLH), also referred to as *vitamin D-resistant rickets*, and autosomal dominant hypophosphatemic rickets (ADHR). In ADHR, the disorder

appears to be due to the overproduction of fibroblast growth factor-23 (FGF-23), one of the long-sought *phosphatonins* (see Chapter 73), and, in XLH, the cause is an inactivating mutation in the *PHEX* gene, which encodes an extracellular protease. Another renal phosphate-wasting syndrome is oncogenic osteomalacia, also referred to as *tumor-induced osteomalacia*. Now appreciated is that this disorder, as in ADHR, is due to overproduction by small, often occult, mesenchymal tumors such as hemangiopericytomas of FGF-23, secreted frizzled-related protein 4 (sFRP4), or matrix extracellular phosphoglycoprotein (MEPE) (see Chapter 73).

Acquired or inherited diffuse renal proximal tubular disorders, such as Fanconi syndrome, may lead to hypophosphatemia as a result of renal phosphate wasting.

Excessive Skeletal Mineralization

In metabolic situations under which the rate of bone formation, or more specifically bone mineralization, is increased with respect to the rate of bone resorption by osteoclasts, large amounts of phosphate may enter the skeleton, leading to hypophosphatemia. One example is the hungry bone syndrome that occurs following parathyroidectomy, as described in the previous section on “Hypocalcemia.” Other examples are osteoblastic metastases and the treatment of vitamin D–deficient rickets of osteomalacia with vitamin D (see the previous section on “Hypocalcemia” for additional details). In each of these settings, phosphate enters the mineralizing phase of osteoid as calcium phosphate (hydroxyapatite) and does so at rates such that hypophosphatemia ensues.

Phosphate Shifts into Extracellular Fluid

Phosphate can be shifted from serum into the intracellular compartment by a rise in ECF pH from low to normal or from normal to high. Thus, recovery from a metabolic acidosis, such as diabetic ketoacidosis, and the development of a respiratory alkalosis both lead to hypophosphatemia. One of the most stunning examples of this phenomenon is the shift of phosphate into cells following the administration of oral carbohydrate or parenteral glucose to victims of starvation or anorexia nervosa. Insulin increases the rate of glucose uptake into cells and its subsequent phosphorylation to glucose 6-phosphate. A person with no phosphate reserves so treated will abruptly become more severely hypophosphatemic and may die suddenly of respiratory or circulatory failure. Hence, refeeding of starvation victims should be accomplished slowly and with attention to phosphate repletion.

TREATMENT

Phosphorus replacement is best accomplished through the oral route and is generally given in divided doses 2 to 4 times per day in the range of 2000 to 4000 g per day. Doses above 1000 to 2000 mg per day will often cause diarrhea initially (phosphate is used as a purgative), but, with gradual increments, larger doses may be well tolerated. Intravenous phosphate should only be given with a clear understanding of the quantities involved (see Chapter 73) and in patients in whom oral administration is not an option. Frequent monitoring of serum phosphorus, calcium, and creatinine are

Table 74-5 Causes of Hypermagnesemia and Hypomagnesemia

Hypokalemia
Hypercalcemia, hypercalciuria
Proximal tubular diseases
Genetic defects

required. Doses up to 500 to 800 mg per day intravenously may be required.

Hypermagnesemia

SYMPTOMS AND SIGNS

Clinically significant hypermagnesemia is uncommon. The symptoms are drowsiness, and the signs are hyporeflexia and eventually neuromuscular, respiratory, and cardiovascular collapse. It may also lead to hypocalcemia (see the previous section on “Hypocalcemia”). Hypermagnesemia is seen in essentially two settings: (1) severe renal failure accompanied by the administration of magnesium-containing antacids, and (2) following the intravenous administration of large doses of magnesium sulfate for eclampsia or preeclampsia.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hypermagnesemia is brief and is limited to the two disorders noted previously (Table 74-5). Mild hypermagnesemia is common in patients on dialysis, but severe hypermagnesemia is less common in renal failure and occurs in the settings of renal failure accompanied by parenteral or oral magnesium salt administration, such as the use of magnesium-containing antacids or phosphate binders. Hypermagnesemia still occurs commonly, but in a controlled fashion, in the treatment of eclampsia, wherein obstetricians administer large doses of intravenous magnesium sulfate, while observing the blood pressure and reflexes, to pregnant women with eclampsia. Indeed, a therapeutic endpoint is when the reflexes diminish or disappear.

Hypomagnesemia

SYMPTOMS AND SIGNS

Hypomagnesemia is common but, as with hypophosphatemia, is often overlooked or ignored. Magnesium is essential

for a broad range of biologic processes, and thus hypomagnesemia may cause a broad array of systemic abnormalities (see Chapter 73 for details). Hypomagnesemia may cause hypocalcemia, seizures, and paresthesias independent of hypocalcemia and may cause a broad array of neuromuscular, cardiovascular, or respiratory symptoms. Commonly, hypomagnesemia occurs in an ICU setting in which magnesium administration and diet are inadequate, magnesium intravenous saline is administered along with diuretics, and serum magnesium is never measured. It responds rapidly and dramatically to parenteral magnesium replacement.

DIFFERENTIAL DIAGNOSIS

Differential diagnoses are listed here and in Table 74-5.

Inadequate Intake

Inadequate intake of magnesium is common among alcoholics and the generally undernourished. It may occur as part of an intestinal malabsorption syndrome and may result from continuous vomiting or nasogastric suctioning. Again, these situations are all common in ICU settings and are often overlooked.

Excessive Renal Losses

Excessive renal losses of magnesium are also common in clinical practice; thiazide and loop diuretics both cause renal

magnesium losses, and saline infusion has a similar effect. Magnesium is also lost by the kidney in response to aldosterone in primary hyperaldosteronism but more commonly in the secondary hyperaldosteronism associated with cirrhosis, volume depletion, congestive heart failure, and other common disorders. Osmotic diuresis, as occurs, for example, with poorly controlled diabetes mellitus, causes renal magnesium loss. Certain nephrotoxic drugs such as cisplatin, aminoglycoside antibiotics, and amphotericin induce proximal tubular injury and a severe form of renal magnesium wasting. Hypokalemia may lead to magnesium wasting by the kidney, and the reverse is true as well. Hypercalcemia and hypercalciuria lead to renal magnesium excretion as well, although the cellular basis for this excretion is not fully understood. Genetic or inherited causes of renal magnesium wasting such as mutations in the paracellin-1 gene also occur but are rare. Finally, many diseases that lead to proximal tubular injury, such as Fanconi syndrome and interstitial nephritis, may lead to magnesium wasting.

TREATMENT

Magnesium can be replaced intramuscularly or intravenously. In general, 24 to 48 mEq per 24 hours as magnesium sulfate is provided (see Chapter 73 for unit conversion). Oral magnesium salts such as magnesium oxide are also available, but administering large doses of magnesium orally is difficult because of the cathartic effects of magnesium.

Prospectus for the Future

As is the case with normal mineral and bone physiology, much remains to be learned regarding disorders of serum minerals. What are the genetic defects that underlie most parathyroid adenomas? What additional disease of the calcium-sensing receptor remains to be defined? Will novel calcium receptor agonists and antagonists be useful to better repress or stimulate PTH secretion on primary and secondary hyperparathyroidism and hypoparathyroidism? Can we develop a long-term regimen for treating hypoparathyroidism that does not result in hypercalciuria, kidney stones, nephrocalcinosis, and renal

failure over time? What will prove to be the most clinically effective and cost-effective agents in treating hypercalcemia of malignancy: the current round of intravenous bisphosphonates or monoclonal antibodies being developed against osteoclasts or their developmental pathways? Finally, what are the real *phosphatonins*, how do they work, and how can we best diagnose and treat rickets and osteomalacia resulting from renal phosphorus losses in disorders such as XLH? These questions and many more will occupy researchers in this area for decades to come.

Metabolic Bone Diseases

Shane O. LeBeau and Andrew F. Stewart

Metabolic bone disease is a term used to describe a host of skeletal diseases (Table 75-1). Most of these disorders are associated with low bone mass, but some, such as the osteosclerotic and osteopetrotic disorders, are not. In a sense, the term is misleading because many of these disorders are not *metabolic* at all; rather, they have genetic, viral, or other causes. Still, *metabolic bone disease* is useful as an umbrella term for all diffuse skeletal disorders. The term in its broadest sense also includes osteoporosis and Paget disease of bone, which are discussed in Chapters 76 and 77, respectively. The term also includes osteosclerotic disorders such as fluoride intoxication and genetic disorders that lead to osteopetrosis. It may also include focal skeletal diseases such as polyostotic fibrous dysplasia. In general, these are rare diseases. In this chapter, the focus is on the other common members of this family, as listed in Table 75-1, that might be encountered by an internist. To be sure, many additional rare “metabolic” bone diseases exist and, depending on the context, should be sought. Perhaps the most important message to be gleaned from this chapter, in this era of widespread access to bone density measurements using dual-energy x-ray absorptiometry (DXA), is the concept that low bone mass identified by DXA is not equivalent to a diagnosis of osteoporosis (see Chapter 76). This concept is not broadly appreciated among internists or even among radiologists who may perform DXA measurements. For example, DXA cannot determine whether a patient has low bone mass as a result of osteoporosis, as opposed to osteomalacia or multiple myeloma, yet commonly, DXA reports refer to *osteoporosis*. Every patient assigned a diagnosis of osteoporosis by DXA warrants full consideration for one of the other diagnoses in Table 75-1. Thus, the primary physician must determine whether a patient with a low bone mass revealed by DXA actually has *osteoporosis* or might actually have a distinct metabolic bone disease.

Differential Diagnosis

HYPERPARATHYROID BONE DISEASE (OSTEITIS FIBROSA CYSTICA)

Hyperparathyroid bone disease, or osteitis fibrosa cystica (OFC), results from chronically elevated parathyroid

hormone (PTH) concentrations. Elevated PTH concentrations, in turn, may result from primary hyperparathyroidism that is due, for example, to a parathyroid adenoma, carcinoma, or hyperplasia; to secondary hyperparathyroidism caused by malabsorption, vitamin D deficiency, or chronic renal failure; or to tertiary hyperparathyroidism in the setting of renal failure (see Chapter 74 for details). Patients with primary and tertiary hyperparathyroidism are characterized by hypercalcemia, whereas those with secondary hyperparathyroidism by definition are eucalcemic or hypocalcemic. PTH elevations are commonly severe.

Patients may complain of bone pain or diffuse aches and pains. The skeletal disease is characterized by *high turnover*, meaning coupled increases in both osteoclastic bone resorption and osteoblastic synthesis of osteoid and accelerated rates of bone mineralization (Fig. 75-1). Markers of bone

Figure 75-1 **A**, A normal bone-remodeling unit (see Chapter 73) provides an example of normal bone histologic mechanisms. At the bottom half of the figure is a normal mineralized trabecular bone surface (*dark blue*). The top half of the slide shows normal bone marrow. In between is the trabecular bone surface. On the bone surface on the extreme left is a binucleated osteoclast that has moved across the bone surface over the previous week or two, resorbing (removing) old bone. On the extreme right surface, the bone surface is covered by osteoid (*light blue*) secreted by the overlying osteoblasts. In between the osteoclast- and osteoblast-covered surfaces of the trabecular bone are a large number of flat, fibroblastoid cells referred to as *lining cells*. **B**, Bone histologic display in a patient with primary hyperparathyroidism showing the classic features of *osteitis fibrosa cystica*. Note that far more osteoid and far more osteoblasts and osteoclasts exist than in the normal example (**A**). Note also that three large microcysts are present that have been created by aggressive osteoclastic bone resorption. These microcysts account for the *cystica* component of osteitis fibrosa cystica. Finally, note that the marrow space, particularly within the microcysts, is filled with fibroblasts. These fibroblasts make up the *fibrosa* component of osteitis fibrosa cystica. **C**, Tetracycline labeling of a bone biopsy from a patient with hyperparathyroid bone disease. Note the bright-yellow parallel lines on the trabecular bone surface. These lines represent the two sets of tetracycline labeling, which occurred 14 days apart. From these sets, the mineralization rate can actually be described in microns per day, the so-called *mineral apposition rate*, and is increased dramatically in this example, as is typical of hyperparathyroid bone disease. Contrast with Figure 75-3B, in which no tetracycline labeling is present.

formation, such as alkaline phosphatase and osteocalcin, are increased, as are markers of bone resorption, such as *N*-telopeptide, hydroxyproline, and deoxypyridinolines. These changes are reflected on undecalcified bone biopsy, which reveals increases in the number and activity of osteoclasts and osteoblasts, increased quantities of unmineralized osteoid, accelerated rates of osteoid mineralization (determined using tetracycline labeling), microcysts in cortex and trabeculae (the *cystica* of OFC), and increased numbers of fibroblasts and marrow stroma (the *fibrosa* of OFC).

Bone density may be normal, as assessed using DXA, or it may be low. The pathognomonic radiologic signs of severe hyperparathyroid bone disease are a *salt-and-pepper* appearance of the calvarium, resorption of the tufts of the terminal phalanges and distal clavicles, subperiosteal resorption of the radial aspect of the cortex of the second phalanges, and

brown tumors (actually collections of osteoclasts that produce gross lytic lesions) of the pelvis and long bones (Fig. 75-2). All these radiologic signs disappear with parathyroidectomy, and bone mass, assessed by DXA, typically increases rapidly and markedly after parathyroidectomy.

The treatment of hyperparathyroid bone disease involves remediation of the chronically elevated PTH concentrations, either through parathyroidectomy in primary or tertiary hyperparathyroidism or through correction of the underlying cause of secondary hyperparathyroidism. If mild and if bone mass is normal, then no treatment may be required. Recently, reduction of serum calcium using the parathyroid calcium receptor mimetic drug cinacalcet has been added to this armamentarium. Cinacalcet is indicated in patients with chronic renal failure with secondary hyperparathyroidism and in patients with parathyroid carcinoma who have failed

Figure 75-2 Skeletal radiographic changes of hyperparathyroidism. **A**, A hand film from a patient with primary hyperparathyroidism. The *arrow* indicates a typical Brown tumor, or giant cell tumor, which is a collection of osteoclasts that lead to macrocystic changes in bone. The *arrowhead* indicates the irregular radial surface of a phalanx resulting from subperiosteal bone resorption, also typical of hyperparathyroidism. Both the Brown tumor and the subperiosteal resorption refill and disappear when the offending parathyroid tumor or hyperplasia is resected. **B**, A normal hand film for comparison. No Brown tumors are present, and the phalangeal periosteal surfaces are smooth. **C**, The classic *salt-and-pepper* appearance of the skull observed in hyperparathyroidism. The periosteal surfaces of the inner and outer cortices or tables of the calvarium are indistinct as a result of subperiosteal bone resorption. In addition, the lateral view of the calvarium is hazy and indistinct, with micropunctations. **D** and **E**, Expanded views of **A** and **C** for greater detail. (Courtesy of Drs. J. Towers and D. Armfield, University of Pittsburgh.)

surgical resection. Although cinacalcet is effective in lowering the serum calcium in primary hyperparathyroidism, evidence of its efficacy in correcting skeletal abnormalities is lacking, and it is not approved for this indication.

Moderate to severe hypocalcemia may postoperatively accompany parathyroidectomy. This condition is referred to as the *hungry bone syndrome* and results from the sudden removal of the stimulus to osteoclastic activity by removing excess PTH in the setting of increased osteoblastic activity with unmineralized, but continuously mineralizing, osteoid. The syndrome abates when the osteoid mineralizes. Of course, postoperative hypocalcemia may also be due to intentional or inadvertent surgical hypoparathyroidism.

Finally, hyperparathyroid bone disease may be *pure*, as in a patient with severe primary hyperparathyroidism caused by a parathyroid adenoma, or it may be *mixed*, occurring as a component of the bone disease in vitamin D-deficient osteomalacia, in immunosuppressant-induced

transplant bone disease, or in renal osteodystrophy (see later discussion).

OSTEOMALACIA AND RICKETS

Osteomalacia and rickets are common both in the United States and in the rest of the world and are commonly overlooked. Two definitions are important. First, osteomalacia and rickets are essentially the same disorders, with the difference being semantic; by definition, rickets occurs in children with open growth plates (epiphyses), whereas osteomalacia occurs in adults with closed epiphyses. Second, the fundamental abnormality in these disorders is an inability to mineralize (i.e., form hydroxylapatite crystals within) *osteoid seams* (see Chapter 73); these patients have osteoblasts and can synthesize osteoid, but they mineralize it inefficiently or not at all. This fundamental inability to mineralize osteoid results in the accumulation of the characteristic thick

Figure 75-3 **A**, Bone histologic display of osteomalacia or rickets. Note the abundant quantities of partially and chaotically mineralized osteoid (orange). These seams are the thick *osteoid seams* and represent osteoid that has been produced by osteoblasts but that cannot mineralize—the signature defect in osteomalacia and rickets. **B**, To confirm that the increase in osteoid seen in **A** is due to a defect in mineralization, tetracycline labeling can be performed. In this example, only very weak tetracycline labeling occurs. Compare with the rapid and aggressive mineralization observed in Figure 75-1C. This confirms the presence of a mineralization defect.

osteoid seams seen on bone biopsy (Fig. 75-3) and a reduction in the mineral component of bone so that it is deficient mechanically, which leads to bone pain, pseudofractures, fractures, bowing of the long bones, and other skeletal deformities (Fig. 75-4). In children (i.e., in rickets), the inability to mineralize the growth plate leads, in addition, to bulbous knobby deformities of the knees, ankles, and costochondral junctions (the *rachitic rosary*) and dental abnormalities. The characteristic radiologic signs of osteomalacia are Looser zones or Milkman pseudofractures. Rickets also shows gross defects in epiphyseal mineralization and compensatory increases in size of the joints and periarticular bone.

Understanding that the disorder is caused by a failure of mineralization, the underlying pathophysiologic mechanism can clearly be understood. These disorders result from an inability to form hydroxyapatite (calcium phosphate) crystals in osteoid, the nonmineralized phase of bone (see Chapter 73). This inability may result from hypophosphatemia (a common cause), a deficiency of calcium (an extremely rare cause), a deficiency of vitamin D (a common cause), or the presence of toxins that interfere with mineralization, such as aluminum, incompletely defined inhibitors of mineralization in uremic plasma, and long-term high-dose anticonvulsant use. Finally, because calcium salts are acid soluble, chronic metabolic acidoses (e.g., as occurs with the chronic bicarbonate wasting seen in patients with ureteral implants into ileal conduits) can result in osteomalacia or rickets. Thus, the causes of these mineralization disorders are, in essence, *vitamin D disorders* (malabsorption, liver disease), *hypophosphatemic disorders* (X-linked hypophosphatemic rickets, autosomal dominant hypophosphatemia, and oncogenic osteomalacia), *metabolic acidoses*, *drug-related disorders*, and *genetic conditions* (vitamin D-dependent rickets types I and II, and hypophosphatasia) (see Chapter 73).

The diagnosis is suggested in the setting of low bone mass, the characteristic radiologic signs noted previously, or unexplained bone pain or weakness. Of course, all these signs are late signs, and the disorder is optimally considered

early in the course of the diseases described previously. The diagnosis is supported by demonstrating reductions of plasma 25-hydroxyvitamin D or its active form, 1,25-dihydroxyvitamin D ($1,25[\text{OH}]_2\text{D}$), hypophosphatemia, or increases in alkaline phosphatase, occurring in an appropriate clinical setting. The diagnosis can often be made clinically but can also be confirmed using undecalcified bone biopsy following oral double tetracycline labeling techniques, which are used to quantitate the degree of failure of mineralization.

Treatment depends on the underlying cause and includes an appropriate vitamin D compound, calcium, or phosphate, or a combination, as appropriate, and removal of the inhibitor of mineralization, when appropriate and possible. These diseases are gratifying to treat because the responses are often dramatic, and patients change rapidly from being chronically ill to feeling robust and healthy.

RENAL OSTEODYSTROPHY

Renal osteodystrophy is actually a collection of disorders that in moderate to severe forms leads to bone pain, pathologic fractures, and demineralization, all occurring in the setting of end-stage renal disease or dialysis. Subclinical renal osteodystrophy is common. The syndrome includes pure secondary hyperparathyroidism (see Fig. 75-1B), occurring as a result of defective renal production of $1,25(\text{OH})_2\text{D}$ combined with an increase in serum phosphate, which lead to hypocalcemia as a result of reduced intestinal calcium absorption and calcium phosphate precipitation into soft tissues, respectively (see Chapter 73). This circumstance, in turn, evokes a severe increase in PTH secretion that then causes dramatic increases in bone turnover, demineralization, and fracture. These patients may respond dramatically to oral or parenteral replacement of $1,25(\text{OH})_2\text{D}$ and the calcium receptor agonist cinacalcet. Other patients with *renal osteodystrophy* have adequately controlled serum calcium and phosphate, and therefore PTH, as a result of adequate oral calcium supplementation and phosphate

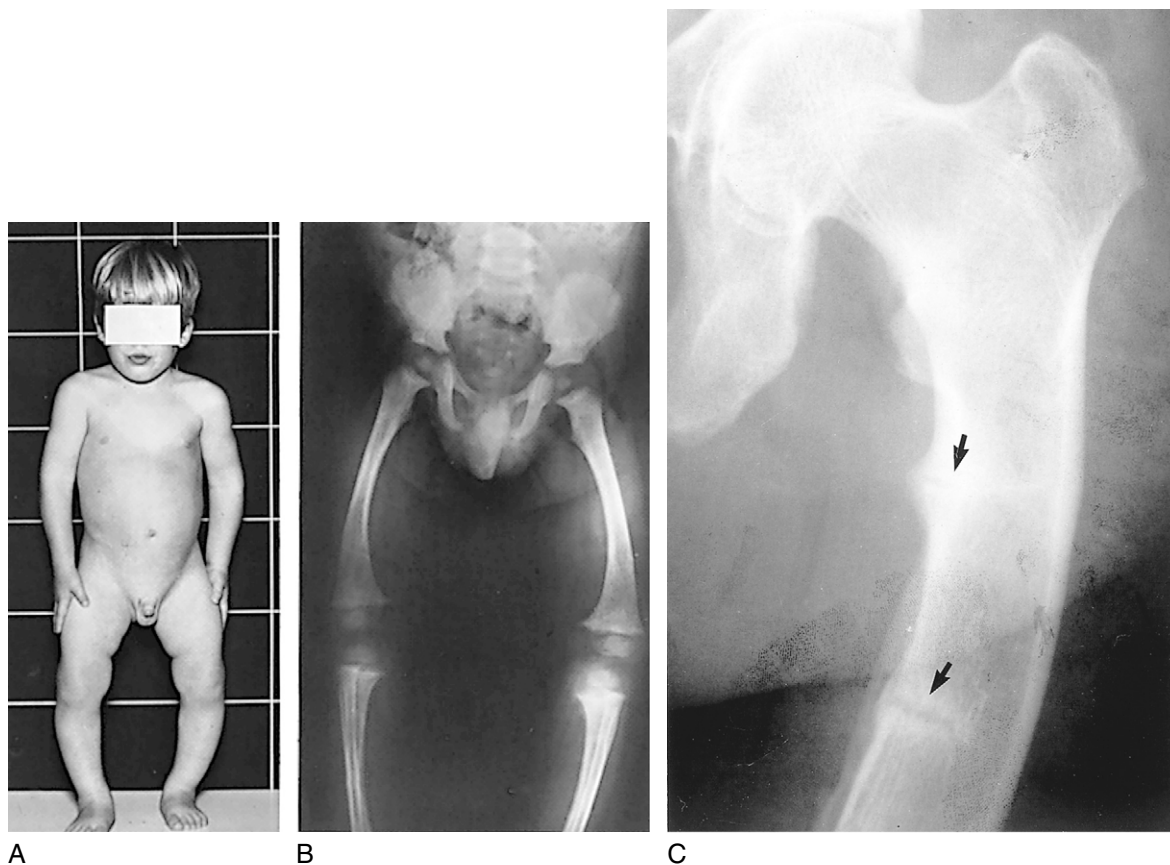

Figure 75-4 **A**, A typical example of rickets. Note the bowing of the femurs and tibiae, which may result from vitamin D deficiency, phosphate deficiency, or other causes. **B**, A skeletal radiograph of a child with rickets. Note that the weight-bearing bones of the lower extremities are bowed and that the epiphyses are open, mottled, and overgrown. **C**, Looser zones or pseudofractures characteristic of osteomalacia or rickets. Because the epiphyses are closed, the patient is an adult. This radiograph is diagnostic of osteomalacia.

binders, but they display severe osteomalacia (bone pain, reduced bone mineral density on DXA or bone biopsy, and thickened osteoid seams on bone biopsy with a mineralization defect apparent from tetracycline labeling) (see Fig. 75-3). The precise cause of the mineralization defect is uncertain. These patients, too, may respond dramatically to vitamin D replacement. Other patients with *renal osteodystrophy* have combinations of secondary hyperparathyroidism and osteomalacia (Fig. 75-5); still others have *low turnover* or *aplastic bone disease*. These terms are intended to describe patients on dialysis who have the opposite of secondary hyperparathyroidism and osteomalacia: little or no osteoblastic activity, osteoid, or osteoclastic activity. The condition may result from inhibitors of bone turnover, such as aluminum intoxication in the past; from excessive treatment with $1,25(\text{OH})_2\text{D}$, with suppression of PTH, causing low bone turnover; or from as yet unidentified causes. As with other bone diseases, understanding the cause is critical for effective treatment. Being aware of the syndrome so that it is recognized early and treated before bone pain and fractures occur is optimal.

GENETIC DISEASES

Genetic diseases that lead to reductions in bone mass are not common but are seen with some frequency in practices devoted to skeletal disease. Perhaps the most common

Figure 75-5 Renal osteodystrophy. This photomicrograph of a biopsy from a patient on dialysis demonstrates many of the classic features of renal osteodystrophy. These features include evidence of aggressive osteoclastic bone resorption (see numerous osteoclastic lacunae on the bone surface, as compared with the smooth surfaces in Figure 75-1A) and abundant partially and chaotically mineralized areas of osteoid (orange).

among these uncommon disorders is *osteogenesis imperfecta*, which may be mild or severe and may be present in neonates or older people, depending on the severity and the mutation involved. Mutations in the collagen I gene most often cause these disorders. *Hypophosphatasia* is due to a mutation

in the tissue-nonspecific alkaline phosphatase gene. These patients also display demineralization, fracture, and bone pain and have little or no measurable alkaline phosphatase. In the past several years, a new genetic disorder has been defined, called the *osteoporosis-pseudoglioma syndrome* (severe autosomal dominant osteoporosis with blindness). This disorder is due to inactivating mutations in the low-density lipoprotein-related protein 5 (*LRP5*) gene and, although very rare, is particularly interesting because activating mutations in the same gene have been shown recently to lead to an autosomal dominant form of very high bone mass. Myriad other genetic disorders exist that lead to low bone mass; some are treatable, others less so.

INFILTRATIVE DISEASES

Patients with multiple myeloma or Waldenström macroglobulinemia classically develop skeletal demineralization, and this is true as well for some patients with leukemia and marrow lymphomas. Other disorders associated with diffuse marrow infiltration by benign, or at least less malignant, processes can also lead to diffuse osteopenia, bone pain, and fracture, and all these disorders should be considered in the setting of unexplained *osteoporosis*. Examples include hemolytic anemias such as thalassemia or sickle cell disease, sarcoidosis with diffuse marrow involvement, Gaucher disease with lipid-laden marrow giant cells, malignant mastocytosis, and diffuse histiocytosis.

TRANSPLANT OSTEODYSTROPHY

Patients who have undergone or are undergoing organ transplantation commonly have severe *osteoporosis*. In some patients, this condition is due to treatment with immunosuppressive drugs such as glucocorticoids, tacrolimus, or cyclosporine, all of which are potent inhibitors of bone formation and regularly lead to reductions in bone mass. Some evidence indicates that they may activate osteoclastic bone resorption as well. In other patients, decreased bone mineral density exists before transplantation as a result of their organ failure or treatment thereof. In still other patients—for example, those with primary biliary cirrhosis—components of osteoblast failure, as well as calcium or vitamin D deficiency, may exist. In patients, such as those with end-stage

lung or cardiac disease, contributing components of physical inactivity and generalized malnutrition may be present as well. In yet other patients with end-stage renal disease, all the components of renal osteodystrophy, as discussed previously, may be operative. This group of patients is particularly vexing because they often have severe, but retrospectively preventable, disease by the time they see an expert in metabolic bone disease, and therapy in late stages is incompletely effective. In addition, these patients may be in the “Catch-22” situation of being denied organ transplantation because of *severe osteoporosis* that, in retrospect, was preventable. This disorder can be expected to become increasingly common as organ transplantation becomes more common.

Treatment

Treatment of all these conditions depends on the underlying disorder. Primary and tertiary hyperparathyroidism are treated, if clinically indicated, with surgical resection of the affected parathyroid tissue. Osteomalacia and rickets improve when either the appropriate replacement drug is administered (e.g., vitamin D, calcium, or phosphate, or a combination) or the offending agent (e.g., anticonvulsants) is removed. Secondary hyperparathyroidism in a patient on dialysis can be treated with a combination of the active form of vitamin D (1,25[OH]₂D [calcitriol] or analogues), calcium supplementation, phosphate binders, and cinacalcet, depending on the clinical situation. Secondary hyperparathyroidism due to vitamin D deficiency can be treated with oral or intramuscular injections of the much less expensive parent compound, vitamin D. Other items in Table 75-1 require attention to the underlying disorder.

The most important therapeutic point is that these disorders are commonly amenable to treatment and can have dramatic and satisfying responses to therapy, both for the physician and for the patient. The main stumbling block is that these diagnoses are commonly never considered, and the DXA report of *osteoporosis* is passively accepted and never investigated. The key clinical message, then, is that, whenever a patient is designated as having *osteoporosis*, the physician should mentally run through the checklist in Table 75-1 and eliminate, or investigate, these disorders as appropriate.

Prospectus for the Future

Better understanding of metabolic bone diseases, including but not limited to osteoporosis, represents one of the largest challenges facing researchers as the population ages. We know so little about how bone is made (we do not even know how it mineralizes) or why some people develop osteoporosis while others with identical risk factors do not. We recognize that postmenopausal women with osteoporotic fracture have bone densities some 50% of normal, yet the current generation of osteoporosis drugs increases bone density by only 2% to 9%. Clearly, we have a long way to go in this arena. Moreover, what is the cause of *low turnover renal osteodystrophy* or *adynamic bone disease* in patients on dialysis? Why do some of these

patients get this disorder while others do not, what are the additional cytokines that cause bone resorption in breast cancer and myeloma, and what drugs can be developed to block these events? Why is rickets still so prevalent in the Third World and in U.S. cities as well, and what can we do at a public health level to prevent this unnecessary disease? How can we teach physicians that, just because low bone density found in a bone density study is interpreted to mean *osteoporosis*, that it might equally well represent multiple myeloma, OFC, or osteomalacia? Thus, basic, clinical, and public health issues abound in this area, and the coming decade will see answers to at least some of these questions.

Osteoporosis

Susan L. Greenspan

Osteoporosis, the most common disorder of bone and mineral metabolism, affects about 50% of women older than 50 years. The National Institutes of Health Consensus Development Panel on Osteoporosis Prevention defines osteoporosis as a skeletal disorder characterized by compromised bone strength, predisposing a person to an increased risk for fracture. Bone strength reflects primarily the integration of two main features: (1) bone density and (2) bone quality. Bone density reflects the peak adult bone mass and the amount of bone lost in adulthood. Bone quality is determined by bone architecture, bone geometry, bone turnover, mineralization, and damage accumulation (i.e., microfractures) (Fig. 76-1).

Epidemiologic Factors

In the United States, 1.5 million osteoporotic fractures occur each year, comprising 700,000 vertebral fractures, 250,000 radial fractures, 250,000 hip fractures, and 300,000 other fractures. Hip fractures have the most serious consequences by far, with a mortality rate of more than 20% within the first year. More than 50% of patients with hip fracture will be unable to return to their previous ambulatory state, and about 10% of them will be placed in long-term care facilities. Three fourths of all hip fractures occur in women. After the age of 50 years, the lifetime risk for hip fracture is 17% for white women, compared with 6% for white men. When defined by bone mineral densitometry, 13 to 17 million women have *low bone mass* at the hip, and 4 to 6 million postmenopausal white women have osteoporosis. Although morbidity is decreased with vertebral fractures, mortality is increased as a result of the risk for cardiovascular and pulmonary disease that is associated with an escalating number of vertebral fractures. Only one third of radiologically diagnosed vertebral fractures receive medical attention.

Risk Factors

The major risk factors for osteoporosis have been previously outlined by the National Osteoporosis Foundation (NOF)

and include personal history of fracture in adulthood, fracture history in a first-degree relative, low body weight (<127 lb), current smoking, and use of oral corticosteroid therapy for longer than 3 months. Additional risk factors include impaired vision, early estrogen deficiency (<45 years of age), dementia, poor health or frailty, recent falls, low calcium intake (lifelong), low physical activity, and alcohol consumption (>2 drinks per day). Risk factors specific to hip fracture were identified by the Study of Osteoporotic Fractures, an epidemiologic trial that prospectively monitored 9704 postmenopausal women older than 65 years. Risk factors for hip fracture included age, history of maternal hip fracture, weight, height, poor health, previous hyperthyroidism, current use of long-acting benzodiazepines, poor depth perception, tachycardia, previous fracture, and low bone mineral density. Investigators found that the more risk factors a woman had, the greater was her risk for fracture.

Peak Bone Mass and Bone Loss

Peak bone mass is determined primarily by genetic factors. Men have a higher bone mass than women, and African Americans and Hispanics have a higher bone mass than whites. Multiple genes, including vitamin D–receptor alleles, estrogen receptor genes, and the *high bone mass* gene, are thought to be associated with bone mass, but studies are ongoing. Other factors that contribute to the development of peak bone mass are the use of gonadal steroids, timing of puberty, calcium intake, exercise, and growth hormone.

The causes of bone loss in adults are multifactorial. The pattern of bone loss differs in women compared with men, and bone loss is greater in sites rich in trabecular bone (e.g., spine) than cortical bone (e.g., femoral neck) (Fig. 76-2). Estrogen deficiency during menopause contributes significantly to bone loss in women because they may lose 1% to 5% of bone mass per year in the first few years after menopause. Women continue to lose bone mass throughout the remainder of their lives, with another acceleration of bone loss occurring after age 75 years. The mechanism of this

Figure 76-1 Three-dimensional reconstruction by microcomputed tomography of a lumbar spine sample from a young adult normal woman and from a woman with postmenopausal osteoporosis. In the osteoporotic woman, not only is bone mass reduced, but also microarchitectural deterioration of bone structure occurs. Whereas the platelike structure in the normal case is very isotropic, the structure in the osteoporotic case shows preferential loss of horizontal struts; the plates have become rods that are thin and farther apart, and there is a concomitant loss of trabecular connectivity. These changes lead to a reduction in bone strength that is more than would be predicted by the decrease in bone mineral density. (From Riggs BL, Khosla S, Melton LJ 3rd: Sex steroids and the construction and conservation of the adult skeleton. *Endocr Rev* 23:279-302, 2002. Images courtesy of Ralph Mueller, PhD, Swiss Federal Institute of Technology [ETH] and University of Zurich, Zurich, Switzerland.)

Figure 76-2 Patterns of age-related bone loss in women and in men. *Dashed line* represents trabecular bone and *solid lines*, cortical bone. The figure is based on multiple cross-sectional and longitudinal studies using dual-energy x-ray absorptiometry. BMD, bone mineral density. accelerated loss in old age is not clear. Estrogen deficiency influences a host of local cytokines, which affect osteoblastic and osteoclastic activity as well as bone turnover. In an adult, skeletal integrity is further influenced by calcium intake, vitamin D intake, physical activity, and body weight. Finally, multiple causes of secondary bone loss have been found.

Medications that commonly cause bone loss include excess thyroid hormone, glucocorticoids, antiseizure medications, heparin, gonadotropin-releasing hormone agonists, aromatase inhibitors, and depo-medroxyprogesterone. Endocrine diseases resulting in female or male hypogonadism also lead to bone loss. Hyperparathyroidism, hyperthyroidism, and

hypercortisolism also commonly cause bone loss, as can vitamin D deficiency. Gastrointestinal problems can contribute to decreased absorption of calcium and vitamin D (Table 76-1).

All patients should have a work-up for secondary causes of bone loss. This would include a serum calcium (albumin) level to rule out hyperparathyroidism or malnutrition; a 25-hydroxyvitamin D level to assess for vitamin D deficiency or insufficiency; alkaline phosphatase level to assess for Paget disease, malignancy, cirrhosis, or vitamin D deficiency; liver and renal function tests to assess for liver or renal abnormalities; 24-hour urine calcium and creatinine to evaluate for hypercalciuria or malabsorption; a test for sprue in patients with anemia or hypocalciuria; thyrotropin to rule out hyperthyroidism; and serum protein electrophoresis to rule out myeloma in older adults with anemia. Often, measurement of the parathyroid hormone level is needed to interpret calcium and vitamin D levels. A more extensive work-up can be done in severe or unusual cases. A bone biopsy is rarely needed. Markers of bone turnover may be helpful but are quite variable in clinical practice and usually reserved for research.

Clinical Manifestations

Unlike many other chronic diseases with multiple signs and symptoms, osteoporosis is considered a *silent* disease until fractures occur. Whereas 90% of hip fractures occur after a fall, two thirds of vertebral fractures are silent and occur with minimal stress such as lifting, sneezing, and bending. An acute vertebral fracture may result in significant back pain, which decreases gradually over several weeks with analgesics and physical therapy. Patients with significant vertebral osteoporosis may have height loss, kyphosis, and severe cervical lordosis (known as a *dowager's hump*).

Diagnosis

The diagnosis of osteoporosis is made following an acute clinical fracture or with bone mineral densitometry assessment. Radiographs can reveal a vertebral compression fracture (Fig. 76-3); however, radiologic evidence of low bone mass may not be present until 30% of bone mass has been lost. In addition, when assessing bone mass, radiographs may be read inappropriately as a result of overpenetration or underpenetration of the film. Therefore, radiographs are a poor indicator of osteoporosis, and the diagnosis is often made based on bone mineral densitometry.

BONE MINERAL DENSITY

Bone mineral density can be assessed through a variety of techniques. In 1994, the World Health Organization (WHO) developed a classification system for osteoporosis and low bone mass (osteopenia) based on data from white postmenopausal women (Table 76-2). Osteoporosis was defined as a bone mineral density less than or equal to 2.5 standard deviations below young adult peak bone mass (T-score ≤ -2.5 SD). Low bone mass (osteopenia) is defined as a bone mass measurement between 1.0 and 2.5 standard deviations

Table 76-1 Secondary Causes of Low Bone Mass

Endocrine Diseases

Female hypogonadism
Hyperprolactinemia
Hypothalamic amenorrhea
Anorexia nervosa
Premature and primary ovarian failure
Female athlete triad
Male hypogonadism
Primary gonadal failure (e.g., Klinefelter syndrome)
Secondary gonadal failure (e.g., idiopathic hypogonadotropic hypogonadism, androgen deprivation therapy for prostate cancer)
Hyperthyroidism
Hyperparathyroidism
Hypercortisolism
Vitamin D insufficiency or deficiency

Gastrointestinal Diseases

Subtotal gastrectomy
Gastric bypass surgery
Malabsorption syndromes
Chronic obstructive jaundice
Primary biliary cirrhosis and other cirrhotoses

Bone Marrow Disorders

Multiple myeloma
Monoclonal gammopathy of unknown significance (MGUS)
Lymphoma
Leukemia
Hemolytic anemias
Systemic mastocytosis
Disseminated carcinoma

Connective Tissue Diseases

Osteogenesis imperfecta
Ehlers-Danlos syndrome
Marfan syndrome
Homocystinuria

Drugs

Alcohol
Antiepileptic medications
Aromatase inhibitors
Chemotherapy
Cyclosporine
Depo-medroxyprogesterone
Excess thyroid hormone
Glucocorticoids
Gonadotropin-releasing hormone agonists
Heparin

Miscellaneous Causes

Immobilization
Rheumatoid arthritis
Chronic obstructive pulmonary disease
Weight loss

below adult peak bone mass (T-score between -1.0 and -2.5 SD). Normal bone mineral density is defined as assessments above 1.0 standard deviation below adult peak bone mass (T-score ≥ -1.0 SD). The *gold standard* for assessing bone mineral density is dual-energy x-ray absorptiometry (DXA), which has excellent precision and accuracy. Measurements are made of the hip and spine, and about 30% of the time, discordance is found between these measurements (Fig. 76-4). Therefore, classification is based on the lowest value (total spine, total hip, or femoral neck). Bone mineral density can also be measured by hip or spine quantitative computed tomography (QCT). However, few normative

Figure 76-3 Lateral spine radiograph demonstrating a thoracic anterior wedge compression fracture.

Table 76-2 World Health Organization Classifications for Osteoporosis

Classification	Criteria for Bone Mineral Density
Normal	Above -1.0 SD of young adult peak mean value
Low bone mass (osteopenia)	Between -1.0 and -2.5 SD of young adult peak mean value
Osteoporosis	Below -2.5 SD of young adult peak mean value

SD, standard deviation.

data are available for hip QCT, vertebral precision is inferior to that of DXA, and radiation doses are significantly higher than those of DXA. Finally, single-photon absorptiometry of the forearm and peripheral measures, such as finger DXA and heel ultrasound, have also been used to assess bone mass (Table 76-3).

Classification can vary significantly by the skeletal site and the device used for assessment. For example, the average woman would be diagnosed with osteoporosis at age 60 years when assessing the lateral spine but not until she is older than 100 years if heel ultrasound is used. Although all these measurements have an accuracy of 1% to 3%, precision is best with forearm or spine DXA (about 1%). Furthermore, the WHO classification should only be used with DXA.

Experts recommend that bone mineral density be monitored after 2 years, depending on the site to be assessed and the type of therapy prescribed. For example, trabecular bone, which is more metabolically active than cortical bone, is more likely to show improvements with stronger-acting

antiresorptive agents. Changes in bone mass with potent antiresorptive therapy are more prominent in the spine compared with other areas. Seeing no changes in forearm bone mineral density over time is common, despite good precision. Although the heel has a high percentage of trabecular bone, precision is poor, and monitoring should not be done at this site.

The NOF recommends obtaining a bone mineral density assessment in all women older than 65 years, postmenopausal women younger than 65 years with one risk factor, and women who have had a fracture (Table 76-4). The U.S. Preventive Services Task Force recommends bone density tests in all women older than 65 years and women between 60 and 64 years with a risk factor. The NOF recommends obtaining a bone mineral density in men 70 years and older. Currently, databases are available for white, African American, and Hispanic men and women.

In general, bone mass measurements by DXA examine the spine and hip. However, in patients with hyperparathyroidism, in which cortical bone loss is often seen, forearm DXA should also be assessed. Older patients with osteoporosis often have falsely elevated bone mineral density measurements at the spine as a result of atypical calcifications from degenerative joint disease, sclerosis, or aortic calcifications. Although lateral bone mineral density measurements eliminate these artifacts, they are often difficult to perform because of overlap of the ribs on L2 and overlap of the pelvic brim on L4. Classification should only be made if two or more vertebrae are available for analysis because of the high error rate when only one vertebra is assessed. QCT is recommended less often than DXA because of the former's high radiation exposure and cost.

The WHO has developed an assessment to predict the 10-year risk for hip or any major osteoporotic fracture for postmenopausal women and men aged 50 years and older. The "FRAX" fracture risk assessment tool, incorporates femoral neck T-score, age, gender, height, weight, and specific risk factors, including history of adult fracture, parental hip fracture, current smoking, glucocorticoids, rheumatoid arthritis, alcohol (≥ 3 drinks per day), and secondary osteoporosis. The fracture risk prediction is specific for race and country and should only be used in patients not on therapy.

Prevention

General preventive measures for all patients include calcium and vitamin D supplementation, exercise, and fall prevention techniques. The recommended daily allowance of calcium was recently reviewed by the National Academy of Science and increased to 1200 mg daily for postmenopausal women. Calcium intake can be accomplished by dietary consumption or supplementation. The supplements should generally be pure calcium carbonate or pure calcium citrate, taken in divided doses of about 500 to 600 mg twice daily. Calcium carbonate must be taken with meals for best absorption, whereas calcium citrate may be taken with or without food. Calcium supplements are currently available as tablets and in chewable and liquid forms. Many foods, such as orange juice and some cereals, are now calcium fortified.

Vitamin D is important for calcium absorption and bone mineralization. Vitamin D has nonskeletal benefits and

Figure 76-4 Right, This patient has a lumbar spine (L1 through L4) bone mineral density (BMD) of 0.733 g/cm² (white circle with cross) as measured by dual-energy x-ray absorptiometry (DXA) and a T-score of -2.9. The reference database graph displays age- and sex-matched mean BMD levels ±2 standard deviations (SDs) (shaded areas) derived from a normative database from the manufacturer (Hologic, Inc., Bedford, Mass). The T-score indicates the difference in SD between the patient's BMD and the predicted sex-matched mean peak young adult BMD; z-value, the difference in SD between the patient's BMD and the sex- and age-matched mean BMD; and percentage of mean, the patient's BMD as a percentage of the mean peak young adult BMD or age-matched BMD level. **Left**, This patient has a total hip BMD of 0.499 g/cm² (white circle with cross) as measured by DXA, a femoral neck T-score of -4.0, and a total hip T-score of -3.6. The reference database graph displays age- and sex-matched mean BMD levels ±2 SDs (shaded areas) derived from the third National Health and Nutrition Examination Survey. The T-score indicates the difference in SD between the patient's BMD and the predicted sex-matched mean peak young adult BMD; z-score, the difference in SD between the patient's BMD and the sex- and age-matched mean BMD; and percentage of mean, the patient's BMD as a percentage of the mean peak young adult BMD or age-matched BMD level. (Adapted from bone densitometry report, QDR-4500A bone densitometer, Hologic, Inc., Bedford, Mass.)

has been associated with improvement in muscle strength, prevention of falls, and decrease in prostate, colon, and breast cancer. Vitamin D comes from two sources: diet and photosynthesis. Because dietary sources of vitamin D are limited (e.g., fortified milk), and patients are often advised to avoid sun exposure for prevention of skin cancer and wrinkles, many studies have now documented vitamin

D deficiency and insufficiency in older adults. In addition, older patients have reduced ability to synthesize vitamin D in the skin. Low vitamin D levels can lead to secondary hyperparathyroidism.

Vitamin D can be taken in a multivitamin, in a calcium supplement, or in pure form. In pure form, cholecalciferol (D₃) is preferable to ergocalciferol (D₂). Most multivitamins

Table 76-3 Techniques for Measuring Bone Mass

Table 76-4 National Osteoporosis Foundation Recommendations for Bone Mineral Density Testing

1. All postmenopausal women younger than 65 years who have one or more additional risk factors for osteoporosis (besides menopause)
2. All women aged 65 years and older regardless of additional risk factors
3. Postmenopausal women who present with fractures (to confirm diagnosis and determine disease severity)
4. All men aged 70 years and older

contain 400 IU to 800 IU of vitamin D. The current recommended dose is up to 1000 IU for adults. Older patients with severe vitamin D deficiency may be given 50,000 IU of vitamin D once per week for 3 months to bring serum vitamin D into the normal range. Activated vitamin D is rarely needed and should not be given on a regular basis for postmenopausal osteoporosis.

Weight-bearing exercise is important for maintaining skeletal integrity. Results are controversial concerning studies on different types and duration of exercise in postmenopausal women and men. In general, however, weight-bearing or resistance training exercises are suggested and have been shown to improve bone mass or maintain skeletal integrity. In patients with new vertebral fractures, physical therapy is important for improving posture and increasing strength in back muscles.

Because 90% of hip fractures and a significant number of vertebral fractures occur during a fall, fall prevention modalities are suggested for frail older patients. Fall-proofing the household includes installing grab bars in the bathroom and hand rails on stairways, avoiding loose throw rugs and cords, ensuring good lighting by the bedside, and moving objects within easy reach in the kitchen. Other fall prevention modalities include eliminating medications that cause dizziness or postural hypotension (if possible), assessing the need

for assistive devices (e.g., canes, walkers), and ensuring appropriate footwear and good vision. In addition, several studies have now demonstrated that hip protectors significantly reduce hip fractures in residents in nursing homes. However, compliance is often poor with these products.

Treatment

The NOF developed treatment guidelines that incorporate the 10-year fracture risk prediction. The NOF suggests treatment for postmenopausal women and men 50 years and older as follows:

1. An adult fragility fracture at the hip or spine
2. Osteoporosis by bone mineral density T-score of less than or equal to 2.5 at the spine, total hip, or femoral neck after appropriate evaluation
3. Other prior fractures and low bone mass (T-score between -1.0 and -2.5 SD)
4. Low bone mass (T-score between -1.0 and -2.5 SD) and a 10-year hip fracture risk of 3% or higher or a 10-year all-major osteoporosis-related fracture risk of 20% or higher based on U.S. adapted model
5. Low bone mass (T-score between -1.0 and -2.5 SD) and secondary causes associated with high risk of fracture (glucocorticoids, total immobilization)

Patients taking glucocorticoids can fracture with a normal bone density. The American College of Rheumatology suggests patients starting glucocorticoids, who will be treated for 3 months or longer, have a bone density and start anti-resorptive therapy. This is especially true for postmenopausal women and men.

BISPHOSPHONATES

Bisphosphonates are the mainstay of osteoporosis prevention and treatment. They inhibit the cholesterol synthesis

Table 76-5 U.S. Food and Drug Administration–Approved Therapies for Prevention and Treatment of Osteoporosis

Agent	Prevention	Treatment	Dose	Vertebral Fracture Reduction	Hip Fracture Reduction	Cost Per Year
Alendronate	Yes	Yes	Prevention: 5 mg PO daily, 35 mg PO weekly Treatment: 10 mg PO daily, 70 mg PO weekly	Yes	Yes	\$965 (but is now generic)
Risedronate	Yes	Yes	Prevention and treatment: 5 mg PO daily, 35 mg PO weekly, 150 mg PO monthly	Yes	Yes	\$965
Ibandronate	Yes	Yes	2.5 mg PO daily, 150 mg PO monthly, 3 mg IV every 3 mo	Yes	No	\$1043 ~\$2000
Zoledronic acid	No	Yes	5 mg IV yearly	Yes	Yes	~\$1000
Raloxifene	Yes	Yes	60 mg PO daily	Yes	No	\$1082
Hormone replacement therapy	Yes	<i>Management</i>	0.625 mg PO daily conjugated estrogen or equivalent (0.45, 0.3 mg also available)	Yes	Yes	\$65-\$522
Calcitonin	No	Yes	200 IU daily intranasal	Yes	No	\$1148
Teriparatide (PTH [1-34])	No	Yes	20 mcg SC daily	Yes	No	\$8528

PO, orally; PTH, parathyroid hormone; SC, subcutaneously.

pathway in the osteoclasts, thereby causing early apoptosis and inhibiting osteoclast migration and attachment. In the United States, the bisphosphonates alendronate, risedronate, ibandronate, and zoledronic acid have been approved for the prevention and treatment of osteoporosis. Alendronate has been shown to increase bone mass by about 8% at the spine and 4% at the hip over 3 years. This increase has been associated with approximately a 50% reduction in spine, hip, and forearm fractures (Table 76-5). Alendronate is prescribed at 5 mg daily or 35 mg once weekly for osteoporosis prevention and 10 mg daily or 70 mg once weekly (with or without vitamin D 2800 IU/tablet or 5600 IU/tablet) for the treatment of osteoporosis. Alendronate has been approved for use in men and patients with glucocorticoid-induced osteoporosis.

Risedronate is approved for the prevention and treatment of osteoporosis at a dose of 5 mg per day, 35 mg per week, 75 mg in two consecutive doses per month, or 150 mg per month. Large-scale, multicenter studies have shown improvements in bone mass of about 6% to 7% at the spine and 3% at the hip over 3 years. In addition, these studies revealed a 50% reduction in vertebral fractures, 40% reduction in nonvertebral fractures, and 40% reduction in hip fractures (see Table 76-5). Risedronate is approved for treatment of osteoporosis in men and for the prevention and treatment of patients with glucocorticoid-induced osteoporosis.

Ibandronate is approved for the prevention and treatment of postmenopausal osteoporosis. After 3 years of treatment, ibandronate increased bone density by 6.5% at the spine and 3.4% at the hip, and reduced new vertebral fractures by 62%. No reductions in nonvertebral or hip fractures were noted. Ibandronate is approved at an oral dose of 2.5 mg daily, or 150 mg monthly. Ibandronate is approved for treatment at an intravenous dose of 3 mg every 3 months.

Zoledronic acid is approved for the treatment of postmenopausal osteoporosis. The pivotal trial demonstrated increases of 6.9% of bone density at the spine and 6.0% at the hip and reduced spine fractures by 70%, nonvertebral fractures by 25%, and hip fractures by 41% after 3 years. Zoledronic acid is given at a dose of 5 mg intravenously once a year.

Because oral bisphosphonates are poorly absorbed, they must be taken first thing in the morning on an empty stomach with a full glass of water. Patients must wait 30 minutes (when taking alendronate and risedronate) to 60 minutes (when taking ibandronate) before eating and must not lie down. Potential side effects of bisphosphonates include epigastric distress, heartburn, and esophagitis. Intravenous bisphosphonates have been associated with an influenza-like syndrome following the infusion. Bisphosphonates can also cause arthralgias and myalgias. Osteonecrosis of the jaw is a rare adverse event of abnormal bone growth in the jaw, more often associated with high-dose intravenous bisphosphonates in patients with cancer. Atrial fibrillation has been reported with intravenous zoledronic acid, but studies are trying to determine whether this is a class event.

The cost of most bisphosphonate therapy averages about \$1000 per year (see Table 76-5). However, generic forms of alendronate are now available.

ESTROGEN AGONISTS-ANTAGONISTS

Estrogen agonists-antagonists were previously called selective estrogen-receptor modulators (SERMs) because they have some estrogen-like and anti-estrogen-like benefits. Raloxifene is currently approved for the prevention and treatment of osteoporosis. The Multiple Outcomes of Raloxifene Evaluation (MORE) trial found that bone mass

was increased by 4% at the spine and 2.5% at the femoral neck over 3 years. This increase was associated with a 50% reduction in vertebral fractures. No change in nonvertebral or hip fractures was seen (see Table 76-5). Treatment was also associated with improved lipid status, as shown by decreased total and low-density lipoprotein cholesterol. Raloxifene is not associated with endometrial hyperplasia, thus patients do not have bleeding or spotting, nor do they have breast tenderness or swelling. Raloxifene also reduces the risk for invasive breast cancer in postmenopausal women with osteoporosis and in women at high risk for invasive breast cancer. Patients do have the same small risk of deep vein thrombosis or pulmonary embolus that is found with hormone replacement therapy (HRT). Raloxifene will not relieve postmenopausal symptoms and may exacerbate hot flashes. Raloxifene can be given with or without food in a daily oral form at 60 mg per day. Studies have not found a significant impact on cardiovascular disease.

HORMONE REPLACEMENT THERAPY

Investigators of the Women's Health Initiative, a large, randomized, placebo-controlled, multicenter trial evaluating HRT, reported a 36% reduction in hip and vertebral fractures after 5.2 years. In addition to improvements in bone mass, other benefits include improved lipid profile, decreased colon cancer, and decreased menopausal symptoms. However, because of the potential risks of HRT (cardiovascular events, breast cancer, deep vein thrombosis, pulmonary embolus, and gallbladder problems), it should only be used for relief of menopausal symptoms, and other agents should be used for the prevention or treatment of osteoporosis.

CALCITONIN

Calcitonin is a 32-amino acid peptide produced by the parafollicular cells of the thyroid gland. It is currently approved in a subcutaneous dose but is rarely used. The U.S. Food and Drug Administration (FDA) approved the use of calcitonin for the treatment of postmenopausal osteoporosis in a nasal form at a dose of 200 IU per day, taken in alternating nostrils. The Prevent Recurrence of Osteoporotic Fractures (PROOF) study, a large, multicenter trial, did not show any significant changes in bone mineral density after 3 years of treatment. However, the 200-IU dose was associated with a 50% reduction in vertebral fractures (see Table 76-5). No effect on nonvertebral or hip fractures was noted.

PARATHYROID HORMONE

Parathyroid hormone (PTH), an anabolic agent, has been shown to significantly increase bone mineral density and reduce both vertebral and nonvertebral fractures over 18 months. In a large study of postmenopausal women, teriparatide (PTH amino acid sequence 1 through 34), 20 µg, increased spinal bone mineral density by 9.7% and hip bone mineral density by 2.6%, and was associated with a 65% reduction in vertebral fractures and a 53% reduction in nonvertebral fractures. Teriparatide is taken as a sub-

cutaneous, daily dose and is approved by the FDA for postmenopausal women and men at high risk for fracture. PTH (1-84) is approved for use in Europe. Other forms of PTH and parathyroid hormone-related protein (PTHrP) are under investigation. Teriparatide is often prescribed for patients who fail, cannot tolerate, or have a contraindication for bisphosphonate therapy. Teriparatide, the only available anabolic agent in the United States, costs roughly \$8500 per year.

FUTURE THERAPIES

The receptor activator of nuclear factor kappa B (RANK) and its ligand (RANKL) are mediators of osteoclast activity. An antibody to RANKL has been shown to reduce osteoclast activity, decrease bone resorption, and improve bone mass. Strontium is an approved agent for the treatment of osteoporosis in Europe. The exact mechanism of action is not fully understood, but strontium is thought to stimulate osteoblast proliferation and inhibit osteoclast formation. Cathepsin K inhibition appears to inhibit bone resorption with no major impact on bone formation. Another anabolic therapeutic target includes inhibition of sclerostin (antibody to sclerostin). Studies are ongoing.

Combination therapy has been examined with two antiresorptive agents or antiresorptive and anabolic agents together. Studies examining two antiresorptive agents have included HRT plus alendronate, HRT plus risenedronate, and alendronate plus raloxifene. Overall, studies with combination therapy have suggested greater improvements in bone mass over therapy with single agents. Although dual treatment with antiresorptive agents appears to be safe and well tolerated, studies have not shown greater fracture reduction, so this type of combination therapy with two antiresorptive agents is generally not given to patients. Studies have suggested greater improvements in bone mineral density with PTH plus raloxifene than with PTH alone. The combination of PTH plus alendronate provides no greater benefit than monotherapy with PTH. However, following PTH therapy, patients benefit from antiresorptive therapy with alendronate rather than calcium supplementation alone.

VERTEBROPLASTY AND KYPHOPLASTY

Vertebroplasty involves injection of cement (polymethylmethacrylate) into a compressed vertebra to prevent the vertebral body from further collapse. Alternatively, kyphoplasty introduces a balloon into the vertebral body to expand it, followed by cement placement inside the balloon. This approach not only expands the vertebral body but also increases some of the height. Although no controlled trials of these procedures have been conducted, studies suggest that they result in significant reductions in pain. Ongoing studies are needed to determine whether differences in outcomes can be found between vertebroplasty and kyphoplasty or whether potential risks exist to adjacent vertebrae after the procedure. Currently, these procedures are only recommended for patients with significant pain from vertebral fractures and are not routinely performed in asymptomatic patients with vertebral osteoporosis.

Prospectus for the Future

Osteoporosis affects about 50% of women older than 50 years. Although many risk factors exist for low bone mass, the major risk factors for osteoporosis include a personal history of fracture in adulthood, fracture history in a first-degree relative, low body weight, current smoking, and use of oral corticosteroid therapy. Because osteoporosis is largely a silent disease until manifestation of fracture, bone mineral density can be used to assess bone mass before a clinical fracture and is also used to monitor the disease. Osteoporosis is classified as a bone mineral density measurement of the hip or spine of equal to or less than -2.5 standard deviations below young adult peak bone mass. National guidelines suggest that all women older than 65 years have a bone mass measurement, and those younger than 65 years have a bone mass measurement if they have additional risk factors. General preventive measures for

all patients include calcium of about 1200 mg daily in divided doses, vitamin D supplementation of up to 1000 IU per day, weight-bearing exercise, and fall prevention for older adults. The mainstays of prevention and treatment include daily, once-weekly, or once-monthly oral bisphosphonates or intravenous bisphosphonates every 3 or 12 months. Raloxifene, an estrogen agonist-antagonist, and calcitonin have also been approved as therapy for osteoporosis. Teriparatide (PTH [1-34]), an anabolic agent, is approved for treatment of patients at high risk for osteoporosis. Future therapies include other forms of PTH, other anabolic agents, an antibody to RANKL (a mediator of osteoclast activity), and cathepsin K. Monotherapy with PTH appears to be of greater benefit than combination therapy with an antiresorptive.

Paget Disease of Bone

Mara J. Horwitz and G. David Roodman

Paget disease is one of the more common bone diseases in adults. In contrast to most other metabolic bone diseases (discussed in previous chapters), which are diffuse and involve the entire skeleton, Paget disease is a focal bone disorder. It can be monostotic (involving a single bone) or polyostotic (involving multiple bones). Although Paget disease is a chronic condition, over the long course of the disease, new lesions rarely develop. The clinical description of Paget disease by Sir James Paget over 100 years ago is still accurate today. The primary cellular abnormality of Paget disease is increased osteoclastic bone resorption. This intense bone resorption is followed by exuberant formation of new bone that is of poor quality. Most patients with Paget disease are asymptomatic, and the disorder is detected by an increased serum alkaline phosphatase level or unexpectedly on a routine radiograph. However, a significant proportion of patients can have bone pain, skeletal deformity, fractures, high-output cardiac failure, or nerve compression syndromes. The most dreaded complication of Paget disease is development of osteosarcoma in the pagetic lesion. Although this development is extremely rare (<1%), the incidence of osteosarcoma in patients with Paget disease is about 1000-fold greater than in age-matched normal controls.

Incidence and Prevalence

Paget disease affects about 2% of the population older than 45 years in the United States. It is common in Great Britain, Germany, France, Australia, and New Zealand but is extremely rare in Scandinavia, Asia, sub-Saharan Africa, and the Arab Middle East. In some areas of Great Britain, the incidence of Paget disease may reach 5% to 6%. However, the incidence of Paget disease appears to have decreased during the past 20 years for unknown reasons. Paget disease is most commonly diagnosed in patients older than 50 years and has only rarely been reported in patients younger than 40 years. Estimates are that the incidence nearly doubles with every decade past the age of 50 years. Both men and women are affected, but it has a slight male predominance.

Etiologic Factors

The cause of Paget disease is unknown. Studies over the past 30 years, including immunohistochemical, ultrastructural, and in situ hybridization studies, have suggested a possible viral origin for Paget disease. Osteoclasts in pagetic lesions are markedly increased in number and size. A striking feature of osteoclasts from patients with Paget disease is the characteristic nuclear inclusions that are similar to nucleocapsids of paramyxoviruses. Several groups have demonstrated that these nuclear inclusions cross-react with antibodies against respiratory syncytial virus, measles virus, and canine distemper virus. Furthermore, in situ hybridization studies have shown the presence of measles virus nucleocapsid transcripts in pagetic osteoclasts. Friedrichs and associates have reported the full-length sequence of the measles virus nucleocapsid protein from a patient with Paget disease. Further supporting a potential role of paramyxoviruses in Paget disease, Kurihara and colleagues transfected normal osteoclast precursors with the measles virus nucleocapsid gene and reported that the osteoclasts that formed were very similar to pagetic osteoclasts. Recently, Kurihara and colleagues have targeted the measles virus nucleocapsid gene to cells in the osteoclast lineage in transgenic mice and shown that these mice develop bone lesions and osteoclasts that are characteristic of pagetic lesions in patients. Other groups in Great Britain have reported that canine distemper virus is present in pagetic osteoclasts. However, other investigators have failed to detect paramyxovirus transcripts in pagetic osteoclasts or their precursors. Thus, the role that paramyxovirus plays in the cause of Paget disease is controversial.

In addition to a viral origin for Paget disease, a strong genetic component exists. Multiple families have been identified that demonstrate vertical transmission of Paget disease in an autosomal dominant fashion with variable penetrance. These large kindred links have led to the identification of several chromosomal loci for Paget disease, including chromosomes 18, 5, 6, and 2. The most common locus that is linked to Paget disease has been identified on chromosome 5. This gene encodes sequestosome 1, an adapter protein that

may be involved in the receptor activator of nuclear factor kappa B ligand (RANKL)–signaling pathway. Mutations in this gene occur in almost 30% of patients with familial Paget disease and have also been reported in a small proportion of patients with sporadic rather than familial Paget disease. In one family from Japan with very-early-onset Paget disease, a mutation in the *RANK* gene on chromosome 18 has been reported. RANKL and its receptor, RANK, are critical factors involved in osteoclast formation and survival. However, the role that mutations in sequestosome 1 play in the development of Paget disease is still unclear. Kurihara and colleagues have recently targeted the mutant sequestosome 1 gene to human osteoclasts in vitro and to osteoclasts in transgenic mice and have shown that the osteoclasts that form do not express the characteristics of pagetic osteoclasts and the mice harboring the mutant gene do not develop pagetic bone lesions.

Pathologic and Pathophysiologic Factors

In pagetic lesions, osteoclasts are increased in number and size and have increased rough endoplasmic reticulum and mitochondria, consistent with their increased metabolic activity. Osteoblasts, which are morphologically normal, are also increased in number in the lesions. Initially, osteoclastic bone resorption is increased, followed by increased numbers of osteoblasts that form large amounts of woven bone (Fig. 77-1). This marked increase in osteoblasts accounts for the sclerotic lesions so typical on radiographic examination (Fig. 77-2), for the increase uptake of radionuclide on bone scan (Fig. 77-3), and for the increase in serum alkaline phosphatase, the biochemical hallmark of Paget disease. Ultimately, the pagetic lesions become sclerotic. The vascularity of the abnormal bone is increased.

The increased bone resorption probably results from increased production of cytokines that enhance osteoclast formation. For example, levels of interleukin-6, a potent stimulator of osteoclast formation, are increased in pagetic lesions but not in normal bone. In addition, RANKL levels also are increased in the bones involved with Paget disease but not in the uninvolved bones from the same patients. The factors that enhance bone formation have not been clearly identified but may include transforming growth factor- β , insulin-like growth factor, and fibroblast growth factor, which are present in large quantities in bone and can be released by osteoclastic bone resorption.

Clinical Presentation

Paget disease may affect any skeletal site. It most commonly involves the pelvis, vertebrae, skull, tibia, and femur. It may be monostotic (affecting only one bone) or more commonly polyostotic (affecting two or more bones) and is often asymmetrical in its distribution. Although progression of the disease may occur at a given site, the appearance of new lesions is rare. As noted previously, most patients with Paget disease are asymptomatic, and the disease is detected by an increased serum alkaline phosphatase level or discovered unexpectedly on a routine radiograph. Among patients

who are symptomatic, bone pain is the most common complaint (Table 77-1). Bone pain in Paget disease can be due to the pagetic lesion itself but more often results from the joint distortion and nerve compression caused by adjacent pagetic bone.

Arthritis is often found in joints near areas involved with Paget disease, particularly when subchondral bone is affected or when the integrity of the joint is compromised by enlarged or distorted bones. Skeletal deformities occur most frequently in affected sites in the skull and long bones of the lower extremities. The skull can become enlarged, and temporal bone involvement may affect hearing and cause other cranial nerve palsies or headaches. Softening of the base of the skull may produce flattening (*platybasia*) with the development of basilar invagination and may lead to cranial nerve and spinal cord compression syndromes. Affected long bones of the lower extremity can become bowed. Fissure fractures along the convex surface of long bones and pathologic fractures in weight-bearing bones are not uncommon. Spinal cord or nerve root compression with associated radicular pain and weakness may result from expanding pagetic lesions in the spine. Because pagetic lesions tend to be highly vascular, increased warmth in the skin over affected areas is often present.

Complications and Associated Conditions

Secondary arthritis is a common and often debilitating complication of periarticular Paget disease. Hyperuricemia and gout may occur with increased frequency in affected persons. Highly vascularized pagetic lesions have been reported to cause a *vascular steal* syndrome, and high-output cardiac failure has been described in severe disease. The most serious complication of Paget disease is sarcomatous degeneration. This situation occurs most often in the setting of severe polyostotic disease and may be heralded by a sudden increase in pain, a soft tissue mass, an abrupt increase in serum alkaline phosphatase, or a pathologic fracture. Although extremely rare (<1%), osteosarcoma in Paget patients is about 1000-fold greater than in age-matched normal controls. Sarcomatous degeneration is the main cause of death caused by Paget disease. Although most Paget-associated tumors are osteosarcomas, fibrosarcomas, and chondrosarcomas may also be seen.

Diagnostic Evaluation

Paget disease is most often diagnosed using a combination of biochemical markers of bone turnover and radiologic abnormalities. Biochemical markers of bone formation (such as serum alkaline phosphatase) and bone resorption (such as N-telopeptide cross-links [NTX], C-telopeptide cross-links [CTX], and phenazopyridine [Pyridium] cross-links) are usually increased in patients with active disease. For most patients with Paget disease, serum total alkaline phosphatase is an adequate and sensitive indicator of disease activity. However, serum bone-specific alkaline phosphatase may be a more sensitive marker than serum total alkaline

Large amounts of sclerotic bone are present. (Photomicrographs courtesy of Dr. David Dempster, Helen Hayes Hospital, Columbia University.)

phosphatase for assessing disease in patients with low levels of disease activity. Serum osteocalcin, another marker of bone formation, is often in the normal range and is not a clinically useful marker of disease activity.

A bone scan at the time of diagnosis is the most useful test to define the location and extent of lesions (see Fig. 77-3). Radiographs of the affected areas confirm the presence of

Paget disease and are useful for evaluating complications and local disease progression (see Fig. 77-2). The radiologic abnormalities seen on standard radiographs may reflect one of the three distinctive stages of pagetic lesions. The earliest lesions are osteolytic lesions, which are often observed as *osteoporosis circumscripta* in the skull (see Fig. 77-2A) or as an advancing *blade of grass* in long bones (see Fig. 77-2B).

Figure 77-2 Typical radiologic abnormalities in patients with Paget disease. **A**, Osteoporosis circumscripta of the skull. **B**, Lytic lesions in the femur with the characteristic *blade-of-grass* lesion. **C**, Blastic involvement of the right ischial ramus of the pelvis with thickening of the medial cortex. **D**, Mixed lytic and blastic disease involving the entire pelvis along with L4 and L5 and both femoral heads. (Courtesy of Dr. Daniel Rosenthal.)

Cortical thickening, coarse trabecular markings, and both lytic and sclerotic lesions in the same bone (see Fig. 77-2C) characterize the second stage of the disease. In the final stage, sclerotic lesions are primarily observed and are often associated with an increase in bone width (see Fig. 77-2D). Bone biopsy is rarely needed to diagnose Paget disease and should be avoided in weight-bearing areas. However, it is important to distinguish Paget disease of bone from other disorders associated with osteoblastic lesions such as metastatic prostate cancer, fibrous dysplasia, focal osteosclerosis, a poorly healing fracture, and giant cell tumors. In addition to radiologic evaluation, formal audiometry to assess hearing loss is indicated in patients with skull involvement.

Treatment

The two major goals of therapy are to relieve symptoms and to prevent complications. Potential indications for treatment include the following four situations:

1. In patients with symptoms caused by metabolically active Paget disease (i.e., bone pain, headache, neurologic complications)
2. In patients planning to undergo elective surgery on a pagetic site to decrease blood flow and minimize intraoperative blood loss
3. In the management of hypercalcemia, which is a rare complication that can occur when a patient with severe Paget disease is immobilized for a prolonged period
4. In patients who may be at high risk for complications if disease progresses locally, such as those at risk for bowing deformities in long bones, for hearing loss as a result of skull enlargement, for neurologic complications resulting from vertebral involvement, and for secondary arthritis where a pagetic lesion is located next to a major joint

Treatment of Paget disease usually involves a combination of nonpharmacologic therapy (i.e., physical therapy) and pharmacologic therapy. Pharmacologic therapy includes antiresorptive agents (Table 77-2) and analgesics for pain

Figure 77-3 Whole-body bone scan demonstrating abnormalities in a patient with polyostotic Paget disease. Increased radionuclide uptake is seen in the skull, right humerus, pelvis, right femur, and left tibia. (Courtesy of The Paget's Foundation.)

management. The second-generation bisphosphonates form the mainstay of therapy for Paget disease. The bisphosphonates decrease bone resorption at pagetic sites by inhibiting osteoclasts both directly and indirectly. The aim of therapy is to decrease the biochemical markers of bone metabolism (i.e., total alkaline phosphatase) well into the normal range. Currently six bisphosphonates have been approved by the U.S. Food and Drug Administration for treating Paget disease: intravenous zoledronate and pamidronate and oral etidronate, tiludronate, alendronate, and risedronate. Etidronate and tiludronate are less potent than the other bisphosphonates and therefore rarely used in the United States today. Previously, etidronate sodium was the only bisphosphonate available, and although effective, its use was limited because of a tendency to induce mineralization disorders when given at higher doses or for a longer period.

Table 77-1 Clinical Manifestations of Paget Disease

Musculoskeletal pain
Degenerative arthritis in joints near affected areas
Headaches
Skeletal deformity
Pathologic fractures
Enlarged skull
Erythema and warmth over pagetic bones
Hearing loss
Platybasia with or without basilar invagination
Neurologic compression syndromes
Angioid streaks in retina
Increased cardiac output; rarely congestive heart failure
Bone tumors
Osteogenic sarcoma
Fibrosarcoma
Chondrosarcoma
Reparative granuloma
Giant cell tumor
Laboratory abnormalities
Increased serum alkaline phosphatase (bone fraction)
Increased urinary hydroxyproline
Hypercalciuria and hypercalcemia during immobilization
Hyperuricemia
Characteristic radiographs
Increased uptake on bone scan

Table 77-2 Treatment of Paget Disease

Drug	Route	Dose
Bisphosphonates		
Alendronate (Fosamax)	Oral	40 mg/day for 6 months
Risedronate (Actonel)	Oral	30 mg/day for 2 months
Pamidronate (Aredia)	Intravenous	30-60 mg/day for 3 days
Zoledronate (Zometa)	Intravenous	5 mg single infusion
Etidronate (Didronel)	Oral	400 mg/day for 6 months
Tiludronate (Skelid)	Oral	400 mg/day for 3 months
Other		
Calcitonin (Miacalcin)	Subcutaneous injection	50-100 U/day

The introduction of the more potent amino-bisphosphonates—pamidronate, alendronate, risedronate, and zoledronate—represents a significant advance in the treatment of Paget disease. These agents often induce a biochemical remission in patients with Paget disease without producing mineralization defects at the recommended doses. Intravenous pamidronate can be given as two or three 30- to 60-mg infusions in patients with mild disease. More severe disease may require 60 to 90 mg on a weekly or twice-weekly basis. Cumulative doses of 240 to 480 mg may be required in some patients. Alendronate normalizes markers of bone turnover in most patients with Paget disease when

given in an oral dose of 40 mg per day for 6 months. Fewer than 10% of patients treated with alendronate have a biochemical recurrence within 12 months. Risedronate has similar effects on biochemical indices for bone turnover and is recommended at 30 mg per day for 2 months. Intravenous zoledronate is the most potent of the bisphosphonates and may be an alternative in patients with refractory disease. It has been shown to normalize alkaline phosphatase levels in more than 88% of patients with sustained remissions lasting at least 24 months after a single dose. It is given as a 5-mg single intravenous infusion. Calcium and vitamin D supplementation therapy is recommended for patients taking the more potent bisphosphonates to prevent hypocalcemia or secondary hyperparathyroidism. Resistance to individual bisphosphonates can occur. However, patients often respond to an alternate bisphosphonate. Therefore, some patients may require the use of more than one medication in the long-term management of the disease. Serum alkaline phosphatase should be measured at baseline and 2 to 3 months after the treatment is completed.

Salmon calcitonin was, at one time, the agent of choice for the treatment of Paget disease. The usual dose of 50 to

100 U per day by subcutaneous injection has been shown to reduce markers of bone turnover by up to 50%, decrease bone pain, and decrease many of the vascular and neurologic complications associated with Paget disease. However, secondary resistance to salmon calcitonin is not uncommon. It is not as potent as the bisphosphonates. Use of salmon calcitonin today is limited primarily to patients who are unable to receive either oral or intravenous bisphosphonates (i.e., creatinine clearance < 35).

Pain caused by bone deformity or arthritic changes is often relieved with acetaminophen or nonsteroidal anti-inflammatory drugs.

Orthopedic surgery may be indicated in the management of pagetic lesions when a complete fracture through pagetic bone occurs, to realign a severely arthritic knee, and for total joint arthroplasty in a severely affected hip or knee. Preoperative treatment with a bisphosphonate is recommended when possible in an attempt to decrease the vascularity of the lesion and minimize intraoperative bleeding. Surgical decompression may also be indicated if cranial nerve involvement or spinal nerve root compression is not relieved with medical therapy.

Prospectus for the Future

Although Paget disease is the second most common bone disease after osteoporosis, for unknown reasons, the incidence appears to be decreasing. Some experts believe this decline may be related to a decrease in the frequency of measles or other paramyxoviral infections with widespread vaccination. The reasons for this decline remain one principal unanswered question in Paget disease. The second major area of controversy in Paget disease continues to surround its cause. The contribution of a genetic component versus a viral component remains the largest area of ongoing Paget research. On the viral side of the argument, although studies during the past 30 years—immunohistochemical, ultrastructural, and *in situ*

hybridization studies—have suggested a paramyxoviral origin for Paget disease, other investigators have failed to detect paramyxovirus transcripts in pagetic osteoclasts or their precursors. On the genetic side, mutations in the gene that encodes an adaptor protein in the RANKL-signaling pathway occur in almost 30% of patients with familial Paget disease. In addition, genetic linkage of Paget disease with chromosomal loci on chromosomes 18, 5, 6, and 2 also exists. Obviously, combined genetic and viral causes are possible and probably likely. Ongoing research in these areas will continue to shed light on this disease of complex origin.

Approach to the Patient with Rheumatic Disease

Niveditha Mohan

Rheumatic diseases encompass a range of musculoskeletal and systemic disorders that often involve joints and periarticular tissues and include diseases that are thought to be autoimmune in cause. The causes of arthritis range from local trauma to infection, gout, osteoarthritis, and autoimmune connective tissue diseases, such as rheumatoid arthritis and systemic lupus erythematosus (SLE). Distinguishing localized processes from those that are systemic, executing logical diagnostic procedures, and embarking on appropriate therapeutic courses depend on careful clinical evaluation. As in other areas of medicine, history and physical examination are paramount, and laboratory tests are more confirmatory than diagnostic. The *connective tissue screen* is performed at the bedside, not in the laboratory. The practice of either including or excluding systemic connective tissue disease on the basis of laboratory panels is unreliable and therefore unwise.

Musculoskeletal History and Examination

Features in the medical history that are useful in distinguishing different types of arthritis are listed in Tables 78-1 and 78-2. When a patient has a musculoskeletal complaint, a thorough history and physical examination will provide the diagnosis in the majority of patients. Further investigations are necessary to confirm or support the clinical diagnosis. A logical approach to musculoskeletal complaints is indispensable to arriving at the correct diagnosis.

The first step is to confirm that the complaint is truly originating from the musculoskeletal system and not referred pain relating to other organ system pathology (e.g., left shoulder pain secondary to cardiac disease). The next question would be to define whether the problem is articular or extra-articular based on the history of the presenting illness. Appreciating the demographics of different illnesses provides useful information for diagnostic evaluation. Spondyloarthropathies are more commonly diagnosed in pre-

dominantly young men, SLE in young women, gout in middle-aged men and postmenopausal women, and osteoarthritis in the older adult population. The age of the patient can be a clue to specific rheumatic disorders. Asymmetrical pain and swelling in the knees have different connotations in a 70-year-old patient than they do in a 20-year-old patient. Other host characteristics that may have a bearing on the cause of disease include immune status.

Immunocompromised patients should always be evaluated for infectious arthritis; patients with HIV may have a severe form of Reiter syndrome or a sudden flare of psoriasis or psoriatic arthritis. The patient's history provides the basis for distinguishing inflammatory from noninflammatory arthropathies. *Inflammatory arthritis* is characterized by pain at rest, morning stiffness, gelling, joint swelling, and joint tenderness. In *osteoarthritis* and *nonarthritic musculoskeletal problems*, pain is generally not present at rest and is precipitated by activity. Occasionally, however, osteoarthritic joints are stiff and are initially improved with activity. In *crystal-induced arthritis* the onset is abrupt, in *septic arthritis* it is less so, and in most other disorders it is slow and insidious. Patterns of joint involvement—monoarthritis (1, septic or crystal-induced arthritis), pauciarthritis or oligoarthritis (2 to 4, Reiter or psoriatic arthritis), or polyarthritis (5 and above, rheumatoid arthritis or lupus)—can be typical of certain disorders. Symmetry, migratory features, large versus small joints, and locations (axial versus appendicular) characteristic of specific diseases are also key items in the patient's history. Presence of enthesopathy can be a clue to the presence of a spondyloarthropathy. Constitutional features such as fatigue, weight loss, and fever are seen in systemic autoimmune disease and infection but not in localized conditions. It is also important to do a thorough review of systems to identify the “company it keeps” that will provide clues to defining associated systemic syndromes. Many exceptions can be found to these basic demographic and clinical generalizations, but they are often helpful starting points when a patient is being evaluated for the first time.

On physical examination, active and passive range of motion in all joints should be carefully assessed, and the

presence of tenderness, swelling, warmth, erythema, deformity, and joint effusions should be evaluated (Fig. 78-1). Patients are frequently unaware of detectable joint abnormalities, including deformity and effusion, and the presence of either is a sign of joint disease. Reported pain may be referred from another site, and this feature can be elucidated by examination. Thus pain in the knee is often a sign of hip disease and may be reproduced on examination of the hip. The presence of palpable synovitis, or a thickening of the synovial membrane, is helpful in diagnosing inflammatory arthritides such as rheumatoid arthritis. Different diseases have distinctive patterns of joint involvement, which provides critical diagnostic information. For example, prominent disease of distal interphalangeal joints is seen in psoriasis and in inflammatory osteoarthritis. Wrist and metacarpophalangeal involvement are almost universal in rheumatoid

arthritis but rare in osteoarthritis. Examination of the axial skeleton may reveal diminished lumbar flexion, decreased rotational motion of the spine, and decreased chest expansion, as well as features of ankylosing spondylitis and other spondyloarthropathies. Patients may report symptoms in only a single joint, but finding additional affected joints on physical examination could change the entire evaluation of a patient.

Rheumatic diseases may involve any organ system, and a full physical examination should be performed on all patients. Alopecia (SLE), fundoscopic changes (SLE), uveitis (spondyloarthropathy and juvenile arthritis), conjunctivitis (reactive arthritis), sicca symptoms (Sjögren syndrome), oral and other mucous membrane ulcers (reactive arthritis, SLE, and Behçet syndrome), lymphadenopathy (SLE and Sjögren syndrome), and cutaneous lesions (psoriasis, dermatomyositis, scleroderma, SLE, and vasculitides) should be considerations. Recurrent otorhinolaryngologic complaints, such as sinusitis, should be suspected for Wegener's granulomatosis. Lesions of psoriasis in the scalp, umbilicus, and anal crease; thickening of the skin on the fingers in scleroderma; and mucous membrane ulcers are often overlooked. The lung examination may show evidence of interstitial fibrosis (scleroderma, SLE, rheumatoid arthritis, and myositis), and a cardiac evaluation may reveal aortic insufficiency (SLE and spondyloarthropathy), pulmonary hypertension (systemic sclerosis), or evidence of cardiomyopathy (systemic sclerosis, myositis, and amyloidosis). Pleural and pericardial rubs may be present in SLE, rheumatoid arthritis, and scleroderma. Hepatosplenomegaly (SLE and rheumatoid arthritis) and abdominal distention (scleroderma) are also valuable clinical clues. Muscular examination may reveal weakness from myositis, neuropathy (vasculitis and SLE), or myopathy (steroid myopathy) or synovitis (rheumatoid arthritis, SLE, spondyloarthropathy). A complete neurologic examination is critical and may reveal carpal tunnel syndrome, peripheral neuropathy such as mononeuritis multiplex (an asymmetrical sensory and/or a motor

Table 78-1 Clinical Features Helpful in Evaluation of Arthritis

Age, sex, ethnicity, family history
Pattern of joint involvement
Monoarticular, oligoarticular, polyarticular
Large versus small joints
Symmetry
Insidious versus rapid onset
Inflammatory versus noninflammatory pain (e.g., morning stiffness, gelling, night pain)
Presence of constitutional symptoms and signs (e.g., fever, fatigue, weight loss)
Presence of synovitis, bursitis, tendinitis
Involvement of other organ systems (e.g., rash, mucous membrane lesions, nail lesions)
Presence of arthritis-associated diseases (e.g., psoriasis, inflammatory bowel disease)
Anemia, proteinuria, azotemia
Presence of erosive joint disease

Table 78-2 Differentiating Features of Common Arthritides

Disease	Demographics	Joints Involved	Special Features	Laboratory Findings
Gout	Men, postmenopausal women	Monoarticular or oligoarticular	Podagra, rapid onset of attack, polyarticular gout, tophi	SF: Crystals, high WBC, >80% PMN
Septic arthritis	Any age	Usually large joints	Fever, chills	SF: High WBC, >90% PMN, culture
Osteoarthritis	Increases with age	Weight-bearing, hands		Noninflammatory SF
Rheumatoid arthritis	Any age, predominantly women ages 20-50 yr	Symmetrical, small joints disease	Rheumatoid nodules, extra-articular	SF: High WBC, >70% PMN
Reactive arthritis (Reiter syndrome)	Young males	Oligoarticular, asymmetrical	Urethritis, conjunctivitis, skin and mucous membranes	SF: Moderate WBC, >50% PMN
Spondyloarthropathy	Young to middle-aged men	Axial skeleton, pelvis (sacroiliac joints)	Uveitis, aortic insufficiency, enthesopathy	
Systemic lupus erythematosus	Women in childbearing years	Hands, knees	Nonerosive joint disease, autoantibodies, mostly mononuclear; multi-organ disease	SF: Low-to-moderate WBC, almost 100% have antinuclear antibodies

PMN, neutrophils; SF, synovial fluid; WBC, white blood cells.

Figure 78-1 Anatomic structures of the musculoskeletal system (left). Location of musculoskeletal disease processes (right). (From Gordon DA: Approach to the patient with musculoskeletal disease. In Bennett JC, Plum F [eds]: Cecil Textbook of Medicine, 20th ed. Philadelphia, WB Saunders, 1996, p 1440.)

neuropathy as seen in many vasculitides), and central nervous system disease (SLE and vasculitis). Recurrent miscarriages, livedo reticularis, Raynaud phenomenon, and recurrent thrombotic events are suspicious for antiphospholipid antibody syndrome (primary or secondary to SLE).

At the initial evaluation, one important question is whether diagnosis and treatment of the patient's problem require urgent attention. Infectious processes obviously belong in this category. The presence of acute joint inflammation, fever, and systemic signs such as chills, night sweats, and leukocytosis all provide supporting evidence for infection. Gouty arthritis may share some or all of these clinical features, but its onset tends to be more abrupt. Inflammation extending beyond the margins of the joint is characteristic of septic arthritis and is otherwise seen only in crystal disease and rheumatoid arthritis. Nonarticular processes—cellulitis, septic bursitis, tenosynovitis, and phlebitis—may mimic infectious arthritis. Analysis of synovial fluid is the key to diagnosis.

Acute nerve entrapment or spinal cord compression, tendon rupture, and fractures may all occur in the absence of obvious trauma. Spinal cord compression may be the result of a herniated disk or vertebral subluxation. Tendon rupture may occur in inflammatory arthritides, particularly in the wrist in rheumatoid arthritis. Pelvic and other *insufficiency* fractures may be seen in patients with osteoporosis or osteomalacia. Careful musculoskeletal and neurologic examinations help in the detection of these disorders, each of which requires urgent treatment.

In systemic rheumatic diseases, the onset is usually more insidious, and the clinical course is prolonged. Treatment is usually less urgent and can be safely deferred, particularly if the diagnosis is uncertain. However, potential threats to life or the possibility of serious and/or irreversible organ damage may exist in some disorders. In SLE and systemic vasculitis, patients may have central or peripheral nervous system disease, including brain and peripheral nerve infarcts, glomerulonephritis, inflammatory or hemorrhagic lung disease, coronary artery involvement, intestinal infarcts, and digital infarcts. Threatened digital loss may also be seen in sclero-

derma and Raynaud's disease. Renal crisis may occur in scleroderma, with vasculopathy leading to renal infarcts, azotemia, micro-angiopathy, and severe hypertension. Urgent therapy to ameliorate or prevent damage may be indicated in these disorders. In giant-cell arteritis, acute blindness is a potential complication, and the diagnosis requires urgent therapy even before confirmatory biopsy. Acute inflammatory myositis should be promptly treated because it may progress rapidly to the involvement of the respiratory musculature. In some cases, major organ involvement may be occult. When systemic disease is suggested, the patient's lung and kidneys should be carefully evaluated.

Laboratory Testing

As noted earlier, *synovial fluid analysis* is an important part of the evaluation of arthritis (Table 78-3). It helps distinguish inflammatory from noninflammatory arthritis and can be diagnostic of infectious arthritis or crystal disease. Synovial fluid consists of an ultrafiltrate of plasma into which synovial lining cells secrete hyaluronic acid, which is responsible for the high viscosity of synovial fluid. Evaluation of synovial fluid should include the following: (1) cell count and differential, (2) crystal examination for sodium urate and calcium phosphate dehydrate crystals, and (3) Gram stain and culture. Synovial fluid glucose and protein are not diagnostically useful tests. Synovial fluid examination should be performed in the evaluation of all acute arthritides and all situations in which joint infection is probable and ideally should be performed on at least one occasion in the evaluation of chronic inflammatory arthritis. Aspiration and analysis of fluid before therapy are critical to appropriate decision making.

Although autoantibodies are often considered the hallmark of rheumatic diseases, their diagnostic utility in individual patients is actually much less than commonly believed. Although almost 100% of patients with SLE have antinuclear antibodies, as do most patients with scleroderma and autoimmune myositis, the proportion of patients with positive

Table 78-3 Classification of Synovial Effusions by Synovial White Cell Count

Group	Diagnosis (Examples)	Appearance	Synovial Fluid White Cell Count (mm ³)*	Polymorphonuclear Cells (%)
Normal		Clear, pale yellow	0-200	<10
I. Noninflammatory	Osteoarthritis; trauma	Clear to slightly turbid	50-2000 (600)	<30
II. Mildly inflammatory	Systemic lupus erythematosus	Clear to slightly turbid	100-9000 (3000)	<20
III. Severely inflammatory (noninfectious)	Gout	Turbid	2000-160,000 (21,000)	~70
	Pseudogout	Turbid	500-75,000 (14,000)	~70
	Rheumatoid arthritis	Turbid	2000-80,000 (19,000)	~70
IV. Severely inflammatory (infectious)	Bacterial infections	Very turbid	5000-250,000 (80,000)	~90
	Tuberculosis	Turbid	2500-100,000 (20,000)	~60

*Mean values in parentheses.

test results in other rheumatic diseases is much lower. Conversely, 15% to 25% of healthy persons have antinuclear antibodies when commercial test kits are used, sometimes in high titers. Older persons and patients with nonrheumatic systemic diseases such as malignant disease and nonrheumatic autoimmune diseases such as thyroiditis or hypothyroidism have even higher frequencies. Other specific autoantibodies may be more useful and are discussed in subsequent chapters. *Rheumatoid factor* is found in approximately 80% to 90% of patients with rheumatoid arthritis but also in a variety of other rheumatic diseases, in chronic infection, in neoplasia, and in almost any state that can cause chronic hyperglobulinemia. Neither a positive nor a negative test result is diagnostic, and results should be interpreted only in clinical context. Antibodies to cyclic citrullinated peptides are helpful in diagnosing rheumatoid arthritis. Antibody tests should be ordered and repeated only if they can be of help in making the diagnosis, assessing the prognosis, or altering treatment plans.

Tests for acute phase proteins, C-reactive protein, and erythrocyte sedimentation rate are nonspecific, but positive results suggest the presence of inflammatory disease. In some cases, such as in patients with giant-cell arteritis and polymyalgia rheumatica, these tests may be useful both in diagnosis and in monitoring the course of disease and therapy. The presence of anemia may suggest chronic disease or hemolytic anemia. Leukopenia, especially lymphopenia, suggests SLE, and thrombocytosis indicates active inflammation. Leukocytosis may also reflect inflammation or infection, and glucocorticoid therapy also elevates the white blood cell count, often dramatically. Urinalysis should always be performed in patients with systemic disease, and proteinuria, red blood cells, and casts should be considered as evidence of occult renal disease. Laboratory tests should always be considered within the context of the clinical presentation.

Radiographic Studies

Radiographic evaluation often shows changes characteristic of particular diseases. In established rheumatoid arthritis, patients often have classically erosive disease of the small joints of the wrists, the ulnar styloid, the metacarpophalan-

geal and proximal interphalangeal joints, and the small joints in the foot. The erosions are bland and nonreactive. In contrast, erosive psoriatic arthritis causes a sclerotic reaction, and the patient may have characteristic telescoping of joints, the so-called *pencil-in-cup lesions*. Large erosions with overhanging sclerotic margins and even juxta-articular tophi may be seen in gout. In ankylosing spondylitis, sacroiliitis is observed on pelvic films and has high diagnostic specificity. *Syndesmophytes* (calcification of the outer rim of the annulus fibrosis), bridging osteophytes, calcification of spinal ligaments, and a typical bamboo spine in late stages are seen on lumbar and chest radiographs. Joint space narrowing, bony spurs, and sclerosis are seen in osteoarthritis. *Chondrocalcinosis* is a common finding and may be asymptomatic or may lead to crystal arthritis (pseudogout). In acute arthritis, radiographs are much less helpful because bony changes take time to develop; only in septic joint disease is destruction observed in the early stages.

Imaging modalities such as magnetic resonance imaging (MRI), radionuclide scans, ultrasound, and computed tomography are often useful in assessing diseases of bones, joints, muscle, and soft tissues. Ultrasound may be used to detect synovial cysts, especially Baker cysts of the knee. MRI is the procedure of choice for evaluating early avascular necrosis of bone, especially the hips, as well as suggested meniscal or rotator cuff disease. MRI is also the preferred procedure for evaluating intervertebral disk disease with suggested radiculopathy and spinal stenosis. MRI is also very useful in evaluating solid lesions of bone and joints, including neoplastic lesions. The sensitivity of MRI for detecting edema (water) makes it useful in evaluating inflammatory muscle disease of both infectious and noninfectious causes. An MRI is a sensitive but not a specific modality for evaluating osteomyelitis, properties shared with radionuclide imaging. MRI should not supplant clinical evaluation or plain radiography.

In many instances, diagnosis can be made with certainty only by pathologic examination of tissue. Muscle biopsy may be necessary to establish a diagnosis of inflammatory muscle disease, and nerve biopsy may be needed to detect vasculitis. Skin biopsy is often quite useful in differentiating the many causes of skin disease in rheumatology. Renal biopsy is often needed for diagnosis, as well as for treatment decisions and prognosis.

Summary

The evaluation of arthritis begins with a careful assessment of the location and pattern of joint involvement, the differentiation of inflammatory from mechanical and other causes, and the consideration of nonarticular systemic fea-

tures. The patient's age and sex, family history, and medication history, as well as the presence of other medical conditions, are also important; they are often key features. Laboratory and radiographic studies, in particular synovial fluid analysis, provide confirmatory and sometimes diagnostic information.

Prospectus for the Future

- A thorough history and physical examination will remain the basis of rheumatic disease diagnosis.
- Improvements in key laboratory studies, including serologic tests and imaging techniques, are useful in confirming or supporting the clinical diagnosis in most patients.

Rheumatoid Arthritis

Larry W. Moreland

Rheumatoid arthritis (RA) is a chronic, systemic, inflammatory disorder of unknown cause. It is characterized by symmetrical, polyarticular pain and swelling, morning stiffness, and fatigue. RA has a variable course, often with periods of exacerbations and, less frequently, true remissions. Outcomes are also variable, ranging from the rarely seen remitting disease to severe disease that brings disability and even, in some patients, premature death. Without treatment, the majority of patients will experience progressive joint damage. In some patients this results in significant disability within just a few years. The past decade has seen an unprecedented change in the treatment paradigm for this disease. Several targeted biologic therapies are available; the most notable are the anti-tumor necrosis factor (TNF) therapies.

Epidemiologic Features and Genetics

RA is a worldwide problem, with a prevalence of 0.5% to 1% of the adult population and an annual incidence of 0.03% with substantial variation across different studies and time periods. Overall, RA appears to be less common in Asia and Africa than in the United States and Europe, and it has been suggested that the incidence of RA decreases from northern to more southern European countries. The disease affects individuals at any age, including infants and the elderly; however, it occurs most commonly in women aged 40 to 50 years. RA is not very common in men under 45 years of age, but the incidence rises steeply with increasing age. In women, the incidence rises to age 45, plateaus until age 75, and then declines. Numerous studies have demonstrated increased mortality in patients with RA compared with the general population. There are reports of increased risk of death from gastrointestinal (GI), cardiovascular, respiratory, hematologic, and infectious diseases.

The pathophysiology of RA has undergone intensive investigation over the past 25 years. It is well known that an individual's genetic background plays a critical role in the susceptibility to and severity of RA. Careful studies have revealed a 15% concordance in monozygotic twins, which

is approximately 4 times greater than the rate in dizygotic twins, which supports a genetic component. Disease transmission is complex and likely involves many genes. The genes with the greatest impact lie in the class II major histocompatibility (MHC) locus. There is a strong association of RA with a specific sequence on the beta chains of select human leukocyte antigen (HLA)-DR haplotypes. This "shared epitope" contains amino acids 70 to 74 (glutamine-leucine-arginine-alanine-alanine) and is also known as QKRAA.

The underlying cause of the disease—that is, the triggers in the susceptible host—are unknown. It is possible that RA may consist of multiple diseases now defined by some common clinical manifestations, and there may not be a single predominant mechanism of initiation or perpetuation.

Pathologic Features

A current concept is that inflammation and tissue destruction in the rheumatoid synovium result from complex cell-cell interactions. The process may be initiated by an interaction between antigen-presenting cells (APCs) and CD4⁺ T cells. APCs display complexes of class II MHC molecules and peptide antigens that bind to specific receptors on the T cells. With an appropriate "second signal" or costimulation delivered by the APC to the T cell, a clonal expansion of T-cell subsets occurs. This stimulates synovial macrophages to secrete proinflammatory cytokines, such as interleukin-1 (IL-1), TNF- α , and IL-6 to activate multiple inflammatory and destructive pathways.

Joint damage in RA results from proliferation of the synovial intimal layer to form a pannus that overgrows, invades, and destroys adjacent cartilage and bone, evident on radiographs as loss of joint space and juxta-articular bone erosion. Fibroblast-like synoviocytes and macrophages are the predominant cellular components of the invading pannus. Extracellular matrix damage resulting from synovial expansion is caused by several families of enzymes, including serine proteases and cathepsins. Matrix metalloproteinases, produced mostly by synoviocytes in the intimal lining, are also important mediators of tissue destruction.

Pathophysiologic Features

The pathogenesis of RA is complex, and the disease is heterogeneous. Multiple pathways independently contribute, as demonstrated by the similar and non-overlapping response rates to cytokine-, T-cell-, and B-cell-targeted therapies (Table 79-1 and Fig. 79-1). It is reasonable to hypothesize that the disease can be divided into multiple stages. An induction phase can provide an environment in the joint that permits recruitment of inflammatory cells. Cigarette smoke, bacterial products, viral components, and other environmental stimuli may enhance and amplify this process. A genetic propensity for autoreactivity might initiate an irreversible pathway to RA. Specific genes are probably part of this process, including MHC class II genes, protein tyrosine phosphatase, non-receptor type 22 (*PTPN22*), and cytokine promoter polymorphisms. The destructive phase then may occur, which can be antigen dependent and independent, involving mesenchymal elements such as fibroblasts and synoviocytes. Bone erosions result from local differentiation and activation of osteoclasts, whereas cartilage damage appears to be caused by proteolytic enzymes produced by synoviocytes, macrophages, and synovial fluid neutrophils. Counter-regulatory mechanisms (e.g., soluble TNF receptors, suppressive cytokines, protease inhibitors, natural cytokine antagonists) are not produced in high enough levels to offset the inflammatory and destructive process. However, therapeutic interventions that modulate any of these pathogenic processes have been shown to have significant impact on both clinical signs of RA and the destructive component of the disease.

Cytokines, which are hormone-like proteins that regulate many immune cell functions, have been implicated in critical components of RA synovial inflammation. The inflammatory milieu of the joint is dominated by proinflammatory factors produced by macrophages and fibroblasts, especially in the synovial intimal lining. These (and other) cytokines, which include IL-1, IL-6, TNF, granulocyte-macrophage colony-stimulating factor [GM-CSF], IL-15, IL-18, IL-32, and most members of the chemokine family, have been identified at both the protein and the mRNA levels.

The autoantibodies found most frequently in patients with RA are antibodies against IgM (IgM rheumatoid factor [IgM-RF]) and anticyclic citrullinated peptide [anti-CCP]). There has been a large body of literature recently on the diagnostic, prognostic, and pathogenic significance of anti-CCP antibodies. Although the research has just begun into the pathophysiologic significance of anti-CCP antibodies, there is emerging data that the presence of these antibodies predicts a less favorable disease course and radiologic progression.

Clinical Features

RA is a symmetrical polyarthritis typically involving the small joints of the hands and feet, the wrists, and the ankles. Other joints frequently involved include the cervical spine, shoulders, elbows, hips, and knees. Any diarthrodial (synovial) joint may be involved, including the apophyseal, temporomandibular, and cricoarytenoid joints. Involved joints are swollen, warm, and tender, and they may have effusions. The synovium, normally a few cell layers thick, becomes palpable on examination (*synovitis*). Prolonged *morning stiffness*, usually lasting more than 1 hour and often many hours, is a classic feature in RA, and symptoms are generally improved with moderate activity (Table 79-2).

Over time, RA progresses to joint destruction and deformity. Erosive lesions of bone and cartilage are radiographically and pathologically visible at the margins of bone and cartilage, the site of synovial attachment. *Tenosynovitis*, or inflammation of tendon sheaths, leads to tendon malalignment, stretching, and/or shortening. Among common deformities are ulnar deviation at the metacarpophalangeal joints and volar subluxation at these joints, volar subluxation at the wrists, and flexion and extension contractures in the proximal and distal interphalangeal (DIP) joints of the fingers that lead to characteristic *swan-neck deformity* (flexion contracture at the DIP joint and hyperextension at the proximal interphalangeal joint) or *boutonnière deformity* (flexion contracture at the proximal interphalangeal joint and hyperextension at the DIP joint). Erosions of the ulnar styloid can lead to sharp bony prominences and rupture of extensor tendons. Synovitis at the wrists can lead to median nerve compression and carpal tunnel syndrome. Cervical spine disease may lead to C1-C2 subluxation and spinal cord compression; caution should be taken in moving the neck when the patient is being anesthetized for a surgical procedure. The degree of subluxation can be monitored by looking at the distance between C1 and the odontoid in flexion-extension films. Rupture of synovial fluid from the knee into the calf (Baker cyst) may mimic deep-venous thrombosis or, occasionally, cellulitis.

Table 79-1 Pathogenesis of Rheumatoid Arthritis

Tissue Phase

Immune cell localization to synovial tissue
 T- and B-cell and monocyte recruitment
 T-cell activation and proliferation and cytokine release
 B-cell elaboration of rheumatoid factor and other antibodies
 Monocyte elaboration of inflammatory cytokines: IL-1, TNF- α , IL-6
 Synovial cell proliferation and activation by IL-1 and TNF- α
 Release of inflammatory eicosanoids (PGE₂)
 Synthesis of collagenase and other matrix metalloproteinases
 Erosions of bone and cartilage
 Osteoclast and chondrocyte activation
 Release of proteases
 Resorption of bone and cartilage

Fluid Phase

Immune complexes in synovial fluid
 Complement activation and release of C3a, C5a
 Neutrophil recruitment and activation
 Release of prostaglandins, leukotrienes, and reactive oxygen species
 Release of lysosomal enzymes
 Vasodilation, development of joint effusions, pain, and swelling
 Superficial cartilage erosions

IL-1, interleukin-1; IL-6, interleukin-6; PGE₂, prostaglandin E₂; TNF- α , tumor necrosis factor- α .

Figure 79-1 Pathogenetic events in rheumatoid arthritis. The proliferative synovial pannus invades at the bone-cartilage interface. Interleukin-1 (IL-1) and tumor necrosis factor- α (TNF) activate synovial cells (SC) to produce prostaglandins and matrix metalloproteinases (MMPs). In the synovial fluid, polymorphonuclear leukocytes (PMN), activated by immune complexes and complement, produce mediators of inflammation and destruction. CD, chondrocyte; MNC, mononuclear cell; OC, osteoclast.

Table 79-2 Clinical Characteristics of Rheumatoid Arthritis

Articular

Morning stiffness, "gelling"
 Symmetrical joint swelling
 Predilection for wrists and proximal interphalangeal, metacarpophalangeal, and metatarsophalangeal joints
 Erosions of bone and cartilage
 Joint subluxation and ulnar deviation
 Inflammatory joint fluid
 Carpal tunnel syndrome
 Baker cyst

Nonarticular

Rheumatoid nodules: subcutaneous, pulmonary, scleral
 Lung disease
 Vasculitis, especially skin, and peripheral nerves
 Pleuropericarditis
 Scleritis and episcleritis
 Leg ulcers
 Felty syndrome

The clinical course and severity of the arthritis are variable. Some patients have mild, slowly progressive disease with few deformities and little bony destructive change. At the opposite extreme are patients who have a rapidly progressive course that, if left untreated, leads to crippling and deforming arthritis. Most patients fall in between these extremes with various levels of disability; some have a waxing

and waning course over a period of years with acute episodes of single- or multiple-joint exacerbations.

RA is a systemic disease with constitutional symptoms: fatigue, low-grade fever, weight loss, and myalgia. Anemia is also common. Specific organs other than the musculoskeletal system may be involved (see Table 79-2). Grossly palpable subcutaneous *rheumatoid nodules* can occur almost anywhere but are common along other extensor tendon surfaces, especially at the elbows, and less commonly in the lungs, pleura, pericardium, sclerae, and other sites, including the heart in rare cases. The occurrence of multiple pulmonary nodules in patients with RA and pneumoconiosis is known as *Caplan syndrome*. Pleuritis, pericarditis, and interstitial lung fibrosis occur in a few patients; pericarditis can be severe, and acute interstitial lung disease can be associated with pulmonary hemorrhage. Vasculitis, associated with circulating complexes of immunoglobulin G (IgG) and rheumatoid factor (RF), leads to cutaneous lesions, including ulcers and skin necrosis, and mononeuritis multiplex. Secondary *Sjögren syndrome* (sicca complex) is often present (see Chapter 85). *Felty syndrome* (splenomegaly, leukopenia, and recurrent pulmonary infections) is a rare complication and is often accompanied by leg ulcers and vasculitis. Extra-articular manifestations of RA are more commonly seen among patients who test positive for RF. Even in patients without vasculitis or pulmonary or pleuropericardial disease, the mortality rate in RA is increased by a variety of causes, including side effects of therapy and infection. Premature and accelerated atherosclerosis is an increasingly

recognized problem among patients with RA and is thought, at least, to be partially a result of the effects of chronic inflammation.

Diagnosis

Diagnosing a chronic illness, such as RA, and separating it from other conditions that may be self-limited or have different outcomes can be difficult. There are no early-onset, disease-specific features, and the characteristic hallmarks of the disease develop over time. There is no single diagnostic test that enables a diagnosis of RA to be made with certainty. Instead, diagnosis depends on the accumulation of characteristic symptoms, signs, laboratory data, and radiologic findings. RA is a clinical diagnosis. Symmetrical synovitis of small joints—that is, warm, swollen joints with synovial hypertrophy, morning stiffness, and fatigue—is the classic symptom. *Systemic lupus erythematosus* (SLE) can have a similar clinical presentation and may be difficult to differentiate unless other features are present. In rare cases, *Lyme disease* is polyarticular and symmetrical at onset. *Viral arthritis* is best distinguished by its limited course. In the older patient, polymyalgia rheumatica, hypothyroidism, and paraneoplastic syndromes, including hypertrophic osteoarthropathy, should be considered. Crystal arthropathies (gout and pseudogout) can, if left untreated, rarely appear clinically as chronic polyarthritis.

No test is necessary to establish a diagnosis of RA, and all laboratory results may be normal in certain patients. Routine tests are often not characteristic and lack specificity; however, certain data may contribute to the diagnosis and assessment of the severity of RA in an individual.

RF was identified as an antibody (typically IgM but also IgG or others) that binds to the Fc fragment of IgG. It is detectable in the serum of 70% to 80% of patients with RA but may not be present in early disease. It is unclear whether the production of RF is of pathologic relevance to RA, because RF production also frequently occurs in patients with SLE; Sjögren syndrome; endocarditis; sarcoidosis; liver and lung diseases, including hepatitis B and C infection; and other conditions. In addition, RF may be detected in the serum of apparently healthy individuals, especially people older than 50 and in smokers. In an individual patient, the titer does not correlate with disease activity, but it does appear that patients with severe erosive arthritis or with extra-articular disease are likely to have relatively high titers. The presence of a positive serum RF does not establish a diagnosis of RA, but when combined with a typical clinical picture, it does help to confirm the clinical impression.

Anti-CCPs have been identified as a more specific marker for RA. Anti-CCP antibodies, detected using enzyme-linked immunosorbent assay, have a much higher specificity (>95%) than RF, with similar sensitivity (68% to 80%). These antibodies, which can be detected several years before the development of clinical RA (and before the development of RF), can be helpful in diagnosing RA in patients with RF-negative (seronegative) arthritis. They also appear to mark more severe outcomes, such as radiographic joint damage and poor prognosis. Because of their higher specificity for RA, anti-CCP antibodies may be useful in differentiating RA

from other conditions with positive rheumatoid factors, including Sjögren syndrome, infection, and hepatitis.

Acute phase reactants, such as erythrocyte sedimentation rate and C-reactive protein, are usually elevated in the presence of active inflammation but are not specific for the diagnosis of RA. They are useful in distinguishing RA from noninflammatory conditions such as osteoarthritis or fibromyalgia. However, a significant number of RA patients have normal levels of these reactants, despite clinical evidence of joint inflammation.

Synovial fluid analysis is usually not necessary when the diagnosis is already established, but arthrocentesis should be performed to rule out infection or crystalline arthropathy in patients who develop disproportionate discomfort and swelling of one joint.

Treatment

The ultimate goals of RA management are to reduce pain and discomfort; prevent deformities and loss of normal joint function, and maintain normal physical, social, and emotional function and capacity to work. Management begins with effective communication between physician and patient. It is very important to educate the patient and his or her family about the nature and course of the disease—the specific causes of the discomfort and the goals, problems, and expectations of treatment. Misunderstandings about the disease may lead to frustration, depression, and withdrawal.

Nonpharmacologic therapeutic options include reduction of joint stress, and physical and occupational therapy. Local rest of an inflamed joint can reduce joint stress, as can weight reduction, splinting, and use of walking aids and specially designed assistive devices. Vigorous activity should be avoided during disease flares, although full range of motion of joints should be maintained by a graded exercise program to prevent contractures and muscle atrophy.

The former pharmacologic approach to the treatment of RA was to begin with symptomatic treatment of inflammation using nonsteroidal anti-inflammatory drugs (NSAIDs) in addition to rest and corticosteroid injections. If the disease did not significantly improve, more potent disease-modifying antirheumatic drugs (DMARDs) were started. This is no longer the recommended approach for the treatment of RA. Maintaining normal joint structure and anatomy can be achieved only by controlling the disease before any irreversible damage has occurred. Studies have revealed that DMARD therapy early in the course of RA slowed disease progression more effectively than did delayed use. Effective, aggressive treatment can improve both signs and symptoms, and radiographic progression, even in long-standing disease. This has led to a general agreement that the inflammation of RA should be controlled as completely as possible, as soon as possible, and that this control should be maintained for as long as possible.

NSAIDs are probably the most frequently used drugs in the treatment of RA, at least early in the disease process. They reduce joint pain and swelling and improve function, but they have no effect on the underlying disease process, and exacerbation of symptoms occurs quickly after metabolic elimination of the drugs. They are rarely, if ever, used alone for treatment of RA.

The major therapeutic effect of NSAIDs relates to their ability to suppress the synthesis of prostaglandins by inhibiting the enzyme cyclo-oxygenase (COX), which exists in two isoforms: COX-1 and COX-2. COX-1 is expressed in many tissues and is primarily responsible for the production of prostaglandins by endothelium and gastric mucosa, leading to homeostatic and cytoprotective effects. COX-2 is undetectable in most tissues; its expression increases during development and inflammation and can be induced by several proinflammatory stimuli. It is hypothesized that the anti-inflammatory effects of NSAIDs are mainly the result of COX-2 inhibition and that inhibition of COX-1 is responsible for most of the GI toxicity.

Glucocorticoids remain important in the treatment of RA, especially for acute exacerbations of disease. These agents are usually used sparingly, in low-to-medium doses, and optimally for short periods. Although glucocorticoids are useful for brief exacerbations of the disease or to bide time while waiting for DMARDs to work, many patients require more prolonged use of low doses for optimal control of disease activity, even when other immunomodulatory drugs are also prescribed. The long-term side effects of glucocorticoids can be substantial and particularly devastating in a disease such as RA that is already marked by relative immobility. Side effects include osteoporosis and pathologic fractures, avascular necrosis of bone, obesity, glucose intolerance, and many other problems. Screening, prevention, and treatment for osteoporosis should be considered in all patients who receive long-term therapy with glucocorticoids. Intra-articular glucocorticoids are extremely useful and efficacious in exacerbations involving only a few joints, and intra-articular delivery of these agents is associated with almost no side effects.

Although NSAIDs and glucocorticoids are important for the treatment of RA, they do not control symptoms or alter the disease course for the majority of patients. Current practice is to place most patients with RA on DMARDs (Table 79-3). Previously, many of these drugs were given only late in the course of disease to patients with severe disease. Recognition of the extent of disability resulting from RA and growing evidence that DMARD use inhibits the progression of erosive disease and disability have led to earlier and more widespread use of these agents.

A wide variety of DMARDs is now available for use in treating RA. Methotrexate remains the most widely used DMARD for RA; its popularity is a result of its high degree of efficacy combined with good tolerability. Table 79-3 includes several agents of historical interest but almost no current use, including D-penicillamine and gold preparations. Similarly, azathioprine and cyclosporine are now less commonly used, whereas cyclophosphamide is used almost only in extremely severe disease, especially with extra-articular manifestations such as vasculitis. Hydroxychloroquine and sulfasalazine are frequently prescribed for patients with mild-to-moderate disease and/or in combination with other agents. Leflunomide is a relatively new immunosuppressive drug that is used for moderate-to-severe RA and shares several potential toxicities with methotrexate.

BIOLOGIC THERAPIES

The newest and seemingly most effective therapeutic agents for RA are DMARDs that are *anticytokine-directed therapies*

Table 79-3 Treatment of Rheumatoid Arthritis

Glucocorticoids

Systemic (oral, intravenous, intramuscular)
Intra-articular

Nonsteroidal Anti-Inflammatory Drugs

Aspirin
Nonacetylated salicylates
Nonsalicylate nonselective prostaglandin inhibitors
Selective cyclo-oxygenase-2 inhibitors

Disease-Modifying Antirheumatic Drugs

Hydroxychloroquine
Sulfasalazine
Azathioprine
Cyclosporine
Cyclophosphamide
Methotrexate
Leflunomide

Disease-Modifying Antirheumatic Drugs—Biologic Agents

Etanercept (soluble TNF receptor)
Infliximab (chimeric anti-TNF antibody)
Adalimumab (fully human anti-TNF antibody)
Anakinra (IL-1-receptor antagonist)
Abatacept (T-cell-costimulation inhibitor)
Rituximab (anti-CD20 B-cell-depleting agent)

IL, interleukin; TNF, tumor necrosis factor.

and commonly referred to as *biologics*. In the past few years, three biologic response modifiers capable of neutralizing TNF have been developed, tested, and approved for patients with RA. The anti-TNF drugs etanercept, infliximab, and adalimumab inhibit inflammation by binding TNF before it reaches its cell-bound receptor. Infliximab and adalimumab also bind to cell-bound TNF. Blockers of TNF have demonstrated remarkable benefit for many patients and have set a new standard for efficacy for DMARDs. All of the available TNF blockers are given by intravenous or subcutaneous injection, are quite expensive, and carry risks of reactivation of tuberculosis and increased risk for some other infections; otherwise, they are well tolerated. Other biologic agents now available for treatment of RA include an IL-1 receptor antagonist, anakinra; an inhibitor of T-cell costimulation, abatacept; and a B-cell-depleting agent, rituximab. Antagonists or modulators of many other cytokines are under development for RA.

Although methotrexate and the biologic drugs have brought about a remarkable overall improvement in the ability to treat RA, it is important to recognize that many patients still have active disease despite using these drugs, even in combination, and the need for different, safer, and more efficacious treatment options for RA still exists.

Joint replacement surgery plays an extremely important role in patients who have had severe destructive joint disease, particularly in the knee and hip. Early reconstructive surgery in the hand and foot can improve function and sometimes can prevent deformity and tendon rupture. Total joint arthroplasty can have life-changing benefits for patients with RA with destructive joint disease.

Physical therapy and *occupational therapy* also continue to play important roles for many patients with RA. Physical therapy improves muscle strength and conditioning and maintains joint mobility. Splints for the wrists, used at night,

may help prevent deformity. Various appliances are available that help protect joints and make daily activities easier, ranging from Velcro “buttons” to special grips for keys and writing implements to raised chairs and toilet seats.

Summary

In summary, considerable strides have been made in understanding the pathogenesis and clinical outcomes of RA.

Although the underlying cause of RA is unknown, advances in cell biology, immunology, and molecular biology have led to dramatic alterations in therapies available to treat this disease. The development of novel effective biologic agents and the earlier introduction of aggressive therapy should prevent joint deformity and destruction and should improve short- and long-term outcomes. Assessment of efficacy in long-term studies and evaluation of long-term risks and toxicities will determine whether these drugs become the new paradigms for the treatment of RA.

Prospectus for the Future

- As the immune abnormalities in individual RA patients are defined, personalized medicine approaches will be developed.
- It is of importance to gain an understanding of the pathology involved with the increased prevalence of accelerated atherosclerosis in RA patients.
- The expense of current biologic therapies often limits their availability. Economic and political considerations will be essential if they are to be made available to all patients.

Spondyloarthropathies

Douglas W. Lienesch

The *spondyloarthropathies* are a related group of inflammatory disorders with clinical features unique among rheumatic diseases. The five types of spondyloarthropathy in adults are ankylosing spondylitis, reactive arthritis (Reiter syndrome), arthritis of inflammatory bowel disease (Crohn disease and ulcerative colitis), psoriatic arthritis, and undifferentiated spondyloarthropathy. A juvenile form of spondyloarthropathy exists that is similar to ankylosing spondylitis and generally persists into adulthood. The cardinal clinical feature of the spondyloarthropathies is inflammation of the sacroiliac joints (sacroiliitis) and the spine (spondylitis). Inflammation of tendon insertion sites (enthesitis), inflammation of entire digits (dactylitis), and inflammation of one to four lower extremity joints (oligoarthritis) are typical extraspinal skeletal findings. A positive family history, eye inflammation (anterior uveitis or conjunctivitis), and the absence of rheumatoid factor and subcutaneous nodules are common. Further classification of these disorders is based on the presence of psoriatic skin or nail changes, inflammatory bowel disease, or a history of preceding gastrointestinal or genitourinary infection.

Epidemiologic Features

One of the most fascinating aspects of the spondyloarthropathies is the strong associations with human leukocyte antigen (HLA) B27, a specific allele of the B locus of the HLA-encoding class I major histocompatibility complex genes. The frequency of HLA-B27 among whites is approximately 6% to 8%. However, up to 90% of white patients with ankylosing spondylitis and 80% of white patients with reactive arthritis or juvenile spondyloarthropathy are HLA-B27 positive; these percentages are even higher among those patients with uveitis. The rate of HLA-B27 positivity among patients with inflammatory bowel disease or psoriasis with peripheral arthritis is not markedly increased unless spondylitis is present, in which case the frequency of HLA-B27 is 50%. The frequency of HLA-B27 varies widely among other ethnic groups and accounts for the wide variation of the prevalence of ankylosing spondylitis in different populations.

Ankylosing spondylitis is much more common among adolescent boys and young men, but this finding may reflect underdiagnosis in women, in whom disease manifestations may be milder than they are in men. *Reactive arthritis* is more common among men when it follows genitourinary *Chlamydia trachomatis* infection, but the sex distribution is even among patients after dysentery. *Inflammatory arthritis* including spondylitis affects approximately 5% to 8% of patients with psoriasis and 10% to 25% of patients with ulcerative colitis or Crohn disease. Men and women are affected equally. The prevalence of spondyloarthropathy, particularly psoriatic and reactive arthritis, is increased in populations with high human immunodeficiency virus (HIV) infection rates.

Pathogenesis and Pathophysiology

Although the strong association of HLA-B27 and the spondyloarthropathies is well established, a specific role in the pathogenesis of these disorders has not been elucidated. Animal models in which rodents transgenic for HLA-B27 develop inflammatory abnormalities strikingly similar to those seen in HLA-B27-associated human diseases provide compelling indirect evidence for a pathogenic role. When raised in a germ-free environment, these animals remain disease free, suggesting a key additional environmental factor.
